Abstract

Suppose that there is a robber hiding on vertices or along edges of a graph or digraph. Graph searching is concerned with finding the minimum number of searchers required to capture the robber. Major results of graph searching problems are surveyed, focusing on algorithmic, structural, and probabilistic aspects of the field.

1 Introduction

Graph searching is a hot topic in mathematics and computer science now, as it leads to a wealth of beautiful mathematics and since it provides mathematical models for many real-world problems such as eliminating a computer virus in a network, computer games, or even counterterrorism. In all searching problems, there is a notion of *searchers* (or *cops*) trying to capture some *robber* (or *intruder* or *fugitive*). A basic optimization question here is: What is the fewest number of searchers required to capture the robber? There are many graph searching problems motivated by applied problems or inspired by some theoretical issues in computer science and discrete mathematics. These problems are defined by (among other things) the class of graphs (e.g., undirected graphs, digraphs, or hypergraphs), the actions of searchers and robbers, conditions of captures, speed, or visibility.

Graph searching has a variety of names in the literature, such as Cops and Robbers games and pursuit-evasion problems. The reader is referred to survey papers [4, 21, 60, 62, 74] for an outline of the many graph searching models. A recent book by Bonato and Nowakowski [29] covers all aspects of Cops and Robbers games.

In this chapter, a broad overview of graph searching is given, focusing on the most important results. The first part considers the so-called searching games where the robber may occupy an edge or vertex and the robber can usually move at high speeds at any time (but not always, depending on the model). The second part considers so-called *Cops and Robbers* games where the cops and robber occupy only vertices and they move alternatively to their neighbors. Searching games are often related to various width-type parameters, while there

¹Research was supported in part by NSERC, MITACS, and Ryerson University.

²Research was supported in part by NSERC and MITACS.

is no such connection in Cops and Robbers. Owing to space constraints, proofs are omitted (however, references are given for all results). The results presented here span probabilistic, algorithmic, and structural results. As such, the chapter is not entirely self-contained; the reader can find most of the relevant background in the books [29, 49, 134]. Note that this chapter is the first reference to give a comprehensive overview of both searching and Cops and Robbers games (although searching is discussed briefly in [29]). The chapter finishes each part with a dozen problems and conjectures which are arguably the most important ones in the field of graph searching.

Let $G = (V, E)$ ($D = (V, E)$) denote a graph (or digraph) with vertex set V and edge set E . Use uv to denote an edge in a graph with two end vertices u and v and (u, v) to denote a directed edge in a digraph with tail u and head v . All graphs and digraphs considered in this chapter are finite and simple, unless otherwise stated.

Part 1. Searching Games

The moniker *searching* is used for the case when the robber can move at great speed at any time or at least when a searcher approaches him (not just move to a neighbor in his turn, as is the case in Cops and Robbers).

Searching has been linked in the literature to pathwidth and vertex separation of a graph [52, 89], to pebbling (and hence, to computer memory usage) [89], to assuring privacy when using bugged channels [58], to VLSI (i.e., very large-scale integrated) circuit design [56], and to motion planning of multiple robots [127]. A large number of graph searching games have been introduced. We will focus here on some of the basic models.

Many graph searching games are closely related to graph width parameters, such as treewidth, pathwidth, and cutwidth. They provide some interpretation of width parameters, and often they can give a deeper insight into the graph structures and produce efficient algorithms. Examples include the proof of a min-max theorem on treewidth [122], the linear time algorithm for computing pathwidth of a tree [52, 87], the polynomial time algorithm for computing branchwidth of a planar graph [123], the linear time algorithm for computing cutwidth of a tree [97], and the computation of the topological bandwidth [40, 98].

Part 1 of the chapter surveys searching games on undirected graphs and digraphs. There are four sections in this part. Section 2 deals with the undirected graph searching games in which the robber can move at high speeds along any searcher-free path. Section 3 deals with the digraph searching games in which the robber usually moves at high speeds along a searcher-free directed path (depending on the game setting). Section 4 deals with more recently introduced searching games. As with the end of Part 2, Part 1 closes with a dozen of open problems in the area.

2 Searching Undirected Graphs

The first searching model was introduced by Parsons [109], after being approached by the author of [36] (a paper dealing with finding a spelunker lost in a system of caves). Let G be a connected, undirected graph embedded in \mathbb{R}^3 with the Euclidean

distance metric such that no pair of edges intersect at a point that is not a common endpoint. Imagine there is a robber in G who can be located at any point of G , that is, anywhere along an edge or at a vertex. We want to capture the robber using the minimum number of searchers. For each positive integer k , let $\mathcal{C}_k(G)$ be the set of all families $F = \{f_1, f_2, \dots, f_k\}$ of continuous functions $f_i : [0, \infty) \rightarrow G$. A *continuous search strategy* for G is a family $F \in \mathcal{C}_k(G)$ such that for every continuous function $h : [0, \infty) \rightarrow G$ (corresponding to the robber), there is a $t_h \in [0, \infty)$ and $f_i \in F$ satisfying $h(t_h) = f_i(t_h)$. We say that f_i captures the robber at time t_h . The *continuous search number* of a graph G is the smallest k such that there exists a search strategy for G in $\mathcal{C}_k(G)$. There are some contexts for which Parsons searching is the model required. For example, in the case of searching for someone lost or a robber hiding in a cave system, the robber and the searchers move continuously. But the notion of Parsons searching presents certain difficulties because the model involves the action of continuous functions defined on the nonnegative real numbers. In this survey, only discrete versions of Parsons searching are considered.

2.1 Robber Is Invisible and Active

When the robber is invisible and active, there are three basic searching games: edge searching, node searching, and mixed searching, which involve placing some restriction on searchers, but placing no restrictions on the robber. In these search games, the discrete time intervals (or time-steps) are introduced. Initially, G contains a robber who is located at a vertex in G , and G does not contain any searchers. Each searcher has no information on the whereabouts of the robber (i.e., robber is *invisible*), but the robber has complete knowledge of the location of all searchers. The goal of the searchers is to capture the robber, and the goal of the robber is to avoid being captured. The robber always chooses the best strategy so that he evades capture. Suppose the game starts at time t_0 and the robber is captured at time t_N and the search time is divided into N intervals $(t_0, t_1]$, $(t_1, t_2]$, \dots , $(t_{N-1}, t_N]$ such that in each interval $(t_i, t_{i+1}]$ (also called *step*), exactly one searcher performs one action: placing, removing, or sliding. The robber can move from a vertex x to a vertex y in G at any time in the interval (t_0, t_N) if there exists a path between x and y which contains no searcher (i.e., robber is *active*).

In the *edge search game* introduced by Megiddo et al. [100], there are three actions for searchers: placing a searcher on a vertex, removing a searcher from a vertex, and sliding a searcher along an edge from one end to the other. The robber is captured if a searcher and the robber occupy the same vertex on G .

In the *node search game* introduced by Kirousis and Papadimitriou [89], there are two actions for searchers: placing a searcher on a vertex and removing a searcher from a vertex. The robber is captured if a searcher and the robber occupy the same vertex of G or the robber is on an edge whose endpoints are both occupied by searchers.

In the *mixed search game* introduced by Bienstock and Seymour [22], searchers have the same actions as those in the edge search game. The robber is captured if a searcher and the robber occupy the same vertex on G or the robber is on an edge whose endpoints are both occupied by searchers.

The *edge search number* of G , denoted by $\text{es}(G)$, is the smallest positive integer k such that k searchers can capture the robber. Analogously, define the *node search number* of G (written $\text{ns}(G)$) and *mixed search number* of G (written $\text{ms}(G)$). The following theorem demonstrates the relationships between search numbers.

Theorem 1 ([22, 89]) *If G is a connected graph, then the following inequalities hold:*

- (1) $\text{ns}(G) - 1 \leq \text{es}(G) \leq \text{ns}(G) + 1$.
- (2) $\text{ms}(G) \leq \text{es}(G) \leq \text{ms}(G) + 1$.
- (3) $\text{ms}(G) \leq \text{ns}(G) \leq \text{ms}(G) + 1$.

The following result shows that all three search problems are **NP**-complete.

Theorem 2 ([22, 89, 93, 100]) *Given a graph G and an integer k , the problem of determining whether $\text{es}(G) \leq k$ ($\text{ns}(G) \leq k$ or $\text{ms}(G) \leq k$) is **NP**-complete.*

Megiddo et al. [100] only showed that the edge search problem is **NP**-hard. This problem belongs to **NP** owing to the monotonicity result of [93], in which LaPaugh showed that recontamination of edges cannot reduce the number of searchers needed to clear a graph. A search strategy is *monotonic* if the set of cleared edges before any step is always a subset of the set of cleared edges after the step. Monotonicity is an important issue in graph search problems. Bienstock and Seymour [22] proposed a method that gives a succinct proof for the monotonicity of the mixed search problem, which implies the monotonicity of the edge search problem and the node search problem. Fomin and Thilikos [61] provided a general framework that can unify monotonicity results in a unique min-max theorem.

Theorem 3 ([22, 93]) *The edge search, node search, and mixed search problems are monotonic.*

Search numbers have close relationships with pathwidth and treewidth [117, 118]. Given a graph G , a *tree decomposition* of G is a pair (T, W) with a tree $T = (I, F)$, $I = \{1, 2, \dots, m\}$, and a family of nonempty subsets $W = \{W_i \subseteq V : i = 1, 2, \dots, m\}$, such that

- (1) $\bigcup_{i=1}^m W_i = V$.
 - (2) For each edge $uv \in E$, there is an $i \in I$ with $\{u, v\} \subseteq W_i$.
 - (3) For all $i, j, k \in I$, if j is on the path from i to k in T , then $W_i \cap W_k \subseteq W_j$.
- The *width* of a tree decomposition (T, W) is

$$\max\{|W_i| - 1 : 1 \leq i \leq m\}.$$

The *treewidth* of G , denoted by $\text{tw}(G)$, is the minimum width over all tree decompositions of G . A tree decomposition (T, W) is a *path decomposition* if T is a path; the *pathwidth* of a graph G , denoted by $\text{pw}(G)$, is the minimum width over all path decompositions of G . One can find more information on treewidth and related problems in the survey papers [23, 115].

Another related graph parameter is the vertex separation introduced by Ellis et al. [52]. A *layout* of a connected graph G is a one-to-one mapping $L: V \rightarrow \{1, 2, \dots, |V|\}$. Let $V_L(i) = \{x : x \in V, \text{ and there exists } y \in V \text{ such that } xy \in E, L(x) \leq i \text{ and } L(y) > i\}$. The *vertex separation of G with respect to L* , denoted by $\text{vs}_L(G)$, is defined as

$$\text{vs}_L(G) = \max\{|V_L(i)| : 1 \leq i \leq |V|\}.$$

The *vertex separation* of G is defined as

$$\text{vs}(G) = \min\{\text{vs}_L(G) : L \text{ is a layout of } G\}.$$

Yang [135] introduced the strong-mixed search game, which is a generalization of the mixed search game. The strong-mixed search game has the same setting as the mixed search game except that searchers have an extra power to clear a neighborhood subgraph; that is, the subgraph induced by $N[v]$ (a set contains v and its neighbors) is cleared if all vertices in $N(v)$ (a set contains only the neighbors of v) are occupied by searchers. The *strong-mixed search number* of G , denoted by $\text{sms}(G)$, is the smallest positive integer k such that k searchers can clear G . The following relationships were given in [87, 89, 135].

Theorem 4 ([87, 89, 135]) *If G is a connected graph, then*

$$\text{sms}(G) = \text{pw}(G) = \text{vs}(G) = \text{ns}(G) - 1.$$

For an edge search strategy, if the subgraph induced by cleared edges is connected in every step, then call it *connected search*. We denote by $\text{cs}(G)$ and $\text{mcs}(G)$, respectively, the connected and monotonic connected search numbers of a graph G defined in the natural way.

The following theorem from [141, 143] demonstrates that the connected search game is not monotonic.

Theorem 5 ([141, 143]) *For any positive integer k , there is a graph W_k such that $\text{cs}(W_k) = 280k + 1$ and $\text{mcs}(W_k) = 290k$.*

Fraigniaud and Nisse [57] investigated visible robber connected node search. They proved that recontamination does help as well to catch a visible robber in a connected way.

Barrière et al. [15] proved that $\text{mcs}(T) \leq 2\text{es}(T)$ for any tree T . Dereniowski [48] extended the result to graphs as follows.

Theorem 6 ([48]) *For any graph G , $\text{mcs}(G) \leq 2\text{es}(G) + 3$.*

Fomin et al. [63] introduced the domination search game, in which the robber hides only on vertices and searchers are placed or are removed from vertices of a graph. In the domination search game, searchers are more powerful than those in the node search game. A searcher “captures” the robber if she can “see” him; that is, a searcher on a vertex v can clear v and all its neighbors. The following theorem gives a relation between the *domination search number*, written $\text{dsn}(G)$, node search number, and the domination number, written $\gamma(G)$.

Theorem 7 ([63]) *For any graph G , let G' be a graph obtained from G by replacing every edge by a path of length three and H be a graph obtained from G by connecting every two nonadjacent vertices by a path of length three. Then,*

$$\text{ns}(G) = \text{dsn}(G') \text{ and } \gamma(G) \leq \text{dsn}(H) \leq \gamma(G) + 1.$$

Kreutzer and Ordyniak [92] extended the domination game to distance d -domination games, in which each searcher can see a certain radius d around her position. That is, a searcher on vertex v can see any other vertex within distance d of v , and if this vertex is occupied by the robber, then the searcher can see the robber and capture him. They showed that all questions concerning monotonicity and complexity about d -domination games can be reduced to the case of $d = 1$. They gave a class of graphs on which two searchers can win on any graph in this class, but the number of searchers required for monotone winning strategies is unbounded. Due to the following result, the domination search problem is much harder than standard graph search problems. For background on **PSPACE** and other complexity classes, see Spiser [125].

Theorem 8 ([92]) *The domination search problem is **PSPACE**-complete. Moreover, the problem of deciding whether two searchers have a winning strategy on a graph is **PSPACE**-complete.*

2.2 Robber Is Visible or Lazy

Dendris et al. [47] introduced the *lazy-robber game*, which has the same setting as the node searching game except that the robber stays only on vertices and moves just before a searcher is going to be placed on the vertex currently occupied by the robber (i.e., robber is *lazy*). When a searcher is going to be placed on a vertex u currently occupied by the robber, the robber can move from u to another vertex v if there is a searcher-free path from u to v ; otherwise, the robber is captured. The following result from Dendris et al. [47] shows that the lazy-robber game is monotonic and the search number of a graph in the lazy-robber game is equal to the treewidth of the graph plus one.

Theorem 9 ([47]) *Let G be a graph. For a lazy robber with unbounded speed, the monotonic search number of G is equal to the search number of G , and moreover, it is equal to $\text{tw}(G) + 1$.*

Dendris et al. [47] also considered the speed-limited lazy robber. They showed that if the speed is 1, then the search number minus 1 is equal to a graph parameter, called width, which is polynomial time computable for arbitrary graphs. Given a layout L of a connected graph G , the *width of a vertex* $v \in V$ with respect to the layout L is the number of vertices which are adjacent to v and precede v in the layout. The *width of the layout* L is the maximum width of a vertex of G . The *width of G* is the minimum width of a layout of G .

Theorem 10 ([47]) *Let G be a graph. For a lazy robber with speed 1, the monotonic search number of G is equal to the search number of G , and moreover, it is equal to the width of G plus 1.*

Seymour and Thomas [122] introduced another variant of graph searching, *visible-robber game*. Its setting differs from node search in that the robber stands only on vertices and is visible to searchers. They showed that the visible-robber game is monotonic and the search number of a graph in the visible-robber game is equal to the treewidth of the graph plus one. They also showed that if there is a non-losing strategy for the robber, then there is a “nice” non-losing strategy with a particularly simple form. In order to show these results, Seymour and Thomas introduced jump-search and haven.

For a graph G and $X \subseteq V$, let $G - X$ be the graph obtained from G by deleting X . The vertex set of a component of $G - X$ is called an X -flap. Let $[V]^{<k}$ be the set of all subsets of V of cardinality less than k . The following lemma describes a strategy for the robber.

Lemma 1 ([122]) *A graph G cannot be cleared by less than k searchers if and only if there is a function σ mapping each $X \in [V]^{<k}$ to a nonempty union $\sigma(X)$ of X -flaps, such that if $X \subseteq Y \in [V]^{<k}$, then $\sigma(X)$ is the union of all X -flaps which intersect $\sigma(Y)$.*

Two vertex sets $X, Y \subseteq V(G)$ touch if either $X \cap Y \neq \emptyset$ or some vertex in X has a neighbor in Y . In *jump-searching*, each searcher can jump from a vertex to another vertex. At the start of the i th step, searchers occupy $X_{i-1} \in [V]^{<k}$ and the robber is in the subgraph R_{i-1} , which is an X_{i-1} -flap. After some searchers jump, the searchers occupy $X_i \in [V]^{<k}$ and the robber chooses an X_i -flap R_i , which touches R_{i-1} . Havens correspond to particularly nice winning strategies for the robber. A *haven* of order k is a function β which assigns an X -flap $\beta(X)$ to each $X \in [V]^{<k}$, in such a way that $\beta(X)$ touches $\beta(Y)$ for all $X, Y \in [V]^{<k}$. A *screen* in G is a set of subsets of $V(G)$ such that each subset induces a connected subgraph of G and any two subsets touch each other. A screen S has thickness at least k if there is no $X \in [V]^{<k}$ such that $X \cap H \neq \emptyset$ for all $H \in S$. The following result from Seymour

and Thomas [122] demonstrates the relations among screen, haven, visible-robber search, monotonic visible-robber search, and treewidth.

Theorem 11 ([122]) *For a graph G and an integer $k \geq 1$, the following are equivalent:*

- (1) *G has a screen of thickness at least k .*
- (2) *G has a haven of order at least k .*
- (3) *Fewer than k searchers cannot jump-search clear G .*
- (4) *Fewer than k searchers cannot clear G ,*
- (5) *Fewer than k searchers cannot monotonically clear G ,*
- (6) *G has treewidth at least $k - 1$.*

The problem of determining whether k searchers can capture the robber in the visible-robber game (or lazy-robber game) is **NP**-complete since it is monotonic and computing treewidth (equivalently, partial k -tree) is **NP**-complete [11].

Theorem 12 ([11]) *Given a graph G and a positive integer k , the problem of determining whether the treewidth of G is at most k is **NP**-complete.*

There are many variants of graph searching games, for example, time constrained searching [7], network security searching [14], weighted graphs searching [144], robber-and-marshals games [73], geometric environment searching [128–130], and more searching games on undirected graphs which can be found in Sect. 4.

3 Searching Digraphs

3.1 Robber Is Visible or Lazy

Johnson et al. [82] generalized the concept of treewidth to digraphs. For a digraph D , let Z and S be two disjoint subsets of V . The set S is Z -normal if for every directed path in D with first and last vertices in S , all vertices of the path belong to $S \cup Z$. An arborecence is a directed tree T with edges oriented away from a unique vertex $r \in V(T)$ (called the root). We write $t > e$ for $t \in V(T)$ and $e \in E(T)$ if e occurs on the unique directed path from r to t and $e \sim t$ if e is incident with t . An arboreal decomposition of a digraph D is a triple (T, X, W) where T is an arborecence and $X = \{X_e \subseteq V(D) : e \in E(T)\}$ and $W = \{W_t \subseteq V(D) : t \in V(T)\}$ satisfy the following items:

- (1) W is a partition of $V(D)$ into nonempty sets.
- (2) If $e \in E(T)$, then $\bigcup\{W_t : t \in V(T) \text{ and } t > e\}$ is X_e -normal.

The width of an arboreal decomposition (T, X, W) is the minimum k such that for all $t \in V(T)$,

$$\left| W_t \cup \bigcup_{e \sim t} X_e \right| \leq k + 1.$$

The *directed treewidth* of D is the least integer k such that D has an arboreal decomposition of width k .

Johnson et al. [82] introduced a generalization of the visible-robber game called the *strong-directed visible-robber game*. In the strong-directed visible-robber game, the robber occupies only vertices and must obey the edge directions when he moves along edges. The searchers have two actions – placing on vertices and removing from vertices. The robber is visible, and the robber can move from vertex u to v if there is a searcher-free directed cycle containing u and v .

Theorem 13 ([82]) *Let D be a digraph and k be an integer. If D has directed treewidth less than k , then k searchers have a winning strategy in the strong-directed visible-robber game.*

Johnson et al. [82] gave an example to show that the winning strategy in **Theorem 13** need not be searcher-monotone in the sense that searchers may have to revisit certain vertices. Adler [1] showed that it may not be robber-monotone either. She constructed a digraph where four searchers have a winning strategy but they have no robber-monotone winning strategy. This is very different from the undirected case, where a graph that has treewidth less than k implies that k searchers have a winning strategy where no vertex is revisited once it has been vacated. The following theorem gives a relation between the treewidth and directed treewidth.

Theorem 14 ([82]) *Let G be a graph, and let D be the digraph obtained from G by replacing every edge with two directed edges directed in opposite directions. Then the directed treewidth of D is equal to the treewidth of G .*

Let $k \geq 1$ be an integer. A *haven* of order k in a digraph D is a function β assigning to every $Z \subseteq V(D)$ with $|Z| < k$ the vertex set of a strong component of $D - Z$ in such a way that if $Z' \subseteq Z \subseteq V(D)$ with $|Z'| < k$, then $\beta(Z) \subseteq \beta(Z')$. In the strong-directed visible-robber game, if $k - 1$ searchers have a winning strategy on the digraph D , then D has no haven of order k . If β is a haven of order k in D , then the robber wins against $k - 1$ searchers by staying in $\beta(Z)$, where Z is the set of vertices occupied by the searchers. Johnson et al. [82] proved the following relation between the directed treewidth and haven.

Theorem 15 ([82]) *Let D be a digraph and k be a positive integer. If D has a haven of order k , then its directed treewidth is at least $k - 1$.*

Adler [1] showed that the converse of **Theorem 15** is not true by constructing a digraph whose directed treewidth is at least 4, but it has no haven of order 5. Johnson et al. [82] showed the following upper bound.

Theorem 16 ([82]) *Let D be a digraph and k be a positive integer. Then either D has directed treewidth at most $3k - 2$ or it has a haven of order k .*

Corollary 1 ([82]) *Let D be a digraph and k be a positive integer. Then either D has directed treewidth at most $3k - 1$ or k searchers do not have a winning strategy in the strong-directed visible-robber game on D .*

Berwanger et al. [19] and Obdržálek [108] introduced another width measure for digraphs called *DAG-width*. Given a digraph D , a set $X \subseteq V$ guards a set $Y \subseteq V$ if $X \cap Y = \emptyset$ and whenever there is an edge $(u, v) \in E$ such that $u \in Y$ and $v \notin X$, then $v \in X$. A DAG-decomposition of D is a pair (T, W) with T an acyclic digraph and $W = \{W_t \subseteq V : t \in V(T)\}$ a family of nonempty subsets, such that the following hold:

- (1) $\bigcup_{t \in V(T)} W_t = V$.
- (2) For all $t, t', t'' \in V(T)$, if t' is on a directed path from t to t'' in T , then $W_t \cap W_{t''} \subseteq W_{t'}$.
- (3) For all edges $(t, t') \in E(T)$, $W_t \cap W_{t'}$ guards $W_{\geq t'} \setminus W_t$, where $W_{\geq t'} = \bigcup\{W_{t''} : t'' \in V(T) \text{ and there is a directed path from } t' \text{ to } t'' \text{ in } T\}$. For all roots $r \in V(T)$, $W_{\geq r}$ is guarded by \emptyset .

The *width* of a DAG-decomposition (T, W) is

$$\max\{|W_t| : t \in V(T)\}.$$

The *DAG-width* of D is the minimum width of any of its DAG-decompositions.

Berwanger et al. [19] and Obdržálek [108] introduced the *directed visible-robber game*, which has the same setting as the strong-directed visible-robber game except that the robber is more powerful. The robber is allowed to move from vertex u to v if there is a searcher-free directed path from u to v . They use this game to characterize the DAG-width.

The directed visible-robber game and the strong-directed visible-robber game have some different properties owing to the different behavior of robbers. One difference is that the search number in the strong-directed visible-robber game is invariant under edge reversal; that is, it does not change if the directions of all edges of the digraph are reversed. But this is not the case for the directed visible-robber game. Another difference is that for the strong-directed visible-robber game with k searchers, there are digraphs that have a robber-monotone winning strategy, but no searcher-monotone winning strategy. However, Berwanger et al. [19] proved the following.

Theorem 17 ([19]) *For the directed visible-robber game with k searchers, if the searchers have a searcher-monotone or robber-monotone winning strategy, then they also have a winning strategy that is both searcher- and robber-monotone.*

A *monotone strategy* is a strategy that is both searcher-monotone and robber-monotone. Berwanger et al. [19] and Obdržálek [108] established the following relation between the search number and the DAG-width.

Theorem 18 ([19, 108]) *Let D be a digraph and k be a positive integer. Then D has a DAG-decomposition of width k if and only if k searchers have a monotone winning strategy in the directed visible-robber game on D .*

Similar to Theorem 14, Berwanger et al. proved the following.

Theorem 19 ([19]) *Let G be a graph, and let D be the digraph obtained from G by replacing every edge with two directed edges directed in opposite directions. Then the DAG-width of D is equal to the treewidth of G minus one.*

Berwanger et al. [19] also proved that if a digraph has DAG-width k , its directed treewidth is at most $3k + 1$. However, there is a family of digraphs with directed treewidth one and arbitrarily large DAG-width. Kreutzer and Ordyniak [91] proved that the directed visible-robber game is non-monotone.

Theorem 20 ([91]) *For any positive integer $k \geq 2$, there is a digraph D_k such that in the directed visible-robber game on D_k , the monotonic search number of D_k is $4k - 2$ and the search number of D_k is $3k - 1$.*

Hunter and Kreutzer [80] extended the lazy-robber game to the *directed lazy-robber game* on digraphs, which has the same setting as the lazy-robber game on graphs except that the robber must obey the edge directions when he moves along edges. They use this game to characterize the digraph width measure called *Kelly-width*.

Given a digraph D , a *Kelly-decomposition* of D is a triple (T, B, W) with T an acyclic digraph, $B = \{B_t \subseteq V : t \in V(T)\}$, and $W = \{W_t \subseteq V : t \in V(T)\}$, such that the following properties hold:

- (1) The set B is a partition of V into nonempty sets.
- (2) For all $t \in V(T)$, W_t guards $B_{\geq t}$, where $B_{\geq t} = \bigcup\{B_{t'} : t' \in V(T)$ and there is a directed path from t to t' in $T\}$.
- (3) For all $s \in V(T)$, there is a linear order on its children t_1, \dots, t_p such that for all $1 \leq i \leq p$,

$$W_{t_i} \subseteq B_s \cup W_s \cup \bigcup_{j < i} B_{\geq t_j}.$$

Similarly, there is a linear order on roots r_1, \dots, r_q of T such that for all $1 \leq i \leq q$,

$$W_{r_i} \subseteq \bigcup_{j < i} B_{\geq r_j}.$$

The *width* of a Kelly-decomposition (T, B, W) is

$$\max\{|B_t \cup W_t| : t \in V(T)\}.$$

The *Kelly-width* of D is the minimum width of any of its Kelly-decompositions.

The following result from Hunter and Kreutzer [80] shows that k searchers have a monotone winning strategy to capture a lazy robber in a digraph D if and only if D has Kelly-width k .

Theorem 21 ([80]) *Let D be a digraph and k be a positive integer. Then D has a Kelly-decomposition of width k if and only if k searchers have a monotone winning strategy in the directed lazy-robbler game on D .*

Hunter and Kreutzer [80] gave the following relation between the directed lazy-robbler game and the directed visible-robbler game.

Theorem 22 ([80]) *Let D be a digraph and k be a positive integer. If k searchers have a robber-monotone winning strategy in the directed lazy-robbler game on D , then $2k - 1$ searchers have a winning strategy in the directed visible-robbler game on D .*

Theorem 23 ([80]) *Let D be a digraph and k be a positive integer. If k searchers have a monotone winning strategy in the directed visible-robbler game on D , then k searchers have a winning strategy in the directed lazy-robbler game on D .*

Kreutzer and Ordyniak [91] proved that the directed lazy-robbler game is non-monotone.

Theorem 24 ([91]) *For any positive integer $k \geq 2$, there is a digraph D_k such that in the directed lazy-robbler game on D_k , the monotonic search number of D_k is $7k$ and the search number of D_k is $6k$.*

The problem of determining whether k searchers can capture the robber in the directed visible-robbler game (resp. directed lazy-robbler game or strong-directed visible-robbler game) is NP-hard.

Besides the above width measures, several new digraph measures are introduced recently, which include K-width [70], DAG-depth [70], entanglement [18], D-width [119], directed pathwidth [13], directed vertex separation [140], and bi-rank-width [84]. See also the thesis of Hunter for more discussions [79].

3.2 Robber Is Invisible and Active

Reed, Seymour, and Thomas introduced the directed pathwidth. Given a digraph D , a directed path decomposition of D is a sequence of subsets of vertices W_1, W_2, \dots, W_m such that the following hold:

- (1) $\bigcup_{i=1}^m W_i = V$.
- (2) For $1 \leq i < j < k \leq m$, $W_i \cap W_k \subseteq W_j$.
- (3) For each edge in D , it either has both endpoints in the same W_i or has its tail in W_i and head in W_j , where $i < j$.

The width of a directed path decomposition of D is

$$\max_{1 \leq i \leq m} \{|W_i| - 1\}.$$

The *directed pathwidth* of D , denoted by $\text{dpw}(D)$, is the minimum width over all directed path decompositions of D .

Barát [13] introduced a generalization of the node searching, called the *directed node search game*, to characterize the directed pathwidth. The directed node search game has the same setting as the node search game on graphs except that the robber occupies only vertices and must obey the edge directions when he moves along edges. He proved that an optimal monotonic search strategy for a digraph needs at most one more searcher than the search number of the digraph, and he also proved that the directed pathwidth and the directed node search number differ by at most one. Specifically, he proved the following theorem.

Theorem 25 ([13]) *For a digraph D and an integer $k \geq 1$, the following downward implications apply:*

- (1) *There is a monotone capture of the robber in D with at most k searchers.*
- (2) *The directed pathwidth of D is at most $k - 1$.*
- (3) *There is a capture of the robber in D with at most k searchers.*
- (4) *There is a monotone capture of the robber in D with at most $k + 1$ searchers.*

Yang and Cao [137–139] generalized the edge searching problem to digraphs by introducing three digraph search games: directed search, strong search, and weak search. In all three games, the robber is invisible and searchers have three types of actions: placing, removing, and sliding. These games differ in the abilities of the searchers and robber depending on whether or not they must obey the edge directions. In the *directed search game*, both searchers and robber must move in the edge directions; in the *strong search game*, the robber must move in the edge directions but searchers need not; and in the *weak search game*, searchers must move in the edge directions but the robber need not. In particular, in the directed and strong search games, the robber can move from vertex u to vertex v along a searcher-free directed path from u to v at a great speed at any time, and in the weak search game, the robber can move from vertex u to vertex v along a searcher-free undirected path between u and v at a great speed at any time.

For a digraph D , let $\text{ds}(D)$, $\text{ss}(D)$, and $\text{ws}(D)$ denote the *directed*, *strong*, and *weak search number*, respectively. Let $\text{mds}(D)$, $\text{mss}(D)$, and $\text{mws}(D)$ denote the monotonic directed, monotonic strong, and monotonic weak search number, respectively. The following result shows that the directed, strong, and weak search problems are all monotonic and **NP**-complete.

Theorem 26 ([137–139]) Let D be a digraph and k be a positive integer. Then $\text{mds}(D) = \text{ds}(D)$, $\text{mss}(D) = \text{ss}(D)$, and $\text{mws}(D) = \text{ws}(D)$. Moreover, the problem of deciding whether $\text{ds}(D) \leq k$, $\text{ss}(D) \leq k$, or $\text{ws}(D) \leq k$ is NP-complete.

Let $\text{es}(D)$ be the edge search number of the underlying undirected graph of D . Yang and Cao gave the following relationships between search numbers.

Theorem 27 ([137–139]) Let D be a digraph. Then the following inequalities hold:

- (1) $\text{ss}(D) \leq \text{ds}(D) \leq \text{ws}(D)$.
- (2) $\text{ss}(D) \leq \text{es}(D) \leq \text{ws}(D)$.
- (3) $\text{ds}(D) - 1 \leq \text{ss}(D) \leq \text{ds}(D)$.
- (4) $\text{ds}(D) \leq \text{es}(D) + 1$.
- (5) $\text{ws}(D) \leq \text{es}(D) + 2$.

Nowakowski [106] and Alspach et al. [5] introduced another three digraph search games: internal directed search, internal strong search, and internal weak search, which have the same setting as the directed search, strong search, and weak search, respectively, except that in the internal games, searchers have only two types of actions: placing and sliding. Yang and Cao [138] proved that the internal directed search problem is monotonic; however, the internal strong and internal weak search problems are not monotonic. Although the internal strong search game is not monotonic, they still proved it is in NP. But the problem of whether the internal weak search game is in NP is still open.

Theorem 28 ([138]) Given a digraph D and an integer k , the problem of determining whether k searchers can capture the robber in the internal directed (or strong) search game is NP-complete, and the problem of determining whether k searchers can capture the robber in the internal weak search game is NP-hard.

Yang and Cao [140] extended the vertex separation to digraphs. Given a digraph D and a linear layout $L : V \rightarrow \{1, 2, \dots, |V|\}$, let $DV_L(i) = \{x \in V : \text{there exists } y \in V \text{ such that edge } (y, x) \in E \text{ and } L(x) \leq i \text{ and } L(y) > i\}$. The directed vertex separation of D with respect to L , denoted by $\text{dvs}_L(D)$, is defined as

$$\text{dvs}_L(D) = \max\{|DV_L(i)| : 1 \leq i \leq |V|\}.$$

The directed vertex separation of D is defined as $\text{dvs}(D) = \min\{\text{dvs}_L(D) : L \text{ is a linear layout of } D\}$. The following relationships were given in [140].

Theorem 29 ([140]) Let D be a digraph. Then the following inequalities hold:

- (1) $\text{dvs}(D) = \text{dpw}(D)$.
- (2) $\text{dvs}(D) + 1 \leq \text{ds}(D) \leq \text{dvs}(D) + 2$.
- (3) $\text{dvs}(D) \leq \text{ss}(D) \leq \text{dvs}(D) + 2$.

4 Other Searching Games

4.1 Mixed Searching with Multiple Robbers

As mentioned in Sect. 2.1, Bienstock and Seymour [22] introduced the mixed search game, in which searchers have three actions: placing, removing, and sliding. The mixed search game can be used to characterize the proper pathwidth introduced by Takahashi et al. [131].

A graph G is a *minor* of graph H if G can be obtained from a subgraph of H by edge contractions, where a contraction of edge uv is the deletion of uv , followed by identifying u and v such that all vertices adjacent to u or v are adjacent to the new vertex. The *proper pathwidth* of a graph G , denoted as $\text{ppw}(G)$, is the least integer k such that G is a minor of the graph $K_k \square P$ for some path P , where K_k is a clique of order k and \square is the Cartesian product operator. Similarly, the *proper treewidth* of a graph G , denoted as $\text{ptw}(G)$, is the least integer k such that G is a minor of the graph $K_k \square T$ for some tree T .

The following result from Takahashi et al. [132] shows the relation between the mixed search number and the proper pathwidth.

Theorem 30 ([132]) *For any graph G , $\text{ms}(G) = \text{ppw}(G)$.*

Richerby and Thilikos [116] studied the mixed search game with multiple robbers who stay only on vertices. A robber is captured if a searcher and the robber occupy the same vertex of G . A set of searchers win the game if they can capture all robbers; otherwise, robbers win.

For a graph G with $\text{ms}(G) = k$, if monotonicity is ignored, then k searchers can capture any number of visible active robbers one at a time by repeating the strategy to capture a single robber. So, monotonicity is crucial in the mixed search game with multiple robbers. The robbers' territory F_i at step i is the union of each robber's territory. A search strategy is *monotonic* if $F_{i+1} \subseteq F_i$ for all i . Let $\text{mvams}(G, r)$ denote the *monotonic mixed search number for r visible active robbers* in G , $\text{vams}(G, r)$ denote the *mixed search number for r visible active robbers* in G , $\text{milms}(G, r)$ denote the *monotonic mixed search number for r invisible lazy robbers* in G , and $\text{ilms}(G, r)$ denote the *mixed search number for r invisible lazy robbers* in G . Richerby and Thilikos showed the following relations.

Theorem 31 ([116]) *For any graph G with n vertices:*

- (1) $\text{mvams}(G, n) = \text{ms}(G) = \text{ppw}(G)$.
- (2) $\text{mvams}(G, 1) = \text{milms}(G, 1)$.
- (3) $\text{ilms}(G, r) = \text{ilms}(G, 1)$.
- (4) $\text{milms}(G, r) = \text{milms}(G, 1) = \text{ptw}(G)$.
- (5) $\text{mvams}(G, r) \leq \min\{\text{ppw}(G), \text{ptw}(G)(\lfloor \log r \rfloor + 1)\}$.

Theorem 32 ([116]) *For any tree T with r robbers,*

$$\text{mvams}(T, r) = \min\{\text{ppw}(T), \lfloor \log r \rfloor + 1\}.$$

4.2 Nondeterministic Graph Searching

Fomin et al. [65] introduced nondeterministic graph searching, which can be used in algorithm design and combinatorial analysis applying to both pathwidth and treewidth. In the nondeterministic graph searching, the searchers and robber stay only on vertices. There are three actions for searchers: placing a searcher on a vertex, removing a searcher from a vertex, and query the oracle that returns the connected component containing the robber. The robber has the same behavior as the node search game. For a nonnegative integer q , a q -limited nondeterministic searching is a nondeterministic searching that performs at most q query actions. Therefore, k searchers win a q -limited nondeterministic search game against a robber if they can capture the robber by querying the oracle at most q times. The q -limited nondeterministic search number of a graph G is the minimum number of searchers required to win the game.

Fomin et al. [65] extended the tree decomposition and treewidth to q -branched tree decomposition and q -branched treewidth. They used the nondeterministic graph search game to characterize the q -branched treewidth. A *rooted tree decomposition* of a graph G is a tree decomposition (T, W) of G in which T is a rooted tree and W is a family of nonempty subsets of $V(G)$ satisfying the three conditions of a tree decomposition. A *branching node* of a rooted tree decomposition is a node with at least two children. For a nonnegative integer q , a *q -branched tree decomposition* of a graph G is a rooted tree decomposition (T, W) of G such that every path in T from the root to a leaf contains at most q branching nodes. The *q -branched treewidth* of G , is the minimum width of any q -branched tree decomposition of G . The following theorem from Fomin et al. [65] shows the relation between the nondeterministic graph search game and the q -branched treewidth.

Theorem 33 ([65]) *For a graph G , a nonnegative integer q , and a positive integer k , at most k searchers win the q -limited nondeterministic search game in a monotonic way if and only if the q -branched treewidth is less than k .*

Fomin et al. used the q -limited nondeterministic graph searching to design an exact exponential-time algorithm for computing the q -branched treewidth of a graph.

Theorem 34 ([65]) *For a graph G with n vertices, there exists an algorithm that computes the q -branched treewidth and its corresponding optimal q -branched tree decomposition of G in time $O(2^n n \log n)$.*

Mazoit and Nisse [99] showed that the q -limited nondeterministic graph searching is monotone for any nonnegative integer q .

Theorem 35 ([99]) *For a graph G , a nonnegative integer q and an integer $k \geq 2$, k searchers win the q -limited nondeterministic search game if and only if they can do it in a monotonic way.*

4.3 Fast Searching

In the edge search game, the goal is to find the minimum number of searchers to clear a given graph. Yang [136] introduced a new game called the *fast edge searching*, which has the same setting as the edge search game except the goal. In the fast edge search game, the goal is to find the minimum number of steps (or equivalently, actions) to clear a given graph. The fast edge search game has a strong connection with the fast search game, which was first introduced by Dyer et al. [51]. The fast search game has the same setting as the edge search game except that every edge is traversed exactly once by a searcher and searchers cannot be removed.

The motivation to consider the fast edge searching and fast searching is that, in some real-life scenarios, the cost of a searcher may be relatively low in comparison to the cost of allowing a fugitive to be free for a long period of time. For example, if a dangerous fugitive hiding along streets in an area, policemen always want to capture the fugitive as soon as possible.

In the fast edge searching game, the minimum number of steps required to clear G is the *fast edge search time* of G , denoted by $\text{fet}(G)$, and the minimum number of searchers required so that G can be cleared in $\text{fet}(G)$ steps is the *fast edge search number* of G , denoted by $\text{fen}(G)$. Similarly, the minimum number of searchers required to clear G in the fast search game is the *fast search number* of G , denoted by $\text{fsn}(G)$. A difference between the two games is that the family of graphs $\{G : \text{fet}(G) \leq k\}$ is minor-closed for the fast edge searching, but the family of graphs $\{G : \text{fsn}(G) \leq k\}$ is not minor-closed for the fast searching. The difference between $\text{fen}(G)$ and $\text{fsn}(G)$ can be large. In fact, there exists a class of graphs H such that the ratio $\text{fsn}(H)/\text{fen}(H)$ is arbitrarily large. Yang gave the following relationship between the fast edge searching game and the fast searching game.

Theorem 36 ([136]) *For any graph G ,*

$$\text{fet}(G) = \text{fsn}(G) + |E|.$$

For a graph G , let G' be a graph obtained from G by adding a vertex a and connecting it to each vertex of G . Let A'_G be a multigraph obtained from G' by replacing each edge with four parallel edges. Let A_G be a graph obtained from A'_G by replacing each edge of A'_G with a path of length two. Then, the following relation between the node search number of G and the fast search number of A_G was given in [136].

Theorem 37 ([136]) *For a graph G and its corresponding graph A_G ,*

$$\text{ns}(G) = \text{fsn}(A_G) - 2 = \text{fen}(A_G) - 2.$$

Although the node search number and the fast search number have the above relation, Stanley and Yang [126] presented a linear time algorithm for computing the fast search number of cubic graphs, while it is **NP**-complete to find the node search number of cubic graphs [98].

Corollary 2 *The fast search problem and the fast edge search problem are **NP**-complete. They remain **NP**-complete for Eulerian graphs.*

Yang showed the following bounds for the fast search number.

Theorem 38 ([136]) *For a connected graph G with minimum degree at least 3,*

$$\max \left\{ \delta(G) + 1, \left\lceil \frac{\delta(G) + |V_{\text{odd}}(G)| - 1}{2} \right\rceil \right\} \leq \text{fsn}(G) \leq |E|,$$

where $\delta(G)$ is the minimum degree of G and $V_{\text{odd}}(G)$ is the set of all odd vertices in G .

The fast searching game has a close relation with the graph brushing problem [3, 71, 101] and the balanced vertex-ordering problem [20, 85]. For all graphs, the brush number is equal to the total imbalance of an optimal vertex-ordering. For some graphs, such as trees, the fast search number is equal to the brush number.

4.4 Graph Guarding

Fomin et al. [64] introduced the graph guarding games, in which a set of cops want to guard a region in a given graph against a robber. The robber and cops stay only on vertices of the graph, and both sides take alternative turns to play. All participants have complete information on the location of all other participants. Initially, the robber is placed on a vertex outside the protected region, and then all cops are placed on vertices inside the protected region. In robber's turn, he can move to any adjacent vertex. The robber wins if he can move to an unguarded vertex in the region. In the cops' turn, each cop can move to an adjacent vertex in the region or stay put. The cops win if they can forever prevent the robber to win. The guarding problem is to find the minimum number of cops needed to win the game.

Fomin et al. [64] showed that the guarding problem is polynomial time solvable if the robber's region is a path. Nagamochi [105] showed that the guarding problem is polynomial time solvable if the robber's region is a cycle.

Theorem 39 ([64]) *For a graph $G = (V, E)$, let C be the protected region (vertex set). If $V \setminus C$ induces a path in G , then the guarding problem can be solved in $O(n_1 n_2 m)$ time, where $n_1 = |C|$, $n_2 = |V \setminus C|$, and $m = |E|$.*

Fomin et al. showed that the guarding problem is **NP-hard** even if the robber's region is a star.

Theorem 40 ([64]) *Given a graph $G = (V, E)$, a protected region C (vertex set), and an integer k , it is **NP-hard** to decide whether k cops can win the guarding game. It remains **NP-hard** even if $V \setminus C$ induces a star. Moreover, the parameterized version of the problem with k (the number of cops) being a parameter is **W[2J-hard**.*

The guarding game can also play on digraphs, in which the robber and cops always follow edge directions when they move to neighbors.

Theorem 41 ([64]) *Given a digraph $D = (V, E)$, a protected region C (vertex set), and an integer k , if $V \setminus C$ induces an acyclic digraph, it is **PSPACE-complete** to decide whether k cops can win the guarding game.*

In the guarding game, the robber moves first. In [66], Fomin et al. also studied a variant of the guarding game, in which cops move first. They showed that the new guarding problem is **PSPACE-hard** on undirected graphs.

4.5 Minimum Cost Searching

Almost all graph search problems are to find search strategies such that the maximum number of searchers used at each step is minimized. Fomin and Golovach [59] proposed a different optimization criterion. They introduced a cost function in the node searching game, which is the sum of the number of searchers in every step of the node search process.

One can interpret the cost of a search as the total sum that searchers earn for doing their job. The *search cost* of a graph G , denoted by $\sigma(G)$, is the minimum cost of a search where the minimum is taken over all searches on G . For monotonic node searching, the *monotonic search cost* of G , denoted by $\sigma_m(G)$, can be defined similarly. Fomin and Golovach [59] proved that their minimum cost searching is monotonic.

Theorem 42 ([59]) *For any graph G , $\sigma(G) = \sigma_m(G)$.*

Kirousis and Papadimitriou [88] found a relation between node searching and interval graphs. An interval graph is one that has an interval model, which is a set of intervals of the real line, one for each vertex, such that two intervals intersect if and only if the corresponding vertices are adjacent. Every graph is a subgraph of an interval graph in a trivial way. The *interval thickness* of a graph G , denoted by $\theta(G)$, is the smallest max-clique over all interval supergraphs of G .

Theorem 43 ([88]) *For any graph G , $\text{ns}(G) = \theta(G)$.*

Fomin and Golovach proved the following relation between minimum cost searching and interval graphs.

Theorem 44 ([59]) *For any graph G and positive integer k , $\sigma(G) \leq k$ if and only if there is an interval supergraph I of G such that $E(I) \leq k$.*

Dyer et al. [51] introduced the following cost function in the edge searching game on a graph G :

$$C_G(s, t) = \alpha s + \beta st + \gamma t,$$

where $\text{es}(G) \leq s \leq \text{fsn}(G)$ and $t = t(s) \geq |E|$. The goal is to minimize the cost function C_G , instead of trying to minimize s , which corresponds to edge searching, or to minimize t , which corresponds to fast searching.

4.6 Pebbling

Pebble games on graphs and digraphs have been studied by both mathematicians and computer scientists [16, 41, 46, 77, 89, 102, 103]. Pebbling is a method of analyzing computational situations, especially situations in which notions such as time (number of operations) and space (number of memory locations) are of interest [45, 78, 83, 86, 90, 94]. We focus on the relationship between graph searching and pebbling [89].

Let D be an acyclic digraph. For an edge $(u, v) \in E(D)$, v is called a *successor* of u , and u is called a *predecessor* of v . We consider two versions of pebbling: one is black pebbling and the other is black and white pebbling. The rules for *black pebbling* are as follows:

- (1) All vertices of D start pebble-free.
- (2) All vertices of D end pebble-free.
- (3) Each vertex receives and loses a pebble at least once.
- (4) A pebble can be placed on a vertex v only if all the predecessors of v have a pebble. Vertices with zero in-degree can be pebbled at any time.
- (5) A pebble can be removed any time.

The rules for *black and white pebbling* are as follows:

- (1) All vertices of D start pebble-free.
- (2) All vertices of D end pebble-free.
- (3) Each vertex receives and loses a pebble at least once.
- (4) A white pebble can be placed on a vertex at any time.
- (5) A white pebble on vertex v turns black at the moment all the predecessors of v are pebbled.
- (6) A black pebble can be removed at any time, but no white pebble can be removed.

The principle application of pebbling is to model computations. We say that a vertex has been pebbled if it had a pebble placed on it at some point. A pebbling scheme is a sequence of placing and removing pebbles so that every vertex has

been pebbled. The size of a pebbling scheme is the maximum number of pebbles deployed at any step. The *black pebble number* of an acyclic digraph D , denoted $\text{bp}(D)$, is the smallest size of a black pebbling scheme. Similarly, the *black and white pebble number* of an acyclic digraph D , denoted $\text{bwp}(D)$, is the smallest size of a black and white pebbling scheme. A black pebbling scheme, or black and white pebbling scheme, is said to be *monotonic* if each vertex is pebbled only one time. The *monotonic black pebble number*, or *monotonic black and white pebble number*, for an acyclic digraph D is denoted by $\text{mbp}(D)$ or $\text{mbwp}(D)$, respectively. The following relation between the node search number and monotonic black pebble number or monotonic black and white pebble number was proved in [89].

Theorem 45 ([89]) *Given a graph G , let $\Omega(G)$ denote the set of acyclic digraphs that are orientations of G . Let $\text{mmbp}(G)$ be the minimum monotonic black pebble number over all digraphs in $\Omega(G)$ and $\text{mmbw}(G)$ be the minimum monotonic black and white pebble number over all digraphs in $\Omega(G)$. Then the following relationships hold:*

- (1) $\text{mmbp}(G) = \text{ns}(G) = \text{mmbw}(G)$.
- (2) *For all $D \in \Omega(G)$ with in-degree at most k ,*

$$\text{bwp}(D) \leq \text{mbwp}(D) \leq (k + 1)\text{ns}(G).$$

5 Open Problems on Searching Games

The area of graph searching games is relatively new; there are several open problems. We present a dozen of them, and note that more problems can be found in the references:

- (1) The problem of determining the edge search number is **NP**-complete [93, 100]. This problem remains **NP**-complete for graphs with a maximum vertex degree of 3 [98]. However, whether the problem remains **NP**-complete for planar graphs is still unknown. In fact, the complexity of determining the search number of planar graphs in all search games mentioned in Sect. 2 is unknown.
- (2) The problems of designing efficient polynomial time approximation algorithms for computing the search number of all search games mentioned in Part 1 are wide open. There are only few results for special classes of graphs. For example, Bodlaender and Fomin [24] gave an $O(n \log n)$ time 2-approximation algorithm for computing the pathwidth (or node search number) of outerplanar graphs.
- (3) Finding good lower bounds for search numbers is a challenge for all search games mentioned in this chapter. There are few results for lower bounds. For example, it is not clear how to improve the following lower bound given by Alspach et al. [6]:

$$\text{es}(G) \geq \max \{\delta(G) + g(G) - 2, \chi(G) - 1\},$$

where the minimum vertex degree $\delta(G) \geq 3$, the girth $g(G) \geq 3$, and the chromatic number $\chi(G) \geq 4$.

- (4) Megiddo et al. [100] showed that the edge search problem is **NP**-hard. This problem belongs to **NP** by the monotonicity result of [93], in which LaPaugh showed that recontamination does not help to clear a graph. Using a reduction from the edge search problem, it can be easily shown that the connected edge search problem is also **NP**-hard. However, Yang et al. [141, 143] showed that the connected search is not monotonic. An interesting problem left open is whether the connected edge search problem belongs to **NP**.
- (5) In [82], Johnson et al. gave a min-max theorem between directed treewidth and the number of searchers required to capture a robber in the strong-directed visible-robbert game. However, the directed treewidth and the search number in this theorem are given by a constant factor between them. Whether there is a modified version of the directed treewidth that has an exact min-max theorem with the search number in the associated game remains an open problem.
- (6) In [91], Kreutzer and Ordyniak gave examples showing that neither the directed visible-robbert game associated with DAG-width nor the directed lazy-robbert game associated with Kelly-width is monotone. It is not clear if the ratio of the monotonic search number to the search number is bounded by a constant in both games. That is, it is unknown if there is a constant c such that whenever k searchers have a winning strategy in one of the games, ck searchers have a monotone winning strategy.
- (7) In [80], Hunter and Kreutzer conjectured that for a digraph, the search number in the directed visible-robbert game and that in the directed lazy-robbert game lie within constant factors of one another.
- (8) Yang and Cao [138] proved that the internal strong and internal weak search problems are not monotonic. Although the internal strong search game is not monotonic, they still proved it is in **NP**. However, the problem of whether the internal weak search game is in **NP** is still open.
- (9) In [138], Yang and Cao showed by examples that the ratio of the monotonic internal strong search number to the internal strong search number may be as large as $\Omega(\log n)$, where n is the number of vertices in the digraph. They conjecture that $O(\log n)$ is an upper bound of the ratio for all digraphs. Another open problem is whether there is a constant c such that whenever k searchers have a winning strategy in the internal weak search game, then ck searchers have a monotone winning strategy. We conjecture that this constant is less than 2 for all digraphs.
- (10) In [139], Yang and Cao proved the monotonicity of the mixed weak searching problem using the crusade method proposed by Bienstock and Seymour [22]. But they applied the LaPaugh's method to prove the monotonicity of the weak searching problem. Since LaPaugh's method is more complicated than the crusade method, an interesting open problem is how to establish a relation between the mixed weak searching and the weak searching so that the monotonicity of the former implies the monotonicity of the latter.

- (11) Many relations between different search numbers are described by inequalities, such as [Theorems 1](#) and [27](#). The related open problems are to find the necessary and sufficient conditions for graphs or digraphs such that equalities hold. For example, for which graphs does the edge search number equal the node search number?
- (12) Bodlaender and Kloks [\[25\]](#) gave a polynomial time algorithm for computing the pathwidth of a graph with constant treewidth. Since the edge search number of a graph equals the pathwidth of its two-expansion, the edge search number of a graph with constant treewidth is polynomial time computable. However, the exponent in the running time of this algorithm is large. Even for a graph with treewidth two, it takes at least $\Omega(n^{11})$ time. The large exponent makes their algorithm impractical. Megiddo et al. [\[100\]](#) presented a linear time algorithm for computing the edge search number of trees, and Peng et al. [\[110\]](#) proposed a linear time algorithm to compute the optimal search strategy of trees. Yang et al. [\[142\]](#) presented a linear time algorithm for computing the edge search number of unicyclic graphs and some special cycle-disjoint graphs. The problem then, is how to design efficient algorithms for computing the search number of graphs with small treewidth, such as outerplanar graphs that have treewidth two.

Part 2. Cops and Robbers

Cops and Robbers is one aspect of graph searching that has received much recent attention. In this two-player game of perfect information, a set of cops tries to capture a robber by moving at unit speed from vertex to vertex. More precisely, *Cops and Robbers* is a game played on a reflexive graph (i.e., there is a loop at each vertex). There are two players consisting of a set of *cops* and a single *robber*. The game is played over a sequence of discrete time-steps or *rounds*, with the cops going first in round 0 and then playing alternate time-steps. The cops and robber occupy vertices; for simplicity, the player is identified with the vertex they occupy. The set of cops is referred to as C and the robber as R . When a player is ready to move in a round, they must move to a neighboring vertex. Because of the loops, players can *pass* or remain on their own vertex. Observe that any subset of C may move in a given round.

The cops win if after some finite number of rounds, one of them can occupy the same vertex as the robber (in a reflexive graph, this is equivalent to the cop landing on the robber). This is called a *capture*. The robber wins if he can evade capture indefinitely. A *winning strategy for the cops* is a set of rules that if followed, result in a win for the cops. A *winning strategy for the robber* is defined analogously.

If a cop is placed at each vertex, then the cops are guaranteed to win. Therefore, the minimum number of cops required to win in a graph G is a well-defined positive integer, named the *cop number* (or *copnumber*) of the graph G . The notation $c(G)$ is used for the cop number of a graph G . If $c(G) = k$, then G is *k-cop-win*. In the special case $k = 1$, G is *cop-win* (or *copwin*).

The game of Cops and Robbers was first considered by Quilliot [\[113\]](#) in his doctoral thesis and was independently considered by Nowakowski and Winkler [\[107\]](#).

Both [107, 113] refer only to one cop. The introduction of the cop number came in 1984 with Aigner and Fromme [2]. Many papers have now been written on cop number since these three early works; see the surveys [4, 74] and the recent book of Bonato and Nowakowski [29]. Cops and Robbers has even found recent application in artificial intelligence and so-called *moving target search*; see Isaza et al. [81] and Moldenhauer et al. [104].

Part 2 is a selective survey of recent results on Cops and Robbers, focusing on algorithmic and probabilistic results, as well as the game in infinite graphs. A much more exhaustive survey with proofs may be found in the book [29]. This part begins with the case of cop-win graphs in Sect. 6. Such graphs have a good characterization in terms of an elimination ordering of their vertices. In Sect. 7 a discussion of graphs with higher cop number is provided. The highlight here is Meyniel's conjecture, which gives an upper bound on the cop number of connected graphs. The cop number in graph classes is discussed in Sect. 8, algorithmic results in Sect. 9, random graphs in Sect. 10, and infinite graphs in Sect. 11. Part 2 closes with 12 of the most important open problems in the field.

6 Cop-Win Graphs

The game of Cops and Robbers historically first considered only the case of one cop, and that is the focus in the present section. The *closed neighbor set* of a vertex x , written $N[x]$, is the set of vertices joined to x (including x itself). A vertex u is a *corner* if there is some vertex v such that $N[u] \subseteq N[v]$.

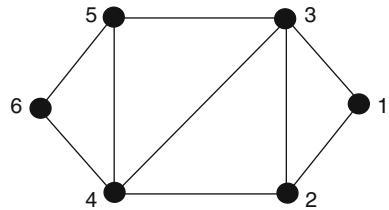

A graph is *dismantlable* if some sequence of deleting corners results in the graph K_1 . For example, each tree is dismantlable: delete leaves repeatedly until a single vertex remains. The same approach holds with chordal graphs, which always contains at least two simplicial vertices (i.e., vertices whose neighbor sets are cliques). The following result characterizes cop-win graphs.

Theorem 46 ([107]) *A graph is cop-win if and only if it is dismantlable.*

Cop-win (or dismantlable) graphs have a recursive structure, made explicit in the following sense. Observe that a graph is dismantlable if the vertices can be labeled by positive integers $[n] = \{1, 2, \dots, n\}$, in such a way that for each $i < n$, the vertex i is a corner in the subgraph induced by $\{i, i+1, \dots, n\}$. This ordering of $V(G)$ is called a *cop-win ordering*. See Fig. 1 for a graph with vertices labeled by a cop-win ordering. Cop-win orderings are sometimes called *elimination orderings*; vertices from lower to higher index are deleted until only vertex n remains.

Let H be an induced subgraph of G formed by deleting one vertex. The graph H is a *retract* of G if there is a homomorphism f from G onto H so that $f(x) = x$ for $x \in V(H)$; that is, f is the identity on H . The map f is called a *retraction* (or *one-point retraction* or *fold*). For example, the subgraph formed by deleting a vertex of degree 1 is a retract. If u is a corner, then the mapping

Fig. 1 A cop-win ordering of a cop-win graph

$$f(x) = \begin{cases} v & \text{if } x = u \\ x & \text{else} \end{cases}$$

is a retraction (recall that graphs are reflexive, so edges may map to a single vertex).

Retracts play an important role in characterizing cop-win graphs. The next theorem, due to Berarducci and Intrigila, shows that the cop number of a retract never increases.

Theorem 47 ([17]) *If H is a retract of G , then $c(H) \leq c(G)$.*

Cop-win orderings suggest a kind of linear structure to cop-win graphs; it roughly suggests that by “sweeping” from largest index vertex to smallest in the ordering, the robber can be captured. This intuition is made precise by the following winning strategy for the cops – first made explicit by Clarke and Nowakowski [44] – in a cop-win graph exploiting the cop-win ordering.

Cop-Win (or No-Backtrack) Strategy [44]. Assume that $[n]$ is a cop-win ordering of G , and for $1 \leq i \leq n$, define

$$G_i = G \upharpoonright \{n, n-1, \dots, i\}.$$

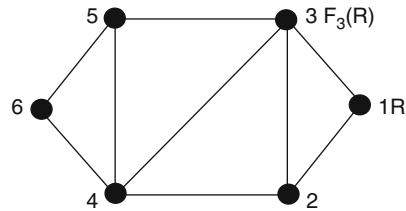

Note that $G_1 = G$ and G_n is just the vertex n . For each $1 \leq i \leq n-1$, let $f_i : G_i \rightarrow G_{i+1}$ be the retraction map from G_i to G_{i+1} mapping i onto a vertex that covers i in G_i . Define F_1 to be the identity mapping on $G : F_1(x) = x$ for all $x \in V(G)$. For $2 \leq i \leq n$, define

$$F_i = f_{i-1} \circ \dots \circ f_2 \circ f_1.$$

In other words, the F_i is the mapping formed by iteratively retracting corners $1, 2, \dots, i-1$. As the f_i are homomorphisms, so are the F_i (recall that graphs are reflexive). Further, for all i , as the f_i are retractions, $F_i(x)$ and $F_{i+1}(x)$ are either equal or joined. If the robber is on vertex x in G , then think of $F_i(x)$ as the robber’s shadow on G_i . See Fig. 2.

The cop-win strategy is described as follows. The cop begins on G_n (the vertex n), which is the shadow of the robber’s position under F_n (note that everything in G

Fig. 2 The robber and his shadow $F_3(R) = f_2 \circ f_1(R)$

maps to n under F_n). Suppose that the robber is on u and the cop is occupying the shadow of the robber in G_i equaling $F_i(u)$. If the robber moves to v , then the cop moves onto the image $F_{i-1}(v)$ of R in the larger graph G_{i-1} .

Theorem 48 ([44]) *The cop-win strategy results in a capture for the cop in at most n moves.*

If both players are playing *optimally* (i.e., the cop is trying to minimize the length of the game, while the robber is trying to maximize it), then in cop-win graph, a cop can win in no more than $n - 3$ moves if $n \geq 5$. See Bonato et al. [31].

Note that the dismantling characterization of [Theorem 46](#) fails badly for infinite graphs. For example, an infinite one-way path (or *ray*) is dismantlable (if infinitely many vertex deletions are allowed) but fails to be cop-win. There is a characterization of cop-win graphs of any order (finite or infinite) included here, owing to Nowakowski and Winkler [107].

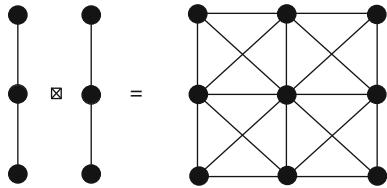

Define a relation \leq on vertices. The relation is defined recursively on ordinals, with $x \leq_0 x$ for all vertices u (in other words, \leq_0 is just the *diagonal* or *equality relation* on $V(G)$). Observe that $u \leq_\alpha v$ will mean that when a robber is on vertex u , a cop is on vertex v , and when it is the robber's turn to move, the robber will lose in at most α rounds. For an ordinal α , define $u \leq_\alpha v$ if and only if for each $a \in N[u]$, there exists a $b \in N[v]$ such that $a \leq_\beta b$ for some $\beta < \alpha$. Let ρ be the least ordinal such that $\leq_\rho = \leq_{\rho+1}$ and define $\leq = \leq_\rho$.

Note that if $\rho < \alpha$, then the relation \leq_ρ is a subset of \leq_α . As such relations are bounded above in cardinality, the ordinal ρ exists. A binary relation on a set X is *trivial* if it equals the Cartesian product of X with itself, $X \times X$.

Theorem 49 ([107]) *A graph G is cop-win if and only if the relation \leq on $V(G)$ is trivial.*

A generalization of [Theorem 49](#) has been found for graphs with higher cop number. Given a graph G , define the k th *strong power* of G , written G^k_{\boxtimes} , to have vertices the ordered k -tuples from G , with two tuples joined if they are equal or joined in each coordinate. See [Fig. 3](#) for an example. The positions of k -many cops in G are identified with a single vertex in G^k_{\boxtimes} . The definition of the strong power allows us to simulate movements of the cops in G by movements of a single cop in G^k_{\boxtimes} .

Fig. 3 The strong power $(P_3)^2$

Let $P = G_{\boxtimes}^k$. For $i \in \mathbb{N}$, the relation \leq_i on $V(G) \times V(P)$ is defined as follows by induction on i . For $x \in V(G)$ and $p \in V(P)$, $x \leq_0 p$ if in position p , at least one of the k cops is occupying x . For $i > 0$, $x \leq_i p$ if and only if for each $u \in N[x]$, there exists a $v \in N[p]$ such that $u \leq_j v$ for some $j < i$. Just as in the cop-win case, the relations \leq_i are nondecreasing sets in i , and hence, there is an ordinal M such that $\leq_M = \leq_{M+1}$ and set $\leq = \leq_M$. Although the notation \leq in this case clashes with the one for cop-win graphs, it is used again here for simplicity.

Theorem 50 ([43]) *A graph G is k -cop-win if and only if there exists $p \in V(P)$ such that $x \leq p$ for every $x \in V(G)$.*

7 Higher Cop Number

Graphs with higher cop number are much less understood than cop-win graphs. Hence, the focus is on finding bounds on the cop number.

7.1 Upper Bounds

An elementary upper bound for the cop number is

$$c(G) \leq \gamma(G), \quad (1)$$

where $\gamma(G)$ is the domination number of G . In general graphs, the inequality (1) is far from tight (e.g., consider a path).

We do not know how large the cop number of a connected graph can be as a function of its order. For a positive integer n , let $c(n)$ be the maximum value of $c(G)$, where G is of order n . *Meyniel's conjecture* states that

$$c(n) = O(\sqrt{n}).$$

The conjecture was mentioned in Frankl's paper [68] as a personal communication to him by Henri Meyniel in 1985 (see page 301 of [68] and reference [7] in that paper). Meyniel's conjecture stands out as one of the deepest (if not *the* deepest) problems on the cop number.

For many years, the best known upper bound for general graphs was the one proved by Frankl [68].

Theorem 51 ([68]) *If n is a positive integer, then*

$$c(n) \leq O\left(n \frac{\log \log n}{\log n}\right).$$

The key to proving **Theorem 51** is the notion of cops guarding an isometric path. For a fixed integer $k \geq 1$, an induced subgraph H of G is k -guardable if, after finitely many moves, k cops can move only in the vertices of H in such a way that if the robber moves into H at round t , then he will be captured at round $t + 1$. For example, a clique or a closed neighbor set (i.e., a vertex along with its neighbors) in a graph are 1-guardable. Given a connected graph G , the *distance* between vertices u and v in G is denoted $d_G(u, v)$. A path P in G is *isometric* if for all vertices u and v of P ,

$$d_P(u, v) = d_G(u, v).$$

The following theorem of Aigner and Fromme [2] on guarding isometric paths has found a number of applications.

Theorem 52 [2] *An isometric path is 1-guardable.*

In 2008 Chiniforooshan [39] gave an improved upper bound once again using a guarding argument.

Theorem 53 ([39]) *For a positive integer n ,*

$$c(n) = O\left(\frac{n}{\log n}\right). \quad (2)$$

The bound (2), therefore, represents the first important step forward in proving Meyniel's conjecture in over 25 years. The key to proving (2) comes again from the notion of guarding an induced subgraph.

An improvement exists to the bound (2) in **Theorem 53**. The following theorem was proved independently by three sets of authors.

Theorem 54 ([69, 95, 121]) *For a positive integer n ,*

$$c(n) \leq O\left(\frac{n}{2^{(1-o(1))\sqrt{\log_2 n}}}\right). \quad (3)$$

The bound in (3) is currently the best upper bound for general graphs that is known, but it is still far from proving Meyniel's conjecture or even the soft version of the conjecture.

7.2 Lower Bounds

A useful theorem of Aigner and Fromme [2] is the following. The girth of a graph is the length of minimum order cycle. The *minimum degree* of G is written $\delta(G)$.

Theorem 55 ([2]) *If G has girth at least 5, then $c(G) \geq \delta(G)$.*

Frankl [68] proved the following theorem generalizing [Theorem 55](#) (which is the case $t = 1$).

Theorem 56 ([2]) *For a fixed integer $t \geq 1$, if G has girth at least $8t - 3$ and $\delta(G) > d$, then $c(G) > d^t$.*

Meyniel's conjecture states that the cop number is at most approximately \sqrt{n} . For graphs with large cop number near the conjectured bound, consider projective planes. A *projective plane* consists of a set of points and lines satisfying the following axioms:

- (1) There is exactly one line incident with every pair of distinct points.
- (2) There is exactly one point incident with every pair of distinct lines.
- (3) There are four points such that no line is incident with more than two of them.

Finite projective planes have $q^2 + q + 1$ points for some integer $q > 0$ (called the *order* of the plane). For a given projective plane P , define $G(P)$ to be the bipartite graph with red vertices representing the points of P and the blue vertices representing the lines. Vertices of different colors are joined if they are incident. This is the *incidence graph* of P . See [Fig. 4](#) for $G(P)$, where P is the Fano plane (i.e., the projective plane of order 2). The incidence graph of the Fano plane is isomorphic to the famous *Heawood graph*.

Hence, [Theorem 55](#) proves that $c(G(P)) \geq q + 1$. As proven in Prałat [111], $c(G(P)) = q + 1$. However, the orders of $G(P)$ depend on the orders of projective planes. The only orders where projective planes are known to exist are prime powers; indeed, this is a deep conjecture in finite geometry. What about integers which are not prime powers? An infinite family of graphs $(G_n : n \geq 1)$ is *Meyniel extremal* if there is a constant d such that for sufficiently large n , $c(G_n) \geq d \sqrt{|V(G_n)|}$.

Recall the famous *Bertrand's postulate*.

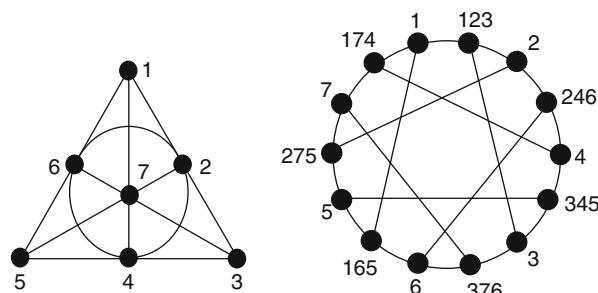

Fig. 4 The Fano plane and its incidence graph. Lines are represented by triples

Theorem 57 ([38]) *For any integer $x > 1$, there is a prime in the interval $(x, 2x)$.*

In Prałat [111] a Meyniel extremal family was given using incidence graphs of projective planes and [Theorem 57](#). Using Bertrand's postulate, it was shown that

$$c(n) \geq \sqrt{\frac{n}{8}}$$

for $n \geq 72$. Using this theorem and a result from number theory, it was shown in Prałat [111] that for sufficiently large n ,

$$c(n) \geq \sqrt{\frac{n}{2}} - n^{0.2625}. \quad (4)$$

Define m_k to be the minimum order of a connected graph G satisfying $c(G) \geq k$. Define M_k to be the minimum order of a connected k -cop-win graph. It is evident that the m_k are monotonically increasing and $m_k \leq M_k$. A recent work [12] establishes that

$$m_3 = 10.$$

The fact that $m_3 \geq 10$ follows by a computer search. The upper bound follows by considering the Petersen graph, which is 3-cop-win. In fact, a computer search in Baird and Bonato [12] shows the surprising fact that the Petersen graph is the *unique* smallest order isomorphism type of connected graph with cop number 3.

Define $f_k(n)$ to be the number of non-isomorphic connected k -cop-win graphs of order n (i.e., the *unlabeled* graphs G of order n with $c(G) = k$). Define $g(n)$ to be the number of non-isomorphic (not necessarily connected) graphs of order n and $g_c(n)$ the number of non-isomorphic connected graphs of order n . Trivially, for all k , $f_k(n) \leq g(n)$. The table below presents the values of g , g_c , f_1 , and f_2 for small orders. The values of g and g_c come from [124]; f_1 was computed by checking for cop-win orderings [107], while f_2 and f_3 were computed using [Algorithm 1](#) given in [Sect. 9](#).

Order n	$g(n)$	$g_c(n)$	$f_1(n)$	$f_2(n)$	$f_3(n)$
1	1	1	1	0	0
2	2	1	1	0	0
3	4	2	2	0	0
4	11	6	5	1	0
5	34	21	16	5	0
6	156	112	68	44	0
7	1,044	853	403	450	0
8	12,346	11,117	3,791	7,326	0
9	274,668	261,080	65,561	195,519	0
10	12,005,168	11,716,571	2,258,313	9,458,257	1

Algorithm 1 CHECK K COP NUMBER

Require: $G = (V, E)$, $k \geq 1$

- 1: initialize $f(u)$ to $V(G) \setminus N_G[u]$, for all $u \in V(G_{\boxtimes}^k)$
- 2: **repeat**
- 3: **for all** $uv \in E(G_{\boxtimes}^k)$ **do**
- 4: $f(u) \leftarrow f(u) \cap N_G[f(v)]$
- 5: $f(v) \leftarrow f(v) \cap N_G[f(u)]$
- 6: **end for**
- 7: **until** the value of f is unchanged
- 8: **if** there exists $u \in V(G_{\boxtimes}^k)$ such that $f(u) = \emptyset$, **then**
- 9: $c(G) \leq k$
- 10: **else**
- 11: $c(G) > k$
- 12: **end if**

The next theorem sets up an unexpected connection between Meyniel's conjecture and the order of m_k .

Theorem 58 ([12])

- (1) $m_k = O(k^2)$.
- (2) *Meyniel's conjecture is equivalent to the property that*

$$m_k = \Omega(k^2).$$

Hence, if Meyniel's conjecture holds, then [Theorem 58](#) implies that $m_k = \Theta(k^2)$.

8 Graph Classes

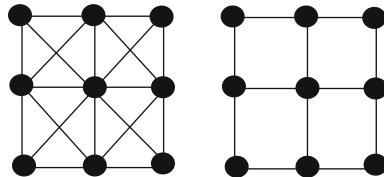

Planar graphs have inspired some of the deepest results in graph theory, most notably the four color theorem (which states that every planar graph has chromatic number at most four; see Appel, Haken, and Koch [10]). A graph is *planar* if it can be drawn in \mathbb{R}^2 without any two of its edges crossing. Aigner and Fromme [2] showed in fact that planar graphs require no more than three cops.

Theorem 59 ([2]) *If G is a planar graph, then $c(G) \leq 3$.*

The idea of the proof of [Theorem 59](#) is to increase the *cop territory*; that is, a set of vertices so that if the robber moved to one of them he would be caught. Hence, the number of vertices the robber can move to without being caught is eventually reduced to the empty set, and so the robber is captured.

For a fixed graph H , Andreae [8] generalized this result by proving that the cop number of a K_5 -minor-free graph (or $K_{3,3}$ -minor-free graph) is at most 3 (recall that planar graphs are exactly those which are K_5 -minor-free and $K_{3,3}$ -minor-free).

Fig. 5 The graph on the *left* is a cop-win non-outerplanar graph, while the graph on the *right* is non-outerplanar with cop number 2

Andreae [9] also proved that for any graph H , the cop number of the class of H -minor-free graphs is bounded above by a constant.

Less is known about the cop number of graphs with positive genus. As such, the survey of such graphs is brief. The main conjecture in this area is due to Schroeder. In [120], Schroeder conjectured that if G is a graph of genus g , then $c(G) \leq g + 3$. Quilliot [114] had shown the following.

Theorem 60 ([114]) *If G is a graph of genus g , then $c(G) \leq 2g + 3$.*

In the same paper as the conjecture, Schroeder showed the following.

Theorem 61 ([120]) *If G is a graph of genus g , then*

$$c(G) \leq \left\lfloor \frac{3g}{2} \right\rfloor + 3.$$

Schroeder also proved the following theorem.

Theorem 62 ([120]) *If G is a graph that can be embedded on a torus, then $c(G) \leq 4$.*

A graph G is *outerplanar* if it has an embedding in the plane with the following properties:

- (1) Every vertex lies on a circle.
 - (2) Every edge of G either joins two consecutive vertices around the circle or is a chord across the circle.
 - (3) If two chords intersect, then they do so at a vertex
- (See Fig. 5). Clarke proved the next result in her doctoral thesis.

Theorem 63 ([42]) *If G be an outerplanar graph, then $c(G) \leq 2$.*

Theorem 63 was generalized by Theis [133] to series-parallel graphs.

Lu and Peng [95] showed that Meyniel's conjecture holds in the class of graphs with diameter two. The proof uses the notion of guarding subgraph but also uses a randomized argument.

Theorem 64 ([95]) *If G is a graph on n vertices with diameter two, then*

$$c(G) \leq 2\sqrt{n} - 1. \quad (5)$$

The same bound (5) was also shown in [95] in the case when G is bipartite and of diameter at most three. The incidence graphs of projective planes are bipartite of diameter three and so show that the bound (5) is asymptotically tight in that class.

9 Algorithmic Results

Another approach to the Cops and Robbers game is an algorithmic one. Consider the following two graph decision problems:

k -COP NUMBER: Given a graph G and a positive integer k , is $c(G) \leq k$?

k -FIXED COP NUMBER: Given a graph G and a fixed positive integer k , is $c(G) \leq k$?

The main difference between the two problems is that in k -COP NUMBER the integer k may be a function of n and so grows with n . In k -FIXED COP NUMBER, k is fixed and not part of the input and so is independent of n .

There is the following result.

Theorem 65 ([17, 75]) *The problem FIXED COP NUMBER is in P .*

An algorithm from Bonato et al. [33] is described which may be used to prove **Theorem 65**. Given a graph G , recall that the k th *strong power* of G , written G_{\boxtimes}^k , is the strong product of G with itself k times. For a set X , define 2^X to be the set of subsets of X . For $S \subseteq V(G)$, define $N_G[S]$ to be the union of the closed neighbor sets of vertices in S .

Theorem 66 ([33]) *Suppose $k \geq 1$ is an integer. Then $c(G) > k$ if and only if there is a mapping $f : V(G_{\boxtimes}^k) \rightarrow 2^{V(G)}$ with the following properties:*

(1) *For every $u \in V(G_{\boxtimes}^k)$,*

$$\emptyset \neq f(u) \subseteq V(G) \setminus N_G[u].$$

(2) *For every $uv \in E(G_{\boxtimes}^k)$,*

$$f(u) \subseteq N_G[f(v)].$$

Consider [Algorithm 1](#) for determining whether $c(G) \leq k$ based on [Theorem 66](#). The following theorem gives [Theorem 65](#) as a corollary.

Theorem 67 ([33]) *[Algorithm 1](#) runs in time $O(n^{3k+3})$.*

If k is not fixed (and hence can be a function of n), then the problem becomes less tractable.

Theorem 68 ([67]) *The problem k -COP NUMBER is NP-hard.*

Theorem 68 does not say that k -COP NUMBER is in NP; that is an open problem! See Sect. 12 below. Theorem 68 is proved in Fomin et al. [67] by using a reduction from the following NP-complete problem:

Domination: Given a graph G and an integer $k \geq 2$, is $\gamma(G) \leq k$?

10 Random Graphs

Random graphs are a central topic in graph theory; however, only recently have researchers considered the cop number of random graphs. Define a probability space on graphs of a given order $n \geq 1$ as follows. Fix a vertex set V consisting of n distinct elements, usually taken as $[n]$, and fix $p \in [0, 1]$. Define the space of *random graphs of order n with edge probability p* , written $G(n, p)$ with sample space equaling the set of all $2^{\binom{n}{2}}$ (labeled) graphs with vertex set V , and

$$\mathbb{P}(G) = p^{|E(G)|} (1-p)^{\binom{n}{2}-|E(G)|}.$$

Informally, $G(n, p)$ may be viewed as the space of graphs with vertex set V , so that two distinct vertices are joined independently with probability p . Even more informally, toss a (biased) coin to determine the edges of your graph. Hence, V does not change, but the number of edges is not fixed: it varies according to a binomial distribution with expectation $\binom{n}{2}p$. Despite the fact that $G(n, p)$ is a space of graphs, it is often called *the random graph of order n with edge probability p* . Random graphs were introduced in a series of papers by Erdős and Rényi [53–55]. See the book [26] for a modern reference.

The cases when p is fixed and when it is a function of n are considered. Graph parameters, such as the cop number, become random variables in $G(n, p)$. For notational ease, the cop number of $G(n, p)$ is referred to simply by $c(G(n, p))$.

An event holds *asymptotically almost surely* (or *a.a.s.* for short) if it holds with probability tending to 1 as $n \rightarrow \infty$. For example, if p is constant, then a.a.s. $G(n, p)$ is diameter two and not planar.

10.1 Constant p

The cop number of $G(n, p)$ was studied in Bonato et al. [30] for constant p , where the following result was proved. For $p \in (0, 1)$ or $p = p(n) = o(1)$, define

$$\mathbb{L}n = \log_{\frac{1}{1-p}} n.$$

Theorem 69 ([30]) Let $0 < p < 1$ be fixed. For every real $\varepsilon > 0$, a.a.s.

$$(1 - \varepsilon)\mathbb{L}n \leq c(G(n, p)) \leq (1 + \varepsilon)\mathbb{L}n. \quad (6)$$

In particular,

$$c(G(n, p)) = \Theta(\log n).$$

The upper bound in [Theorem 69](#) follows by considering the domination number of $G(n, p)$ [50], while the lower bounds follow by considering an adjacency property. If the case of $p = 1/2$ is considered, then $G(n, p)$ corresponds to the case of uniformly choosing a labeled graph of order n from the space of all such graphs. Hence, [Theorem 69](#) may be interpreted as saying “most” finite graphs of order n have cop number approximately $\log n$.

Properties of randomly chosen k -cop-win graphs (with the uniform distribution) are described next. For this, it is equivalent to work in the probability space $G(n, 1/2)$. Let **cop-win** be the event in $G(n, 1/2)$ that the graph is cop-win, and let **universal** be the event that there is a universal vertex. If a graph has a universal vertex w , then it is cop-win; in a certain sense, graphs with universal vertices are the simplest cop-win graphs. The probability that a random graph is cop-win can be estimated as follows:

$$\begin{aligned} \mathbb{P}(\text{cop-win}) &\geq \mathbb{P}(\text{universal}) = n2^{-n+1} - O(n^22^{-2n+3}) \\ &= (1 + o(1))n2^{-n+1}. \end{aligned}$$

A recent surprising result of Bonato et al. [35] showed that this lower bound is in fact the correct asymptotic value for $\mathbb{P}(\text{cop-win})$.

Theorem 70 ([35]) In $G(n, 1/2)$,

$$\mathbb{P}(\text{cop-win}) = (1 + o(1))n2^{-n+1}.$$

Hence, almost all cop-win graphs contain a universal vertex.

10.2 The Dense Case

Now consider the cop number of *dense* random graphs, with average degree pn at least \sqrt{n} . The main results in this case were given in Bonato et al. [32].

Theorem 71 ([32])

(1) Suppose that $p \geq p_0$ where p_0 is the smallest p for which

$$p^2/40 \geq \frac{\log((\log^2 n)/p)}{\log n}$$

holds. Then, a.a.s.

$$\mathbb{L}n - \mathbb{L}((p^{-1}\mathbb{L}n)(\log n)) \leq c(G(n, p)) \leq \mathbb{L}n - \mathbb{L}((\mathbb{L}n)(\log n)) + 2.$$

(2) If $(2\log n)/\sqrt{n} \leq p = o(1)$ and $\omega(n)$ is any function tending to infinity, then a.a.s.

$$\mathbb{L}n - \mathbb{L}((p^{-1}\mathbb{L}n)(\log n)) \leq c(G(n, p)) \leq \mathbb{L}n + \mathbb{L}(\omega(n)).$$

By [Theorem 71](#), the following corollary gives a concentration result for the cop number. In particular, for a wide range of p , the cop number of $G(n, p)$ concentrates on just the one value $\mathbb{L}n$.

Corollary 3 ([32]) If $p = n^{-o(1)}$ and $p < 1$, then a.a.s.

$$c(G(n, p)) = (1 + o(1))\mathbb{L}n.$$

From [Theorem 71](#) part (1), it follows that if p is a constant, then there is the concentration result that

$$c(G(n, p)) = \mathbb{L}n - 2\mathbb{L}\log n + \Theta(1) = (1 + o(1))\mathbb{L}n.$$

10.3 The Sparse Case and Zigzag Theorem

Bollobás, Kun, and Leader [\[27\]](#) established the following bounds on the cop number in the sparse case, when the expected degree is $np = O(n^{1/2})$.

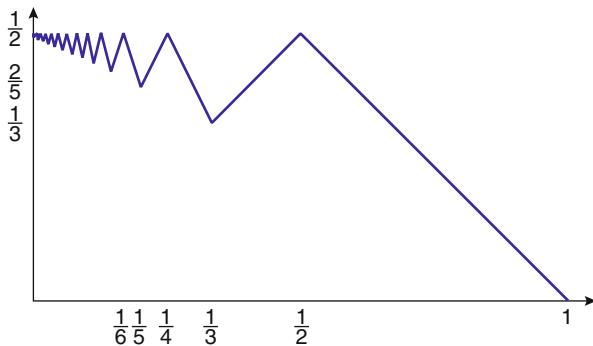

Theorem 72 ([27]) If $p(n) \geq 2.1 \log n/n$, then a.a.s.

$$\frac{1}{(np)^2} n^{\frac{1}{2} \frac{\log \log(np)-9}{\log \log(np)}} \leq c(G(n, p)) \leq 160,000\sqrt{n} \log n. \quad (7)$$

In particular, [Theorem 72](#) proves Meyniel's conjecture for random graphs up to a logarithmic factor of n from the upper bound in (7). Recent work by Prałat and Wormald [\[112\]](#) removes the $\log n$ factor in the upper bound of (7) and hence proves the Meyniel bound for random graphs.

It would be natural to assume that the cop number of $G(n, p)$ is close to \sqrt{n} also for $np = n^{\alpha+o(1)}$, where $0 < \alpha < 1/2$. The so-called zigzag theorem of Łuczak and Prałat [\[96\]](#) demonstrated that the actual behavior of $c(G(n, p))$ is much more complicated.

Fig. 6 The zigzag-shaped graph of the cop number of $G(n, p)$

Theorem 73 (Zig-Zag Theorem, [96]) Let $0 < \alpha < 1$, and $d = d(n) = np = n^{\alpha+o(1)}$.

(1) If $\frac{1}{2j+1} < \alpha < \frac{1}{2j}$ for some $j \geq 1$, then a.a.s.

$$c(G(n, p)) = \Theta(d^j).$$

(2) If $\frac{1}{2j} < \alpha < \frac{1}{2j-1}$ for some $j \geq 1$, then a.a.s.

$$\mathcal{O}\left(\frac{n}{d^j}\right) = c(G(n, p)) = O\left(\frac{n \log n}{d^j}\right).$$

Consider the function $f : (0, 1) \rightarrow \mathbb{R}$ defined by

$$f(x) = \frac{\log \bar{c}(G(n, n^{x-1}))}{\log n},$$

where $\bar{c}(G(n, n^{x-1}))$ is the median of the cop number for $G(n, p)$. See Fig. 6, which justifies Theorem 73's moniker. In particular,

$$f(x) = \begin{cases} \alpha j & \text{if } \frac{1}{2j+1} \leq \alpha < \frac{1}{2j} \text{ for some } j \geq 1, \\ 1 - \alpha j & \text{if } \frac{1}{2j} \leq \alpha < \frac{1}{2j-1} \text{ for some } j \geq 1. \end{cases}$$

11 Infinite Graphs

Infinite graphs exhibit properties often quite different than finite ones. In this regard, the cop number is no exception. For example, the *ray* (i.e., the one-way infinite path) is an infinite tree with infinite cop number: one robber can always stay ahead of finitely many cops.

11.1 Cop Density

When dealing with countable graphs, note that they are limits of chains of finite graphs. To analyze the cop number of infinite graphs, consider the *cop density* of a finite graph first introduced in [30]. Define

$$D_c(G) = \frac{c(G)}{|V(G)|}.$$

Note that $D_c(G)$ is a rational number in $[0, 1]$. Every countable graph G is the limit of a chain of finite graphs, and there are infinitely many distinct chains with limit G . Suppose that $G = \lim_{n \rightarrow \infty} G_n$, where $\mathcal{C} = (G_n : n \in \mathbb{N})$ is a fixed chain of induced subgraphs of G . The chain \mathcal{C} is a *full chain for* G . Define

$$D(G, \mathcal{C}) = \lim_{n \rightarrow \infty} D_c(G_n),$$

if the limit exists (and then it is a real number in $[0, 1]$). This is the *cop density of G relative to \mathcal{C}* ; if \mathcal{C} is clear from context, this is referred to as the *cop density of G* .

The *upper cop density of G* , written $UD(G)$, is defined as

$$\sup\{D(G, \mathcal{C}) : \mathcal{C} \text{ is a full chain for } G\}.$$

Note that $UD(G)$ does not depend on the chain and is a parameter of G .

For a positive integer n , a graph G is *strongly n -e.c.* if for all disjoint finite sets of vertices A and B from G with $|A| \leq n$, there is a vertex z correctly joined to A and B . Note that the infinite random graph is the unique isomorphism type of countable graph which is strongly n -e.c. for all n ; see [37]. The following result, proved in Bonato et al. [30], finds connections between infinite-cop-win graphs and the strongly 0- and 1-e.c. properties.

Theorem 74 ([30])

- (1) If G is strongly 1-e.c., then $c(G)$ is infinite.
- (2) If $c(G)$ is infinite, then G satisfies the strongly 0-e.c. property.

If G is strongly 1-e.c., then the cop density of G may be *any* real number in $[0, 1]$. This property applies, therefore, to a large number of graphs: for each $n \geq 0$, there are 2^{\aleph_0} many non-isomorphic countable graphs that are strongly n -e.c. but not strongly $(n + 1)$ -e.c.; see Theorem 4.1 of [28].

Theorem 75 ([30]) If G is strongly 1-e.c., then for all $r \in [0, 1]$, there is a chain \mathcal{C} in G such that $D(G, \mathcal{C}) = r$.

The next result completely characterizes the upper cop density of a graph G : $UD(G)$ takes on one of the two values 0 or 1 and equals 1 exactly when G is strongly 0-e.c. This fact, proven in [30], is somewhat unexpected.

Theorem 76 ([30]) *The following are equivalent:*

- (1) $UD(G) = 1$.
- (2) $UD(G) > 0$.
- (3) G is strongly 0-e.c.

We note that the strongly 0-e.c. graphs are precisely the spanning subgraphs of the infinite random graph; see Cameron [37].

11.2 Chordal Graphs

As another instance where results from finite graphs do not translate to infinite ones, consider chordal graphs. The graph G is *chordal* if each cycle of length at least four has a chord. A vertex of G is *simplicial* if its neighborhood induces a complete graph. Every finite chordal graph contains at least two simplicial vertices, and the deletion of a simplicial vertex leaves a chordal graph. As a simplicial vertex is a corner, a finite chordal graph is dismantlable and so cop-win.

However, an infinite tree containing a ray is chordal but not cop-win. Such trees have infinite diameter. Inspired by a question of Martin Farber which asked if infinite chordal graphs (more generally, bridged graphs) of finite diameter are cop-win, it was shown in Hahn et al. [76] that there exist infinite chordal graphs of diameter two that are not cop-win. The difficulty lies in finding examples with finite diameter.

Theorem 77 ([76]) *For each infinite cardinal κ , there exist chordal, robber-win graphs of order κ with diameter two.*

11.3 Large Families of Cop-Win Graphs

From Theorem 77, the cop number of infinite graphs behaves rather differently than in the finite case. Vertex-transitive cop-win finite graphs are cliques; see Nowakowski and Winkler [107]. However, this fails badly in the infinite case, which is the focus of this section.

A class of graphs is *large* if for each infinite cardinal κ , there are 2^κ many non-isomorphic graphs of order κ in the class. In other words, a large class contains as many as possible non-isomorphic graphs of each infinite cardinality. For example, the classes of all graphs, all trees, and all k -chromatic graphs for k finite are large. Recall that a graph G is *vertex-transitive* if for each pair of vertices x and y , there is an automorphism of G mapping x to y . The following result of Bonato et al. [34] showed that for any integer $k > 0$, there are large families of k -cop-win graphs that are vertex-transitive.

Theorem 78 ([34]) *The class of cop-win, vertex-transitive graphs with the property that the cop can win in two moves is large.*

To describe the large family in [Theorem 78](#), recall some properties of the strong product of a set of graphs over a possibly infinite index set. Let I be an index set. The *strong product* of a set $\{G_i : i \in I\}$ of graphs is the graph $\boxtimes_{i \in I} G_i$ defined by

$$\begin{aligned} V(\boxtimes_{i \in I} G_i) &= \{f : I \rightarrow \bigcup_{i \in I} V(G_i) : f(i) \in V(G_i) \text{ for all } i \in I\}, \\ E(\boxtimes_{i \in I} G_i) &= \{fg : f \neq g \text{ and for all } i \in I, \\ &\quad f(i) = g(i) \text{ or } f(i)g(i) \in E(G_i)\}. \end{aligned}$$

Products exhibit unusual properties if there are infinitely many factors.

Fix a vertex $f \in V(\boxtimes_{i \in I} G_i)$ and define the *weak strong product* of $\{G_i : i \in I\}$ with base f as the subgraph $\boxtimes_f^I G_i$ of $\boxtimes_{i \in I} G_i$ induced by the set of all $g \in V(\boxtimes_{i \in I} G_i)$ such that $\{i \in I : g(i) \neq f(i)\}$ is finite. The graph $\boxtimes_f^I G_i$ is connected if each factor is, and if $|I| \leq \kappa$ and $|V(G_i)| \leq \kappa$ for each $i \in I$, then $|V(\boxtimes_f^I G_i)| \leq \kappa$. For $i \in I$, the *projection mapping* $\pi_i : \boxtimes_f^I G_i \rightarrow G_i$ is defined by $\pi_i(g) = g(i)$.

Let $\{G_i : i \in I\}$ be a set of isomorphic copies of G . Denote by $\boxtimes^I G$ the strong product $\boxtimes_{i \in I} G_i$. If $f \in V(\boxtimes^I G)$ is fixed, denote by G_f^I the weak strong product $\boxtimes_f^I G$ with base f . One particular power of a graph is of special interest as it allows us to construct vertex-transitive graphs out of non-transitive ones. Let κ be a cardinal, and let H be a graph of order κ . Let $I = \kappa \times V(H)$, and define $f : I \rightarrow V(H)$ by $f(\beta, v) = v$. The power H_f^I of H with base f will be called the *canonical power* of H and will be denoted by H^H .

As automorphisms of the factors applied coordinate-wise yield an automorphism of the product, it follows that the weak strong product of vertex-transitive graphs is vertex-transitive. However, the following technical lemma from [34] demonstrates the paradoxical property that if there are infinitely many factors, the weak strong product may be vertex-transitive even if none of the factors are!

Lemma 2 ([34]) *If H is an infinite graph, then the canonical power of H^H is vertex-transitive.*

12 A Dozen Problems on Cops and Robbers

To serve as a record and a challenge, 12 open problems on Cops and Robbers are stated. These are arguably the most central (and relevant) problems in the field at the moment. Solutions to problems (1) and (11), in particular, would be exceptional breakthroughs:

- (1) Most likely the deepest open problem in the area is to settle *Meyniel's conjecture*: If G is a graph of order n , then

$$c(G) = O(\sqrt{n}). \quad (8)$$

- (2) An easier problem than (1) would be to settle the so-called *soft Meyniel's conjecture*: For a fixed constant $\epsilon > 0$,

$$c(n) = O(n^{1-\epsilon}),$$

- (3) Meyniel's conjecture remains open for familiar graph classes. For example, does it hold in graphs whose chromatic number is bounded by some constant k ?
(4) While the parameters m_k are nonincreasing, an open problem is to determine whether the M_k are in fact nonincreasing. A possibly more difficult problem is to settle whether $m_k = M_k$ for all $k \geq 1$.
(5) Can the lower bound (Eq. 4)

$$c(n) \geq \sqrt{\frac{n}{2}} - n^{0.2625}$$

- be improved for sufficiently large n ?
(6) For $k > 1$, it is conjectured in [35] that almost all k -cop-win graphs in fact have a dominating set of cardinality k . If this is the case, then the number labeled k -cop-win graphs of order n satisfies

$$F_k(n) = 2^{o(n)} (2^k - 1)^{n-k} 2^{\binom{n-k}{2}}.$$

- (7) Characterize the planar graphs with cop numbers 1, 2, and 3.
(8) Determine the cop number of the giant component of $G(n, p)$, where $p = \Theta(1/n)$. In particular, show that the cop number is a.a.s. $O(\sqrt{n})$.
(9) *Schroeder's conjecture*: If G is a graph of genus g , then $c(G) \leq g + 3$.
(10) Is the decision problem **k -COP NUMBER** in **NP**?
(11) Is **COP NUMBER** **EXPTIME**-complete? Goldstein and Reingold [72] proved that the version of the Cops and Robbers game on directed graphs is **EXPTIME**-complete. They also proved that the version of the game on undirected graphs when the cops and the robber are given their initial positions is also **EXPTIME**-complete.
(12) Are there large classes of infinite cop-win graphs whose members are k -chromatic, where $k \geq 2$ is an integer?

13 Conclusion

The chapter focused on two major aspects of graph searching: *searching* games and *Cops and Robbers* games. A broad overview of searching was given for both graphs and digraphs, focusing on the cases when the robber is invisible and active or is visible or lazy. Related games such as minimum cost searching and pebbling were also considered. Structural characterizations were given in these cases, along with

complexity results and bounds on various searching parameters. In the game of Cops and Robbers, a summary of known bounds and techniques were presented, focusing on Meyniel's conjecture as one of the most important problems on the cop number. Results were presented on algorithmic and probabilistic aspects of the cop number, and results were considered on infinite graphs. For both searching and Cops and Robbers, several problems and conjectures were given.

Given the broad diversity of techniques, applications, and problems in graph searching, it is evident that the field is now occupying an increasingly central position in graph theory and theoretical computer science. The subject has seen an explosive growth of interest in recent years. The wealth of new research on graph searching points to many more years of fruitful research in the field.

adjacency in the cluster becomes overly restrictive in such situations. Graph theoretic clique relaxations address this need by relaxing structural properties of a clique in a controlled manner via user-specified parameters. This chapter surveys such clique relaxations available in the literature primarily focusing on polyhedral results, complexity studies, approximability, and exact algorithmic approaches.

1 Introduction

A clique in a graph is a set of pairwise adjacent vertices. Given a simple, undirected, and finite graph, finding a clique of maximum cardinality, clustering the graph into minimum number of cliques that cover or partition the vertex set, and enumerating inclusionwise maximal cliques are fundamental combinatorial optimization problems associated with cliques. This basic model and the associated problems have been well studied in graph theory, polyhedral combinatorics, and complexity theory, leading to many deep results in these areas.

Cliques and many graph theoretic *clique relaxations* were proposed in *social network analysis* (SNA) to model *cohesive subgroups* in social networks [149]. Such applications of the clique model in SNA can be viewed within the broader scope of graph-based clustering and data mining [18, 41, 55] where data is modeled by a graph in which an edge implies similarity, dissimilarity, or some other relationship between the entities represented by the endpoints of the edge.

One could formalize the notion of a graph-theoretic cluster by requiring one or more of the following structural properties:

1. Each vertex has a large number of vertices adjacent to it inside the cluster.
2. The pairwise distances between vertices in the cluster are small.
3. The cluster has a large number of edges with both endpoints inside the cluster.
4. The cluster has a large fraction of the maximum possible number of edges, with both endpoints inside the cluster.
5. The cluster requires a large number of vertices or edges to be deleted in order to be disconnected.

Clique is an *ideal* graph model for this purpose as it represents a cluster in which every vertex has maximum possible number of adjacent vertices, maximum possible edges within a cluster, and minimum possible pairwise distances within a cluster. Furthermore, for a clique with n vertices, at least $n - 1$ edges must be deleted to disconnect the clique or $n - 1$ vertices must be deleted resulting in a trivial graph.

The need for relaxations of the clique model arises in practice when dealing with massive data sets which are inevitably prone to errors that manifest in the graph model as false or missing edges. The clique definition which requires complete pairwise adjacency in the cluster becomes overly restrictive in such situations. Graph theoretic clique relaxations address this need by relaxing the aforementioned structural properties in a controlled manner via user-specified parameters.

This chapter surveys graph theoretic clique relaxations that have witnessed a resurgent interest in recent literature in operations research, computer science, and graph-based data mining. Several comprehensive surveys on the maximum clique problem and its applications are available that also cover application areas other than data mining such as coding theory and fault diagnosis [31, 122]. This chapter adds to recent focused surveys on clique relaxations [27, 103, 125] by providing a more comprehensive overview and surveying some more recent developments. In particular, this chapter focuses on polyhedral results, complexity studies, approximability, and exact algorithmic approaches addressing clique relaxation models. When appropriate, proofs for some of the relevant results are also included from the original works.

1.1 Notations

In this chapter, an arbitrary, simple, finite, undirected graph of order n and size m is denoted by $G = (V, E)$ where $V = \{1, \dots, n\}$ and $(i, j) \in E$ when vertices i and j are adjacent, with $|E| = m$. For an introduction to graph theory, readers are referred to texts by West [150] or Diestel [62]. The edge density of a nontrivial graph G is the ratio of number of edges in G to the number of maximum possible edges in this graph, that is, $m / \binom{n}{2}$. The edge density of a single vertex graph is taken to be unity. The *complement graph* of G is denoted by $\overline{G} = (V, \overline{E})$ where \overline{E} is the complement of the edge set E .

Given $S \subseteq V$, *induced subgraph* $G[S]$ is obtained by deleting from G all vertices (and incident edges) in $V \setminus S$. The graph obtained by the deletion of a vertex i , an edge e , a set of vertices I , or a set of edges J from G is denoted by $G - i$, $G - e$, $G - I$, and $G - J$, respectively.

The *complete graph* on n vertices is denoted by K_n , and the *complete bipartite graph* with partitions of sizes p and q is denoted by $K_{p,q}$. In particular, the graph $K_{1,n}$ is called a *star*, and $K_{1,3}$ is called a *claw*. *Cycle* and *path* on n vertices are denoted by C_n and P_n , respectively. The *adjacency matrix* A_G is a symmetric 0,1-matrix of order $n \times n$ with $a_{i,j} = 1 \Leftrightarrow (i, j) \in E$.

For a vertex $i \in V$, $N_G(i)$ denotes the set of vertices adjacent to i in G , called the *neighborhood* of i , and $N_G[i] = \{i\} \cup N_G(i)$ denotes the *closed neighborhood* of i . The set of *non-neighbors* of i is given by $V \setminus N_G[i]$. Denote by $\deg_G(i)$, the degree of vertex i in G given by $|N_G(i)|$. The maximum and minimum degrees in a graph are denoted, respectively, by $\Delta(G)$ and $\delta(G)$.

For two vertices $i, j \in V$, $d_G(i, j)$ denotes the length of a shortest path between i and j in G . By convention, when no path exists between two vertices, the shortest distance between them is infinity. The *diameter* of a graph is defined as $\text{diam}(G) = \max_{i,j \in V} d_G(i, j)$. For a graph $G = (V, E)$ and positive integer k , the k th power of G is defined as $G^k = (V, E^k)$, where $E^k = \{(i, j) : i, j \in V, d_G(i, j) \leq k\}$. The simple graph G^k is constructed from the original graph by adding edges corresponding to all pairs of vertices with distance no more than k between them in G .

The *vertex connectivity* $\kappa(G)$ and *edge connectivity* $\lambda(G)$ of a graph are the minimum number of vertices and edges, respectively, whose removal results in a disconnected or trivial graph. A graph is said to be t -connected if $\kappa(G) \geq t$ and t -edge connected if $\lambda(G) \geq t$. It is known that when G is nontrivial, $\kappa(G) \leq \lambda(G) \leq \delta(G)$ [150]. If the graph G under consideration is obvious, the subscript G in the neighborhood, degree, and distance notations is sometimes dropped for simplicity.

1.2 Cliques and Related Models

Definition 1 A clique is a subset of vertices that are pairwise adjacent in the graph.

Definition 2 An independent set (stable set, vertex packing) is a subset of vertices that are pairwise nonadjacent in the graph.

The *maximum clique problem* is to find a clique of maximum cardinality. The *clique number* $\omega(G)$ is the cardinality of a maximum clique in G . The maximum cardinality of an independent set of G is called the *independence number* of the graph G and is denoted by $\alpha(G)$. The associated problem of finding a largest independent set is the *maximum independent set problem*. Clearly, I is an independent set in G if and only if I is a clique in \overline{G} and consequently $\alpha(G) = \omega(\overline{G})$.

In this chapter, *maximality* and *minimality* of sets are always defined based on inclusion and exclusion, respectively. For instance, a *maximal clique* is one that is not a proper subset of another clique. The maximum clique and independent set problems on arbitrary graphs are NP-hard [74] and are hard to approximate within $n^{1-\epsilon}$ for any $\epsilon > 0$ [79]. Furthermore, finding cliques and independent sets parameterized by solution size are not known to be fixed-parameter tractable problems and, in fact, are basic $W[1]$ -hard problems [65].

Definition 3 A proper coloring of a graph is one in which every vertex is colored such that no two vertices of the same color are adjacent.

A graph is said to be t -colorable if it admits a proper coloring with t colors. Vertices of the same color are referred to as a *color class*, and they induce an independent set. The *chromatic number* of the graph, denoted by $\chi(G)$, is the minimum number of colors required to properly color G . For any graph G , $\omega(G) \leq \chi(G)$, as different colors are required to color the vertices of a clique.

Definition 4 A vertex cover is a subset of vertices such that every edge in the graph is incident at some vertex in the subset.

Clearly, C is a vertex cover of G if and only if $V \setminus C$ is an independent set in G . The *minimum vertex cover problem* seeks to find a vertex cover of minimum cardinality.

Definition 5 A dominating set is a subset of vertices such that every vertex in the graph is either in this set or has a neighbor in this set.

The minimum cardinality of a dominating set is called the *domination number*, denoted by $\gamma(G)$. It should be noted that every maximal independent set is also a minimal dominating set.

2 Degree-Based Clique Relaxation: k -Plex

The degree-based clique relaxation, called a k -plex, was introduced by Seidman and Foster for modeling cohesive subgroups in social network analysis [133]. The parameter $k \geq 1$ is a positive integer that controls the “degree” of relaxation and includes clique as a special case. A complementary model to k -plex can also be defined along similar lines that relaxes independent sets.

Definition 6 A subset $S \subseteq V$ is a k -plex if $\delta(G[S]) \geq |S| - k$.

Definition 7 A subset $J \subseteq V$ is a co- k -plex if $\Delta(G[J]) \leq k - 1$.

Clearly, 1-plexes and co-1-plexes are simply cliques and independent sets, respectively. For $k > 1$, a k -plex is a degree-based relaxation of the clique definition which allows for at most $k - 1$ non-neighbors in S , while the co- k -plex is a degree-based relaxation of the independent set definition which allows for at most $k - 1$ neighbors in J . Clearly, S is a k -plex in G if and only if S is a co- k -plex in \bar{G} . Figure 1 illustrates this concept. The set $\{1, 2, 3, 4\}$ is a 1-plex (clique), sets $\{1, 2, 3, 4, 5\}$ and $\{1, 2, 3, 4, 6\}$ are 2-plexes (maximal and maximum), and the entire vertex set forms a 3-plex. In the same graph $\{5, 6\}$ forms a co-1-plex (independent set), while $\{1, 5, 6\}$ forms a co-2-plex.

The *maximum k -plex problem* is to find a largest cardinality k -plex in G , the cardinality of which is the *k -plex number* of G denoted by $\omega_k(G)$. The *maximum co- k -plex problem* is similarly defined with the *co- k -plex number* denoted by $\alpha_k(G)$. Some early results on k -plexes established by Seidman and Foster [133] are summarized in Theorem 1. An alternate characterization of k -plexes, Theorem 2, was also established therein.

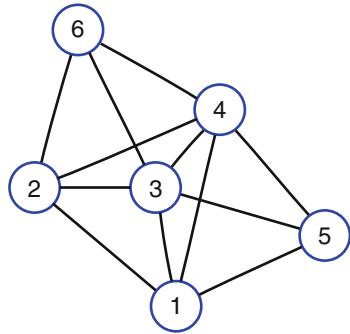

Theorem 1 ([133]) *Let graph G be a k -plex on n vertices. Then,*

1. *Any vertex-induced subgraph of G is a k -plex.*
2. *If $k < \frac{n+2}{2}$, then $\text{diam}(G) \leq 2$.*
3. $\kappa(G) \geq n - 2k + 2$.

Proof

1. Every induced subgraph of G can be obtained by deleting vertices, one at a time. If G is a k -plex, $\delta(G) \geq n - k$. In G' obtained by deleting some vertex from G ,

Fig. 1 Illustration of k -plexes and co- k -plexes

- the degree of all the vertices and hence the minimum degree can drop by at most 1. Hence, the new graph continues to be a k -plex as $\delta(G') \geq (n - 1) - k$.
2. For any vertex v in the k -plex G , the number of vertices in the closed neighborhood $|N[v]| \geq n - k + 1$. Thus, for two arbitrary vertices u, v we have $|N[u]| + |N[v]| \geq 2n - 2k + 2 > n$ by the given condition. Hence, $N[u]$ and $N[v]$ are not disjoint. Thus, for all u, v , $d_G(u, v) \leq 2 \Rightarrow \text{diam}(G) \leq 2$.
 3. Suppose we delete t vertices from G . The resulting graph G' is still a k -plex and the above argument still holds. If $k < \frac{n-t+2}{2}$, then $\text{diam}(G') \leq 2$. Thus, G' is still connected if $t < n - 2k + 2 \Rightarrow \kappa(G) \geq n - 2k + 2$.

Remark 1 Note that the condition for a diameter-two bound is sharp. Consider the graph $K_{k-1} \cup K_{k-1}$ which is a k -plex for every k . Thus, a k -plex could be disconnected even for $k = \frac{n+2}{2}$. However, no isolated vertex could be present in a k -plex of size $k + 1$ or more.

Remark 2 It is also useful to note that in an arbitrary graph G , any k -element subset of vertices is a k -plex and any k -plex is also a $k + 1$ -plex.

Theorem 2 ([133]) $G = (V, E)$ is a k -plex if and only if every k -element subset of vertices forms a dominating set in G .

Proof Suppose there exist k vertices that do not form a dominating set, then there must be some vertex v distinct from these k vertices that is not adjacent to any of these k vertices. This contradicts the fact that G is a k -plex.

Now suppose that G is not a k -plex. Hence, $|V| \geq k + 1$, and there exists a vertex $v \in V$ such that $|N(v)| \leq |V| - k - 1$. Hence, $|V \setminus N[v]| \geq k$, and it does not dominate G , specifically the vertex v . \square

A characterization of 2-plexes via the co-2-plex number is provided in [Proposition 1 \[105\]](#). This characterization does not extend to general k in a straightforward manner.

Proposition 1 ([105]) $G = (V, E)$ is a 2-plex if and only if $\alpha_2(G) = \min\{2, |V|\}$.

Proof Suppose G is a 2-plex and $\alpha_2(G) \geq 3$. Then, V contains a subset $S = \{u, v, w\}$ that forms a co-2-plex. At least one vertex in S must have zero degree in $G[S]$, which contradicts the fact that $G[S]$ is a 2-plex.

Conversely, suppose G is graph with $|V| \geq 3$ and $\alpha_2(G) = 2$. If G is not a 2-plex, there exists $u \in V$ such that $|N(u) \cap V| \leq |V| - 3$. Hence, there exist vertices $v, w \in V \setminus N[u]$, and the set $\{u, v, w\}$ forms a co-2-plex of size 3. \square

There is a close relationship between the maximum k -plex problem and the *minimum bounded-degree- d vertex deletion problem* (d -BDD) studied in [114]. The d -BDD problem defined next is a generalization of the minimum vertex cover problem.

Definition 8 Given a graph $G = (V, E)$ and a fixed integer $d \geq 0$, a bdd- d -set is defined as a subset $S \subseteq V$ for which $G[V \setminus S]$ is a graph with maximum vertex degree at most d [113].

The minimum bounded-degree- d vertex deletion problem is to find a minimum cardinality bdd- d -set in G . Note that for $d = 0$, a bdd-0-set is precisely a vertex cover of G . Further note that if S is a bdd- d -set, then $V \setminus S$ by definition is a co- k -plex with $k = d + 1$. Lemma 2 shows the relationship between the maximum k -plex problem and the minimum d -BDD problem.

Proposition 2 ([113]) A graph $G = (V, E)$ contains a k -plex of size c if and only if \overline{G} contains a bdd- d -set of size $|V| - c$ with $d = k - 1$.

Proof It follows from the observation that $S \subseteq V$ is a k -plex of size c in G if and only if S is a co- k -plex in \overline{G} . \square

A natural degree-based generalization of graph coloring is the following.

Definition 9 A proper co- k -plex coloring of a graph $G = (V, E)$ is an assignment of colors to V such that each vertex has at most $k - 1$ neighbors in the same color class.

Co- k -plexes have also been called $(k - 1)$ -dependent sets in the literature [64] and co- k -plex coloring has also been studied under other names such as defective coloring [59] and k -improper coloring [80]. A proper co- k -plex coloring of G partitions G into co- k -plexes and is equivalent to a k -plex partitioning of \overline{G} . Obviously, an independent set cannot contain a clique of size larger than one, while k -plexes of size two or more can be found inside a co- k -plex for $k \geq 2$. A sharp upper bound on the maximum size of the intersection was established in [20] showing that if $\Delta(G) \leq k - 1$, then $\omega_k(G) \leq 2k - 2 + (k \bmod 2)$. In light of this observation, two graph invariants can be defined to relax the graph coloring problem as discussed next.

The minimum number of colors required in a proper co- k -plex coloring of G is called the *co- k -plex chromatic number* denoted by $\chi_k(G)$ [21]. The *weighted co- k -plex chromatic number* denoted by $\chi_k^w(G)$ is defined as the minimum weighted sum of the color classes, where the weight of a color class is the size of a maximum k -plex contained in the color class [104]. These definitions are equivalent when $k = 1$, but not for $k > 1$. The latter provides a tighter upper bound on the k -plex number as the following inequality is true for any graph G [20, 104]:

$$\omega_k(G) \leq \chi_k^w(G) \leq [2k - 2 + (k \bmod 2)]\chi_k(G).$$

2.1 Complexity and Approximation

For arbitrary k , where the parameter is considered as part of the input for each instance of the problem, the maximum k -plex problem is trivially NP-hard as it includes the maximum clique problem as a special case. However, the complexity of the problems for fixed k (prescribed as part of the problem definition) is a nontrivial question.

A graph property Π is said to be *hereditary on induced subgraphs*, if G is a graph with property Π and the deletion of any subset of vertices does not produce a graph violating Π . Property Π is said to be *nontrivial* if it is true for a single vertex graph and is not satisfied by every graph. A property Π is said to be *interesting* if there are arbitrarily large graphs satisfying Π . The *maximum Π problem* is to find the largest order induced subgraph that does not violate property Π . Naturally, this optimization problem is meaningful only if Π is nontrivial and interesting.

Yannakakis [153] obtained a general complexity result for such properties Π showing that the maximum Π problem for nontrivial, interesting graph properties that are hereditary on induced subgraphs is NP-hard. Inapproximability of such problems was also established by Lund and Yannakakis in [96]. Since k -plexes and co- k -plexes are nontrivial, interesting, and hereditary, the maximum k -plex and co- k -plex problems are NP-hard based on this result and hard to approximate within $O(n^\epsilon)$ for some $\epsilon > 0$ unless $P = NP$.

The NP-hardness of the maximum k -plex problem and the maximum co- k -plex problem for every fixed k was also independently established in [20, 64], respectively. In [61], the maximum co- k -plex problem was shown to be NP-hard even on planar and bipartite graphs for fixed $k \geq 2$. Recently in [81, 88], this problem was shown to be NP-hard for every fixed k on unit-disk graphs (UDGs, intersection graphs of unit-disks in a Euclidean plane [54]). Note that the maximum independent set problem is NP-hard on planar graphs [74] and unit-disk graphs [54], but it is polynomial time solvable on bipartite graphs through graph-matching techniques [56]. Analogous to what is known for cliques and vertex covers, the maximum k -plex problem parameterized by solution size is $W[1]$ -hard [91], while the d -BDD problem is fixed-parameter tractable when parameterized by solution size [91, 118].

The maximum co- k -plex problem admits a polynomial time approximation scheme (PTAS) on UDGs [81, 88] and a $3k$ -approximation algorithm on

UDGs [21]. The PTAS employs a “divide-and-conquer” approach similar to that used for independent sets in UDGs [84], and the constant factor approximation employs approaches similar to those developed in [100] for independent sets. The minimum co- k -plex coloring problem is also NP-hard for every fixed k on UDGs [81, 88]. A polynomial time 6-approximation algorithm for this problem was developed in [81, 88], and a 3-approximate algorithm for this problem was presented in [21]. Some bounds on the graph invariants $\omega_k(G)$, $\alpha_k(G)$, and $\chi_k(G)$ were also developed in [21], used to establish the aforementioned approximation guarantees for UDGs and generalized claw-free graphs. These identities summarized in **Theorem 3** generalize some well-known results for cliques, independent sets, and coloring (see for instance [83, 100]).

Theorem 3 ([21]) Consider a graph $G = (V, E)$,

1. $\alpha_k(G) \leq k\alpha(G)$.
2. $\omega_k(G) \leq k\omega(G)$.
3. If G is a $(p + 1, k)$ -claw-free, that is, $\alpha_k(G[N(v)]) \leq p \forall v \in V$, then

$$|J| \geq \frac{\alpha_k(G)}{p}$$

for any maximal co- k -plex J .

4. If G is a unit-disk graph with an embedding specified in the Euclidean X - Y plane, then $\alpha_k(G[N(v)]) \leq 5k \forall v \in V$, and if v is the vertex corresponding to the minimum X -coordinate, then $\alpha_k(G[N(v)]) \leq 3k$.
5. $\chi_k(G) \leq \lfloor \frac{d(G)}{k} \rfloor + 1$ where the polynomial time computable invariant $d(G)$ denotes the largest d such that G has an induced subgraph of minimum degree at least d .
6. If G is a unit-disk graph, then $\chi_k(G) \geq \frac{d(G)}{3k}$.

Proof

1. Suppose $\alpha_k(G) \geq k\alpha(G) + 1$. Let $G^{(0)}$ be a co- k -plex induced in G of size $k\alpha(G) + 1$. Apply the following greedy algorithm for a maximal independent set in graph $G^{(0)}$, with set I initially empty and $i = 0$. Pick any vertex v from $V(G^{(i)})$, let $I \leftarrow I \cup \{v\}$ and $G^{(i+1)} \leftarrow G^{(i)} - N[v]$. Increment i and repeat until $G^{(i+1)}$ is null. Since $G^{(0)}$ is a co- k -plex, so are all $G^{(i)}$, and thus $\Delta(G^{(i)}) \leq k - 1$. So $|V(G^{(i+1)})| = |V(G^{(i)})| - 1 - |N(v) \cap V(G^{(i)})| \geq |V(G^{(i)})| - k$. After $\alpha(G)$ iterations $|I| = \alpha(G)$ and $|V(G^{(\alpha(G))})| \geq k\alpha(G) + 1 - k\alpha(G) = 1$. So the algorithm can add at least one more vertex to independent set I , a contradiction.
2. Implied by 1.
3. Suppose J^* is a maximum co- k -plex in G . Further assume that $p \geq k$, as the only $(p + 1, k)$ -claw-free graphs with $p < k$ are themselves co- k -plexes. Then

$$J^* \setminus \bigcup_{v \in J} N[v] = \emptyset;$$

otherwise, there exists a $v \in J^*$ such that $N[v] \cap J = \emptyset$ contradicting the maximality of J . Hence, we have

$$|J^*| = \alpha_k(G) \leq \sum_{v \in J} |N[v] \cap J^*| \leq p|J|.$$

4. By Part 1 we have $\alpha_k(N(v)) \leq k\alpha(N(v)) \leq 5k$ where the last inequality follows from the result of Marathe et al. [100] that for a UDG, $\alpha(N(v)) \leq 5 \forall v \in V$. The bound for the minimum X-coordinate can be obtained similarly by extending an analogous result from [100].
5. Denote by $d(G)$ the largest d such that G has an induced subgraph of minimum degree at least d . The invariant $d(G)$ can be found in polynomial time using a simple algorithm [83] along with an associated ordering v_1, \dots, v_n of vertices of G such that any v_i has at most $d(G)$ neighbors in v_1, \dots, v_{i-1} . In that order, for each vertex, assign the smallest *available* color. A color is said to be *available* at a vertex if it has been assigned to at most $k - 1$ neighbors of the current vertex, already processed in the list ordering.

Consider any vertex v_i , $i = 2, \dots, n$. It can have at most $d(G)$ neighbors already colored in the list so far. There must exist a color from the set $\{1, \dots, \lfloor \frac{d(G)}{k} \rfloor + 1\}$ that has been assigned to at most $k - 1$ neighbors of v_i . If not, the number of colored neighbors of v_i exceeds $d(G)$. Since this is true for any v_i , the above algorithm uses no more than $\lfloor \frac{d(G)}{k} \rfloor + 1$ colors.

6. Let H be the induced subgraph of G such that $\delta(H) = d(G)$. Consider a vertex $v \in V(H)$ of minimum X-coordinate, and let H' denote the graph induced by $N(v)$. Any proper co- k -plex coloring of G is also proper for H' , and it partitions H' into co- k -plexes. Hence, we have

$$\chi_k(G) \geq \chi_k(H') \geq \frac{|V(H')|}{\alpha_k(H')} \geq \frac{d(G)}{3k}. \quad \square$$

2.2 Polyhedral Results

The maximum k -plex problem can be formulated as the following integer program:

$$\omega_k(G) = \max \sum_{i \in V} x_i$$

Subject to

$$\begin{aligned} \sum_{j \in V \setminus N[i]} x_j &\leq (k-1)x_i + |V \setminus N[i]|(1-x_i) \quad \forall i \in V \\ x_i &\in \{0, 1\} \quad \forall i \in V. \end{aligned}$$

Given a graph $G = (V, E)$, the k -plex polytope of G denoted by $P_k(G)$ is the convex hull of the incidence vectors of all k -plexes in G . The k -plex polytope is full dimensional and the variable 0,1-bound constraints are facet inducing as stated in [Theorem 4](#). The case $k = 1$ which corresponds to the well-known clique polytope is excluded from consideration.

Theorem 4 ([20]) *Given a graph $G = (V, E)$ and an integer $k > 1$,*

1. $\dim(P_k(G)) = n$,
2. *For each $i \in V$, inequalities $x_i \geq 0$ and $x_i \leq 1$ are facet inducing for $P_k(G)$.*

Several facets and valid inequalities for $P_k(G)$ for arbitrary and restricted graph classes are available from [20, 105]. The results for the co- k -plex polytope developed in [105] are adapted via complementation for $P_k(G)$ in this chapter. It should be noted that these results extend several analogous results known for the clique and stable set polytopes [49, 50, 116, 117, 121, 142].

2.2.1 Co- k -plex and Independent Set Inequalities

Proposition 3 ([20]) *(Co- k -plex inequalities) Given a graph $G = (V, E)$ and an integer $k \geq 1$, let $r_k = 2k - 2 + (k \bmod 2)$. If $I \subseteq V$ is a maximal co- k -plex of size at least $r_k + 1$ in G , then the following inequality is valid for $P_k(G)$:*

$$\sum_{i \in I} x_i \leq r_k.$$

[Proposition 3](#) can be further strengthened for the case, $k = 2$ as outlined in [Theorem 5](#).

Theorem 5 ([20]) *(Co-2-plex facets) Given a graph $G = (V, E)$ and $J \subseteq V$ such that $|J| \geq 3$, the inequality $\sum_{i \in J} x_i \leq 2$ induces a facet of $P_2(G)$ if and only if J is a maximal co-2-plex.*

Proof The validity of this inequality for $P_2(G)$ follows from [Proposition 3](#). So, it suffices to show that the face of $P_2(G)$ induced by this inequality,

$$\left\{ x \in P_2(G) : \sum_{i \in J} x_i = 2 \right\},$$

is of dimension $n - 1$.

Note that if J is a maximal co- k -plex, for every $v \in V \setminus J$, at least one of the following conditions must hold:

1. $\exists j \in J \cap N(v)$ such that $|N(j) \cap J| = k - 1$ and including v would cause degree of j in the induced subgraph to be k .
2. $|N(v) \cap J| \geq k$ and upon inclusion, v would have degree k or more in the induced subgraph.

For every $v \in V \setminus J$, the above two conditions for a maximal co-2-plex imply the existence of two vertices $u, w \in J$ such that $\{v, u, w\}$ is a 2-plex. Indeed, if the first

case holds, let $u \in J \cap N(v)$, then $N(u) \cap J = \{w\}$ and $\{v, u, w\}$ is a 2-plex. If the second case holds, $\{u, w\} \subseteq J \cap N(v)$ and again $\{v, u, w\}$ is a 2-plex.

W.l.o.g. assume that $J = \{1, \dots, r\}$ and $V \setminus J = \{r + 1, \dots, n\}$, where $r \geq 3$. Let $e_i \in \mathbb{R}^n$ denote the unit vector with i th component one and all others zero. The affinely independent vectors are constructed as follows:

$$\begin{aligned} x^v &= e_v + e_r, \quad \forall v = 1, \dots, r - 1, \\ x^r &= e_1 + e_2 \text{ (note that } x^r \text{ is distinct from } x^1, \dots, x^{r-1} \text{ as } r \geq 3), \\ x^v &= e_v + e_u + e_w, \quad \forall v = r + 1, \dots, n, \end{aligned}$$

where for each $v \in V \setminus J$, $u, w \in J$ are particular vertices described before. Clearly, $x^v \in \{x \in P_2(G) : \sum_{i \in J} x_i = 2\}$, $\forall v \in V$, and it is easy to verify that they are affinely independent.

Conversely, suppose $\sum_{i \in J} x_i \leq 2$ induces a facet of $P_2(G)$ and J is not a co-2-plex. Then, there exists some $v \in J$ with 2 neighbors in J which form a 2-plex that violates the facet-inducing inequality, leading to a contradiction. Hence, J must be a co-2-plex. If J is not maximal, then there exists a valid maximal co-2-plex inequality that dominates the given facet-inducing inequality. Hence, J must be a maximal co-2-plex. \square

Padberg [121] (see also [71]) showed that the maximal independent set inequalities are facet inducing for the clique polytope, and [Theorem 5](#) is a direct analogue for the 2-plex polytope. However, for $k \geq 3$, co- k -plex inequalities are not necessarily facets of $P_k(G)$ for arbitrary graphs. It should be noted that the bound r_k while sharp is not necessarily achieved in all co- k -plexes and the k -plex number could be strictly smaller than r_k . Even in co- k -plexes where the bound is achieved, there may not be enough affinely independent incidence vectors of k -plexes achieving that bound. This motivated the study of k -plex rank inequalities of $P_k(G)$ [105]. For any $I \subseteq V$, the following k -plex rank inequality is valid for $P_k(G)$:

$$\sum_{i \in I} x_i \leq \omega_k(G[I]).$$

A sufficient condition under which the k -plex rank inequality derived based on the k -plex number of G induces a facet of $P_k(G)$ was developed in [105], extending a result of Chvátal [53].

Definition 10 Given a graph $G = (V, E)$ and an edge $e \in \overline{E}$ in the complement graph \overline{G} , e is called k -plex critical if $\omega_k(G + e) = \omega_k(G) + 1$ where $G + e = (V, E \cup \{e\})$.

Theorem 6 ([105]) Let $E^* \subseteq \overline{E}$ be the set of all k -plex critical edges of G . If the graph $G^* = (V, E^*)$ is connected, then the k -plex rank inequality $\sum_{i \in V} x_i \leq \omega_k(G)$ induces a facet of $P_k(G)$.

Maximal independent set inequalities play an important role in describing the clique polytope of graphs. Specifically, along with nonnegativity constraints, they are sufficient to completely describe the clique polytope of perfect graphs [58]. Preliminary results in this direction established in [105] show that the co-2-plex facets and the variable bounds are sufficient to describe the 2-plex polytope of paths, mod-3 cycles (see [Definition 11](#)), and co-2-plexes.

The co- k -plex inequalities for the k -plex polytope generalize the independent set inequalities for the clique polytope. Note that $r_1 = 1$, and hence, the co-1-plex inequalities are precisely the independent set inequalities for the 1-plex (clique) polytope. An alternate approach based on the observation that an independent set can contain at most k vertices from a k -plex for any k leads to the independent set inequalities for the k -plex polytope.

Proposition 4 ([20]) (*Independent set inequalities*) Given a graph $G = (V, E)$ and an integer $k \geq 1$, if $I \subseteq V$ is a maximal independent set of size at least $k + 1$ in G , then $\sum_{i \in I} x_i \leq k$ is a valid inequality for $P_k(G)$. Furthermore, if $E = \emptyset$ and $n \geq k + 1$, the inequality induces a facet of $P_k(G)$.

When $k = 1$, co-1-plex and independent set inequalities described here coincide with the well-known inequalities for the clique polytope. For $k = 2$, independent set inequalities are dominated by the facet-inducing co-2-plex inequalities since $r_k = k = 2$. However, that is not the case for $k \geq 3$ as maximal independent set inequalities upon lifting can produce facets of $P_k(G)$ that are not identified as co- k -plex inequalities or k -plex rank inequalities [20].

In addition to independent set inequalities, some other well-known class of inequalities for the clique polytope are hole and antihole inequalities [116, 121], wheel inequalities and their generalizations [23, 49], web and antiweb inequalities [142], and many others [24, 33, 75]. Extensions of some of these results to the k -plex polytope is presented next.

2.2.2 Hole Inequalities and Special Cases

Definition 11 A hole is an induced chordless cycle of size 4 or more. For a positive integer k , a hole on n vertices with $n \equiv 0 \pmod{k}$ is called a mod- k hole, otherwise it is an odd mod- k hole. The complement of a hole is called an antihole.

Valid inequalities based on holes were developed in [20] for the k -plex polytope. These are also known to be facet inducing for $P_k(C_n)$ depending on n and k .

Proposition 5 ([20]) (*Hole inequalities*) Given a graph $G = (V, E)$ and a positive integer k , if $I \subseteq V$ is a hole of size $\geq k + 3$, then $\sum_{i \in I} x_i \leq k + 1$ is a valid inequality for $P_k(G)$.

Theorem 7 ([20]) Consider a cycle C_n on n vertices, positive integer k with $n \geq k + 3$ such that n and $k + 1$ are relatively prime. Then, the inequality $\sum_{i \in V} x_i \leq k + 1$ induces a facet of $P_k(C_n)$.

Theorem 7 for odd mod- $(k+1)$ holes is a direct analogue of the result developed by Nemhauser and Trotter [116]. Interestingly, however, mod- $(k+1)$ holes can also induce facets of $P_k(C_n)$ [20].

Theorem 8 ([20]) Consider a cycle C_n on n vertices and a positive integer $k \geq 4$ such that $n \geq k+3$ and n is a multiple of $k+1$. Then, the inequality $\sum_{i \in V} x_i \leq k+1$ induces a facet of $P_k(C_n)$.

Note that antiholes are k -plexes for $k \geq 3$. However, when $k=2$, antiholes do lead to valid inequalities for the 2-plex polytope [105]. Lifting this inequality leads to the *antiwheel* inequality, details of which can be found in [105].

Theorem 9 ([105]) Consider the complement of a cycle on n vertices \bar{C}_n with $n \geq 4$ such that $n \not\equiv 0 \pmod{3}$. Then, the inequality $\sum_{i \in V} x_i \leq \lfloor \frac{2n}{3} \rfloor$ induces a facet of $P_2(\bar{C}_n)$.

Definition 12 Given a graph $G = (V, E)$ and an integer p , suppose $n \geq 2$, $1 \leq p \leq \frac{n}{2}$. If $E = \{(i, j) : j = i + p, \dots, i + n - p, \forall i \in V\}$ where sums are written modulo n , then G is called a web, denoted by $W(n, p)$. The complement of a web is an antiweb.

Webs were introduced by Trotter [142] to generalize odd hole and antihole inequalities for the stable set polytope. This result was extended in [105] to show that antiwebs induce facets of the 2-plex polytope as outlined next. It should be noted that $W(n, 1)$ is a complete graph, for $p \geq 2$, $W(2p+1, p)$ is an odd hole and $W(2p+1, 2)$ is an odd antihole.

Theorem 10 ([105]) (Web inequalities) Consider the antiweb $\bar{W}(n, p)$ where n and $p+1$ are relatively prime and $p < \lfloor \frac{n}{2} \rfloor$, then the inequality $\sum_{i \in V} x_i \leq p+1$ induces a facet of $P_2(\bar{W}(n, p))$.

This section is concluded with valid inequalities produced by generalizing claws. These were originally developed for the co- k -plex polytope in [105].

Definition 13 Given a graph $G = (V, E)$ and an integer $k \geq 1$, if there exists a vertex $u \in V$ such that $N(u) = V \setminus \{u\}$, $N(u)$ is a co- k -plex, and $|N(u)| \geq \max\{3, k\}$, then G is called a k -claw. Vertex u is called the center of the k -claw.

Theorem 11 ([105]) Consider a graph $G = (V, E)$ such that \bar{G} is a k -claw with center $u \in V$ and integer $k \geq 2$, the inequality $(n-k)x_u + \sum_{i \notin N_G[u]} x_i \leq n-1$ is a facet of $P_k(G)$.

Of particular note is that a k -claw can properly contain another k -claw, and both would give rise to distinct facets.

2.3 Algorithms

Exact algorithms for the maximum k -plex problem can be broadly categorized as combinatorial approaches and polyhedral approaches. A branch-and-cut framework is developed in [20] that incorporates maximal independent set and co- k -plex inequalities identified via heuristic separation procedures. An *iterative peel-branch-and-cut* algorithm to solve the maximum k -plex problem to optimality on “scale-free” graphs is also developed in [20] that uses the branch-and-cut algorithm in combination with preprocessing and graph decomposition approaches.

Scale-free graphs [22, 52] are very large and sparse graphs which exhibit a power-law degree distribution. The large-scale and sparse nature of such graphs present computational challenges that are addressed by exploiting the power-law nature of such graphs. The need for such specialized techniques are motivated by graph-based data mining applications where the graph models exhibit a power-law degree distribution [20].

Numerous exact combinatorial algorithms are known for the maximum clique problem such as those developed by Bron and Kerbosch [38], Balas and Yu [16], Applegate and Johnson [7], Carraghan and Pardalos [43], Babel [13], Balas and Xue [15], Wood [151], Sewell [134], Östergård [120], and Tomita and Kameda [141].

Östergård’s algorithm [120], which extends the approaches proposed by Applegate and Johnson [7] and Carraghan and Pardalos [43], has been extended to the maximum k -plex problem by McClosky and Hicks [102, 106] and by Trukhanov et al. [143, 144]. Design of such algorithms and variations, implementation details, computational results on DIMACS benchmarks [63], as well as comparisons between algorithms can be found in [106, 114, 144].

Algorithm 1 presents a basic extension of Östergård’s clique algorithm [120] to the maximum k -plex problem, which works by first ordering vertices in V based on degree or other criteria as v_1, v_2, \dots, v_n . Let set $S_i \subseteq V$ be defined as $S_i = \{v_i, v_{i+1}, \dots, v_n\}$ and let $c(i)$ denote the size of the maximum k -plex in $G[S_i]$. Clearly $c(n) = 1$ and $c_1 = \omega_k(G)$. **Algorithm 1** recursively computes $c(i)$ starting from $c(n)$ and down to $c(1)$ for which the following holds:

$$c(i) = \begin{cases} c(i + 1) + 1, & \text{if the corresponding solution contains } v_i, \\ c(i + 1), & \text{otherwise.} \end{cases}$$

A different approach is undertaken in [114] where the close relationship to the minimum bounded-degree- d vertex deletion problem and its fixed-parameter tractability with respect to the solution size is exploited to develop an exact algorithm for the maximum k -plex problem. Another important result in advancing this line of research is the following. A basic result of Nemhauser and Trotter [117] is fundamental to many fixed-parameter tractable and approximation algorithms for the minimum vertex cover problem. In [70], a generalization of this result is

Algorithm 1 Maximum k -plex algorithm

```

1: procedure MAXKPLEX(G)
2:   Order vertices in  $V$  as  $v_1, \dots, v_n$ 
3:   max := 0
4:   for  $i := n$  downto 1 do
5:      $C := \{v \in S_i \setminus \{v_i\} : \{v, v_i\}$  is a  $k$ -plex}
6:     found := false
7:     FINDKPLEX( $C, \{v_i\}$ )
8:      $c(i) := \max$ 
9:   end for
10:  return max
11: end procedure
12: procedure FINDKPLEX(C,P)
13:   if  $C = \emptyset$  then
14:     if  $|P| > \max$  then
15:       max :=  $|P|$ 
16:       found := true
17:     end if
18:     return
19:   end if
20:   while  $C \neq \emptyset$  do
21:     if  $|C| + |P| \leq \max$  then
22:       return
23:     end if
24:      $i := \min\{j : v_j \in C\}$ 
25:     if  $c(i) + |P| \leq \max$  then
26:       return
27:     end if
28:      $C := C \setminus \{v_i\}; P' := P \cup \{v_i\}; C' := \{v \in C : P' \cup \{v\}$  is a  $k$ -plex}
29:     FINDKPLEX( $C', P'$ )
30:     if found = true then
31:       return
32:     end if
33:   end while
34: end procedure

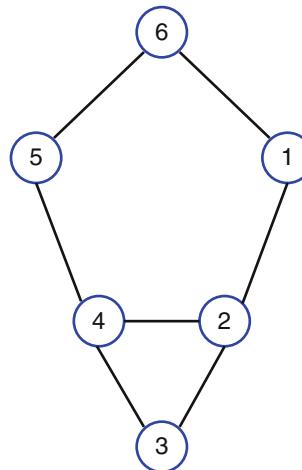

```

presented which can further improve the parameterized algorithmics of the d -BDD problem.

3 Distance-Based Clique Relaxations: k -Cliques and k -Clubs

The distance-based clique relaxations were introduced in social network analysis by Luce [94] soon after cliques were used to model cohesive subgroups [95]. These models relaxed the adjacency requirement of cliques to a short path requirement, with the models being refined and redefined by others [3, 112]. A discussion of the different definitions can be found in [19]. Two basic models based on relaxing pairwise distances can be defined as follows.

Fig. 2 A graph in which set $S = \{1, 2, 3, 4, 5\}$ is a 2-clique but not a 2-club

Definition 14 A subset of vertices $S \subseteq V$ is a k -clique if $d_G(u, v) \leq k$ for all $u, v \in S$.

Definition 15 A subset of vertices $S \subseteq V$ is a k -club if $d_{G[S]}(u, v) \leq k$ for all $u, v \in S$, that is, $\text{diam}(G[S]) \leq k$.

By definition, 1-clique and 1-club correspond to the classical clique. Clearly, every k -club is also a k -clique since $\text{diam}(G[S]) \leq k \Rightarrow d_{G[S]}(u, v) \leq k \forall u, v \in S \Rightarrow d_G(u, v) \leq k \forall u, v \in S$. The converse, however, is not always true. In fact for $k \geq 2$, a k -clique S can contain vertices $u, v \in S$ such that $d_G(u, v) \leq k$ but $d_{G[S]}(u, v) > k$. In Fig. 2 [3], set $S = \{1, 2, 3, 4, 5\}$ forms a 2-clique which is not a 2-club. It should be noted that $d_G(1, 5) = 2$ and $d_{G[S]}(1, 5) = 3$.

The k -clique model was originally introduced in social network analysis by Luce [94] to model cohesive subgroups. The k -club model [3, 112] was developed to address the drawback of k -cliques where members outside the cohesive subgroup can be used on the short paths required between members inside the group. The k -club number of G denoted by $\overline{\omega}_k(G)$ is the cardinality of a maximum k -club in G , and the maximum k -club problem is to find a k -club of the maximum cardinality in G . The k -clique number of G denoted by $\widetilde{\omega}_k(G)$ and the maximum k -clique problem are similarly defined. For a given graph G and a positive integer k , the following inequality is true:

$$\omega(G) \leq \overline{\omega}_k(G) \leq \widetilde{\omega}_k(G).$$

It should be noted that $S \subseteq V$ is a k -clique in G , if and only if S is a clique in the power graph G^k . Accordingly, given a graph G and a positive integer k , $\widetilde{\omega}_k(G) = \omega(G^k)$. Hence, the maximum k -clique problem for any k is equivalent to the maximum clique problem on the corresponding power graph. Because of this

close correspondence between k -cliques in original graph and cliques in the power graph, the k -clique model has not been extensively studied.

Two concepts of particular relevance to these problems are distance- k independence [45] and distance- k coloring [107].

Definition 16 Given a graph $G = (V, E)$, $I \subseteq V$ is a distance- k -independent set if for every distinct pair $i, j \in I$, $d_G(i, j) \geq k + 1$.

Clearly, distance-1 independence is equivalent to pairwise nonadjacency, which corresponds to a classical independent set. It should be noted that the definition becomes more restrictive as k increases. A distance- $(k + 1)$ independent set is also distance- k independent, but the converse is not always true. Further, a k -clique or a k -club can intersect a distance- k -independent set in at most one vertex.

Definition 17 Given a graph $G = (V, E)$ and a positive integer k , a proper distance- k coloring is one in which the pairwise distance in G between any two vertices that receive the same color is at least $k + 1$.

A graph is distance- k t -colorable if it has a proper distance- k coloring that uses at most t colors. The minimum number of colors t that admits a proper distance- k t -coloring is the distance- k chromatic number of G denoted by $\chi_k^d(G)$. It should be noted that each color class forms a distance- k -independent set. [Figure 3](#) shows a proper distance-2 5-coloring of a graph.

By definition, in any proper distance- k coloring of a graph G , a k -clique in G can intersect any color class in at most one vertex. Then the following relationship [97] holds:

$$\overline{\omega}_k(G) \leq \widetilde{\omega}_k(G) \leq \chi_k^d(G).$$

Some remarks on the nonhereditary nature of k -clubs. For any integer $k \geq 1$, the k -clique model like the k -plex model is hereditary on induced subgraphs in the sense described in [Sect. 2.1](#). However, this property does not hold for the k -club model for $k \geq 2$. For example, the graph shown in [Fig. 4b](#) is a 2-club which means it is also a 2-clique. Every subset of this set is a 2-clique, but $\{1, 2, 3, 4\}$ for instance is not a 2-club.

Inclusionwise maximality of any polynomially verifiable hereditary property such as k -clique can be tested in polynomial time. For example, to verify maximality of a k -clique S , it suffices to show that there is no single vertex in $V \setminus S$ that could be added to S to form a larger k -clique. However, for the k -club model, nonexistence of a vertex that could increase the size of the k -club by one is a necessary but not sufficient condition for its maximality. For example, in the graph shown in [Fig. 4a](#), set $S_1 = \{1, 2, 3\}$ is a 2-clique and since sets $S_2 = S_1 \cup \{4\}$ and $S_3 = S_1 \cup \{5\}$ are not 2-cliques, it can be concluded that S_1 is a maximal 2-clique. In [Fig. 4b](#), S_1 is not a maximal 2-clique which can be deduced by observing that both S_2 and S_3 are also

Fig. 3 A proper distance-2 5-coloring using colors $\{a, b, c, d, e\}$

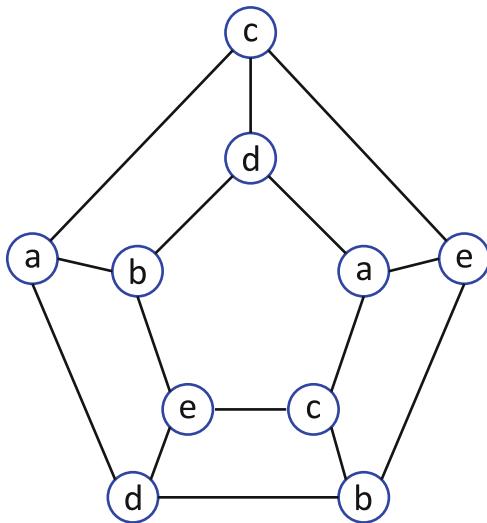

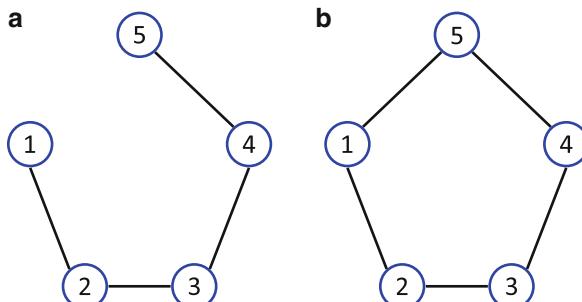

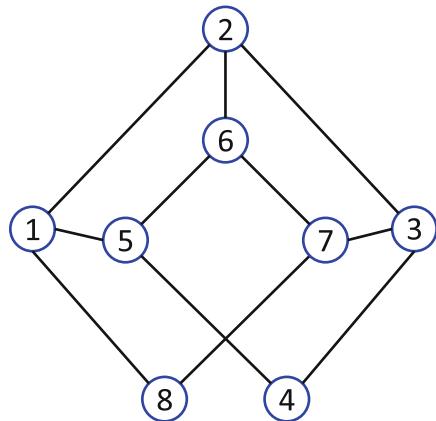

Fig. 4 Inclusionwise maximality testing of 2-cliques and 2-clubs

2-cliques. Set S_1 in the graph shown in Fig. 4b forms a 2-club, while sets S_2 and S_3 are not 2-clubs. But S_1 is not a maximal 2-club since $V = S_1 \cup \{4, 5\}$ is a larger 2-club containing S_1 .

Since the k -club definition is more restrictive than the k -clique, it is possible that a maximal k -club is not a maximal k -clique. For instance, $\{1, 2, 3, 4\}$ is a maximal 2-club in Fig. 2, but not a maximal 2-clique as it is contained in 2-clique $\{1, 2, 3, 4, 5\}$. By contrast, if a maximal k -clique satisfies the diameter requirement, it is also a maximal k -club. However, it is possible in a graph for $k \geq 2$ that no maximal k -clique is a k -club. Figure 5 shows a graph with exactly two maximal 2-cliques $\{1, 2, 3, 4, 5, 6, 7\}$ and $\{1, 2, 3, 5, 6, 7, 8\}$, neither of which is a 2-club. Hence, even enumerating all maximal k -cliques in the graph to select the ones satisfying the diameter- k condition may not identify a maximum k -club. Furthermore, in the extreme case, it fails to identify a single k -club.

Fig. 5 A graph in which every maximal 2-clique is not a 2-club

3.1 Complexity and Approximation

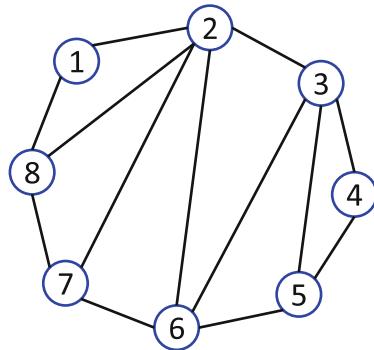

The maximum k -clique and k -club problems are NP-hard for any *fixed* positive integer k [19, 35], and they remain NP-hard even in graphs of fixed diameter with $\text{diam}(G) > k$ [19]. Hence, the maximum k -club problem is known to be NP-hard for every fixed k even on graphs of diameter $k + 1$.

For given positive integers k and l ($k \neq l$), the problem of recognizing whether $\overline{\omega}_k(G) = \overline{\omega}_l(G)$ is also NP-hard. This gap-recognition complexity result was further used to show that for an integer $k \geq 2$ and in a graph G with $\overline{\omega}_k(G) > \Delta(G) + 1$, unless $P=NP$, there does not exist a polynomial time algorithm for finding a k -club of size strictly larger than $\Delta(G) + 1$ [40]. Recalling that $\Delta(G)$ denotes the maximum vertex degree in G , it is clear that a vertex of maximum degree along with all its neighbors forms a k -club in G for any $k \geq 2$.

The maximum k -club problem for fixed $k \geq 2$ was shown to be inapproximable within a factor of $n^{\frac{1}{3}-\epsilon}$ for any $\epsilon > 0$, if $NP \neq ZPP$ [101], which has been strengthened to $n^{\frac{1}{2}-\epsilon}$ recently under the assumption $P \neq NP$ [12]. Approximation algorithms of factor $n^{\frac{1}{2}}$ and $n^{\frac{2}{3}}$ for even and odd k , respectively, have also been proposed recently [12].

In contrast to what is observed for cliques, an encouraging result for k -clubs is that it is fixed-parameter tractable when parameterized by solution size [131, 132]. The k -club problem is one of the few parameterized problems for which nonexistence of a polynomial-size many-to-one kernel and existence of a polynomial-size Turing kernel are known [131, 132]. The k -club problem can be solved on trees and interval graphs in $O(nk^2)$ and $O(n^2)$, respectively, and it is polynomial time solvable on graphs with bounded tree- or cliquewidth [131]. The 2-club problem can be solved on bipartite graphs in $O(n^5)$ [131].

Fig. 6 An asymmetric partitionable cycle with respect to nodes 1 and 4

Recently, it has been shown that testing inclusionwise maximality of k -clubs is NP-hard, which is a direct consequence of their nonhereditary property [97]. However, maximality of a k -club can be tested in polynomial time in graphs that do not contain an *asymmetric partitionable cycle* of a certain size [97]. We provide some details on this result next.

A k -clique which induces a connected subgraph is called a *connected k -clique*. Given a graph $G = (V, E)$, maximality of a connected k -clique D can be checked by testing nodes in $V \setminus D$ that have at least one edge to some node in D , one at a time, to see if they can be added to D to form a larger k -clique. For graphs in which every connected k -clique is also a k -club, maximality of k -clubs can then be checked in polynomial time. By definition, every k -club is a connected k -clique, and in such graphs every connected k -clique is also a k -club, and hence, a maximal connected k -clique is also a maximal k -club.

Definition 18 A graph $G = (V, E)$ is called a partitionable cycle, if it contains a spanning cycle W and a pair of nonadjacent nodes i and j such that every edge in $E \setminus E(W)$ has one endpoint in $A_W(i, j)$ and the other endpoint in $A_W(j, i)$, where $A_W(i, j)$ and $A_W(j, i)$ are the internal nodes on the two paths between i and j in W . A partitionable cycle is said to be asymmetric if $|A_W(i, j)| \neq |A_W(j, i)|$. (See Fig. 6.)

Theorem 12 ([97]) *Given a graph $G = (V, E)$ and fixed integer $k \geq 2$, every connected k -clique is a k -club if G does not contain an asymmetric partitionable cycle on c vertices as an induced subgraph, where $5 \leq c \leq 2k + 1$.*

Corollary 1 ([97]) *In a bipartite graph, every connected 2-clique is a 2-club.*

3.1.1 Formulations

The maximum k -club problem admits the following integer programming formulation [19, 35]:

$$\bar{\omega}_k(G) = \max \sum_{i \in V} x_i$$

Subject to

$$\begin{aligned}
 x_i + x_j &\leq 1 + \sum_{l:P_{ij}^l \in \mathcal{P}_{ij}} y_{ij}^l \quad \forall (i, j) \notin E \\
 x_p &\geq y_{ij}^l \quad \forall p \in V(P_{ij}^l), P_{ij}^l \in \mathcal{P}_{ij}, (i, j) \notin E \\
 x_i &\in \{0, 1\} \quad \forall i \in V \\
 y_{ij}^l &\in \{0, 1\} \quad \forall P_{ij}^l \in \mathcal{P}_{ij}, (i, j) \notin E,
 \end{aligned}$$

where \mathcal{P}_{ij} is an indexed collection of all paths of length at most k between vertices i, j in G and P_{ij}^l is the path with index l between vertices i, j . The formulation ensures that if two vertices are in a k -club, then all the vertices in at least one path between them with length less than or equal to k are also included in the k -club. It should be noted that the size of \mathcal{P}_{ij} could be very large, making this formulation difficult to handle. But the formulation for the maximum 2-club problem stated next is much more compact.

$$\bar{\omega}_2(G) = \max \sum_{i \in V} x_i$$

Subject to

$$\begin{aligned}
 x_i + x_j - \sum_{k \in N(i) \cap N(j)} x_k &\leq 1 \quad \forall (i, j) \notin E \\
 x_i &\in \{0, 1\} \quad \forall i \in V.
 \end{aligned}$$

It should also be noted that while the exponential formulation for the maximum k -club problem discussed here is unsuitable for explicit use with integer programming solvers for large k , a more compact formulation has been recently developed in [145] that permits such use. We present this formulation next.

Recall that $A_G = [a_{i,j}]_{n \times n}$ is the symmetric adjacency matrix of G . We use subscripts of the form $\sigma(u, v)$ where u refers to the position of the term and v refers to the position of the summation. For example, $\sigma(3, 2)$ is the index over which the second summation of the third term runs. The formulation is such that $1 \leq v \leq u \leq k - 1$. Specifically, the term using indices $\sigma(u, .)$ models paths of length $u + 1$. The formulation requires that whenever vertices i and j are included in a k -club, at least one of these terms is 1, thereby requiring a path between i and j of length at most k as well as the requirement that the vertices on that path are included. The compact 2-club formulation presented above can be viewed as a special case of the formulation presented next.

$$\bar{\omega}_k(G) = \max \sum_{i \in V} x_i$$

subject to

$$\begin{aligned}
& a_{i,j} + \sum_{\sigma(1,1)=1}^n a_{i,\sigma(1,1)} a_{\sigma(1,1),j} x_{\sigma(1,1)} \\
& + \sum_{\sigma(2,1)=1}^n \sum_{\sigma(2,2)=1}^n a_{i,\sigma(2,1)} a_{\sigma(2,1),\sigma(2,2)} a_{\sigma(2,2),j} x_{\sigma(2,1)} x_{\sigma(2,2)} \\
& + \sum_{\sigma(3,1)=1}^n \sum_{\sigma(3,2)=1}^n \sum_{\sigma(3,3)=1}^n a_{i,\sigma(3,1)} a_{\sigma(3,1),\sigma(3,2)} a_{\sigma(3,2),\sigma(3,3)} a_{\sigma(3,3),j} x_{\sigma(3,1)} x_{\sigma(3,2)} x_{\sigma(3,3)} \\
& \quad + \cdots + \\
& \sum_{\sigma(k-1,1)=1}^n \cdots \sum_{\sigma(k-1,k-1)=1}^n a_{i,\sigma(k-1,1)} a_{\sigma(k-1,1),\sigma(k-1,2)} \cdots a_{\sigma(k-1,k-1),j} x_{\sigma(k-1,1)} x_{\sigma(k-1,2)} \\
& \quad \cdots x_{\sigma(k-1,k-1)} \\
& \geq x_i + x_j - 1, \quad \forall i, j \in V : i < j \\
& x_i \in \{0, 1\} \quad \forall i \in V.
\end{aligned}$$

To see the correctness of this formulation, consider $x \in \{0, 1\}^n$ which is an incidence vector of a k -club in G . Then for a pair i, j such that $x_i = x_j = 1$ and $i < j$, the corresponding constraint requires the left-hand side of the constraint to be at least 1. Since x corresponds to a k -club, if $(i, j) \in E$ then $a_{i,j} = 1$ and the constraint is satisfied. Otherwise, there exists a path $i = i_0 - i_1 - \cdots - i_u = j$ where $2 \leq u \leq k$ such that $x_{i_s} = 1, s = 0, \dots, u$ and the term corresponding to u has the product corresponding to $\sigma(u, s) = i_s, s = 1, \dots, u-1$ equal to 1. Hence, every constraint is satisfied by incidence vectors of k -clubs.

Conversely, let $x \in \{0, 1\}^n$ be a feasible solution to the formulation. Then, it suffices to show that $S = \{i \in V : x_i = 1\}$ is a k -club. Consider $i, j \in S, i < j$. Since x satisfies the corresponding constraint, at least one term in the left-hand side is 1. Suppose $a_{i,j} = 0$, then for some u between 1 and $k-1$, a product in term u equals 1. Suppose

$$a_{i,\sigma(u,1)} a_{\sigma(u,1),\sigma(u,2)} \times \cdots \times a_{\sigma(u,u-1),\sigma(u,u)} a_{\sigma(u,u),j} x_{\sigma(u,1)} x_{\sigma(u,2)} \cdots x_{\sigma(u,u)} = 1.$$

Hence, $\sigma(u, s) \in S$ for $s = 1, \dots, u$, and $i - \sigma(u, 1) - \sigma(u, 2) - \cdots - \sigma(u, u-1) - \sigma(u, u) - j$ is a path of length $u+1 \leq k$ in G . This shows S is a k -club.

The approach taken here is to formulate the problem as a nonlinear (binary) integer program. Note that the polynomial products of binary variables can be linearized using standard techniques. The authors [145] show that this formulation can be linearized into a linear integer program which uses $O(kn^2)$ variables and constraints by exploiting the properties of a k -club.

The authors of [145] also introduce the notion of an *r-robust k-club* which is a subset of vertices S such that $G[S]$ has at least r internally vertex disjoint, edge disjoint, or simply distinct paths (differing in at least one edge) of length at most k (in $G[S]$) between every pair of vertices. Clearly when $k = 2$, distinct paths are also edge/vertex disjoint, and the three ideas coincide. Note that a 2-club which is 2-connected is not necessarily a 2-robust 2-club although the converse is true. A cycle on five vertices is a 2-connected 2-club, but it is not a 2-robust 2-club since the pair of paths between any two vertices are not both of length at most two.

The formulation for the maximum k -club problem presented above can be extended for the case where r distinct paths of length at most k are required between pairs of vertices. This can be accomplished by replacing the right-hand side with $r(x_i + x_j - 1)$ instead. Specifically, the r -robust 2-club model allows the detection of diameter-two clusters that are robust, in the sense that they preserve the diameter-two bound under vertex or edge deletions (up to $r - 1$).

3.2 Polyhedral Results

Given a graph $G = (V, E)$, the convex hull of the incidence vectors of k -clubs in G is called the k -club polytope of G denoted by $C_k(G)$. Some preliminary results on these polytopes, especially the 2-club polytope, are available from [19, 44]. **Theorem 13** [19] presents the basic results on $C_2(G)$ and the first family of facets developed. It should also be noted that the maximal 2-independent set inequalities are analogous to Padberg's maximal independent inequalities for the clique polytope [121].

Proposition 6 ([17]) (*Distance-k-independent set inequalities*) *Given a graph $G = (V, E)$, let $I \subseteq V$ be a maximal k -independent set. Then the following inequality is valid for $C_k(G)$:*

$$\sum_{i \in I} x_i \leq 1.$$

Theorem 13 ([19]) *Consider the 2-club polytope $C_2(G)$ of a graph $G = (V, E)$.*

1. $\dim(C_2(G)) = n$.
2. $x_i \geq 0$ induces a facet of $C_2(G)$ for every $i \in V$.
3. For $i \in V$, $x_i \leq 1$ induces a facet of $C_2(G)$ if and only if $d_G(i, j) \leq 2 \forall j \in V$.
4. The inequality $\sum_{i \in I} x_i \leq 1$ induces a facet of $C_2(G)$ if and only if I is a maximal distance-2-independent set in G .

Proof The full dimension of the 2-club polytope follows from the fact that $\emptyset, \{i\}$ are 2-clubs for each $i \in V$. The nonnegativity facet also follows from the same observation. The unit upper-bound facet is a special case of a 2-independent set facet that is proved next.

Suppose I is a maximal distance-2-independent set. We establish the maximality of the face $F_I = \left\{ x \in C_2(G) : \sum_{i \in I} x_i = 1 \right\}$, thereby showing it is a facet. Suppose

there exists a valid inequality $\alpha^T x \leq \beta$ such that, $F = \{x \in C_2(G) : \alpha^T x = \beta\} \supseteq F_I$. Since $e_i \in F_I \subseteq F \forall i \in I$, we have $\alpha_i = \beta \forall i \in I$. Now for every $j \in V \setminus I$, there exists a vertex $i \in I$ such that at least one of the following two conditions are satisfied:

1. $(i, j) \in E$ and so $e_i + e_j \in F_I \subseteq F$.
2. $N(i) \cap N(j) \neq \emptyset$, that is, they have a common neighbor $k \in V \setminus I$ in which case $e_i + e_j + e_k, e_i + e_k \in F_I \subseteq F$.

Now for every $j \in V \setminus I$, in the first case we obtain, $\alpha_i + \alpha_j = \beta \Rightarrow \alpha_j = 0$ and in the second case we obtain $\alpha_i + \alpha_k + \alpha_j = \beta$ and $\alpha_i + \alpha_k = \beta \Rightarrow \alpha_j = \alpha_k = 0$. Thus, $F_I = F$ is a facet.

Suppose the inequality induces a facet of $C_2(G)$. If I is not a 2-independent set, then there exist $i, j \in I$ such that either $(i, j) \in E$ or if I is independent, there exists $k \in N(i) \cap N(j)$. In the first case, $e_i + e_j$ which is a feasible point violates the inequality. In the second case, $e_i + e_j + e_k$ which is feasible violates the inequality. Either situation contradicts the validity of this inequality. Hence, I must be a 2-independent set. If I is not maximal, there exists $I \cup \{u\}$ which is 2-independent and $x_u + \sum_{i \in I} x_i \leq 1$ is valid and dominates a facet-defining inequality, which is a contradiction. Hence, I is maximal. \square

This line of research has been recently furthered in [44]. **Theorem 14** provides necessary and sufficient conditions under which the common neighborhood constraint in the formulation induces a facet. **Theorem 15** introduces another facet-defining inequality for $C_2(G)$.

Theorem 14 ([44]) *Given a graph $G = (V, E)$, let $a, b \in V$, and $I \subseteq V \setminus \{a, b\}$ be such that $I \cup \{a\}$ and $I \cup \{b\}$ are distance-2-independent sets in G and $\text{dist}_G(a, b) = 2$. The following inequality is valid for $C_2(G)$ and induces a facet if and only if I is a maximal set:*

$$\sum_{i \in I \cup \{a, b\}} x_i - \sum_{j \in N(a) \cap N(b)} x_j \leq 1.$$

Theorem 15 ([44]) *Given a graph $G = (V, E)$, let $a, b, c \in V$, and $I \subseteq V \setminus \{a, b, c\}$ be such that set $\{a, b, c\}$ is independent and sets $I \cup \{a\}$, $I \cup \{b\}$ and $I \cup \{c\}$ are distance-2-independent in G . The following inequality is valid for $C_2(G)$ and induces a facet if and only if I is a maximal set:*

$$\sum_{i \in I \cup \{a, b, c\}} x_i - \sum_{j \in V} \alpha_j x_j \leq 1,$$

where

$$\alpha_j = \begin{cases} 2, & \text{if } j \in N(a) \cap N(b) \cap N(c), \\ 1, & \text{if } j \in [N(a) \cap N(b)] \cup [N(a) \cap N(c)] \cup [N(b) \cap N(c)] \setminus [N(a) \cap N(b) \cap N(c)], \\ 0, & \text{Otherwise.} \end{cases}$$

Recently in [98], a new family of facets called the *independent distance-2-dominating set inequalities* for the 2-club polytope have been introduced that include all known facets other than nonnegativity constraints as special cases. The k -club polytope for $k \geq 3$ has fewer associated results, and there is ongoing research on polyhedral approaches to these cases. Alternate formulations and valid inequalities for the maximum 3-club problem were introduced along with computational experiments in [4, 5].

3.3 Algorithms

Combinatorial exact algorithms appear to be more prevalent presently for solving the maximum k -club problem for arbitrary k . The results on the 2-club polytope have also led to preliminary branch-and-cut approaches incorporating maximal distance-2-independent set facets discussed in [17, 19]. A sequential cutting-plane method is also proposed in [44]. Heuristic algorithms for finding large k -cliques or k -clubs in a given graph have been proposed in [34, 44, 66] that can be used to produce lower bounds in some exact approaches like the combinatorial branch-and-bound algorithms.

Due to the intractability of testing inclusionwise maximality of k -clubs and its nonhereditary nature, well-known exact combinatorial algorithms for cliques like Carraghan-Pardalos and Östergård's algorithms [43, 120] are unlikely to be applicable to k -clubs although they can naturally be applied to the power graph to find k -cliques. The existing branch-and-bound algorithms from [35, 97] are classical partitioning approaches based on variable dichotomy but differ in the approach taken to obtain upper bounds.

The approach taken in [35] is to obtain upper bounds at each node of the search tree via the k -clique number. In [97], the authors employ the distance- k coloring problem to obtain upper bounds in the search tree. From the inequality presented in Sect. 3, the former has the potential to produce tighter bounds than the latter approach. However, in the first approach, the maximum k -clique problem (which is also NP-hard) must be solved to optimality to produce a valid bound. Whereas, a heuristic coloring algorithm is sufficient with the second approach to produce potentially weaker upper bounds. Details on these algorithms and available benchmark instances can be found in [35, 97]. A fixed-parameter tractable algorithm is presented in [131] to find a k -club of size c if one exists in G in $O((c - 2)^c \cdot c! \cdot c^3 n + nm)$ time.

4 Density-Based Models: Densest t -Subgraph and γ -Quasi-clique

Two types of optimization problems can be developed to identify dense clusters in graphs. In the first type, given a graph $G = (V, E)$ and a fixed positive integer $t \leq n$, the problem is to find a subgraph on t vertices of maximum edge density.

Since the order of the subgraph is fixed (t), this is equivalent to finding a t -vertex subgraph with maximum number of edges or average degree. In the second type, given a graph $G = (V, E)$ and a fixed real number $\gamma \in [0, 1]$, the problem is to find a subgraph of maximum order with edge density at least γ . The first type is analogous to finding a k -plex, k -clique, or a k -club of fixed order t with minimum k . In other words, the most cohesive or tightly knit cluster of a given order t where cluster cohesion is quantified by the parameter k . The second type generalizes the maximum clique problem which is a special case when $\gamma = 1$ and hence is a clique relaxation in a manner similar to the foregoing models in this chapter.

4.1 The Densest t -Subgraph Problem

The problem of the first type is referred to in the literature by various names such as *the t -cluster problem* [57], *the heaviest (unweighted) t -subgraph problem* [92], *the densest t -subgraph problem* [68], and *the maximum edge subgraph problem* [10]. The edge-weighted version of this problem has also been studied in [10, 11, 78, 129]. A different but closely related *densest subgraph problem* is to choose a nonempty subgraph $G' = (V', E')$ of an edge-weighted graph G such that the ratio $w(E')/|V'|$ is maximized. The densest subgraph problem can be solved in polynomial time using maximum-flow algorithms [73, 92] (see also [46]).

4.1.1 Complexity and Approximation

The densest t -subgraph problem is NP-hard even on bipartite graphs, perfect graphs, chordal graphs [57], and planar graphs [89]. No PTAS exists under the assumption that NP does not have subexponential time algorithms [90]. It is shown to have a PTAS on dense instances ($|E| = \Omega(n^2)$) if $t = \Omega(n)$ in [8]. Other types of approximation algorithms for the problem are also available in the literature. A $O(n^{0.3885})$ approximation algorithm is available in [92], and an improved approximation guarantee of $O(n^{\frac{1}{3}-\epsilon})$ for some $\epsilon > 0$ is presented in [68, 69]. A more recent algorithm [25] provides an approximation guarantee of $O(n^{\frac{1}{4}+\epsilon})$ for any $\epsilon > 0$.

The approximation guarantee of $O(n/t)$ from the greedy algorithm where the vertex of minimum degree is recursively deleted until a set of size t remains is also established in [10]. A 3-approximate algorithm is available for the problem on chordal graphs [93] and a 1.5-approximate algorithm is known for proper interval graphs and bipartite permutation graphs (the complexity on these graph classes is unknown) [69, 138].

The complexity threshold of this problem was studied in [11], designated as *the t - $f(t)$ -dense subgraph problem* which asks if G contains a t -vertex subgraph with at least $f(t)$ edges. This is the decision version of the maximum clique problem when $f(t) = \binom{t}{2}$ which is known to be NP-complete. It is established

that the problem remains NP-complete when $f(t) = \Theta(t^{1+\epsilon})$ and when $f(t) = mt^2/n^2(1 + O(n^{\epsilon-1}))$ for any constant ϵ such that $0 < \epsilon < 1$.

Semidefinite programming-based approximation algorithms are also available for this problem in [69, 138]. A deterministic approximation algorithm for the problem is also presented in [130] that applies rounding techniques to the optimal solution of a linear programming relaxation of the following binary quadratic program:

$$\max \sum_{(ij) \in E} x_i x_j$$

Subject to

$$\begin{aligned} \sum_{i \in V} x_i &= t \\ x_i &\in \{0, 1\} \quad \forall i \in V. \end{aligned}$$

4.1.2 Polyhedral Results and Algorithms

Different integer programming formulations are presented for this problem in [26], obtained by different linearizations and tightening of the aforementioned binary quadratic program. Polyhedral study of a particular linearization of this formulation undertaken in [32] is presented next. Summarized are some families of valid inequalities, sufficient conditions under which they are facet inducing, and the associated separation problems investigated in [32].

$$\max \sum_{(ij) \in E} z_{ij}$$

Subject to

$$\begin{aligned} \sum_{i \in V} x_i &= t \\ z_{ij} &\leq x_i \quad \forall (ij) \in E \\ z_{ij} &\leq x_j \quad \forall (ij) \in E \\ x_i &\in \{0, 1\} \quad \forall i \in V \\ z_{ij} &\in \{0, 1\} \quad \forall (ij) \in E. \end{aligned}$$

Theorem 16 ([32]) Given $G = (V, E)$ and a positive integer $t \leq n$, let $D_t(G)$ denote the convex hull of feasible solutions to the above integer program. Then, $\dim(D_t(G)) = n + m - 1$.

Theorem 17 ([32]) (Generalized neighborhood inequalities) Given $G = (V, E)$, $i \in V$, and a set $A^i \subseteq V \setminus \{i\}$ with $|A^i| \leq t - 2$, the following inequality is valid for $D_t(G)$:

$$\sum_{j \in A^i} x_j + \sum_{j \in N(i) \setminus A^i} z_{ij} \leq |A^i| + (t - |A^i| - 1)x_i.$$

Furthermore, if $|N(i) \cap A^i| \geq t$ and $t \leq n - 2$, the generalized neighborhood inequality induces a facet of $D_t(G)$.

In [32], the authors also show that the generalized neighborhood inequalities can be separated in polynomial time. Another family of inequalities, similar to the odd-set inequalities for the matching polyhedron [67], were also developed and the associated separation problem was shown to be polynomial time solvable in [32].

Theorem 18 ([32]) (Matching inequalities) Given $G = (V, E)$, $T \subseteq V$ and a maximal matching M of $G[V \setminus T]$, the following inequality is valid for $D_t(G)$, if $|T| + t$ is odd:

$$\sum_{j \in T} x_j + \sum_{(ij) \in M} z_{ij} \leq \frac{|T| + t - 1}{2}.$$

In addition, if $t - 2|M| + 1 \leq |T| \leq t - 1$ and $t \leq n - 3$, then the matching inequality induces a facet of $D_t(G)$.

Similar results on validity and facet-inducing conditions are developed in [32] for more families such as forest inequalities, tree inequalities, and disjoint matching inequalities. Separating these inequalities is shown to be NP-hard. Computational experiments to study the effectiveness of these inequalities in a branch-and-cut framework are also conducted in [32]. This work appears to be the only polyhedral approach to this problem in the literature presently. In addition to the approximation algorithms discussed in Sect. 4.1.1, a variable neighborhood search [111] metaheuristic is also available for the problem in [36].

4.2 The Maximum γ -Quasi-clique Problem

The second type of problem designed to identify dense clusters in a graph is called the maximum γ -quasi-clique problem studied in [1, 2, 124].

Definition 19 Given a graph $G = (V, E)$ and a real number $0 \leq \gamma \leq 1$, $S \subseteq V$ is a γ -quasi-clique¹ if the edge density of $G[S]$ is at least γ .

The maximum γ -quasi-clique problem is to find a maximum cardinality γ -quasi-clique in G , and this cardinality is the γ -quasi-clique number of G , denoted by $\omega_\gamma^q(G)$. This problem includes the maximum clique problem as a special case when $\gamma = 1$ and is shown to be NP-hard for fixed $\gamma \in (0, 1)$ in [124]. This result is also extended to show a variant of the model studied in [39] is also NP-hard.

¹It should be noted that a subset $S \subseteq V$ such that $\delta(G[S]) \geq \gamma(|S| - 1)$ has also been called a γ -quasi-clique in some literature (see for instance [39, 87, 154]).

Similar to k -clubs, the γ -quasi-cliques are nonhereditary. But they are said to be *quasi-hereditary*, a notion introduced in [124]. A graph property Π is said to be *quasi-hereditary*; if G has property Π , then there exists a vertex $v \in V$ such that $G - v$ also satisfies property Π . If G has edge density at least γ , deleting a vertex with degree no larger than the average degree (specifically a vertex of minimum degree) will result in a graph with edge density at least γ [124].

Summarized next are bounds on $\omega_\gamma^q(G)$ extending results known for $\omega(G)$ [6, 115] and its relationship to the clique number developed in [124].

Proposition 7 ([124]) *Given a graph $G = (V, E)$, and $0 < \gamma \leq 1$*

$$\omega_\gamma^q(G) \leq \frac{\gamma + \sqrt{\gamma^2 + 8m\gamma}}{2\gamma}.$$

Moreover if G is connected,

$$\omega_\gamma^q(G) \leq \frac{\gamma + 2 + \sqrt{(\gamma + 2)^2 + 8(m - n)\gamma}}{2\gamma}.$$

If $\gamma > 1 - \frac{1}{\omega(G)}$,

$$\omega_\gamma^q(G) \leq \frac{\gamma\omega(G)}{1 - \omega(G)(1 - \gamma)}.$$

The maximum γ -quasi-clique problem can be formulated as the following quadratically constrained binary integer program [124]. Recall that $A_G = [a_{i,j}]_{n \times n}$ is the symmetric adjacency matrix of G . Denote by M , a zero-diagonal $n \times n$ matrix in which every entry except the diagonal entries are ones.

$$\omega_\gamma^q(G) = \max \sum_{i \in V} x_i$$

Subject to

$$\begin{aligned} x^T A_G x &\geq \gamma x^T M x \\ x_i &\in \{0, 1\} \forall i \in V. \end{aligned}$$

Some preliminary computational experiments are performed in [124] by linearizing this formulation into two different linear mixed-integer programs, solved using a commercial solver. These linearizations are presented next.

The following formulation is obtained by a simple linearization that introduces a new variable (and associated constraints) for each binary quadratic term. Note that this formulation has $O(n^2)$ variables and constraints.

$$\omega_{\gamma}^q(G) = \max \sum_{i=1}^n x_i$$

Subject to

$$\begin{aligned} \sum_{i=1}^n \sum_{j=i+1}^n (\gamma - a_{ij}) z_{ij} &\leq 0 \\ z_{ij} &\leq x_i, \forall j > i = 1, \dots, n \\ z_{ij} &\leq x_j, \forall j > i = 1, \dots, n \\ z_{ij} &\geq x_i + x_j - 1, \forall j > i = 1, \dots, n \\ z_{ij} &\geq 0, \forall j > i = 1, \dots, n \\ x_i &\in \{0, 1\}, \forall j > i = 1, \dots, n. \end{aligned}$$

The following formulation is also a binary mixed-integer program based on an alternate linearization scheme which results in a more compact formulation with $O(n)$ variables and constraints.

$$\omega_{\gamma}^q(G) = \max \sum_{i=1}^n x_i$$

Subject to

$$\begin{aligned} \sum_{i=1}^n y_i &\geq 0 \\ l_i x_i &\leq y_i \leq u_i x_i, \forall i = 1, \dots, n \\ \gamma x_i + \sum_{j=1}^n (a_{ij} - \gamma) x_j - u_i(1 - x_i) &\leq y_i, \forall i = 1, \dots, n \\ \gamma x_i + \sum_{j=1}^n (a_{ij} - \gamma) x_j - l_i(1 - x_i) &\geq y_i, \forall i = 1, \dots, n \\ x_i &\in \{0, 1\}, \forall i = 1, \dots, n \\ y_i &\in \mathbb{R}, \forall i = 1, \dots, n \end{aligned}$$

$$\text{where } u_i = (1 - \gamma) \sum_{j=1}^n a_{ij} \text{ and } l_i = - \left(n - 1 - \sum_{j=1}^n a_{ij} \right) \gamma.$$

The asymptotic behavior of the maximum γ -quasi-clique size in uniform random graphs has been studied in [146]. A greedy randomized adaptive search procedure (GRASP) was introduced in [1] to find large γ -quasi-cliques in a graph. In [2], the

authors defined a *potential function* by introducing the notion of the potential of a vertex or an edge set with respect to a given γ -quasi-clique. This potential function was used to develop another GRASP to find maximal γ -quasi-cliques in a given graph. A combinatorial branch-and-bound algorithm for the maximum γ -quasi-clique problem was recently developed in [99]. Clearly, theoretical developments on this model are presently limited even though numerous heuristic approaches have been employed to find quasi-cliques in various applications.

5 Selected Applications

Recent advances in high-throughput data collection in different fields such as Internet research, social network analysis, text analytics, bioinformatics, computational finance, and telecommunication among others have led to an increased demand for effective models and tools for data mining. Data mining is the process of summarizing, visualizing, and processing large data sets in order to extract useful knowledge from the data by using advanced mathematical techniques [139].

In a variety of data mining applications, the elements of a system and the relationships among them are modeled as a graph, wherein graph algorithms and optimization techniques are used to uncover the specific patterns in such data sets [55, 148]. Graph-based data mining is particularly advantageous for studying unstructured or partially structured data compared to methods that almost exclusively deal with numerical data. Cliques and their relaxations have been used to identify “tightly knit” clusters which often provide valuable insights in a variety of different application settings.

An *Internet graph* has vertices representing IP addresses, and edges in such graphs are determined based on information from routing protocols or using traceroute probes [37]. In web mining and Internet research, the web can be modeled by a graph in which each webpage is represented by a vertex and two vertices are adjacent if the corresponding webpages are linked together [140]. The 2-club model has been used for topical clustering of hyperlinked documents [110] and web sites [140] to expedite search procedures. A k -plex-based approach to mine databases is proposed in [154].

In *call graphs*, vertices represent telephone numbers and an edge represents a call placed from one vertex to another in a specified time interval [1]. A call graph representing telecommunications traffic data over one 20-day period with 290 million vertices and 4 billion edges was mined using quasi-cliques in [1].

Stock-market graphs have vertices representing stocks, and two stocks are connected by an edge if they are positively correlated over some threshold value based on calculations over a period of time in history [28–30]. In [29, 30], the authors studied the US stock market and used clique relaxation models in order to classify this market and find robust diversified portfolios.

Social networks are graph models representing sociological information such as friendship or acquaintance among people. Vertices usually represent people, and an

edge indicates a “tie” between two people. A tie could mean that they know each other, they visited the same place, or any other sociological connection. *Scientific collaboration networks* with vertices representing authors (in a particular field or with publications in a particular journal) and edges indicating coauthorship fall under this category [42, 77, 82, 85, 135].

In social network analysis, finding cohesive subgroups in contact networks, friendship networks, and collaboration networks are traditional applications that employ cliques and clique relaxations. A special case is criminal network analysis [9, 47, 48, 60, 136], used to detect organized criminal activities such as money laundering [119] and terrorism [108, 109]. Detecting cohesive subgroups in contact networks has also been used for disease contagiousness studies and what-if analysis by healthcare providers [76, 135]. Mining friendship networks and finding dense clusters can provide useful information for advertising and marketing purposes [82, 85, 152].

Biological networks such as *protein interaction networks* and *gene co-expression networks* are used to model biological information. A protein interaction network is represented by a graph with the proteins of an organism as vertices, and an edge exists between two vertices if the proteins are known to interact based on two-hybrid assays and other biological experiments [72, 86, 137]. In gene co-expression networks, vertices represent genes, and an edge exists between two vertices if the corresponding genes are co-expressed with correlation higher than a specified threshold in microarray experiments [127].

Detecting clusters in protein interaction networks helps identify *protein complexes* and *functional modules* that influence cellular functions [137]. Clustering of gene co-expression networks has been used to detect network motifs using cliques, quasi-cliques, and k -plexes in [51, 87, 127, 147]. Protein interaction networks of organisms like *Helicobacter pylori* and *Saccharomyces cerevisiae* have been mined using k -clubs [19, 123], quasi-cliques [14, 137], and k -plexes [126]. Additionally, finding cliques in graph models of electroencephalogram time series data has been used to help identify epileptic seizures [128].

6 Conclusion

Graph theoretic clique relaxations provide practical alternatives to cliques for modeling clusters in graph-based data mining applications. The variety of models available make this an attractive approach to consider in many such applications where the best clustering model can only be identified after it has proved itself to be useful in the application context. In massive data sets, the clique relaxations discussed in this chapter allow a level of tolerance to edges missed due to data errors. At the same time, these models provide specific structural guarantees controlled by the user, so that the significance of the cluster under edges included in error is also satisfactory. Hence, clique relaxations, for appropriate values of their respective parameters, provide a hierarchy of models that enable the user to derive valuable insights by detecting large clusters in massive data sets.

The results presented in this chapter are focused on polyhedral and combinatorial approaches, as well as complexity and approximation results that indicate the limits of solvability. More is needed with regard to results of this nature, as well as practical metaheuristic approaches designed for massive data sets. Studying these models under uncertainty with respect to the edges in the graph is also important. With ongoing active research in this area driven by practical needs and theoretical challenges, interesting developments can be expected in the future.

Abstract

Greedy strategy is a simple and natural method in the design of approximation algorithms. This chapter presents greedy approximation algorithms for very broad classes of maximization problems and minimization problems and analyzes their approximation bounds. A number of applications of these greedy approximation algorithms are also described in this chapter. For many applications, the greedy approximation algorithm can achieve the best known approximation bound in a straightforward manner. For some applications, they have different formulations, and the corresponding greedy approximation algorithms have different approximation bounds. In addition, some applications can have better approximation algorithm than the greedy approximation algorithm.

1 Introduction

Greedy strategy is one of the major techniques in the design of approximation algorithms for NP-hard optimization problems. A greedy approximation algorithm is an iterative algorithm which produces a partial solution incrementally. Each iteration makes a locally optimal or suboptimal augmentation to the current partial solution, so that a globally suboptimal solution is reached at the end of the algorithm. This chapter presents a number of classes of optimization problems to which the greedy strategy can be applied to produce good approximate solutions.

The following standard terms and notations are adopted throughout this chapter. Consider a ground set E and a real function f defined on 2^E . f is *increasing* if, for any two subsets A and B of E , $A \subset B$ implies $f(A) \leq f(B)$. f is *proper* if, for any $X \subseteq E$,

$$f(X) \leq \sum_{e \in X} f(e).$$

f is *submodular* if, for any two subsets A and B of E ,

$$f(A) + f(B) \geq f(A \cup B) + f(A \cap B).$$

f is a *polymatroid function* if $f(\emptyset) = 0$ and f is submodular and increasing. The *marginal value* of $B \subseteq E$ with respect to $A \subseteq E$ is defined by

$$\Delta_B f(A) = f(A \cup B) - f(A).$$

Similarly, the *marginal value* of an element $e \in E$ with respect to $A \subseteq E$ is defined by

$$\Delta_e f(A) = f(A \cup \{e\}) - f(A).$$

Then, f is increasing if and only if $\Delta_x f(A) \geq 0$ for any $A \subseteq E$ and $x \in E \setminus A$. f is submodular if and only if for any $A \subseteq E$ and *different* $x, y \in E \setminus A$, the inequality $\Delta_x f(A) \geq \Delta_x f(A \cup \{y\})$ holds (see, e.g., [28]). In addition, the following are equivalent:

- f is increasing and submodular.
- For any $A, B \subseteq E$,

$$f(B) - f(A) \leq \sum_{x \in B \setminus A} \Delta_x f(A).$$

- For any $A \subseteq E$ and $x, y \in E \setminus A$,

$$\Delta_x f(A) \geq \Delta_x f(A \cup \{y\}).$$

2 Independence Systems

Consider a finite ground set E and a collection \mathcal{I} of subsets of E . (E, \mathcal{I}) is called an *independence system* if \mathcal{I} is hereditary (i.e., for any two subsets I and J of E , $I \subseteq J \in \mathcal{I}$ implies $I \in \mathcal{I}$). Each member of \mathcal{I} is called an *independent set* or a *stable set*. A subset I of E is said to be a *maximal independent set* (or *base*) if $I \in \mathcal{I}$, but for any $e \in E \setminus I$, $I + e \notin \mathcal{I}$. A subset I of E is said to be a *circuit* if $I \notin \mathcal{I}$, but for any $e \in I$, $I - e \in \mathcal{I}$. This section presents greedy approximation algorithms for the following two general maximization problems:

- *Maximum Independent Set (MIS)*: given an independent system (E, \mathcal{I}) , compute a set $I \in \mathcal{I}$ maximizing $|I|$.
- *Maximum-Weight Independent Set (MWIS)*: given an independent system (E, \mathcal{I}) and an increasing nonnegative weight (or profit) function f on 2^E , compute a set $I \in \mathcal{I}$ maximizing $f(I)$.

2.1 Maximum Independent Set

Consider an independent system (E, \mathcal{I}) and an ordering $\langle e_1, e_2, \dots, e_n \rangle$ of E ; an independent set I can be computed by a first-fit greedy algorithm *GreedyMIS* described in [Table 1](#).

We derive an upper bound on the approximation ratio of the algorithm *GreedyMIS* in terms of the exchangeability of an ordering of E . Let \prec be an ordering of E . For a subset $X \subset E$ and an element $e \in X$, $X \prec e$ (respectively, $e \prec X$) means for each $x \in X$, $x \prec e$ (respectively, $e \prec x$). The ordering \prec is said to be *q-exchangeable* if the following holds: If $X \subset Y \in \mathcal{I}$, $X \prec e \prec Y \setminus X$, and $X + e \in \mathcal{I}$, then there is a set $Z \subseteq Y \setminus X$ such that $|Z| \leq q$ and $(Y \setminus Z) + e \in \mathcal{I}$.

Theorem 1 *The approximation ratio of the algorithm GreedyMIS in a q-exchangeable ordering is at most q.*

Proof Let x_1, x_2, \dots, x_k be the sequence of elements selected by the greedy algorithm. Denote $I_0 = \emptyset$, and $I_j = \{x_1, \dots, x_j\}$ for each $1 \leq j \leq k$. Let O be an optimal solution. We construct k subsets C_1, C_2, \dots, C_k of O as described in [Table 2](#). We will show that $\{C_1, C_2, \dots, C_k\}$ is a partition of O and $|C_j| \leq q$ for each $1 \leq j \leq k$, from which the theorem follows.

We first claim that for each $1 \leq j \leq k$, $I_j \cup B_j \in \mathcal{I}$ and $I_j \cap B_j = \emptyset$. The claim is proved by induction on j . The claim holds trivially for $j = 0$. Assume that the claim holds for some $j - 1$ with $1 \leq j < k$. We consider two cases:

Case 1: $x_j \in B_{j-1}$. Then, $C_j = \{x_j\}$ and $B_j = B_{j-1} \setminus \{x_j\}$. So

$$I_j \cup B_j = (I_{j-1} + x_j) \cup (B_{j-1} - x_j) = I_{j-1} \cup B_{j-1} \in \mathcal{I},$$

$$I_j \cap B_j = (I_{j-1} + x_j) \cap (B_{j-1} - x_j) \subseteq I_{j-1} \cap B_{j-1} = \emptyset.$$

Table 1 The first-fit selection of a maximal independent set

	<i>Greedy MIS</i>
	$I \leftarrow \emptyset;$
	For $i = 1$ to n do
	if $I + e_i \in \mathcal{I}$ then $I \leftarrow I + e_i$;
	Output I .

Table 2 A partition of O

	$B_0 \leftarrow O;$
	for $j = 1$ to k do
	if $x_j \in B_{j-1}$ then $C_j \leftarrow \{x_j\}$;
	else $C_j \leftarrow$ a smallest subset C of B_{j-1} such that
	$I_j \cup (B_{j-1} \setminus C) \in \mathcal{I};$
	$B_j \leftarrow B_{j-1} \setminus C_j;$
	output $\{C_1, C_2, \dots, C_k\}$.

Case 2: $x_j \notin B_{j-1}$. Then,

$$\begin{aligned} I_j \cup B_j &= I_j \cup (B_{j-1} \setminus C_j) \in \mathcal{I}, \\ I_j \cap B_j &= (I_{j-1} + x_j) \cap B_j \subseteq (I_{j-1} + x_j) \cap B_{j-1} = I_{j-1} \cap B_{j-1} = \emptyset. \end{aligned}$$

Therefore, the claim holds for j as well.

Next, we show that $|C_j| \leq q$ for each $1 \leq j \leq k$ in two cases:

Case 1: $x_j \in B_{j-1}$. Then, $|C_j| = 1 \leq q$.

Case 2: $x_j \notin B_{j-1}$. Since $I_{j-1} \cup B_{j-1} \in \mathcal{I}$, we have $I_{j-1} \prec x_j \prec B_{j-1}$ by the first-fit greedy principle. Since $I_{j-1} + x_j = I_j \in \mathcal{I}$ and $I_{j-1} \cap B_{j-1} = \emptyset$, there is a set $C \subseteq (I_{j-1} \cup B_{j-1}) \setminus I_{j-1} = B_{j-1}$ such that $|C| \leq q$ and $((I_{j-1} \cup B_{j-1}) \setminus C) + x_j = I_j \cup (B_{j-1} \setminus C) \in \mathcal{I}$. Therefore, $|C_j| \leq q$.

Finally, we show that $\{C_1, C_2, \dots, C_k\}$ is a partition of O . By the first-fit greedy principle, I_k is a maximal independent set. Since $I_k \cup B_k \in \mathcal{I}$ and $I_k \cap B_k = \emptyset$, we have $B_k = \emptyset$. As

$$B_k = O \setminus (C_1 \cup C_2 \cup \dots \cup C_k),$$

$\{C_1, C_2, \dots, C_k\}$ is a partition of O . ■

For the application of [Theorem 1](#) to specific problems, the major task is to find an ordering of the ground set with small exchangeability. Two prominent examples are seeking the maximum number of interference-free node transmissions [[37](#), [38](#)] or link transmissions [[32](#), [36](#)] in wireless networks. Certain natural node orderings or link orderings have been shown to have constant-bounded exchangeability.

2.2 Maximum-Weight Independent Set

Consider an independence system (E, \mathcal{I}) and a nonnegative weight (or profit) function f on 2^E . In the general greedy approximation strategy for this instance of *MWIS*, each iteration optimally or suboptimally solves the augmentation problem: For any $I \in \mathcal{I}$, find one $e \in E \setminus I$ with $I + e \in \mathcal{I}$ that maximizes $\Delta_e f(I)$. Let \mathcal{A} be a polynomial μ -approximation algorithm for this augmentation (the case $\mu = 1$ means the exact algorithm). [Table 3](#) describes the greedy algorithm *GreedyMWIS* which utilizes the algorithm \mathcal{A} in each iteration.

To derive the approximation bound of the algorithm *GreedyMWIS*, we introduce some relevant terms. Consider a subset X of E . A subset I of X is said to be a *maximal independent set* (or *base*) of X if $I \in \mathcal{I}$, but for any $x \in X \setminus I$, $I + x \notin \mathcal{I}$. Let $\mathcal{B}(X)$ denote the set of maximal independent subsets of X . The (*upper*) *rank* (or *independence number*) of X is defined by

$$r^+(X) = \max \{|I| : I \in \mathcal{B}(X)\},$$

and the *lower rank* of X is defined by

$$r^-(X) = \min \{|I| : I \in \mathcal{B}(X)\}.$$

The *rank quotient* of (E, \mathcal{I}) is defined by

$$\max \left\{ \frac{r^+(X)}{r^-(X)} : X \subseteq E, \ell(X) > 0 \right\}.$$

Note that an independence system whose rank quotient is one is termed as a *matroid*.

Theorem 2 *Let q be the rank quotient of (E, \mathcal{I}) . The approximation ratio of the algorithm GreedyMWIS is at most $q\mu + 1$ if f is polymatroid and at most $q\mu$ if f is linear.*

The proof of [Theorem 2](#) makes use of the following exchange property of independent systems.

Theorem 3 *Suppose that (E, \mathcal{I}) has rank quotient q . Let X and Y be two bases and $X \setminus Y = \{x_1, x_2, \dots, x_k\}$. Denote $X_0 = X \cap Y$ and $X_i = (X \cap Y) \cup \{x_1, x_2, \dots, x_i\}$ for $1 \leq i \leq k$. Then, there is a partition $\{C_1, C_2, \dots, C_k\}$ of $Y \setminus X$ such that for each $1 \leq i \leq k$, (1) $|C_i| \leq q$, and (2) for each $e \in C_i$, $X_{i-1} + e \in \mathcal{I}$.*

Proof We construct k subsets C_1, C_2, \dots, C_k of $Y \setminus X$ as described in [Table 4](#). Clearly, for each $1 \leq i \leq k$, (1) $|C_i| \leq q$, and (2) for each $e \in C_i$, $X_{i-1} \cup \{e\} \in \mathcal{I}$. So, we only have to show that $\{C_i : 1 \leq i \leq k\}$ is a partition of $Y \setminus X$ or equivalently $Y_0 = \emptyset$. We prove a stronger claim that for each $0 \leq i \leq k$, $|Y_i| \leq iq$ by induction downward on i . As

Table 3 A partition of $Y \setminus X$

<i>GreedyMWIS</i>
$I \leftarrow \emptyset, A \leftarrow E;$
While $A \neq \emptyset$ do
$x \leftarrow$ the augmentation to I output by \mathcal{A} ;
$I \leftarrow I + x;$
$A \leftarrow \{e \in A \setminus I : I + e \in \mathcal{I}\};$
Output I .

Table 4 A partition of $Y \setminus X$

$Y_k \leftarrow Y \setminus X;$
for each $i = k$ down to 1 do
$B_i \leftarrow \{e \in Y_i : X_{i-1} \cup \{e\} \in \mathcal{I}\};$
$C_i \leftarrow$ a subset of B_i of cardinality $\min\{ B_i , q\};$
$Y_{i-1} \leftarrow Y_i \setminus C_i;$
output $\{C_1, C_2, \dots, C_k\}$.

$$|Y_k| = |Y| - |X \cap Y| \leq q |X| - |X \cap Y| \leq q (|X| - |X \cap Y|) = kq,$$

the claim holds for $i = k$. Now, suppose that $|Y_i| \leq iq$ for some $1 < i \leq k$. We show that $|Y_{i-1}| \leq (i-1)q$ in two cases:

Case 1: $|B_i| \geq q$. Then $|C_i| = q$ and $|Y_{i-1}| = |Y_i| - |C_i| \leq (i-1)q$.

Case 2: $|B_i| < q$. Then, $C_i = B_i$ and $Y_{i-1} = Y_i \setminus B_i$. By the definition of B_i , X_{i-1} is a base of

$$X_{i-1} \cup Y_{i-1} = X_{i-1} \cup (Y_i \setminus B_i).$$

Hence, $|Y_{i-1}| \leq q |X_{i-1}| = (i-1)q$. ■

From [Theorem 3](#), we obtain the following weak exchange property of independent systems.

Corollary 1 Suppose that (E, \mathcal{I}) has rank quotient q . Let $X = \{x_1, x_2, \dots, x_k\}$ be a base of E and denote $X_0 = \emptyset$ and $X_j = \{x_1, \dots, x_j\}$ for $1 \leq j \leq k$. Then, for any base Y of E , there is a partition $\{C_1, C_2, \dots, C_k\}$ of Y such that for each $1 \leq i \leq k$, (1) $|C_i| \leq q$ (2) $X_{i-1} \cap C_i = \emptyset$, and (3) for each $e \in C_i$, $X_{i-1} + e \in \mathcal{I}$.

Now, we prove [Theorem 2](#). Let x_1, x_2, \dots, x_k be the sequence of elements selected by the greedy algorithm. Denote $I_0 = \emptyset$, and $I_j = \{x_1, \dots, x_j\}$ for each $1 \leq j \leq k$. Let O be an optimal solution. By [Corollary 1](#), there is a partition $\{C_1, C_2, \dots, C_k\}$ of O such that for each $1 \leq j \leq k$, (1) $|C_j| \leq q$, (2) $I_{j-1} \cap C_j = \emptyset$, and (3) for each $e \in C_j$, $I_{j-1} + e \in \mathcal{I}$. We first consider the case that f is polymatroid. By the greedy rule, for each $e \in C_j$,

$$\Delta_e f(I_{j-1}) \leq \mu \Delta_{x_j} f(I_{j-1}),$$

which implies that

$$\Delta_{C_j} f(I_{j-1}) \leq |C_j| \cdot \mu \Delta_{x_j} f(I_{j-1}) \leq q\mu \Delta_{x_j} f(I_{j-1}).$$

Therefore,

$$\begin{aligned} f(O) - f(I) &\leq \sum_{j=1}^k \Delta_{C_j} f(I) \leq \sum_{j=1}^k \Delta_{C_j} f(I_{j-1}) \\ &\leq q\mu \sum_{j=1}^k \Delta_{x_j} f(I_{j-1}) = q\mu f(I). \end{aligned}$$

So,

$$f(O) \leq (q\mu + 1) f(I).$$

Next, we consider the case that f is linear. In this case, for each $e \in C_j$, $f(e) \leq \mu f(x_j)$, which implies that $f(C_j) \leq q\mu f(x_j)$. So, $f(O) \leq q\mu f(I)$. This completes the proof of [Theorem 2](#).

Remark For linear f and $q = \mu = 1$, [Theorem 2](#) is the classic result on greedy algorithm for matroid due to Rado [29] and Edmonds [9, 10]. For linear f and $\mu = 1$, [Theorem 2](#) was proved by Jenkyns [19] and Korte and Hausmann [22]. For polymatroid f and $\mu = 1$, [Theorem 2](#) was proved by Fisher et al. [12]. For polymatroid f and $\mu \geq 1$, the theorem was proved by Calinescu et al. [4].

A matroid (E, \mathcal{I}) is called a uniform matroid if

$$\mathcal{I} = \{I \subseteq E : |I| \leq k\}$$

for some positive integer k . For uniform matroid (E, \mathcal{I}) , the algorithm *GreedyMWIS* achieves better approximation bound.

Theorem 4 *If (E, \mathcal{I}) is a uniform matroid and f is a polymatroid function, then the approximation ratio of the algorithm GreedyMWIS is at most $\frac{1}{1-e^{-1/\mu}}$.*

The proof of the above theorem utilizes the following algebraic inequality.

Lemma 1 *Suppose that c_1, c_2, \dots, c_k are k positive numbers less than a . Then, for any k nonnegative numbers x_1, x_2, \dots, x_k ,*

$$\min_{i=1}^k \left(\sum_{j=1}^{i-1} c_j x_j + a x_i \right) \leq \frac{\sum_{i=1}^k c_i x_i}{1 - \prod_{i=1}^k \left(1 - \frac{c_i}{a}\right)}.$$

Proof For each $1 \leq i \leq k$, let

$$\lambda_i = \frac{\frac{c_i}{a} \prod_{j=i+1}^k \left(1 - \frac{c_j}{a}\right)}{1 - \prod_{i=1}^k \left(1 - \frac{c_j}{a}\right)}.$$

Then $\sum_{i=1}^k \lambda_i = 1$, and hence,

$$\begin{aligned} \min_{i=1}^k \left(\sum_{j=1}^{i-1} c_j x_j + ax_i \right) &\leq \sum_{i=1}^k \lambda_i \left(\sum_{j=1}^{i-1} c_j x_j + ax_i \right) \\ &= \sum_{i=1}^k \left(\frac{a}{c_i} \lambda_i + \sum_{j=i+1}^k \lambda_j \right) c_i x_i = \frac{\sum_{i=1}^k c_i x_i}{1 - \prod_{i=1}^k \left(1 - \frac{c_j}{a}\right)}. \end{aligned}$$

So, the lemma follows. ■

Now, we prove [Theorem 4](#). Let x_1, x_2, \dots, x_k be the sequence of elements selected by the greedy algorithm. Then, $|O| = k$. By the greedy rule, for each $1 \leq i \leq k$ and each $y \in O \setminus I_{i-1}$,

$$\Delta y f(I_{i-1}) \leq \mu \Delta x_i f(I_{i-1}),$$

and consequently,

$$\begin{aligned} f(O) &\leq f(I_{i-1}) + \sum_{y \in O \setminus I_{i-1}} \Delta y f(I_{i-1}) \\ &\leq f(I_{i-1}) + |O \setminus I_{i-1}| \mu \Delta x_i f(I_{i-1}) \\ &\leq \sum_{j=1}^{i-1} \Delta x_j f(I_{j-1}) + k \mu \Delta x_i f(I_{i-1}). \end{aligned}$$

By [Lemma 1](#), we have

$$f(O) \leq \min_{i=1}^k \left(\sum_{j=1}^{i-1} \Delta x_j f(I_{j-1}) + k \mu \Delta x_i f(I_{i-1}) \right)$$

$$\begin{aligned} &\leq \frac{\sum_{j=1}^k \Delta x_j f(I_{j-1})}{1 - \left(1 - \frac{1}{k\mu}\right)^k} = \frac{f(I_k)}{1 - \left(1 - \frac{1}{k\mu}\right)^k} \\ &\leq \frac{f(I_k)}{1 - e^{-1/\mu}}. \end{aligned}$$

This completes the proof of [Theorem 4](#).

Remark Maximizing submodular functions subject to a uniform matroid constraint appears to have come from an application to a facility location problem in the work of Cornuejols et al. [6]. In [26], Fisher et al. formally proved the special case of [Theorem 4](#) in which $\mu = 1$. For this special case, Nemhauser and Wolsey [27] further showed that any algorithm with better approximation bound requires an exponential number of queries of the values of f , and Feige [11] showed that $\frac{1}{1-e^{-1}}$ is the best approximation ratio unless $\mathbf{P} = \mathbf{NP}$. For $\mu \geq 1$, Wan and Liu [35] obtained the same approximation bound as the one in [Theorem 4](#) of the greedy approximation algorithm for throughput maximization in wavelength-routed optical networks, and Hochbaum and Pathria [18] also derived the same approximation bound of the greedy approximation algorithm for maximum k -coverage.

For the application of [Theorem 2](#) to specific problems, the main task is to estimate the rank quotient of the underlying independence system. [Theorem 1](#) can often be applied for this purpose. An independence system (E, \mathcal{I}) is said to be q -exchangeable if every ordering of E is q -exchangeable. By [Theorem 1](#), the rank quotient of any q -exchangeable system is at most q . It is easy to verify that:

- (E, \mathcal{I}) is q -exchangeable if and only if for any $X \subset Y \in \mathcal{I}$ and $e \in E$ with $X + e \in \mathcal{I}$, there is a set $Z \subseteq Y \setminus X$ such that $|Z| \leq q$ and $(Y \setminus Z) + e \in \mathcal{I}$.
- (E, \mathcal{I}) is q -exchangeable if for any $I \in \mathcal{I}$ and $e \in E$, $I + e$ contains at most q circuits.
- (E, \mathcal{I}) is q -exchangeable if it is the intersection of q matroids.

Below is the list of instances of MWIS with linear weight function and non-matroid independent systems.

Maximum-Weight Hamiltonian Cycle: Given an edge-weighted complete graph, find a Hamiltonian cycle with maximum total weight.

- Ground set: the set of edges
- Independent sets: Hamiltonian cycles or vertex-disjoint paths
- Rank quotient: 2

Maximum-Weight Directed Hamiltonian Cycle: Given an edge-weighted complete digraph, find a Hamiltonian cycle with maximum total weight.

- Ground set: the set of arcs
- Independent sets: directed Hamiltonian cycles or vertex-disjoint paths.
- Rank quotient: 3

Maximum-Weight Stable Set of Unit-Disk Graphs: Given a vertex-weighted unit-disk graph, find a stable set with maximum total weight.

- Ground set: the set of vertices.
- Independent sets: stable sets. An independent set or stable set of a graph is a set of vertices in the graph, no two of which are adjacent.
- Rank quotient: 5.

A number of applications of [Theorem 4](#) were surveyed by Goundan and Schulz [15].

3 Dependence Systems

Consider a finite ground set E and a collection \mathcal{D} of subsets of E . (E, \mathcal{D}) is called a *dependence system* if for any two subsets X and Y of E , $X \subseteq Y$ and $X \in \mathcal{D}$ implies $Y \in \mathcal{D}$. Each member of \mathcal{D} is called a *dependent set*. A subset X of E is said to be a *minimal dependent set* if $X \in \mathcal{D}$, but for any $e \in X$, $X - e \notin \mathcal{D}$. Given an dependent system (E, \mathcal{D}) and an increasing and proper nonnegative cost function c on 2^E , the problem $\min_{X \in \mathcal{D}} c(X)$ is referred to as *Minimum-Cost Dependent Set*. For many instances of *Minimum-Cost Dependent Set*, the dependence system (E, \mathcal{D}) is implicitly defined by an increasing *coverage function* f on 2^E : For each $X \subseteq E$, $X \in \mathcal{D}$ if and only if $f(X) = f(E)$, or it is implicitly defined by a decreasing *coverage deficiency function* (also called *potential function*) f on 2^E ; for each $X \subseteq E$, $X \in \mathcal{D}$ if and only if $f(X) = 0$. If the coverage function is a polymatroid function, the problem *Minimum-Cost Dependent Set* is commonly known as the *Minimum-Cost Submodular Cover*, and each dependent set is also called as a *submodular cover*.

Minimum-Cost Submodular Cover is well behaved. In [Sect. 3.1](#), we present a general greedy approximation algorithm for *Minimum-Cost Submodular Cover* and its approximation bound. For other instances of *Minimum-Cost Dependent Set* which cannot be cast as *Minimum-Cost Submodular Cover*, they lack such unified framework for both design and analysis of greedy approximation algorithms. In [Sects. 3.2](#) and [3.3](#), we present greedy approximation algorithms for *Minimum Connected Dominating Set (MCDS)* and *Minimum-Weight Connected Dominating Set (MWCDS)*, respectively. A connected dominating set (CDS) of a connected graph $G = (V, E)$ is a subset of vertices U such that U is a dominating set (i.e., each vertex $v \in V \setminus U$ is adjacent to at least one vertex in U) and the induced subgraph $G[U]$ is connected. The problem *MCDS* seeks a CDS of the smallest size in a given graph G , and the problem *MWCDS* seeks a CDS of the smallest weight in a given vertex-weighted graph G . They are selected as representative examples for the following reasons:

- *MCDS* is associated with a coverage function which is not submodular but has a special shifted submodularity. Such shifted submodularity can still be exploited to design and analyze the greedy approximation algorithm in the manner similar to those for *Minimum-Cost Submodular Cover*.

- The naive extension of the greedy approximation algorithm for *MCDS* to *MWCDS* has a very poor approximation ratio.
- The design and analysis of the greedy approximation algorithm for *MWCDS* can be slightly modified to some other well-known minimization problems, which are listed in Sect. 3.3.

3.1 Minimum-Cost Submodular Cover

Consider an instance of *Minimum-Cost Submodular Cover* specified by the ground set E , the polymatroid coverage function f , and the increasing and proper cost function c . In the general greedy approximation strategy for this instance, each iteration optimally or suboptimally solves the augmentation problem: For any given $X \subset E$, find one $e \in E \setminus X$ that maximizes $\Delta_e f(X) / c(e)$. Let \mathcal{A} be a polynomial μ -approximation algorithm for this augmentation (the case $\mu = 1$ means the exact algorithm). Table 5 describes the greedy algorithm *GreedyMCSC* which utilizes the algorithm \mathcal{A} in each iteration.

Let x_1, x_2, \dots, x_k be the sequence of elements selected by the algorithm *GreedyMCSC*. Denote $X_0 = \emptyset$, and $X_i = \{x_1, x_2, \dots, x_i\}$ for each $1 \leq i \leq k$. For each $1 \leq i \leq k$, let $p_i = \frac{c(x_i)}{\Delta_{x_i} f(X_{i-1})}$, which is referred to the price of x_i . Let opt be the cost of an optimal solution. When f is integer-valued, c is linear, and \mathcal{A} is optimal, it is well known that $c(X_k) / \text{opt} \leq H(q)$, where $q = \max_{e \in E} f(e)$ and

$$H(q) = 1 + \frac{1}{2} + \dots + \frac{1}{q}$$

is the k th Harmonic number. For the general case, we define the *curvature* to be

$$\rho = \frac{\min \left\{ \sum_{e \in S} c(e) : S \text{ is a cover} \right\}}{\text{opt}}.$$

Note that $\rho = 1$ if c is linear. We have the following two general performance bounds.

Theorem 5 *If f is integer-valued, then $c(X_k) / \text{opt} \leq \rho \mu H(q)$, where $q = \max_{e \in E} f(e)$.*

Theorem 6 *If $f(E) \geq \text{opt}$ and $p_i \leq 1$ for each $1 \leq i \leq k$, then $c(X_k) / \text{opt} \leq 1 + \rho \mu \ln \frac{f(E)}{\text{opt}}$.*

The proof of both theorems utilizes the following algebraic inequalities. Suppose that $\ell_0, \ell_1, \dots, \ell_{k-1}$ are decreasing positive numbers. Then,

$$\sum_{i=1}^{k-1} \frac{\ell_{i-1} - \ell_i}{\ell_{i-1}} \leq \ln \frac{\ell_0}{\ell_{k-1}}.$$

Table 5 Greedy algorithm for minimum submodular cover

<i>GreedyMCSC</i>
$X \leftarrow \emptyset;$
While $f(X) < f(E)$ do
$x \leftarrow$ the augmentation to X output by \mathcal{A} ;
$X \leftarrow X + x;$
Output X .

If all of them are integers, then

$$\sum_{i=1}^{k-1} \frac{\ell_{i-1} - \ell_i}{\ell_{i-1}} \leq H(\ell_0) - H(\ell_{k-1}) \leq \ln \frac{\ell_0}{\ell_{k-1}}.$$

We prove [Theorem 5](#) by a charging argument. Let $O = \{y_1, y_2, \dots, y_m\}$ be a cover satisfying that

$$\sum_{j=1}^m c(y_j) \leq \rho \cdot \text{opt}.$$

Denote $O_0 = \emptyset$, and $O_j = \{y_1, y_2, \dots, y_j\}$ for each $1 \leq j \leq m$. Each x_i charges on y_j with

$$p_i (\Delta_{y_j} f(X_{i-1} \cup O_{j-1}) - \Delta_{y_j} f(X_i \cup O_{j-1})).$$

Then, the total charge by x_i on O is exactly $c(x_i)$ as

$$\begin{aligned} p_i \sum_{j=1}^m (\Delta_{y_j} f(X_{i-1} \cup O_{j-1}) - \Delta_{y_j} f(X_i \cup O_{j-1})) \\ &= p_i [(f(X_{i-1} \cup O) - f(X_{i-1})) - (f(X_i \cup O) - f(X_i))] \\ &= p_i [f(X_i) - f(X_{i-1})] \\ &= p_i \Delta_{x_i} f(X_{i-1}) \\ &= c(x_i). \end{aligned}$$

Thus, the total charge on O is $\sum_{i=1}^k c(x_i)$. On the other hand, we claim that the total charge on each y_j is at most $\mu H(q) c(y_j)$. Indeed, let l be the first i such that $\Delta_{y_j} f(X_i \cup O_{j-1}) = 0$. Then, the charge on y_j by each x_i with $i \geq l$ is 0. For each $1 \leq i \leq l$, $\Delta_{y_j} f(X_{i-1} \cup O_{j-1}) > 0$ which implies that $y_j \notin X_{i-1} \cup O_{j-1}$, and hence by the greedy rule, we have

$$p_i = \frac{c(x_i)}{\Delta_{x_i} f(X_{i-1})} \leq \mu \frac{c(y_j)}{\Delta_{y_j} f(X_{i-1})} \leq \mu \frac{c(y_j)}{\Delta_{y_j} f(X_{i-1} \cup O_{j-1})}.$$

Thus,

$$\begin{aligned}
& \sum_{i=1}^l p_i (\Delta_{y_j} f(X_{i-1} \cup O_{j-1}) - \Delta_{y_j} f(X_i \cup O_{j-1})) \\
& \leq \mu c(y_j) \sum_{i=1}^l \frac{\Delta_{y_j} f(X_{i-1} \cup O_{j-1}) - \Delta_{y_j} f(X_i \cup O_{j-1})}{\Delta_{y_j} f(X_{i-1} \cup O_{j-1})} \\
& \leq \mu c(y_j) H(\Delta_{y_j} f(O_{j-1})) \leq \mu c(y_j) H(\Delta_{y_j} f(\emptyset)) \\
& \leq \mu H(q) c(y_j).
\end{aligned}$$

So, our claim holds. As

$$\begin{aligned}
& \sum_{j=1}^m \mu H(q) c(y_j) = \mu H(q) \sum_{j=1}^m c(y_j) \\
& \leq \mu H(q) \rho \cdot c(O) = \rho \mu H(q) \cdot \text{opt}.
\end{aligned}$$

The total charge on O is at most $\rho \mu H(q) \cdot \text{opt}$. Therefore,

$$c(X) \leq \sum_{i=1}^k c(x_i) \leq \rho \mu H(q) \cdot \text{opt}.$$

This completes the proof for [Theorem 5](#).

Next, we prove [Theorem 6](#). Let O be a cover satisfying that

$$\sum_{y \in O} c(y) \leq \rho \cdot \text{opt}.$$

For each $0 \leq i \leq k$, let $\ell_i = f(E) - f(X_i)$ be the ‘‘coverage deficiency’’ at the end of iteration i . Let t be the subscript satisfying that $\ell_t \geq \text{opt} > \ell_{t+1}$. We claim that for each $1 \leq i \leq k$,

$$p_i \leq \min \left\{ \rho \mu \frac{\text{opt}}{\ell_{i-1}}, 1 \right\}.$$

Indeed, the inequality $p_i \leq 1$ holds by assumption. By the greedy rule, we have

$$\begin{aligned}
\frac{1}{p_i} &= \frac{\Delta_{x_i} f(X_{i-1})}{c(x_i)} \geq \frac{1}{\mu} \max_{y \in O \setminus X_{i-1}} \frac{\Delta_y f(X_{i-1})}{c(y)} \\
&\geq \frac{1}{\mu} \frac{\sum_{y \in O \setminus X_{i-1}} \Delta_y f(X_{i-1})}{\sum_{y \in O \setminus X_{i-1}} c(y)}
\end{aligned}$$

$$\begin{aligned} &\geq \frac{1}{\mu} \frac{f(O) - f(X_{i-1})}{\sum_{y \in O} c(y)} \\ &\geq \frac{1}{\mu} \frac{\ell_{i-1}}{\rho \cdot \text{opt}} = \frac{\ell_{i-1}}{\rho \mu \cdot \text{opt}}. \end{aligned}$$

So, our claim holds. Thus, for each $1 \leq i \leq k$,

$$\begin{aligned} c(x_i) &= p_i \Delta_{x_i} f(X_{i-1}) = p_i (\ell_{i-1} - \ell_i) \\ &\leq \min \left\{ \rho \mu \frac{\text{opt}}{\ell_{i-1}}, 1 \right\} \cdot (\ell_{i-1} - \ell_i) \\ &= \min \left\{ \rho \mu \cdot \text{opt} \frac{\ell_{i-1} - \ell_i}{\ell_{i-1}}, \ell_{i-1} - \ell_i \right\}. \end{aligned}$$

Hence,

$$\begin{aligned} &\sum_{i=1}^t c(x_i) + \frac{\ell_t - \text{opt}}{\ell_t - \ell_{t+1}} c(x_{t+1}) \\ &\leq \rho \mu \cdot \text{opt} \left(\sum_{i=1}^t \frac{\ell_{i-1} - \ell_i}{\ell_{i-1}} + \frac{\ell_t - \text{opt}}{\ell_t} \right) \\ &\leq \rho \mu \cdot \text{opt} \ln \frac{\ell_0}{\text{opt}} \\ &= \text{opt} \cdot \rho \mu \ln \frac{f(E)}{\text{opt}}, \end{aligned}$$

and

$$\frac{\text{opt} - \ell_{t+1}}{\ell_t - \ell_{t+1}} c(x_{t+1}) + \sum_{i=t+2}^k c(x_i) \leq (\text{opt} - \ell_{t+1}) + \sum_{i=t+2}^k (\ell_{i-1} - \ell_i) = \text{opt}.$$

Summing up the above two inequalities, we have

$$c(X) \leq \sum_{i=1}^k c(x_i) \leq \left(1 + \rho \mu \ln \frac{f(E)}{\text{opt}} \right) \text{opt}.$$

This completes the proof for [Theorem 6](#).

Remark For linear c and $\mu = 1$, [Theorem 5](#) was proved by Wolsey [39]. For submodular c and $\mu = 1$, [Theorems 5](#) and [6](#) were proved by Wan et al. [34].

For many specific *Minimum-Cost Submodular Cover* problems, the coverage function f is not given explicitly. For these problems, the main task is to find the proper submodular coverage function. For some *Minimum-Cost Submodular Cover* problems, such as set cover, the submodular potential functions can be easily defined. But for some others, it is far from trivial to find the submodular potential function. A prominent example is *Weighted Connected Vertex Cover* (WCVC). An instance of WCVC is a connected vertex-weighted graph $G = (V, E)$. A solution to WCVC is a connected vertex cover, which is a subset of vertices inducing a connected subgraph and covering all edges. The objective is to find a connected vertex-cover with the minimum total weight. While the unweighted variant of WCVC has a simple 2-approximation algorithm [13], WCVC has the same approximation hardness as weighted set cover [13]. It can be formulated as a special case of *Minimum-Cost Submodular Cover* in which the ground set is V and the coverage of a subset $U \subseteq V$ is the number of edges in G incident to U minus the number of connected components of the subgraph of G induced by U [7]. By Theorem 5, the approximation ratio of greedy approximation algorithm is at most $H(\Delta - 1)$.

For some specific *Minimum-Cost Submodular Cover* problems, they may have different formulations which lead to different approximation bounds. A prominent example is *Minimum-Power Spanning Tree*. Let $G = (V, E; c)$ be an edge-weighted graph with $c(e) > 0$ for each $e \in E$. Any subgraph H induces a power assignment $p_H : V(H) \rightarrow \mathbb{R}_+$ defined by

$$p_H(u) = \max_{e \in \delta_H(u)} c(e), \forall u \in V(H);$$

the power of H is defined by $\sum_{u \in V(H)} p_H(u)$. The problem of finding a spanning tree of minimum power is referred to as *Minimum-Power Spanning Tree* and may have two different formulations into *Minimum-Cost Submodular Cover*. In the first formulation [20], the ground set is the set E of edges; for any subset any $A \subseteq E$, its coverage is the rank of the graphic matroid on (V, A) , and its cost is the power of (V, F) . For this formulation, $q = \mu = 1$ and the curvature is at most 2. So the approximation ratio of the greedy algorithm is at most 2. In the second formulation [1], the ground set consists of all k -restricted trees (i.e., subtrees of G containing at most k vertices) for some fixed integer $k \geq 2$. Let $\text{mst}(G)$ denote the weight of a minimum-weight spanning tree of G . For any subgraph H of G , let $\text{mst}(G : H)$ denote the weight of the minimum-weight spanning forest F such that $H \cup F$ is connected. For any subset of k -restricted trees whose union is H , its coverage is defined to be $2[\text{mst}(G) - \text{mst}(G : H)]$, and its cost is the power of H . It was proved in [24] that the curvature is at most

$$\rho_k \leq 1 + \frac{1}{\lfloor \log k \rfloor - 1 + k/2^{\lfloor \log k \rfloor}}.$$

By [Theorem 6](#), the approximation ratio of the greedy algorithm is at most

$$1 + \left(1 + \frac{1}{\lfloor \log k \rfloor - 1 + k/2^{\lfloor \log k \rfloor}} \right) \ln 2.$$

When k tends to infinity, the above approximation bound approaches to $1 + \ln 2$, which is better than the approximation bound 2 obtained in the first formulation.

The remaining of the subsection provides the formulations of some well-known optimization problems as instances of *Minimum-Cost Submodular Cover*. For all of them, $\mu = 1$. Below is the list of problems with linear cost.

Generalized Set Multi-cover [14]: Given a matrix $A \in N_{m \times n}$ and two vectors $b \in N_{m \times 1}$, compute

$$\min \left\{ \sum_{j=1}^n c_j x_j : Ax \geq b, x \in \{0, 1\}^n \right\}.$$

- Ground set: $\{1, 2, \dots, n\}$.
- Coverage function: for any $S \subseteq \{1, 2, \dots, n\}$,

$$f(S) = \sum_{i=1}^m \min \left\{ \sum_{j \in S} a_{ij}, b_i \right\}.$$

Capacitated Set Cover [39]: Given a bipartite graph $G = (V, W; E)$ and a capacity bound $b : V \rightarrow \mathbb{N}$, find a subgraph $H = (U, W; E)$ such that $\deg_H(u) \leq b(u)$ for each $u \in U$, $\deg_H(w) \geq 1$ for each $w \in W$, and $|U|$ is minimized.

- Ground set: V .
- Coverage function: for any $U \subseteq V$, $f(U)$ is the maximum number of vertices in W that can be covered by U under the capacity constraint.

Weakly Connected Dominating Set: Given a vertex-weighted graph G , find a minimum-weight weakly connected dominating set.

- Ground set: the set of vertices.
- Coverage function: for any $U \subseteq V$, $f(U)$ is the rank of the graphic matroid on the spanning subgraph of G consisting of all edges incident to U .

Minimum-Label Spanning Tree [33]: Given a graph G in which each edge has a label from $\{1, 2, \dots, L\}$, find a spanning tree with the smallest number of different labels.

- Ground set: $\{1, 2, \dots, L\}$.
- Coverage function: For any $S \subseteq \{1, 2, \dots, L\}$, $f(S)$ is the rank of the graphic matroid on the spanning subgraph of G consisting of all edges with label $l \in S$.

Subset Interconnection Design [8]: Given an edge-weighted graph G and m subsets V_1, \dots, V_m of vertices, find a minimum-weight subgraph H of G satisfying that the subgraph of H induced by each V_i for $1 \leq i \leq m$ is connected.

- Ground set: E .
- Coverage function: for any $A \subseteq E$, let $f_i(A)$ be rank of the graphic matroid on the subgraph of (V, A) induced by V_i for each $1 \leq i \leq m$. The coverage of A is given by

$$f(A) = \sum_{i=1}^m f_i(A).$$

Below are two problems with polymatroid cost functions.

Minimum Steiner Tree: Given an edge-weight graph G and a subset S of vertices, find a minimum-weighted subgraph H of G interconnecting S .

- Ground set: fix a positive integer $k \geq 2$. For any subset U of terminals with $2 \leq |U| \leq k$, we compute a minimum-weight Steiner tree and add the output tree to the ground set if it is full.
- Cost function: for any subset of trees in the ground set whose union is H , its cost is the total weight of the edges in H .
- Coverage function: for any subset of k -restricted full trees whose union is H , its coverage is defined to be $\text{mst}(G) - \text{mst}(G : H)$, and its cost is $c(H)$.
- Curvature: it was shown in [3] that the curvature is at most

$$\rho_k = 1 + \frac{1}{\lfloor \log_2 k \rfloor - 1 + k/2^{\lfloor \log_2 k \rfloor}}.$$

Minimum Node-Weighted Steiner Tree in Unit-Disk Graphs: Given a node-weighted unit-disk graph G and a subset S of vertices, find a minimum node-weighted subgraph H of G interconnecting S .

- Ground set: fix a positive integer $k \geq 2$. For any subset U of terminals with $2 \leq |U| \leq k$, we compute a Minimum Node-Weighted Steiner Tree and add the output tree to the ground set if it is full.
- Cost function: for any subset of trees in the ground set whose union is H , its cost is the total weight of the vertices in H other than the terminals.
- Coverage function: the *length* of a simple path in G is the sum of the weights of all its internal nodes. The *distance* between two nodes in G is the length of the shortest path between them and can be computed in polynomial time. The *terminal distance graph* of G is the complete graph K on S in which the length of each edge is the distance between its two endpoints. For any subset of trees in the ground set whose union is H , its coverage is $\text{mst}(K) - \text{mst}(K : H)$.
- Curvature: it was shown in [40] that the curvature is at most

$$\rho_k = 1 + \frac{4}{\lfloor \log_2 k \rfloor - 1 + k/2^{\lfloor \log_2 k \rfloor}}.$$

3.2 Minimum CDS

Consider a connected graph $G = (V, E)$. If the maximum degree Δ of G is either one or two, then a minimum CDS of G can be computed trivially. Indeed, if $\Delta = 1$, then G contains only one edge and a minimum CDS consists of any single vertex. If $\Delta = 2$, G is a path or a cycle. When G is a path, the minimum CDS consists of all internal nodes; when G is a cycle, a minimum CDS can be obtained by deleting two adjacent nodes. So we assume $\Delta \geq 3$ from now on and let γ_c be the size of a minimum CDS and $n = |V|$. This subsection presents a simple greedy $(2 + \ln(\Delta - 2))$ -approximation algorithm [30] for *MCDS*.

We first describe the coverage function used by the greedy algorithm. For any subset U of V , let $G \langle U \rangle$ denote the spanning subgraph of G including all edges incident to U and $f_1(U)$ be the rank of the graphic matroid on $G \langle U \rangle$ (in other words, $f_1(U)$ equals to n minus the number of connected components of $G \langle U \rangle$) and $f_2(U)$ be the number of connected components of the graph $G[U]$. The coverage of U is then defined to be

$$f(U) = f_1(U) + f_2(U) - 1.$$

Clearly, $f(\emptyset) = 0$; for any $U \subseteq V$, $f(U) \leq n - 2 = f(V)$, and the equality holds if and only if U is a CDS. For any $U \subset V$ and any $v \in V \setminus U$, $\Delta_v f_1(U)$ is the number of connected components of $G \langle U \rangle$ adjacent to but not containing v , and $-\Delta_v f_2(U)$ is the number of connected components of $G[U]$ adjacent to v minus one; consequently, $\Delta_v f(U) \geq 0$. Therefore, f is increasing. However, f is not submodular. Therefore, the general greedy approximation algorithm for *Minimum-Cost Submodular Cover* cannot be directly applied to *MCDS*.

While f is not submodular, it has a “shifted submodularity” as stated in the next lemma.

Lemma 2 Suppose that U and W are two subsets of V satisfying that $G[W]$ is connected. Then, for any vertex $v \in V$,

$$\Delta_v f(U \cup W) \leq \Delta_v f(U) + 1.$$

Proof Since f_1 is submodular, we have

$$\Delta_v f_1(U \cup W) \leq \Delta_v f_1(U).$$

As $G[W]$ is connected, the number of connected components in $G[U \cup W]$ adjacent to v is at most one more than the number of connected components in $G[U]$ adjacent to v . Hence,

$$-\Delta_v f_2(U \cup W) \leq -\Delta_v f_2(U) + 1.$$

Summing up the above two inequalities yields the inequality in the lemma. ■

In addition, f still has the following growth property.

Lemma 3 *If $U \subseteq V$ is not a CDS of G , then there exists a vertex v satisfying that*

$$\Delta_v f(U) \geq \max \left\{ 1, \frac{n - 1 - f(U)}{\gamma_c} - 1 \right\}.$$

Proof We first show that there is a vertex v satisfying that $\Delta_v f(U) \geq 1$. We consider three cases:

Case 1: $U = \emptyset$. Let v be the vertex with maximum degree. Then,

$$\begin{aligned}\Delta_v f_1(U) &= \Delta, \\ \Delta_v f_2(U) &= -1, \\ \Delta_v f(U) &= \Delta - 1 \geq 1.\end{aligned}$$

Case 2: U is nonempty but is not a dominating set. Let v be a vertex which is adjacent to both U and some vertex two hops away from U . Then,

$$\begin{aligned}\Delta_v f_1(U) &\geq 1, \\ \Delta_v f_2(\emptyset) &\geq 0, \\ \Delta_v f(\emptyset) &\geq 1.\end{aligned}$$

Case 3: U is a dominating set. Let U_1 and U_2 be two connected components of $G[U]$ separated by the smallest number of hops. Then the number of hops between U_1 and U_2 is either two or three. So, we further consider two subcases:

Subcase 3.1: U_1 and U_2 are separated by two hops. Let v be a vertex adjacent to both U_1 and U_2 . Then,

$$\begin{aligned}\Delta_v f_1(U) &= 0, \\ \Delta_v f_2(\emptyset) &\geq 1, \\ \Delta_v f(\emptyset) &\geq 1.\end{aligned}$$

Subcase 3.2: U_1 and U_2 are separated by three hops. Let v be a vertex in the shortest (3-hop) path joining U_1 and U_2 . Then,

$$\begin{aligned}\Delta_v f_1(U) &\geq 1, \\ \Delta_v f_2(\emptyset) &= 0, \\ \Delta_v f(\emptyset) &\geq 1.\end{aligned}$$

Next, we show that there is a vertex v satisfying that

$$\Delta_v f(U) \geq \frac{f(U)}{\gamma_c} - 1.$$

Consider a MCDS

$$W = \{v_i : 1 \leq i \leq \gamma_c\}$$

sorted in a breadth-first search order. For each $1 \leq i \leq \gamma_c$, let

$$W_j = \{v_i : 1 \leq i \leq j\}.$$

Then, $G[W_j]$ is connected for each $1 \leq j \leq \gamma_c$. By [Lemma 2](#),

$$\begin{aligned} n - 2 - f(U) &= f(U \cup W) - f(U) \\ &= \Delta_{v_1} f(U) + \sum_{j=2}^{\gamma_c} \Delta_{v_j} f(U \cup W_{j-1}) \\ &\leq \Delta_{v_1} f(U) + \sum_{j=2}^{\gamma_c} (\Delta_{v_j} f(U) + 1) \\ &= \gamma_c - 1 + \sum_{j=1}^{\gamma_c} \Delta_{v_j} f(U) \\ &\leq \gamma_c - 1 + \gamma_c \cdot \max_{1 \leq j \leq \gamma_c} \Delta_{v_j} f(U). \end{aligned}$$

Hence,

$$\max_{1 \leq j \leq \gamma_c} \Delta_{v_j} f(U) \geq \frac{n - 1 - f(U)}{\gamma_c} - 1.$$

Let v be the vertex in W which has the largest gain with respect to U . Then,

$$\Delta_v f(U) \geq \frac{n - 1 - f(U)}{\gamma_c} - 1.$$

This completes the proof of the lemma. ■

Now, we are ready to describe the greedy algorithm *GreedyCDS* in [Table 6](#). By [Lemma 3](#), the algorithm *GreedyCDS* runs in at most $n - 2$ iterations, and the output is a CDS.

We prove the approximation bound $2 + \ln(\Delta - 2)$ of the algorithm *GreedyCDS* in the theorem below.

Theorem 7 *The approximation ratio of GreedyCDS is at most $2 + \ln(\Delta - 2)$.*

Table 6 Outline of the algorithm *GCDS*

<i>GreedyCDS</i>	$B \leftarrow \emptyset;$ While $f(B) < n - 2$ do select $v \in V \setminus B$ with maximum $\Delta_v f(B)$; $B \leftarrow B \cup \{v\}$; Output B .
------------------	--

Proof Let γ_c be the size of a minimum CDS. We claim that $\gamma_c \geq \frac{n-2}{\Delta-1}$. Consider a breadth-first search ordering of a MCDS. The first vertex dominates at most $\Delta + 1$ nodes. Each subsequent vertex dominates at most $\Delta - 1$ additional nodes. Thus,

$$n \leq (\Delta + 1) + (\Delta - 1)(\gamma_c - 1) = (\Delta - 1)\gamma_c + 2.$$

Hence, $\gamma_c \geq \frac{n-2}{\Delta-1}$.

Let B be the output of the algorithm. For each $1 \leq i \leq |B|$, B_i denotes the sequence of the first i nodes in B ; furthermore, let $B_0 = \emptyset$. Let k be the first (smallest) nonnegative integer such that

$$f(B_k) \geq n - 2 - 2\gamma_c.$$

We claim that

$$\begin{aligned} |B \setminus B_k| &\leq 2\gamma_c - 1, \\ k - 1 &\leq \gamma_c \ln(\Delta - 2), \end{aligned}$$

These two inequalities imply that

$$|B| \leq (2 + \ln(\Delta - 2))\gamma_c,$$

and so the theorem follows.

We first prove the first inequality in the claim. By Lemma 3, each vertex in $B \setminus B_k$ has gained at least one. If $f(B_k) > n - 2 - 2\gamma_c$, then

$$|B \setminus B_k| \leq n - 2 - f(B_k) < 2\gamma_c.$$

If $f(B_k) = n - 2 - 2\gamma_c$, then the first vertex in $B \setminus B_k$ has gained at least two with respect to B_k by Lemma 3, and hence,

$$2 + (|B \setminus B_k| - 1) \leq n - 2 - f(B_k) = 2\gamma_c,$$

which also implies that

$$|B \setminus B_k| \leq 2\gamma_c - 1.$$

Next, we prove the second inequality in the claim. This inequality holds trivially if $k \leq 1$. So we assume that $k > 1$. For each $0 \leq i < k$, let $\ell_i = n - 1 - f(B_i) - \gamma_c$, which is referred to as the shifted coverage deficiency. Then

$$n - 1 - \gamma_c = \ell_0 > \ell_1 > \dots > \ell_{k-1} \geq \gamma_c + 2.$$

By [Lemma 3](#), for each $0 \leq i < k$,

$$\ell_{i-1} - \ell_i \geq \frac{n - 1 - f(B_{i-1})}{\gamma_c} - 1 = \frac{\ell_{i-1}}{\gamma_c},$$

and hence,

$$\frac{\ell_{i-1} - \ell_i}{\ell_{i-1}} \geq \frac{1}{\gamma_c}.$$

Therefore,

$$\frac{k-1}{\gamma_c} \leq \sum_{i=1}^{k-1} \frac{\ell_{i-1} - \ell_i}{\ell_{i-1}} \leq \ln \frac{\ell_0}{\ell_{k-1}} \leq \ln \frac{n-1-\gamma_c}{\gamma_c+2}.$$

Since $\gamma_c \geq \frac{n-2}{\Delta-1}$, we have $n-2 \leq (\Delta-1)\gamma_c$, and hence,

$$\begin{aligned} n - 1 - \gamma_c &\leq (\Delta - 1)\gamma_c + 1 - \gamma_c \\ &= (\Delta - 2)\gamma_c + 1 \\ &= (\Delta - 2)(\gamma_c + 2) - (2\Delta - 5) \\ &\leq (\Delta - 2)(\gamma_c + 2) - 1 \\ &< (\Delta - 2)(\gamma_c + 2). \end{aligned}$$

Thus,

$$\frac{k-1}{\gamma_c} < \ln(\Delta - 2)$$

which implies

$$k - 1 \leq \gamma_c \ln(\Delta - 2).$$

This completes the proof of the theorem. ■

The approximation bound $2 + \ln(\Delta - 2)$ in [Theorem 7](#) is slightly better than the approximation bound $2 + \ln \Delta$ derived in [\[30\]](#). Du et al. [\[7\]](#) presented a generalization of *GreedyCDS* which chooses at each iteration a set of up to $2k - 1$ vertices with the maximum gain-cost ratio for some fixed positive integer parameter k . The approximation ratio of this generalization is at most $(1 + \frac{1}{k})(1 + \ln(\Delta - 1))$. This implies that for any $\varepsilon > 0$, there is a $(1 + \varepsilon)(1 + \ln(\Delta - 1))$ -approximation

algorithm for *MCDS*. An interesting observation is that for greedy approximation algorithms with submodular coverage functions, the above generalization cannot lead to better performance ratio.

3.3 Minimum-Weight CDS

The algorithm *GreedyCDS* for *MCDS* augments the partial solution by a single vertex in each iteration. While it can be modified for *MWCDS*, the proof of [Theorem 7](#) cannot be extended to prove a logarithmic approximation bound in the weighted case. This subsection presents a different greedy approximation algorithm [16] for *MWCDS*, which can achieve the logarithmic approximation bound. The main difference is that a group of nodes are selected to augment the partial solution in each iteration. This technique is adapted from the greedy approximation algorithm [21] for Minimum Node-Weighted Steiner Tree.

We begin with the definition of the potential (or coverage deficiency) function. Let B be a set of nodes in V . A *piece* with respect to B is either a vertex not in $N[B]$ or a connected component of $G[B]$. Let $f(B)$ denote the number of pieces with respect to B . Then, B is a CDS if and only if $f(B) = 1$. Let D be the arc-weighted digraph obtained from G by replacing each edge uv in G with two arcs (u, v) and (v, u) of weights $c(u)$ and $c(v)$, respectively. The greedy algorithm maintains a set B of black nodes, which is initially empty. Repeat the following iteration while $f(B) > 1$. Choose an arborescence T in D on some greedy manner, add all internal nodes of T to B , and then update $f(B)$. When $f(B) = 1$, B is output as the CDS. The key ingredient of this algorithm is the greedy strategy used by each iteration to select a proper arborescence T . The detail of this greedy strategy is presented below.

For any arborescence T in D , $I(T)$ denotes the set of all internal nodes in T . Fix a subset B of V with $f(B) > 1$. The *head* of a piece with respect to B is defined to be the vertex in this piece with the smallest ID. The *price* of an arborescence T in D with respect to B is defined to be the ratio of $c(I(T))$ to the number of heads with respect to B contained in T . Ideally, one would greedily wish to use a cheapest (i.e., least priced) arborescence in each iteration. While a cheapest arborescence can be computed easily when $f(B)$ is small, it is hard to be computed in general. In general, a cheapest arborescence is selected among a polynomial number of specially defined candidates. Let $\mathcal{T}(B)$ denote the set of candidates. The construction of $\mathcal{T}(B)$ is described below. For each vertex u , let A_u be the shortest-path spanning arborescence in D rooted at u . Suppose that B is a set of black nodes with $f(B) > 1$. Sort all the $f(B)$ heads in the increasing distance from u in A_u . For each $2 \leq j \leq f(B)$, $T_j(B, u)$ is the minimal arborescence in A_u spanning u and the first j heads. Then, $\mathcal{T}(B)$ consists of $(f(B) - 1)n$ candidates:

$$\mathcal{T}(B) = \{T_j(B, u) : u \in V, 2 \leq j \leq f(B)\}.$$

The greedy algorithm *GreedyWCDS* is described in [Table 7](#).

Next, we derive an approximation bound of *GreedyWCDS*.

Table 7 Outline of the algorithm *GreedyWCDS*

<i>GreedyWCDS</i>
$B \leftarrow \emptyset;$
while $f(B) > 1$,
construct $\mathcal{T}(B)$;
find a cheapest $T \in \mathcal{T}(B)$;
$B \leftarrow B \cup I(T);$
output B .

Theorem 8 *The approximation ratio of GreedyWCDS is at most $2(H(n) - 1)$.*

To prove the above theorem, we first give a lower bound on the “gain” of each candidate arborescence in $\mathcal{T}(B)$ in terms of the reduction on the number of pieces.

Lemma 4 *Suppose that $f(B) > 1$. Then for any $T \in \mathcal{T}(B)$ containing h heads with respect to B ,*

$$f(B) - f(B \cup I(T)) \geq h/2.$$

Proof After the addition of $I(T)$, all pieces with respect to B containing a head in T (and possibly some other pieces with respect to B) get merged into some new (and larger) piece with respect to $B \cup I(T)$. Thus,

$$f(B) - f(B \cup I(T)) \geq h - 1 \geq h/2.$$

So, the lemma holds. ■

The next lemma presents an upper bound on the price of the cheapest candidate in $\mathcal{T}(B)$.

Lemma 5 *Suppose that $f(B) > 1$. Then the price of the cheapest tree in $\mathcal{T}(B)$ is at most $\frac{\text{opt}}{f(B)}$.*

Proof We prove the lemma by a decomposition argument. A spider is an arborescence in D in which all nodes except the root have out-degree at most 2. Initialize T^* to be a spanning arborescence of D whose internal nodes form an optimal solution and j to be 0. Repeat the following iteration while T^* contains at least two heads. Increment j by one. Repeatedly prune the sinks of T^* which are not heads until all sinks are heads. Choose a deepest vertex u in T^* such that the maximal u -arborescence contained in T^* (which is the subgraph of T^* induced by u and all its descendants in T^*) contains at least two heads. Set S_j to be the maximal u -arborescence contained in T^* . By the maximum depth of u , every child arborescence of S_j has exactly one head, and hence, S_j is a spider. Delete S_j from T^* . If T^* still contains one head, then augment the last S_j by the path from the root of S_j to this head.

Let S_1, S_2, \dots, S_q be the sequence of spiders obtained by this construction. Then, they are vertex disjoint. In addition, their union contains all heads. For each $1 \leq j \leq q$, let h_j denote the number of heads contained in S_j . Then,

$$\sum_{j=1}^q h_j = f(B),$$

and

$$\sum_{j=1}^q c(I(S_j)) \leq \text{opt}.$$

Thus,

$$\min_{1 \leq j \leq q} \frac{c(I(S_j))}{h_j} \leq \frac{\sum_{j=1}^q c(I(S_j))}{\sum_{j=1}^q h_j} \leq \frac{\text{opt}}{f(B)}.$$

Let S be the cheapest one among S_1, S_2, \dots, S_q . Then, the price of S is at most $\frac{\text{opt}}{f(B)}$.

Let u be the root of S . We show that $T_\ell(B, u)$ is at least as cheaper as S , from which the lemma follows. Let v_1, v_2, \dots, v_ℓ be the heads in S and $v'_1, v'_2, \dots, v'_\ell$ be the heads in $T_\ell(B, u)$. By treating S as a subgraph of D , we have

$$\begin{aligned} & c(I(T_\ell(B, u))) + (\ell - 1)c(u) \\ & \leq \sum_{i=1}^\ell \text{dist}_D(u, v'_i) \leq \sum_{i=1}^\ell \text{dist}_D(u, v_i) \leq \sum_{i=1}^\ell \text{dist}_S(u, v_i) \\ & = c(I(S)) + (\ell - 1)c(u). \end{aligned}$$

So, $c(I(T_\ell(B, u))) \leq c(I(S))$. As $T_\ell(B, u)$ and S have the same number of heads, $T_\ell(B, u)$ is at least as cheaper as S . ■

Finally, we prove [Theorem 8](#) by applying [Lemmas 4](#) and [5](#). Suppose that the algorithm runs in k iterations. Let $h_0 = n$ which is the number of initial pieces. For any $1 \leq i \leq k$, let T_i be the arborescence selected at iteration i and let ℓ_i be the number of pieces just after iteration i . Let b_i be the cost of T_i and h_i be the number of heads in T_i . Then by [Lemma 4](#), for each $1 \leq i \leq k$,

$$\ell_{i-1} - \ell_i \geq h_i/2,$$

and hence,

$$h_i \leq 2(\ell_{i-1} - \ell_i).$$

By [Lemma 5](#), for each $1 \leq i \leq k$,

$$\frac{b_i}{h_i} \leq \frac{\text{opt}}{\ell_{i-1}}$$

and consequently

$$b_i \leq \frac{h_i}{\ell_{i-1}} \text{opt} \leq 2\text{opt} \frac{\ell_{i-1} - \ell_i}{\ell_{i-1}}.$$

So,

$$\begin{aligned} \sum_{i=1}^k b_i &\leq 2\text{opt} \sum_{i=1}^k \frac{\ell_{i-1} - \ell_i}{\ell_{i-1}} \\ &\leq 2\text{opt} \sum_{i=1}^k \sum_{j=\ell_i+1}^{\ell_{i-1}} \frac{1}{j} \\ &= 2\text{opt} \sum_{j=\ell_k+1}^{\ell_0} \frac{1}{j} \\ &= 2(H(\ell_0) - H(\ell_k)) \text{opt} \\ &= 2(H(n) - 1) \text{opt}. \end{aligned}$$

This completes the proof of [Theorem 8](#).

By choosing more sophisticated pool $\mathcal{T}(B)$ of candidates as introduced in [16], better approximation bounds $1.5 \ln n$ and $(1.35 + \varepsilon) \ln n$ for arbitrary constant $\varepsilon > 0$ can be achieved. The same algorithmic techniques have been applied to other problems including *Minimum Node-Weighted Steiner Tree* [16], *Minimum-Power Spanning Arborescence* [5], and *Minimum Node-Weighted Strongly Connected Dominating Set* [23].

4 Graph Coloring

Let $G = (V, E)$ be an undirected graph. A (vertex) *coloring* of G is an assignment of colors to V satisfying that adjacent vertices are assigned with distinct colors. Equivalently, a vertex coloring corresponds to a partition of V into stable sets. The *chromatic number* of G , denoted by $\chi(G)$, is the smallest number of colors required by any vertex coloring of G . The problem *Minimum Vertex Coloring* seeks a vertex coloring of a given graph with the smallest colors. It is NP-hard in general. It can be cast as *Minimum-Cost Submodular Cover* with the following formulation: The ground set is the collection \mathcal{I} of all stable sets of G . For a subcollection of k stable sets whose union is U , its coverage is $|U|$ and its cost is k . For this formulation, the curvature is one, and the augmentation problem is *Maximum Stable Set* in graphs. Suppose that there is a μ -approximation algorithm \mathcal{A} for such *Maximum Independent Set* problem. The adaptation of the general greedy algorithm

Table 8 Greedy link scheduling

<i>GreedyColoring</i>
$U \leftarrow V;$
$i \leftarrow 0;$
While $U \neq \emptyset$ do
$i \leftarrow i + 1$
$I \leftarrow$ the stable set of $G [U]$ output by \mathcal{A} ;
assign the i th color to all vertices in I ;
$U \leftarrow U \setminus I.$

GreedyMCSC for *Minimum Vertex Coloring*, called *GreedyColoring*, is described in Table 8. By Theorem 5, the approximation ratio of *GreedyColoring* is at most $\mu H(\alpha)$, where α is the independence number of G .

This section presents yet another greedy algorithm of first-fit type which can outperform *GreedyColoring* in many graph classes. We introduce some standard notations and terms. Let $G = (V, E)$ be an undirected graph. For any vertex $v \in V$, $\deg_G(v)$ denotes the degree of v in G , and $N_G(v)$ denotes the set of neighbors of v in G . The minimum degree of G is denoted by $\delta(G)$. Consider a vertex ordering \prec of V . For each $v \in V$, $N_G^\prec(v)$ denotes the set of neighbors of v preceding v in the ordering \prec , and $N_G^\prec[v]$ denotes $\{v\} \cup N_G^\prec(v)$. For any subset U of V , $G[U]$ denotes the subgraph of G induced by U . Suppose that $D = (V, A)$ is digraph. For each $v \in V$, $\deg_D^{\text{in}}(v)$ (respectively, $\deg_D^{\text{out}}(v)$) denotes the in-degree (respectively, out-degree) of v in D , and $N_D^{\text{in}}(v)$ (respectively, $N_D^{\text{out}}(v)$) denotes the set of in-neighbors (respectively, out-neighbors) of v in D . For any subset U of V , $D[U]$ denotes the subgraph of D induced by U .

Given a vertex ordering \prec of V given by $\langle v_1, v_2, \dots, v_n \rangle$, a coloring of V with colors represented by natural numbers can be produced in the following first-fit manner: Assign the color 1 to v_1 . For $i = 2$ up to n , assign to v_i with the smallest color which is not used by any vertex in $N_\prec(v_i)$. Such coloring of V is referred to as the *first-fit coloring* in the ordering \prec . It is easy to verify that the number of colors used by the first-fit coloring in the ordering $\langle v_1, v_2, \dots, v_n \rangle$ is at most $1 + \max_{v \in V} |N_\prec(v)|$. The value $\max_{v \in V} |N_\prec(v)|$ is referred to as the *inductivity* of the ordering \prec . The smallest inductivity of all vertex orderings is referred to as the *inductivity* of G and is denoted by $\delta^*(G)$. It was shown in [25] that

$$\delta^*(G) = \max_{U \subseteq V} \delta(G[U]),$$

and it can be achieved by a special vertex ordering known as *smallest-degree-last ordering*, which can be produced iteratively as follows: Initialize H to G . For $i = n$ down to 1, let v_i be a vertex of the smallest degree in H and delete v_i from H . Then the ordering $\langle v_1, v_2, \dots, v_n \rangle$ is a smallest-degree-last ordering. In the next, we derive the approximation bound of the first-fit coloring in the smallest-degree-last ordering.

For any vertex ordering \prec of V , its *backward local independence number* (BLIN) is defined to be the parameter

$$\max_{v \in V} \max_{I \in \mathcal{I}} |I \cap N_G^<(v)|.$$

The *backward local independence number* (BLIN) of G , denoted by $\alpha^*(G)$, is the smallest BLIN of all vertex orderings of G . An *orientation* of G is a digraph obtained from G by imposing an orientation on each edge of G . For any orientation D of G , its *inward local independence number* (ILIN) is defined to be the parameter

$$\max_{v \in V} \max_{I \in \mathcal{I}} |I \cap N_D^{\text{in}}(v)|.$$

The *inward local independence number* (ILIN) of G , denoted by $\beta^*(G)$, is the smallest ILIN of all orientations of G . The following theorem was proved in [32,37].

Theorem 9 *The first-fit coloring of G in the smallest-degree-last ordering has approximation bound $\min\{\alpha^*(G), 2\beta^*(G)\}$.*

Proof Since the first-fit coloring of G in the smallest-degree-last ordering uses at most $1 + \delta^*(G)$ colors, it is sufficient to show that

$$1 + \delta^*(G) \leq \chi(G) \cdot \min\{\alpha^*(G), 2\beta^*(G)\}.$$

Consider an optimal coloring which partitions V into $\chi(G)$ stable sets $\{I_j : 1 \leq j \leq \chi(G)\}$.

Let \prec be a vertex ordering of G whose BLIN is $\alpha^*(G)$. Then, for any vertex $v \in V$,

$$|N_{\prec}(v)| = \sum_{j=1}^{\chi(G)} |N_{\prec}(v) \cap I_j| \leq (\chi(G) - 1) \alpha^*(G).$$

Hence, the of the ordering \prec is at most $\alpha^*(G)(\chi(G) - 1)$. This implies that

$$\delta^*(G) \leq (\chi(G) - 1) \alpha^*(G).$$

Therefore,

$$1 + \delta^*(G) \leq 1 + (\chi(G) - 1) \alpha^*(G) \leq \chi(G) \cdot \alpha^*(G).$$

Let D be an orientation of G whose ILIN is $\beta^*(G)$ and U be the subset of V such that $\delta^*(G) = \delta(G[U])$. Then, there exists at least one vertex $u \in U$ such that

$$\deg_{D[U]}^{\text{in}}(u) \geq \deg_{D[U]}^{\text{out}}(u).$$

Thus,

$$\delta^*(G) = \delta(G[U]) \leq \deg_{G[U]}(u) = \deg_{D[U]}^{\text{in}}(u) + \deg_{D[U]}^{\text{out}}(u)$$

$$\begin{aligned} &\leq 2 \deg_{D[U]}^{\text{in}}(u) \leq 2 \deg_D^{\text{in}}(u) = 2 \sum_{j=1}^{\chi(G)} |N_D^{\text{in}}(u) \cap I_j| \\ &\leq 2(\chi(G) - 1) \beta^*(G). \end{aligned}$$

So,

$$1 + \delta^*(G) \leq 1 + 2(\chi(G) - 1) \beta^*(G) \leq 2\chi(G) \cdot \beta^*(G).$$

This completes the proof of the theorem. \blacksquare

Theorem 9 has found many applications in the wireless scheduling of node transmissions [37, 38] and link transmissions [32, 36]. These wireless scheduling problems can be formulated as the minimum graph coloring of some conflict graphs, which have constant-bounded BLINs and/or constant-bounded ILINs.

5 Conclusion

This chapter presents a number of general greedy approximation algorithms for a broad class of optimization problems. For many specific problems, a straightforward greedy approximation algorithm can achieve the best known approximation bound. But for some problems, they may have different formulations, and the corresponding greedy approximation algorithms have different approximation bounds as illustrated in Sect. 3.1. Furthermore, some problems have approximation algorithms with better approximation bounds than that of the greedy approximation algorithm. Below are some examples of these problems:

- The problem of maximizing the sum of weighted rank functions of matroids over an arbitrary matroid constraint has a $1/(1-e^{-1})$ -approximation algorithm [4], while the greedy approximation algorithm has an approximation ratio 2 by Theorem 2.
- The problem *Maximum-Weight Stable Set of Unit-Disk Graphs* described in Sect. 2.2 admits a polynomial-time approximation scheme [17, 31], while the greedy approximation algorithm has an approximation ratio 5.
- The two problems *Minimum-Weight Vertex Cover* and *Minimum-Weight Feedback Vertex Set* both have 2-approximation algorithms [2], (Bafna et al., 1994, Approximating feedback vertex set for undirected graphs within ratio 2, unpublished), while the greedy approximation algorithms are logarithmic approximation ratios.

Abstract

Assessing network vulnerability is a central research topic to understand networks structures, thus providing an efficient way to protect them from attacks and other disruptive events. Existing vulnerability assessments mainly focus on investigating the inhomogeneous properties of graph elements, node degree, for example; however, these measures and the corresponding heuristic solutions cannot either provide an accurate evaluation over general network topologies

or performance guarantees to large-scale networks. To this end, this chapter introduces two new optimization models to quantify the network vulnerability, which aim to discover the set of *key node/edge disruptors*, whose removal results in the maximum decline of the global pairwise connectivity. Results presented in this chapter consist of the NP-completeness and inapproximability proofs of these problems along with pseudo-approximation algorithms.

1 Introduction

Complex network systems such as the Internet, WWW, MANETs, and the power grids are often greatly affected by several uncertain factors, including external natural or man-made interferences (e.g., severe weather, enemy attacks, malicious attacks). Additionally, they are extremely vulnerable to attacks, that is, the failures of a few *critical nodes* (*links*) which play a vital role in maintaining the network's functionality can break down its operation [1].

In order to assess the network vulnerability, we need to address several fundamental questions such as the following: How do we quantitatively measure the vulnerability degree of a network? What are the key nodes (*links*) that play a vital role in maintaining the network's functionality? What is the minimum number of nodes (*links*) do we need to take down in order to break down an adversarial network?

Despite numerous methods have been investigated on the network vulnerability, they neither reveal the global damage done on the network when multiple nodes (*links*) fail simultaneously nor correctly identify the key nodes who play a vital role in maintaining the network's functionality [2–8]. (More details of related work are discussed later in Sect. 6.) In this chapter, two optimization models along with their four related problems to assess the network vulnerability are discussed as follows:

Model 1: Critical Vertex (Edge) Disruptor [CVD (CED)] : Given a graph $G = (V, E)$ representing a network (where V is a set of nodes and E is a set of links in the network) and a positive integer $k < |V|$ ($k < |E|$), determine a set of vertices (*edges*) $S \subset V$ ($S \subset E$) with $|S| = k$ so as to minimize the total pairwise connectivity in the induced graph $G[V \setminus S]$ ($G[E \setminus S]$), obtained by removing S from G , where the total pairwise connectivity in G is defined as the total number of connected pairs of vertices in G . A pair of nodes is connected if there is a path between them in graph G .

Note that E is a set of links where links can be physical links or logical links between two endpoints. For example, if there is a communication between nodes u and v in the network, there will be an edge (u, v) in the representing graph G . If G is used to represent the functional dependency between each node in a network, then there is an edge (u, v) in G iff there is a functional relationship between u and v in the network. Therefore, the connectivity discussed in this chapter is not simply a physical connectivity in a given network.

Clearly, this model aims to discover vertices (edges) whose removal maximizes the network fragmented and maximumly destroys the network. The ratio between the size of S and the number of pairwise disconnectivity in $G[V \setminus S]$ determines the degree of vulnerability of G , that is, the smaller this ratio is, the more vulnerable the network is. Thus, this model represents a new paradigm for quantitatively characterizing the vulnerability of an underlying network.

Model 2. β -Vertex (Edge) Disruptor [β -VD (β -ED)] : Given a graph $G = (V, E)$ and $0 \leq \beta < 1$, find a subset of vertices (edges) $S \subseteq V$ ($S \subseteq E$) with the minimum cardinality so that the total pairwise connectivity of $G[V \setminus S]$ ($G[E \setminus S]$) is at most $\beta \binom{n}{2}$.

This model also reveals the vulnerability degree of the networks. That is, the more key nodes (edges) there are (i.e., the more nodes (edges) whose deletion is required to meet the requirement of pairwise connectivity), the less vulnerability the network is. Conversely, the fewer the key nodes (edges), the more vulnerability the network will be to the attacks.

Model 1 can be used to maximally disrupt the network with a given cost, whereas Model 2 can be used in the study of breaking down an adversarial social network to a certain degree with the minimum cost. For example, this concept can be applied to destroy, that is, arrest, a small number of key individuals in an adversarial social network (e.g., terrorist networks) in order to maximally disrupt the networks, ability to deploy a coordinated attack. The set of nodes S obtained from the two models present critical nodes in networks, such as a key person, a commander of military networks, or a key computer components in computer networks.

Moreover, the two models present a deeper meaning and greater potentials on the study of multiple disruption levels (different values of k and β). Several recent studies in the context of wireless networks have aimed to discover the nodes/edges whose removal disconnects the network, regardless of how disconnected it is [9–11]. However, it is not reasonable to limit the possible disruption to only disconnecting the graph, ignoring how fragmented it is since the giant connected component still exists and the network may function well. For example, a scale-free network can tolerate high random failure rates [1], since the destructions to boundary vertices may not significantly decline the network connectivity even though the whole graph becomes disconnected. In addition, different disruption levels may require different sets of disruptors on which these two models can differentiate, whereas existing methods cannot. For example, the node centrality method always returns a set of nodes with nonincreasing degrees regardless of the disruption level.

The study of these models also finds applications in several other fields, such as network immunization, offering control of epidemic outbreaks, and containment of viruses. For example, instead of an expensive mass vaccination, we can vaccinate a small number of individuals (corresponding to key nodes of a network). The immunized nodes cannot propagate the virus, thus minimizing the overall transmissibility of the virus.

This chapter presents the hardness complexity of the four problems, CED, CVD, β -ED, and β -VD, along with their pseudo-approximation solutions. The results are discussed in the following sections.

2 Hardness Results

2.1 NP-Completeness of Critical Edge Disruptor

In this section, the NP-completeness of CED in general graphs and in unit disk graphs (UDGs) is shown. Furthermore, this section presents an NP-completeness of CED in power-law graphs (PLGs), strengthening its intractability. UDGs are often used in the networking research field to model the homogeneous wireless networks where all nodes have the same transmission range where PLGs represent a class of complex networks whose nodes follow the power-law distribution such as the Internet and social and biological networks [12]. That is, the fraction of nodes in the network having degree k is proportional to $k^{-\beta}$, where β is a parameter whose value is typically in the range $2 < \beta < 3$.

The hardness proof of CED in general graphs uses a reduction from the p -multiway cut problem, which is defined as follows:

Definition 1 (p -Multiway Cut) Given an undirected graph $G = (V, E)$ and a subset of terminals $T \subseteq V$ with $|T| = p$, find a minimum set of edges of G whose removal disconnects all vertices in T . That is, each vertex in T belongs to each connected component.

Note that p -multiway cut is NP-complete for any $p \geq 3$ according to E. Dahlhaus et al. [13].

Fact 1 *Given a graph $G = (V, E)$ with p -connected components, the total pairwise connectivity of G is lower bounded by $p\binom{\lfloor n/p \rfloor}{2}$ and upper bounded by $\binom{n-p+1}{2}$ where $n = |V|$.*

Theorem 1 *The critical edge disruptor (CED) problem is NP-complete.*

Proof Consider the decision version of CED that asks whether $G = (V, E)$ contains a set of edges $S \subset E$ of size k such that the total pairwise connectivity of $G[E \setminus S]$ is at most c for a given positive integer c .

It is easy to see that $\text{CED} \in \text{NP}$ since a nondeterministic algorithm needs only guess a subset S of edges and checks in polynomial time whether S has the appropriate size k and the total pairwise connectivity of $G[E \setminus S]$ is at most c by using the depth-first search.

The reduction from the 3 -*multiway cut* (3-MC) problem to CED is used to prove its NP-hardness. Let an undirected graph $G = (V, E)$ where $|V| = n$, a set $T \subseteq V$ of three terminals and a positive integer $k \leq |E|$ be any instance of 3-MC. The graph $G' = (V', E')$ is constructed as follows: For each terminal $v \in T$, $l = n^2$, more vertices are added onto v to construct a clique of size $n^2 + 1$, as illustrated in Fig. 1. We now show that there is a 3-MC cut of size k in G iff G' has a CED

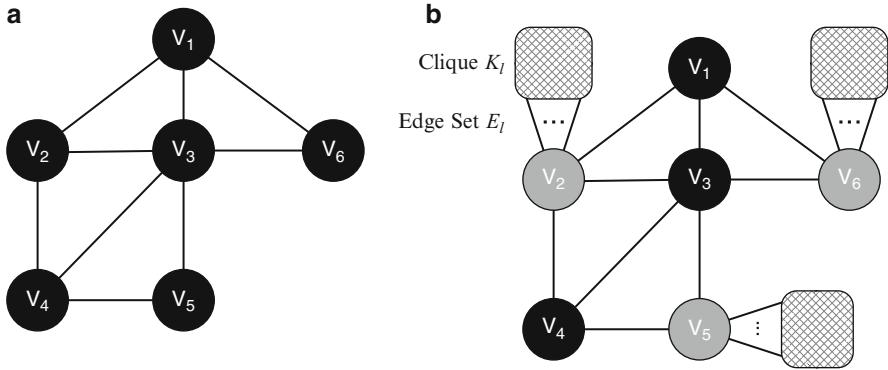

Fig. 1 The reduction from 3-multiway cut instance to a CED instance. (a) Graph G with $T = \{v_2, v_5, v_6\}$. (b) Reduction from 3-multiway cut to CED

S of size k such that the pairwise connectivity of $G[E \setminus S]$ is at most c where $2\binom{n^2+1}{2} + \binom{n^2+n-2}{2} < c < \binom{2n^2+2}{2}$.

First, suppose $S \subseteq E$ is a 3-MC for G with $|S| \leq k$. By our construction and according to Fact 1, the total pairwise connectivity of $G'[E' \setminus S]$ is upper bounded by

$$2\binom{n^2+1}{2} + \binom{n^2+n-2}{2} \quad (1)$$

which is less than c . Thus, S is also a CED of G' .

Conversely, suppose that $S \subseteq E'$ with $|S| = k \leq |E|$ is a CED of G' , that is, the total pairwise connectivity of $G'[E' \setminus S] \leq c$. We show that S indeed is also a 3-MC of G . Note that $S \cap (E' \setminus E) = \emptyset$, that is, for any $e \in S$, e cannot be an edge in the constructed cliques since removing k edges cannot disconnect the cliques; thus, the total pairwise connectivity is $\binom{n+3n^2}{2}$, which is larger than c . Therefore, $S \subseteq E$. Now, we further state that set S also disconnects all the three terminals. Assume that it is not, then the two cliques of these two terminals are connected; thus, the total pairwise connectivity is at least $\binom{2n^2+2}{2} > c$, contradicting to the fact the total pairwise connectivity of $G'[E' \setminus S] \leq c$. \square

We now show that CED still remains NP-complete in UDGs by reducing from the planar independent set (PIS) with maximum degree 3. Given a planar graph $G = (V, E)$, the PIS problem asks us to find a subset $S \subseteq V$ with the maximum size such that no two vertices in S are adjacent.

Lemma 1 (L.G. Valiant [14]) *A planar graph G with maximum degree 4 can be embedded in the plane using $O(|V|)$ area in such a way that its vertices are at integer coordinates and its edges are drawn so that they are made up of line segments of the form $x = i$ or $y = j$, for integers i and j .*

Theorem 2 *The critical edge disruptor (CED) problem is NP-complete in UDGs.*

Proof Consider the decision version of CED that asks whether a UDG $G = (V, E)$ contains a set of edges $S \subset E$ of size k' such that the pairwise connectivity in the induced graph $G[E \setminus S]$ is at most c for a given positive integer c . Clearly, CED \in NP in UDGs.

To prove that CED on UDGs is NP-hard, we reduce the planar independent set (PIS) with maximum degree 3 to it. Let a planar graph $G = (V, E)$ where $|V| = n$ with maximum degree 3 and a positive integer $k \leq n$ be an arbitrary instance of PIS. We must construct in polynomial time a UDG $G' = (V', E')$ and positive integers k' and c such that G has an independent set of size k iff $G' = (V', E')$ has a CED of size k' where the pairwise connectivity of G' after removing this CED is at most c .

The construction of G' is as follows: Given a planar graph G , we first embed it into the plane according to [Lemma 1](#). For each node $v_i \in V$, convert it to a triangle $T_{v_i} = \{v_{i1}, v_{i2}, v_{i3}\}$ (dark gray triangles in [Fig. 2b](#)). Each edge in T_{v_i} is set to be a unit length $r = \frac{\sqrt{3}}{3}$. Since each node v_i in G has at most three neighbors, say x, y , and z , we attach these neighbors to v_{i1}, v_{i2} , and v_{i3} . That is, three edges $(v_i, x), (v_i, y)$, and (v_i, z) in G become $(v_{i1}, x), (v_{i2}, y)$, and (v_{i3}, z) . If the degree is less than 3, we only need to arbitrarily choose one or two from them to attach. Afterwards, for each embedded edge $e_{uv} = (u, v)$, we divide it into $|e_{uv}|$ “pieces” according to its length and replace each piece by a concatenation of two triangles as shown in [Fig. 2b](#). Thus, G' is composed of $2 \sum_{u,v \in V} |e_{uv}| K_3$ cliques where $|e_{uv}|$ is the length of edges between node u and v after embedded onto the plane. Note that G' is a unit disk graph with radius $r = \frac{\sqrt{3}}{3}$. Finally, we set $k' = 2 \sum_{u,v \in V} |e_{uv}| + 3(n - k)$ and $c = 3(\sum_{u,v \in V} |e_{uv}| + k)$.

First, suppose $S \subseteq V$ is an independent set of G with $|S| = k$. For each piece in all edges of G , we remove two edges from two concatenation triangles such that each piece has one triangle left. After doing this, all triangles T_{v_i} corresponding to the node $v_i \in S$ will be disconnected from other nodes in G' . For each node $v_i \notin S$, we remove all edges in the corresponding triangles T_{v_i} in G' . Consider a set S' consisting of all the removed edges (2 edges per piece and 3 edges for each T_{v_i} where $v_i \notin S$). Then clearly $|S'| = k'|$ and the pairwise connectivity in G' after removing S' is c . Therefore, S' is a CED of G' .

Conversely, suppose that $S' \subset V'$ with $|S'| = k'$ is a CED of G' , that is, the pairwise connectivity of $G'[E' \setminus S']$ is at most c . First, it is easy to see that the pairwise connectivity will increase by $\sum_{u,v \in V} |e_{uv}|/2$ if two triangles corresponding to every other pieces are connected since there is one more connected node pair. Thus, either one of the two triangles for each piece in G' will be disconnected. It implies that two edges will be removed from each piece. Apart from this, in order to reduce the pairwise connectivity to c , we remove $3(n - k)$ more edges to avoid the connectivity between the nodes in different triangles. Note that for each triangle T_{v_i} , either all three edges are removed or none since the removal of edges in a

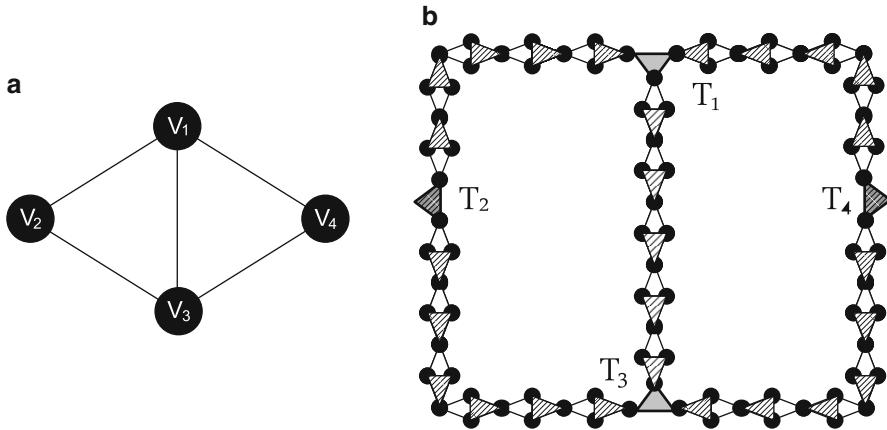

Fig. 2 The reduction from a planar independent set instance to a CED instance. **(a)** An instance G . **(b)** A reduced graph G'

connected component does not help to reduce the pairwise connectivity if it cannot disconnect the component. Some edges belonging to K_2 are exchangeable with the nodes in other triangles within polynomial time. This implies the nodes v_i (in V) corresponding to T_{v_i} which has all their edges remained is an independent set of G . Since the number of T_{v_i} is k , the IS also has size k . \square

Now our attention is turned to the study of CED's NP-completeness in power-law graphs. The $P(\alpha, \beta)$ model mentioned in [15] is used to describe a power-law graph. In this model, the number of vertices of degree d is $\lfloor \frac{e^\alpha}{d^\beta} \rfloor$, where e^α is the normalization factor. To show CED's hardness, we reduce from the clique separator (CS) problem, which is defined as follows:

Definition 2 (Clique Separator (CS)) Given a graph $G = (V, E)$, find a set of edges S such that the induced graph $G[E \setminus S]$ has the connected components to be cliques and each clique has size at least 3. A subgraph of G is called a clique iff all its vertices are pairwise adjacent. The CS problem asks us to find such a clique separator with the minimum size.

Before proceeding, let us first present the following fundamental lemma, which states that a PLG can be constructed from any given simple graph by choosing an appropriate value α :

Lemma 2 (Ferrante et al. [16]) Let $G_1 = (V_1, E_1)$ be a simple graph with n nodes and $\beta \geq 1$. For $\alpha \geq \max\{4\beta, \beta \log n + \log(n+1)\}$, we can construct a power-law

graph $G = G_1 \cup G_2$ with exponential factor β and the number of nodes $e^\alpha \zeta(\beta)$ by constructing a bipartite G_2 as a maximal component in G . Here $\zeta(\gamma) = \sum_{i=1}^{\infty} \frac{1}{i^\gamma}$ is the Riemann zeta function.

Since the hardness proof of CED is based on the reduction from CS, the hardness of CS must be investigated first as follows:

Lemma 3 *The CS problem is NP-hard.*

Proof To prove that CS is NP-hard, we reduce the planar independent set (PIS) problem with maximum degree 3 to it. By using the same reduction in [Theorem 2](#), it can be shown that G has an independent set of size k iff G' has a CS of size $k' = 2 \sum_{u,v \in V} |e_{uv}| + 3(n - k)$.

First, suppose $S \subseteq V$ is an independent set of G with $|S| = k$. To disconnect the triangles from other nodes, two edges from two concatenation triangles for each piece are removed. For each T_{v_i} where $v_i \in S$, since all three nodes will not overlap with other cliques, the triangle T_{v_i} will be selected as a connected component of size 3. For the other T_{v_i} where $v_i \notin S$, T_{v_i} cannot be selected as a clique since at least one of its endpoints overlaps with other triangle. Thus, the removed edges have size k' . And after removing these edges, the obtained connected components are cliques of size 3. That said, the removed edges set is a CS of G' .

Conversely, suppose that $S' \subseteq V'$ is a CS of G' with $S' = k'$. For each piece, at least two edges have to be removed to disconnect the triangle from other nodes. For each T_{v_i} , its edges belongs to S' if at least one has been used by the other triangles. Since $k' = 2 \sum_{u,v \in V} |e_{uv}| + 3(n - k)$, it is easily to modify S' to be an independent set of G . \square

Theorem 3 *The critical edge disruptor (CED) problem is NP-complete in power-law graphs.*

Proof Again, consider the decision version of CED that asks whether a power-law graph $G = (V, E)$ contains a set of links $S \subset V$ of size k' such that the pairwise connectivity in $G[E \setminus S]$ is at most c for a given positive integer c .

To prove that CED in PLGs is NP-hard, we reduce the clique separator (CS) to it. Given G , a power-law graph $G' = G \cup G_b$ where the bipartite graph $G_b = (U_b, V_b; E_b)$ is a maximal component in G' is constructed according to [Lemma 2](#). We show that there is a CS of size k in G iff G' has a CED S' of size k' such that the pairwise connectivity of $G'[E' \setminus S']$ is at most c , where $k' = k + |E_b| - |M_b|$ and $c = |E| - k + |M_b|$. Here M_b denotes the set of edges in the maximum matching of G_b .

First, suppose $S \subseteq V$ is a clique separator of G with $|S| = k$. The total pairwise connectivity of $G[E \setminus S]$ is equal to $|E| - k$ since all components in this graph are cliques. Since the maximum matching on G_b can be found in polynomial time using Hopcroft-Karp algorithm [17], the pairwise connectivity of G' is c after removing additional $E_b \setminus M_b$ edges. Therefore, the set $S' = S \cup (E_b \setminus M_b)$ with size $k' = k + |E_b| - |M_b|$ is a CED of G' .

Conversely, suppose that $S' \subset V'$ is a CED of G' with size k' . Let $S' = A \cup S_b$, where A and S_b are the removed edges (in S') in G and G_b , respectively. We show that $|S_b| = |E_b| - |M_b|$. If $|S_b| < |E_b| - |M_b|$, the pairwise connectivity of G_b is increased at least two when adding one more edge into the maximum matching. On the other hand, the removal of l edges on G can reduce the pairwise connectivity at most l after removing the CS k . Therefore, we have $|S_b| \geq |E_b| - |M_b|$ in order to maximally reduce the number of pairwise connectivity. If $|S_b| > |E_b| - |M_b|$, the pairwise connectivity of G_b is reduced by one when removing one more edge from the maximum matching. Meanwhile, an edge added into the residual graph of G will increase the pairwise connectivity at least one if it connects to two independent nodes and at least 3 if it has one endpoint belonging to some component in the residual graph of G . Therefore, maximally reducing the number of pairwise connectivity requires $|S_b| \leq |E_b| - |M_b|$. Combining both conditions, we have $S_b = |E_b| - |M_b|$. Thus, $|A| = k$, which should be a CS of G in order for $G[E \setminus A]$ having the pairwise connectivity of size $|E| - k$. \square

2.2 NP-Completeness of Critical Vertex Disruptor

In this section, the NP-completeness of CVD on both UDGs and PLGs are shown.

Definition 3 (Minimum Vertex Cover) Given a graph $G = (V, E)$, find a subset $C \subseteq V$ with the minimum size such that for each edge in E at least one end vertex belongs to C .

Lemma 4 (Garey et al. [18]) *Minimum vertex cover remains NP-complete on planar graphs with maximum degree 3.*

Lemma 5 *For any planar graph $G = (V, E)$ with maximum degree 3, it can be embedded into a UDG with the radius $1/2$ such that there exists an independent-space $\Gamma(v)$ for each vertex $v \in V$ satisfying $\Gamma(v) \neq \emptyset$ and any new vertices in $\Gamma(v)$ will be incident to v and independent from all other vertices.*

Proof After mapping $G = (V, E)$ into an integer coordinates based on Lemma 1, a $G_u = (V_u, E_u)$ UDG can be constructed as follows: Each edge $e = (v_i, v_j) \in E$ is replaced by a path $(v_i, w_1, w_2, \dots, w_{2p_e}, v_j)$ where p_e is the length of e and the radius r is set to $1/2$. Now, we prove that such independent-space $\Gamma(v)$ exists for each $v \in V$. Since G has the maximum degree 3, that is, for each vertex $v \in V$, there are at most 3 neighbors (in the form of w_i) in V_u . Thus, there exists a nonempty space $\Gamma(v)$ for each v such that the maximum distance between the vertices in this area to vertex v is at most $1/2$ and the minimum distance between such vertices to all other vertices is larger than $1/2$. As shown in Fig. 3, the shadow area corresponds to $\Gamma(v_1)$. \square

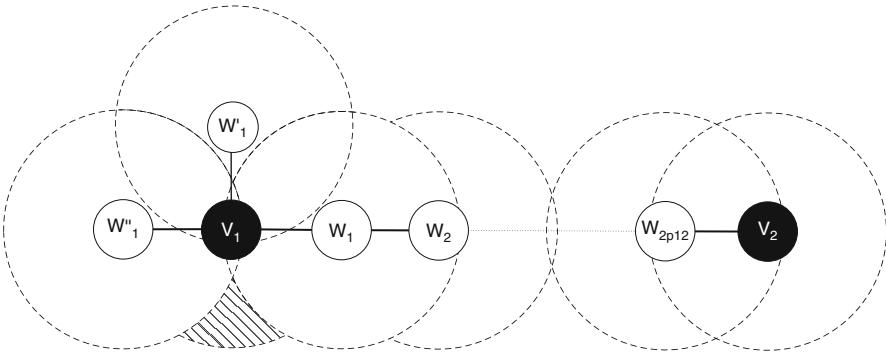

Fig. 3 An independent-space $\Gamma(v_1)$

Theorem 4 *The critical vertex disruptor (CVD) problem is NP-complete in UDGs.*

Proof Consider the decision version of CVD that asks whether a UDG $G = (V, E)$ contains a set of vertices $S \subset V$ of size k' such that the total pairwise connectivity of $G[V \setminus S]$ is at most c for a given positive integer c .

Again, it is easy to see that $\text{CVD} \in \text{NP}$.

Now, to prove that CVD is in NP-hard, we reduce the planar vertex cover (PVC) with maximum degree 3 to it. Let a planar graph with maximum degree 3 $G = (V, E)$ where $|V| = n$ and a positive integer $k \leq n$ be an arbitrary instance of PVC. We must construct in polynomial time a UDG $G' = (V', E')$ and positive integers k' and c such that G has a vertex cover of size at most k iff $G' = (V', E')$ has a CVD of size k' and the pairwise connectivity of G' after removing this CVD is at most c .

Such a construction is described as follows: Given G , construct a G_u according to Lemma 5. On G_u , for each independent-space $\Gamma(v_i)$, a new gray vertex u_i is added such that there is an edge only between v_i and u_i to obtain G' as shown in Fig. 4. Finally, set $k' = k + \sum_{e \in E(G)} p_e$ and $c = n - k$.

First, suppose $S \subseteq V$ is a vertex cover of G with $|S| \leq k$. It is easy to verify that G has a vertex cover S with size at most k iff G_u has a vertex cover S_u with size at most $k + \sum_{e \in E(G)} p_e$. That is, S_u consists of S and a half of nodes w_i on each path $(v_i, w_1, \dots, w_{2p_{(v_i, v_j)}}, v_j)$. We show that S_u is also a CVD of G' . Removing S_u from G' returns all disjoint edges (v_i, u_i) left where $v_i \notin S$. Thus, the pairwise connectivity is $n - k$, which is equal to c .

Conversely, suppose that $S' \subset V'$ with $|S'| = k'$ is a CVD of G' , that is, the total pairwise connectivity of $G'[V' \setminus S']$ is at most c . If $u_i \in S'$, that is, S' contain a gray node, replacing u_i with any v_i or w_i (black or white nodes) will further decrease the pairwise connectivity. Thus, it can be assumed that S' does not contain any gray node. Since $|S'| = k + \sum_{e \in E(G)} p_e$, it is easily to modify the set S' to be a vertex cover of G_u . In this case, the total pairwise connectivity is at most $c = n - k$. Thus, $S' \cap V$ is a VC of G . \square

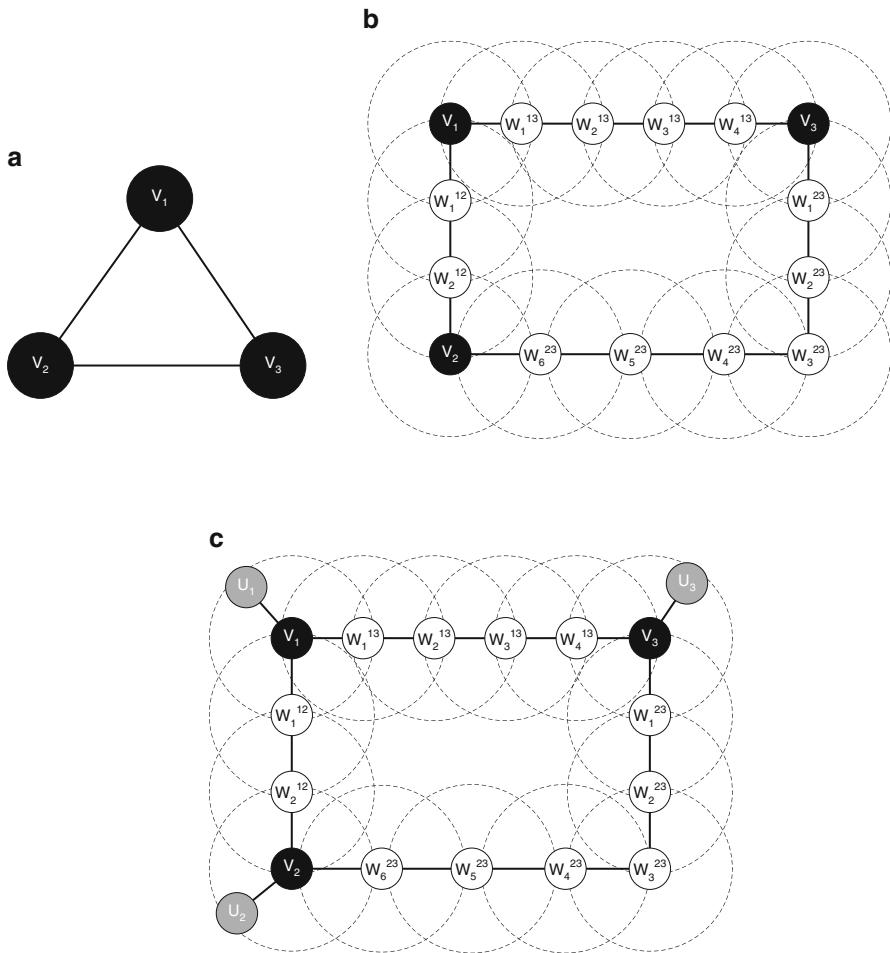

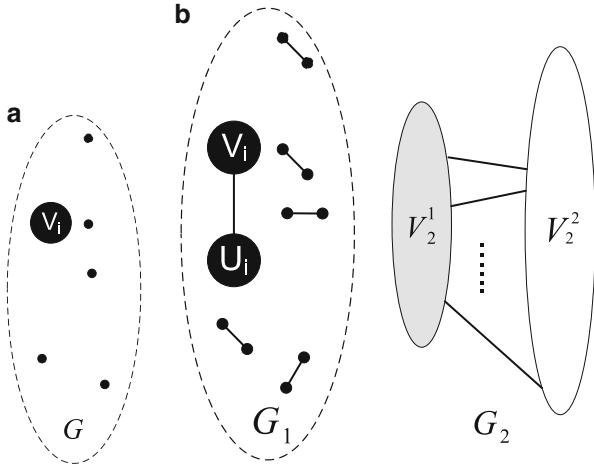

Fig. 4 The reduction for a planar vertex cover instance to a CVD instance. (a) A planar graph G (b) Embed G onto a UDG G_u . (c) Create G' by adding gray modes at independent-spaces

Theorem 5 *The critical vertex disruptor (CVD) problem is NP-complete in power-law graphs.*

Proof Again, consider the decision version of CVD that asks whether a power-law graph $G = (V, E)$ contains a set of nodes $S \subset V$ of size k' such that the pairwise connectivity in $G[V \setminus S]$ is at most c for a given positive integer c .

Now, to prove that CVD in power-law graphs is *NP*-hard, we reduce the vertex cover (VC) to it. Let a graph $G = (V, E)$ where $|V| = n$ and a positive integer $k \leq n$ be any instance of VC. A power-law graph $G' = (V', E')$ is constructed

Fig. 5 The reduction from a vertex cover instance to CVD instance in power-law graphs. For simplicity, all edges in G are omitted. (a) An instance G . (b) Reduced graph $G' = G_1 \cup G_2$

as follows. First, for each node $v_i \in V$, one additional node u_i is added onto it, denoted by G_1 where $V_1 = V \cup U$ and $U = \{u_i\}$. Then according to Lemma 2, a power-law graph $G' = (V', E')$ can be constructed by embedding G_1 and a bipartite graph $G_2 = (V_2^1, V_2^2; E_2)$ where V_2^1 and V_2^2 are two sets of disjoint nodes in G_2 and $\alpha \geq \max\{4\beta, \beta \log(2n) + \log(2n + 1)\}$ with some specific β . Note that V_2^1 and V_2^2 are marked gray and white separately as shown in Fig. 5. We show that there is a VC of size k in G iff G' has a CVD S' of size k' such that the pairwise connectivity of $G'[V' \setminus S']$ is at most c , where $k' = k + \min\{|V_2^1|, |V_2^2|\}$ and $c = n - k$.

First, suppose $S \subseteq V$ is a vertex cover of G with $|S| = k$. Therefore, G has a vertex cover S of size k iff $G \cup G_2$ has a vertex cover S' of size $k + \min\{|V_2^1|, |V_2^2|\}$ since VC is polynomially solvable in any bipartite graphs according to König's theorem [19]. Then after removing S' from G' , only all disjoint links (v_i, u_i) are left where $v_i \notin S$. Therefore, the pairwise connectivity in G' is $n - k$, which is equal to c . That said, S' is a CVD of G' .

Conversely, suppose that $S' \subset V'$ with $|S'| = k'$ is a CVD of G' , that is, the total pairwise connectivity of $G'[V' \setminus S']$ is at most c . First, if $u_i \in S'$, this u_i can be replaced with any v_i without increasing the pairwise connectivity. Since $|S'| = k' = k + \min\{|V_2^1|, |V_2^2|\}$, it is easily to modify the S' to be a vertex cover of $G \cup G_2$, where the total pairwise connectivity on G' is at most $c = n - k$. Thus, $S' \cap V$ is a VC of G . \square

2.2.1 Inapproximability

As the CVD is NP-complete, one will question how tightly one can approximate the solution, leading to the theory of inapproximability. The inapproximability factor gives us the lower bound of near-optimal solution with theoretical performance guarantee. That said, no one can design an approximation algorithm

with a better ratio than the inapproximability factor. In this section, the inapproximability of CVD is further investigated in general graphs by showing the gap-preserving reduction from maximum clique problem, which is defined as follows:

Definition 4 (Maximum Clique) Given a graph $G = (V, E)$, find a clique of maximum size.

Theorem 6 *The CVD problem is NP-hard to be approximated within $\Theta\left(\frac{k}{n^\epsilon}\right)$ for any $\epsilon < 1 - \log_n 2$ in general graphs unless $P = NP$.*

Proof In the proof, a gap-preserving reduction from maximum clique problem to CVD is shown. According to Håstad [20], maximum clique is proven NP-hard to be approximated within $n^{1-\epsilon}$. Let a graph $G = (V, E)$ and a positive integer $k \leq |V| = n$ be an instance of maximum clique problem (MC). Now we construct the graph $G' = (V', E')$ as follows: Firstly, a complement graph $\bar{G} = (V, \bar{E})$ where $\bar{E} = \{(v_i, v_j) | (v_i, v_j) \notin E\}$ is constructed. Next, for each vertex v in \bar{G} , $l \leq n^{1-\epsilon} - 1$, more nodes are added to construct a clique of size $l + 1$ and obtain G' , as shown in Fig. 6. Let ϕ be a feasible solution of MC on G and φ be a feasible solution of CVD on G' where $|\varphi| = n - k$. Define $c = (n - k)\binom{l}{2} + k\binom{l+1}{2}$; the completeness and soundness are shown respectively as follows:

Completeness: In this step, we need to show that if $OPT(\phi) = k$ then $OPT(\varphi) = c$

Let $OPT(\phi)$ be the maximum clique in graph G , then $OPT(\phi)$ is the maximum independent set in \bar{G} . Since the minimum vertex cover and the maximum independent set are complementary on the same graph, removing the set of nodes $V \setminus OPT(\phi)$ in \bar{G} will result into a set of only isolated nodes. Thus, the pairwise connectivity in G' after removing such $n - k$ critical nodes is $(n - k)\binom{l}{2} + k\binom{l+1}{2}$, which is equal to c . It implies that $OPT(\varphi) = c$.

Soundness: In this step, we need to show that if $OPT(\phi) < \frac{1}{n^{1-\epsilon}}k$, then $OPT(\varphi) > \Theta\left(\frac{k}{n^\epsilon}\right)c$.

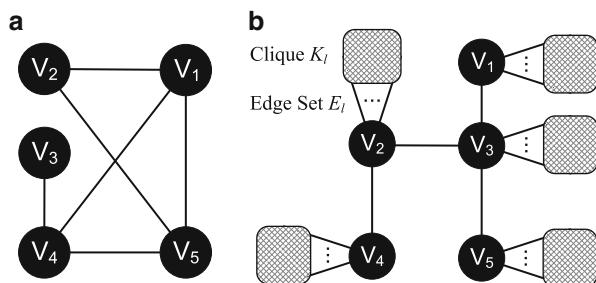

Fig. 6 The gap-preserving reduction from a maximum clique instance to a CVD instance. (a) A graph instance (b) Reduced graph G' from MC

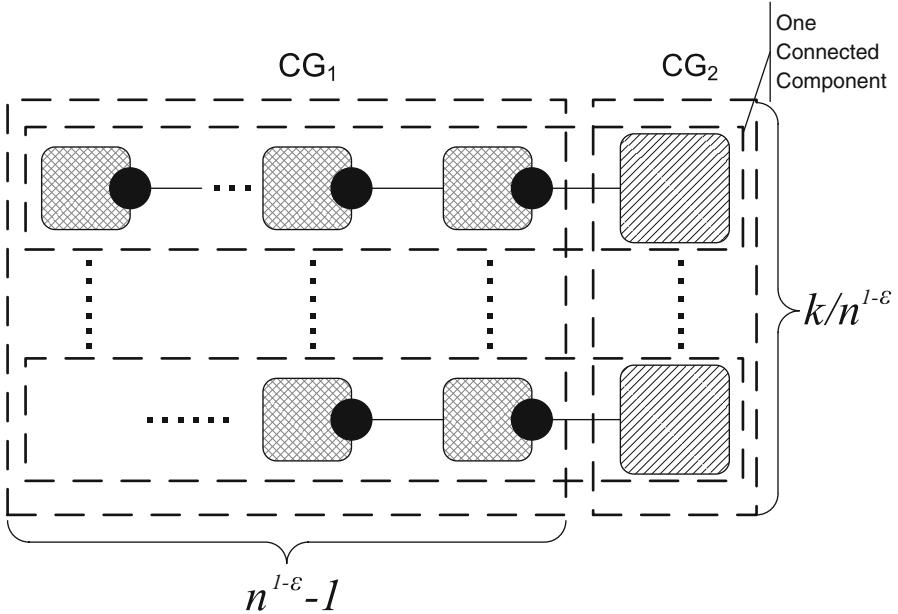

Fig. 7 The lower bound instance of CVD in G' given that $|\varphi| = n - k$ and $OPT(\phi) < \frac{1}{n^{1-\epsilon}}k$

First of all, since $OPT(\phi) < \frac{1}{n^{1-\epsilon}}k$, we cannot remove as many as $n - \frac{1}{n^{1-\epsilon}}k$ critical nodes for any $\epsilon < 1$. Therefore, it is impossible to reduce the pairwise connectivity on G' to $(n - \frac{1}{n^{1-\epsilon}}k) \binom{l}{2} + \frac{1}{n^{1-\epsilon}}k \binom{l+1}{2}$ by fragmenting G' into n components.

For any $\epsilon < 1 - \log_n 2$, it is easy to verify that $1 - \frac{1}{n^{1-\epsilon}} > \frac{1}{n^{1-\epsilon}}$. In this case, the lower bound of the pairwise connectivity in G' after removing $n - \frac{1}{n^{1-\epsilon}}k$ critical nodes is shown to be $\Theta\left(\frac{k}{n^\epsilon}\right)c$. Note that the pairwise connectivity is minimized when the number of connected components are maximized and each connected component has the same size as shown in Fig. 7. That is, since $1 - \frac{1}{n^{1-\epsilon}} > \frac{1}{n^{1-\epsilon}}$, the lower bound is achieved when the same number of cliques CG_1 connects to one CG_2 , where CG_1 and CG_2 denote the group of cliques of size l and cliques of size $l + 1$, respectively, after removing $n - \frac{1}{n^{1-\epsilon}}k$ nodes. Therefore, the following lower bound is obtained:

$$\begin{aligned} & \left(\left\lfloor \frac{\frac{1}{n^{1-\epsilon}} + 1}{2} \right\rfloor (l + 1) \right) \frac{1}{n^{1-\epsilon}} k \\ & \geq \left(\binom{n^{1-\epsilon} - 1}{2} (l + 1) \right) \frac{1}{n^{1-\epsilon}} k \end{aligned}$$

$$\begin{aligned}
&= \frac{\binom{(n^{1-\epsilon}-1)(l+1)}{2} \frac{1}{n^{1-\epsilon}} k}{(n-k)\binom{l}{2} + k\binom{l+1}{2}} c \\
&\geq \frac{\binom{ln^{1-\epsilon}}{2} \frac{1}{n^{1-\epsilon}} k}{n\binom{l}{2} + lk} c \\
&> \frac{\binom{ln^{1-\epsilon}}{2} \frac{1}{n^{1-\epsilon}} k}{n\binom{l+1}{2}} c \\
&= \Theta\left(\frac{k}{n^\epsilon}\right) c
\end{aligned}$$

Step 2 holds since $\lfloor z \rfloor \geq z - 1$ for any real number z ; steps 4 and 5 hold since $l \leq n^{1-\epsilon} - 1$ and $k \leq n$. \square

2.3 NP-Completeness of β -Edge Disruptor

In this section, the NP-completeness of β -ED is shown by reducing from the balanced cut problem. This section begins with several needed definitions as follows:

Definition 5 A cut $\langle S, V \setminus S \rangle$ corresponding to a subset $S \in V$ in G is the set of edges with exactly one endpoint in S . Usually $V \setminus S$ is denoted by \bar{S} . The cost of a cut is the sum of its edges' costs (or simply its cardinality in the case all edges have unit costs) and denoted by $c(S, \bar{S})$.

Finding a min cut in the graph is polynomial solvable [21]. However, if one asks for a somewhat “balanced” cut of minimum size, the problem becomes intractable. A balanced cut is defined as following:

Definition 6 (Balanced cut) Let f be a function from the positive integers to the positive reals. An f -balanced cut of a graph $G = (V, E)$ asks us to find a cut $\langle S, \bar{S} \rangle$ with the minimum size such that $\min\{|S|, |\bar{S}|\} \geq f(|V|)$.

Abusing notations, for $0 < c \leq \frac{1}{2}$, c -balanced cut is used to find the cut $\langle S, \bar{S} \rangle$ with the minimum size such that $\min\{|S|, |\bar{S}|\} \geq c|V|$. The following results on balanced cut shown in [22] will be used in the proofs:

Corollary 1 (Monotony) Let g be a function with

$$0 \leq g(n) - g(n-1) \leq 1$$

Then $f(n) \leq g(n)$ for all n , implies f -balanced cut is polynomially reducible to g -balanced cut.

Corollary 2 (Upper bound) αn^ϵ -balanced cut is NP-complete for $\alpha, \epsilon > 0$.

It follows from Corollaries 1 and 2 that for every $f = O(\alpha n^\epsilon)$, f -balanced cut is NP-complete. It is now ready to prove the NP-completeness of β -edge disruptor:

Theorem 7 β -edge disruptor is NP-complete.

Proof Theorem 7 is proven for a special case when $\beta = \frac{1}{2}$. For other values of β , the proof can go through with a slight modification of the reduction. In the proof, n is considered to be a large enough number, say $n > 10^3$.

Consider the decision version of the problem that asks whether an undirected graph $G = (V, E)$ contains a $\frac{1}{2}$ -edge disruptor of a specified size:

$$\frac{1}{2}\text{-ED} = \{\langle G, K \rangle \mid G \text{ has a } \frac{1}{2}\text{-edge disruptor of size } K\}$$

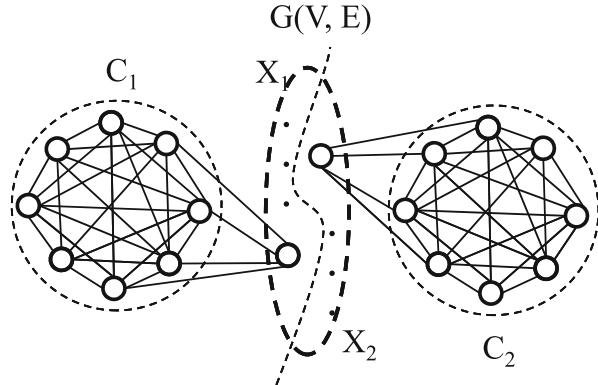

To show that $\frac{1}{2}\text{-ED}$ is in NP-complete, we must show that it is in NP and that all NP-problems are polynomial time reducible to it. The first part is easy; given a candidate subset of edges, it is easily check in polynomial time if it is a $\frac{1}{2}$ -edge disruptor of size K . To prove the second part, we show that f -balanced cut is polynomial time reducible to $\frac{1}{2}\text{-ED}$ where $f = \lfloor \frac{n - \sqrt{2\lfloor \frac{n^2}{3} \rfloor + n}}{2} \rfloor$.

Let $G = (V, E)$ be a graph in which one seeks to find an f -balanced cut of size k . Now construct the graph $H(V_H, E_H)$ as follows: $V_H = V' \cup C_1 \cup C_2$ where $V' = \{v_i \mid i \in V\}$ and C_1, C_2 are two cliques of size $\lfloor \frac{n^2}{3} \rfloor$. The total number of nodes in H is, hence, $N = 2\lfloor \frac{n^2}{3} \rfloor + n$. Beside edges inside two cliques, an edge (v_i, v_j) is added for each edge $(i, j) \in E$. Next each vertex v_i connects to $\lfloor \frac{n^2}{4} \rfloor + 1$ vertices in C_1 and $\lfloor \frac{n^2}{4} \rfloor + 1$ vertices in C_2 so that the degree difference of nodes in the cliques are at most one. The construction of $H(V_H, E_H)$ is illustrated in Fig. 8. Now we need to show that there is a f -balanced cut of size k in G iff H has an $\frac{1}{2}$ -edge disruptor of size $K = n(\lfloor \frac{n^2}{4} \rfloor + 1) + k$ where $0 \leq k \leq \lfloor \frac{n^2}{4} \rfloor$. Note that the cost of any cut $\langle S, \bar{S} \rangle$ in G is at most $|S||\bar{S}| \leq \lfloor \frac{(|S|+|\bar{S}|)^2}{4} \rfloor = \lfloor \frac{n^2}{4} \rfloor$.

On the one hand, an f -balanced cut $\langle S, \bar{S} \rangle$ of size k in G induces a cut $\langle C_1 \cup S, C_2 \cup \bar{S} \rangle$ with size exactly $n(\lfloor \frac{n^2}{4} \rfloor + 1) + k$. If the cut is selected as the disruptor, the pairwise connectivity will be at most $\frac{1}{2}\binom{N}{2}$.

On the other hand, assume that H has a $\frac{1}{2}$ -edge disruptor of size $K = n(\lfloor \frac{n^2}{4} \rfloor + 1) + k$. Because separating n nodes in a clique from the other nodes

Fig. 8 Construction of $H = (V_H, E_H)$ from $G = (V, E)$

in that clique requires cutting at least $n(\lfloor \frac{n^2}{3} \rfloor - n) > n(\lfloor \frac{n^2}{4} \rfloor + 1) + k$ edges, there are at most n nodes separated from both the cliques. A direct consequence is that at least $(\lfloor \frac{n^2}{3} \rfloor - n)$ nodes remain connected in each clique after removing edges in the disruptor. Denote the sets of those nodes by C'_1 and C'_2 , respectively. C'_1 and C'_2 cannot be connected otherwise the pairwise connectivity will exceed $\frac{1}{2} \binom{N}{2}$. Denote by X_1 and X_2 the set of nodes in V' that are connected to C'_1 and C'_2 respectively. Since C'_1 and C'_2 are disconnected we must have $X_1 \cap X_2 = \emptyset$.

The disruptor can be modified without increasing its size and the pairwise connectivity such that no nodes in the cliques are split. For each $u \in C_1 \setminus C'_1$, we remove from the disruptor all edges connecting u to C'_1 and add to the disruptor all edges connecting u to X_2 . This will move u back to the connected component that contains C'_1 while reducing the size of the disruptor at least $(\lfloor \frac{n^2}{3} \rfloor - n) - n$. At the same time, an arbitrary node $v \in X_1$ is selected and added to the disruptor all remaining v 's adjacent edges. This increases the size of the disruptor at most $(\lfloor \frac{n^2}{4} \rfloor + 1) + n$ while making v isolated. By doing so, the size of the disruptor decreases by $(\lfloor \frac{n^2}{3} \rfloor - n) - n - ((\lfloor \frac{n^2}{4} \rfloor + 1) + n) > 0$. In addition, the pairwise connectivity will not increase when connecting u to C'_1 and disconnecting v from C'_1 . If no nodes are left in X_1 , a node $v \in X_2$ can be selected (as in that case $|C'_2 \cup X_2| > |C'_1 \cup X_1|$) to make sure the pairwise connectivity will not be increased. The same process is repeated for every node in $C_2 \setminus C'_2$ and at the end of the process, $C'_1 = C_1$ and $C'_2 = C_2$.

We will prove that $X_1 \cup X_2 = V'$, that is, $\langle X_1, X_2 \rangle$ induces a cut in $V(G)$. Assume not, the cost to separate $C_1 \cup X_1$ from $C_2 \cup X_2$ will be at least $(\lfloor \frac{n^2}{4} \rfloor + 1)(|V' - X_1| + |V' - X_2|) = (\lfloor \frac{n^2}{4} \rfloor + 1)(2n - |X_1| - |X_2|) \geq (\lfloor \frac{n^2}{4} \rfloor + 1)(n + 1) > n(\lfloor \frac{n^2}{4} \rfloor + 1) + k$ that is a contradiction.

Since $X_1 \cup X_2 = V'$, the disruptor induces a cut in G . To have the pairwise connectivity at most $\frac{1}{2} \binom{N}{2}$, both $(C_1 \cup X_1)$ and $(C_2 \cup X_2)$ must have size

at least $\frac{N-\sqrt{N}}{2}$. It follows that X_1 and X_2 must have size at least $f(n) = \lfloor \frac{n-\sqrt{2\lfloor \frac{n^2}{3} \rfloor + n}}{2} \rfloor$. The cost of the cut induced by $\langle X_1, X_2 \rangle$ in G will be $n \left(\lfloor \frac{n^2}{4} \rfloor + 1 \right) + k - n(\lfloor \frac{n^2}{4} \rfloor + 1) = k$. \square

2.4 Hardness of β -Vertex Disruptor

Theorem 8 β -vertex disruptor is NP-complete.

Proof The details of the proof will be ignored. Instead, only the sketch is presented by showing that the vertex cover is polynomial time reducible to β -vertex disruptor. Let $G = (V, E)$ be a graph in which one seeks to find a vertex cover of size k . Note that if we remove nodes in a vertex cover from the graph, the pairwise connectivity in the graph will be zero. Hence, by setting $\beta = 0$, G has a vertex cover of size k iff G has an β -vertex disruptor of size k .

One can also avoid using $\beta = 0$ by replacing each vertex in G by a clique of large enough sizes, say $O(n)$, that ensures no vertices in cliques will be selected in the β -vertex disruptor. \square

Given the NP-hardness of the β -vertex disruptor, the best possible result is a polynomial-time approximation scheme (PTAS) that given a parameter $\epsilon > 0$, produces a $(1 + \epsilon)$ -approximation solution in polynomial time. Unfortunately, this is impossible unless $P = NP$.

Theorem 9 Unless $P = NP$, β -vertex disruptor has no polynomial-time approximation scheme.

Proof In the case $\beta = 0$, the problem is equivalent to finding the minimum vertex cover in the graph. In [23], Dinur and Safra showed that approximating vertex cover within constant factor less than 1.36 is NP-hard. Hence, a PTAS scheme for β -vertex disruptor does not exist unless $P = NP$. \square

3 Approximation Algorithm for β -Edge Disruptor

This section presents an $O(\log^{\frac{3}{2}} n)$ pseudo-approximation algorithm for the β -edge disruptor problem in *directed* graphs. (Note that in directed graphs, a pair (u, v) is said to be connected if there exists a directed path from u to v and vice versa, from v to u .) Formally, the algorithm finds in a directed graph G a β' -edge disruptor whose cost is at most $O(\log^{\frac{3}{2}} n)OPT_{\beta-ED}$, where $\frac{\beta'}{4} < \beta < \beta'$ and $OPT_{\beta-ED}$ is the cost of an optimal β -edge disruptor.

As shown in [Algorithm 1](#), the approximation solution consists of two main steps: (1) constructing a decomposition tree of G by recursively partitioning the

graph into two halves with a directed c -balanced cut and (2) solving the problem on the obtained tree using a dynamic programming algorithm and transform this solution to the original graph. These two main steps are explained in the next two subsections.

3.1 Balanced Tree Decomposition

Let us first introduce some definitions before describing the balanced tree decomposition algorithm.

Definition 7 Given a directed graph $G = (V, E)$ and a subset of vertices $S \subset V$. The set of edges outgoing from S and the set of edges incoming to S are denoted by $\delta^+(S)$ and $\delta^-(S)$, respectively. A cut $\langle S, \bar{S} \rangle$ in G is defined as $\delta^+(S)$. A c -balanced cut is a cut $\langle S, \bar{S} \rangle$ s.t. $\min\{|S|, |\bar{S}|\} \geq c|V|$. The directed c -balanced cut problem is to find the minimum c -balanced cut. And finally, $\mathcal{P}(G)$ denotes the total pairwise connectivity in G .

Note that a cut $\langle S, \bar{S} \rangle$ separates pairs $(u, v) \in S \times (\bar{S})$ so that there is no path u to v , that is, there is no strongly connected component (SCC) containing vertices both in S and \bar{S} .

The tree decomposition procedure is as follows: As shown in [Algorithm 1](#) (lines 3–13), the procedure starts with a tree $T = (V_T, E_T)$ containing only one root node t_0 . t_0 is associated with the vertex set V of G , that is, $V(t_0) = V(G)$. For each node $t_i \in V_T$ whose $V(t_i)$ contains more than one vertex and $V(t_i)$ has not been partitioned, the subgraph $G[V(t_i)]$ induced by $V(t_i)$ in G is partitioned using a c -balanced cut algorithm [24] where constant $c = 1 - \sqrt{\frac{\beta}{\beta'}}$. For each c -balanced cut on $G[V(t_i)]$, two children nodes t_{i1} and t_{i2} of t_i in V_T are created. These two children nodes correspond to two sets of vertices returning by the cut. Finally, each node t_i is assigned a cost $cost(t_i)$ which is equal to the cost of the cut performed on $G[V(t_i)]$. This procedure continues until $V(t_i)$ contains only a single vertex. That is, the leaves of T represent nodes in G . Therefore, T has n leaves and $n - 1$ internal nodes where each internal node in T represents a subset of nodes in V .

Note that the root node t_0 is at level 1. If a node is at level l , all its children are defined to be at level $l + 1$. Note that all collections of vertices corresponding to nodes in a same level form a partition in V .

Lemma 6 *The height of T obtained in the above balanced tree decomposition procedure is at most $O(-\log_{1-c'} n)$*

Proof Note that the directed c -balanced cut algorithm [24] finds in polynomial time a c' -balanced cut within a factor of $O(\sqrt{\log n})$ from the optimal c -balanced cut for $c' = \alpha c$ and fixed constant α . Thus, when separating $G[V(t_i)]$ using c -balanced cut, the size of the larger part is at most $(1 - c')|V(t_i)|$. By induction

method, it can be shown that if a node t_i is on level l , the size of the corresponding collection $V(t_i)$ is at most $|V| \times (1 - c')^{l-1}$. It follows that the tree's height is at most $O(-\log_{1-c'} n)$. \square

3.2 Pseudo-approximation Algorithm and Analysis

This subsection presents the second main step which uses the dynamic programming to search for the right set of nodes in T such that the cuts to partition those corresponding sets of vertices in G have the minimum cost and the obtained pairwise connectivity is at most $\beta' \binom{n}{2}$ where $\beta < \beta' < 1$. The details of this step are shown in [Algorithm 1](#) (lines 14–23).

Denote a set $F = \{t_1, t_2, \dots, t_k\} \subset V_T$ such that $V(t_1), V(t_2), \dots, V(t_k)$ is a partition of $V(G)$, that is, $V(G) = \bigcup_{i=1}^k V(t_i)$ and for any pair t_i and $t_j \in F$, $V(t_i) \cap V(t_j) = \emptyset$. Such a subset F is called G -partition. Denote by $\mathcal{A}(t_i)$ the set

Algorithm 1 β -edge disruptor

```

1: Input: A directed graph  $G = (V, E)$  and  $0 \leq \beta < \beta' < 1$ 
2: Output: A  $\beta'$ -edge disruptor of  $G$ 
   {Construct the decomposition tree}
3:  $c \leftarrow 1 - \sqrt{\frac{\beta}{\beta'}}$ 
4:  $T(V_T, E_T) \leftarrow (\{t_0\}, \phi)$ ,  $V(t_0) \leftarrow V(G)$ ,  $l(t_0) = 1$ 
5: while  $\exists$  unvisited  $t_i$  with  $|V(t_i)| \geq 2$  do
6:   Mark  $t_i$  visited, create new child nodes  $t_{i1}, t_{i2}$  of  $t_i$ 
7:    $l(t_{i1}), l(t_{i2}) \leftarrow l(t_i) + 1$ 
8:    $V_T \leftarrow V_T \cup \{t_{i1}, t_{i2}\}$ 
9:    $E_T \leftarrow E_T \cup \{(t_i, t_{i1}), (t_i, t_{i2})\}$ 
10:  Separate  $G[V(t_i)]$  into two using directed  $c$ -balanced cut
11:  Assign two obtained partitions to  $V(t_{i1})$  and  $V(t_{i2})$ 
12:   $cost(t_i) \leftarrow$  The cost of the balanced cut

18:     else
19:        $cost(t_i, p) \leftarrow \min\{cost(t_{i1}, \pi) + cost(t_{i2}, p - \pi) + cost(t_i) \mid \pi \leq p\}$ 
20:     end if
21:   end for
22: end for
23: Find  $F$  with  $\mathcal{P}(F) = \min\{cost(t_0, p) \mid p \leq \beta' \binom{n}{2}\}$ 
24: Return union of cuts used at  $\mathcal{A}(F)$  during tree construction

```

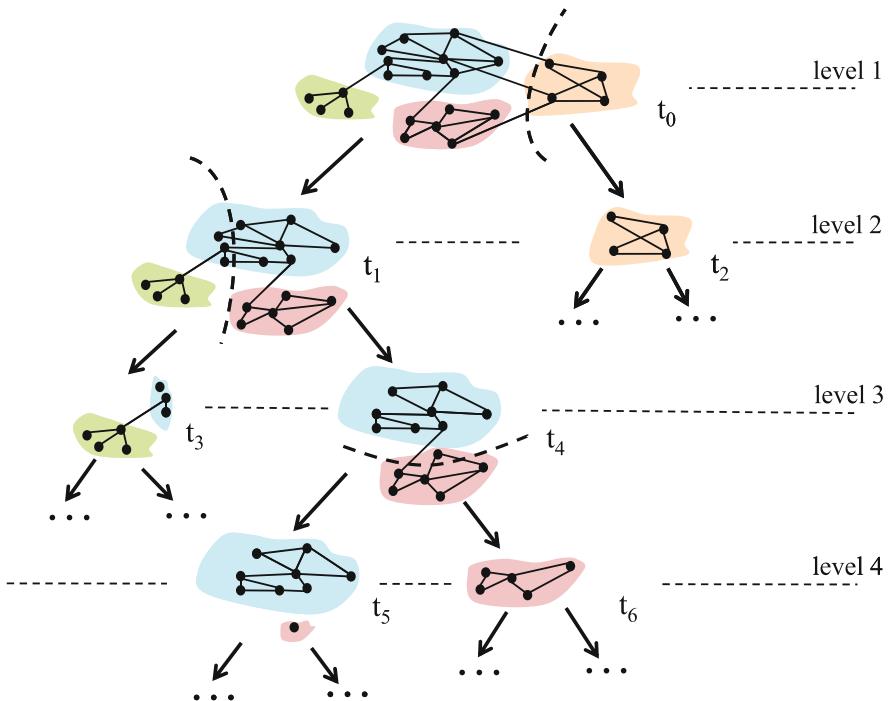

Fig. 9 A part of a decomposition tree. $F = \{t_2, t_3, t_5, t_6\}$ is a G -partition. The corresponding partition $\{V(t_2), V(t_3), V(t_5), V(t_6)\}$ in G can be obtained by using cuts at ancestors of nodes in F , that is, t_0, t_1, t_4

of nodes corresponding to ancestor of t_i in T and $\mathcal{A}(F) = \bigcup_{t_i \in F} \mathcal{A}(t_i)$. It is clear that

an F is G -partition iff F satisfies:

1. $\forall t_i, t_j \in F : t_i \notin \mathcal{A}(t_j)$ and $t_j \notin \mathcal{A}(t_i)$
2. $\forall t_i \in V_T, t_i$ is a leaf: $\mathcal{A}(t_i) \cap F \neq \emptyset$

In case $F = \{t_1, t_2, \dots, t_k\}$ is G -partition, $V(t_1), V(t_2), \dots, V(t_k)$ can be separated by performing the cuts corresponding to ancestors of nodes in F during the tree construction. For example, a decomposition tree with a G -partition set $\{t_2, t_3, t_5, t_6\}$ in Fig. 9. The corresponding partition $\{V(t_2), V(t_3), V(t_5), \text{ and } V(t_6)\}$ in G can be obtained by cutting $G[V(t_0)]$, $G[V(t_1)]$, and $G[V(t_4)]$ successively using c -balanced cuts in the tree construction. The cut cost, hence, will be $cost(t_0) + cost(t_1) + cost(t_4)$. In general, the total cost of all the cuts to separate $V(t_1), V(t_2), \dots, V(t_k)$ is equal to

$$cost(F) = \sum_{t_i \in \mathcal{A}(F)} cost(t_i)$$

And the pairwise connectivity in G is equal to

$$\mathcal{P}(F) = \sum_{t_i \in F} \mathcal{P}(G[V(t_i)])$$

Our goal now is to find a G -partition $F \in V_T$ so that $\mathcal{P}(F) \leq \beta' \binom{n}{2}$ with a minimum $\text{cost}(F)$ since the cut associated to F on T is the β' -edge disruptor of G . Clearly, finding such a set F has an optimal substructure; thus, it can be found in $O(n^3)$ using dynamic programming as described next.

Let $\text{cost}(t_i, p)$ denote the minimum cut cost to make the pairwise connectivity in $G[V(t_i)]$ be less than or equal to p using only c -balanced cuts corresponding to nodes in the subtree rooted at t_i . The minimum cost for a G -partition subset F that induces a β' -edge disruptor of G is then $\min\{\text{cost}(t_0, p) \mid p \leq \beta' \binom{n}{2}\}$ where t_0 is the root node in T .

The value of $\text{cost}(t_i, p)$ can be calculated using following recursive formula:

$$\text{cost}(t_i, p) = \begin{cases} 0 & \text{if } \mathcal{P}(G[V(t_i)]) \leq p \\ \min_{\pi \leq p} \text{cost}(t_{i1}, \pi) + \text{cost}(t_{i2}, p - \pi) + \text{cost}(t_i) & \text{otherwise} \end{cases}$$

where t_{i1}, t_{i2} are children of t_i .

In the first case, when $\mathcal{P}(G[V(t_i)]) \leq p$, no cut is required; thus, $\text{cost}(t_i, p) = 0$. Otherwise, all possible combinations of pairwise connectivity π in $V(t_{i1})$ and $p - \pi$ in $V(t_{i2})$ for all $\pi \leq p$ can be investigated. The combination with the smallest cut cost is then selected.

Based on the above recursive formula, a dynamic programming (shown in lines 14–23 of [Algorithm 1](#)) can find a minimum cost G -partition set F that induces a β' -edge disruptor in G .

The only part left is to prove that such a set F exists in T and the cost of the β' -edge disruptor induced from F found in the dynamic programming algorithm is no more than $O(\log^{\frac{3}{2}} n) \text{Opt}_{\beta}\text{-ED}$. The proof is shown as follows:

Lemma 7 *There exists a G -partition subset F in T that induces a β' -edge disruptor whose cost is no more than $O(\log^{\frac{3}{2}} n) \text{Opt}_{\beta}\text{-ED}$.*

Proof We first show that such a set F exists. That is, we are able to find a set G -partition set F such that $\mathcal{P}(F) \leq \beta' \binom{n}{2}$. Denote D_β an optimal β -edge disruptor in G . Removing D_β from G , we obtain a set of strongly connected components (SCCs), denote as $\mathcal{C}_\beta = \{C_1, C_2, \dots, C_k\}$.

We construct a G -partition subset F based on \mathcal{C}_β as shown in the [Algorithm 2](#). Nodes in T are visited in a top-down manner, that is, every parent must be visited before its children. This can be done by visiting nodes in breadth first search (BFS) order from the root node t_0 . For each node t_i , if there exists some component $C_j \in \mathcal{C}_\beta$ such that $V(t_i)$ contains more than $(1 - c)|V(t_i)|$ nodes in C_j (all leaves in T

satisfies this condition) and no ancestors of t_i has ever been selected into F , then we select t_i as a member of F . It is clear to see that F is a G -partition as it satisfies two conditions mentioned earlier.

The total pairwise connectivity of G induced by F is bounded as

$$\begin{aligned}
\mathcal{P}(F) &\leq \sum_{t_i \in F} \binom{|V(t_i)|}{2} \\
&= \frac{1}{2} \sum_{C_j \in \mathcal{C}_\beta} \sum_{|V(t_i) \cap C_j| \geq (1-c)|V(t_i)|} |V(t_i)|^2 - \frac{n}{2} \\
&\leq \frac{1}{2} \sum_{C_j \in \mathcal{C}} \left(\sum_{|V(t_i) \cap C_j| \geq \sqrt{\frac{\beta'}{\beta'}} |V(t_i)|} |V(t_i)| \right)^2 - \frac{n}{2} \\
&\leq \frac{1}{2} \sum_{C_j \in \mathcal{C}} \left(\sqrt{\frac{\beta'}{\beta}} |C_j| \right)^2 - \frac{n}{2} \\
&< \frac{\beta'}{2\beta} \left(\sum_{C_j \in \mathcal{C}} |C_j|^2 - n \right) \leq \beta' \binom{n}{2}
\end{aligned}$$

Thus, such a set F exists.

Next, we show that $\text{cost}(F) \leq O(\log^{\frac{3}{2}} n) \text{Opt}_{\beta}\text{-ED}$. Let $h(T)$ and L_T^u denote the height of T and the set of nodes at level u of T , respectively. We have

$$\text{cost}(F) = \sum_{u=1}^{h(T)} \sum_{t_i \in (L_T^u \cap \mathcal{A}(F))} \text{cost}(t_i) \tag{2}$$

If $t_i \in \mathcal{A}(F)$, then t_i is not selected to F . Hence, there exists $C_j \in \mathcal{C}_\beta$ so that $|V(t_i) \cap C_j| < (1-c)|V(t_i)|$ (otherwise t_i was selected into F as it satisfies the conditions in the line 3, [Algorithm 2](#)). To guarantee $c < 1-c$ we constrain $c < 1/2$, that is, $\beta > \frac{\beta'}{4}$.

The edges in the optimal β -edge disruptor D_β separate C_j from the other SCCs. Hence, D_β also separates $C_j \cap V(t_i)$ from the $V(t_i) \setminus C_j$ in $G[V(t_i)]$. Denote $\text{sep}(t_i, D_\beta)$ the set of edges in D_β separating $C_j \cap V(t_i)$ from the rest in $G[V(t_i)]$. Clearly, $\text{sep}(t_i, D_\beta)$ is a directed c -balanced cut of $G[V(t_i)]$. Since, the cut algorithm we used in the tree construction has a pseudo-approximation ratio of only $O(\sqrt{\log n})$, we have $\text{cost}(t_u) \leq O(\sqrt{\log n}) |\text{sep}(t_i, D_\beta)|$.

Algorithm 2 Find a good G -partition set F of T that induces a β' -edge disruptor in G

```

 $F \leftarrow \emptyset$ 
for  $t_i \in T$  in BFS order from  $t_0$  do
    if  $(\exists C_j \in \mathcal{C}_\beta : |V(t_i) \cap C_j| \geq (1 - c)|V(t_i)|)$  and  $(\mathcal{A}(t_i) \cap F = \emptyset)$  then
         $F \leftarrow F \cup \{t_i\}$ 
    end if
end for

```

Recall that if two nodes t_i and t_j are on the same level, then $V(t_i)$ and $V(t_j)$ are two disjoint subsets. It follows that $\text{sep}(t_i, D_\beta)$ and $\text{sep}(t_j, D_\beta)$ are also disjoint sets. Therefore, we have

$$\begin{aligned}
& \sum_{t_i \in (L_T^u \cap \mathcal{A}(F))} \text{cost}(t_i) \\
& \leq O(\sqrt{\log n}) \sum_{t_i \in (L_T^u \cap \mathcal{A}(F))} |\text{sep}(t_i, D_\beta)| \\
& \leq O(\sqrt{\log n}) \left| \bigcup_{t_i \in (L_T^u \cap \mathcal{A}(F))} \text{sep}(t_i, D_\beta) \right| \\
& = O(\sqrt{\log n}) \text{Opt}_{\beta\text{-ED}}
\end{aligned}$$

Since $h(T)$ is at most $O(\log n)$ (Lemma 6), it follows from Eq. 2 that $\text{cost}(F) \leq O(\log^{\frac{3}{2}} n) \text{Opt}_{\beta\text{-ED}}$. It completes the proof. \square

Since there exists a G -partition subset of T that induces a β' -edge disruptor whose cost is no more than $O(\log^{\frac{3}{2}} n) \text{Opt}_{\beta\text{-ED}}$ as shown in Lemma 7 and the dynamic programming is always able to find such a set F , the following theorem follows immediately:

Theorem 10 *Algorithm 1* achieves a pseudo-approximation ratio of $O(\log^{\frac{3}{2}} n)$ for the β -edges disruptor problem.

4 Approximation Algorithm for β -Vertex Disruptor

This section presents a polynomial-time algorithm (shown in Algorithm 3) that finds in a directed graph $G = (V, E)$ a β' -vertex disruptor whose the size is at most $O(\log n \log \log n)$ times the optimal β -vertex disruptor where $0 < \beta < \beta'^2$.

At the high level, Algorithm 3 consists of two main phases: (1) vertex conversion and (2) size constraint cut. In the first phase, a given graph G is converted into G' in a way that removing $v \in G$ has the same effects as removing edge in G' . In the second phase, G' is cut into SCCs capping the sizes of the largest component

while minimizing the number of removed edges. The constraint on the size of each component is kept relaxing until the set of cut edges induces a β' -vertex disruptor of G .

4.1 Algorithm Description

Phase 1: Vertex Conversion. Given a directed graph $G = (V, E)$ for which we want to find a small β' -vertex disruptor, a new directed graph $G' = (V', E')$ is constructed as follows:

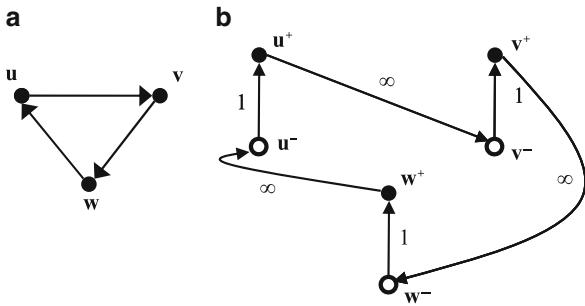

1. *V' construction:* For each vertex $v \in V$, create two vertices v^- and v^+ in V' . Thus, $V' = \{v^-, v^+ \mid v \in V\}$.
2. *E' construction:* For each vertex $v \in V$, add a directed edge $(v^- \rightarrow v^+)$ to E' . And for each directed edge $(u \rightarrow v) \in E$, add a directed edge $(u^+ \rightarrow v^-) \in E'$. That is, $E' = \{(v^- \rightarrow v^+) \mid v \in V\} \cup \{(u^+ \rightarrow v^-) \mid (u \rightarrow v) \in E\}$.
3. *Edge cost assignment:* Assign 1 for all edges $(v^- \rightarrow v^+)$ and $+\infty$ to other edges in E' .

An example of this construction is shown in Fig. 10.

Based on this conversion, a careful edge cut on G' will return a vertex disruptor on G . Indeed, let $E'_V = \{(v^- \rightarrow v^+) \mid v \in V\}$ and consider a cut set $D'_e \subset E'$ that contains only edge in E'_V , we have a one-to-one correspondence between D'_e and $D_v = \{v \mid (v^- \rightarrow v^+) \in D'_e\}$ which is a vertex disruptor set of G . However, G and G' have different maximum pairwise connectivity, $\frac{(n-1)n}{2}$ for G and $\frac{(2n-1)2n}{2}$ for G' , the fractions of pairwise connectivity remaining in G and G' after removing D_v and D'_e are, therefore, not simply related to each other. Thus, we next describe what a “careful edge cut” is and how good a vertex disruptor of G can be obtained.

Phase 2: Size Constraint Cut. Observe that if edges are removed in order to separate a graph into SCCs, then there is a relation between the pairwise connectivity in the remaining graph and the maximum size of SCC. The smaller the maximum size of SCC, the smaller pairwise connectivity in the graph. However, the smaller the maximum size of each SCC, the more edges are needed to be cut. Therefore, a good range of the maximum size of SCC in G' needs to be found in order to return a good vertex disruptor of G with the minimum cut. Along this direction, a binary search can be performed to find a right upper bound $\bar{\beta}|V'|$ and lower bound $\beta|V'|$ of the size of each SCC in G' . As shown in Algorithm 3, at each step, we find in $G' = (V', E')$ a minimum cost edge set whose removal partitions the graph into strongly connected components, each has size at most $\tilde{\beta}|V'|$, where $\tilde{\beta} = \lfloor \frac{\beta + \bar{\beta}}{2\epsilon} \rfloor \times \epsilon$. The value of $\tilde{\beta}$ is rounded to the nearest multiple of ϵ so that the number of steps for the binary search is bounded by $\log \frac{1}{\epsilon}$. The problem of finding a minimum cost edge set to decompose a graph of size n into strongly connected components of size at most ρn is known as ρ -separator problem. At this step, the

Fig. 10 Phase 1: Vertex conversion which converts a graph G into G' such that removing a vertex $v \in G$ has the same effects as removing an edge in G'

Algorithm 3 β' -vertex disruptor

Input: Directed graph $G = (V, E)$ and fixed $0 < \beta' < 1$
Output: A β' -vertex disruptor of G
 $G'(V', E') \leftarrow (\phi, \phi)$
 $\forall v \in V : V' \leftarrow V' \cup \{v^+, v^-\}$
 $\forall v \in V : E' \leftarrow E' \cup \{(v^- \rightarrow v^+)\}, c(v^-, v^+) \leftarrow 1$
 $\forall (u \rightarrow v) \in E : E' \leftarrow E' \cup \{u^+ \rightarrow v^-\}, c(u^+, v^-) \leftarrow \infty$
 $\beta \leftarrow 0, \tilde{\beta} \leftarrow 1$
 $D_V \leftarrow V(G)$
while ($\bar{\beta} - \underline{\beta} > \epsilon$) **do**
 $\tilde{\beta} \leftarrow \lfloor \frac{\bar{\beta} + \underline{\beta}}{2\epsilon} \rfloor \times \epsilon$
 Find $D_e \subset E'$ to separate G' into strongly connected components of sizes at most $\tilde{\beta}|V'|$ using algorithm in [25]
 $D_v \leftarrow \{v \in V(G) \mid (v^+ \rightarrow v^-) \in D_e\}$
 if $\mathcal{P}(G[V \setminus D_v]) \leq \beta \binom{n}{2}$ **then**
 $\underline{\beta} = \tilde{\beta}$
 Remove nodes from D_v as long as $\mathcal{P}(G[V \setminus D_v]) \leq \beta \binom{n}{2}$
 if $|D_V| > |D_v|$ **then**
 $D_V = D_v$
 end if
 else
 $\bar{\beta} = \tilde{\beta}$
 end if
end while
Return D_V

algorithm presented in [25] which finds a ρ -separator in a directed graph G with a pseudo-approximation ratio of $O\left(\frac{1}{\epsilon^2} \cdot \log n \log \log n\right)$ for a fixed $\epsilon > 0$ is used. In our context, $\rho = \tilde{\beta}|V'|$. By the cost assignment step in the vertex construction phase, the edge cut obtained in this step must be a subset of E'_V as other edges e' not in E'_V have a cost of $+\infty$; hence, e' never got selected. Finally, the cut edges in G' is converted to vertices in G to obtain the β' -vertex disruptor. Simply, for each edge $(v^- \rightarrow v^+)$ in a cut set, we have a corresponding vertex $v \in V$.

4.2 Theoretical Analysis

Lemma 8 *Algorithm 3* always terminates with a β' -vertex disruptor.

Proof We show that whenever $\tilde{\beta} \leq \beta'$ then the corresponding D_v found in **Algorithm 3** is a β' -vertex disruptor of G . Consider the edge separator D'_e of G' induced by D_v . We first show the mapping between SCCs in $G[V \setminus D_v]$ and SCCs in $G'[E' \setminus D'_e]$, the graph obtained by removing D'_e from G' . Partition the vertex set V of G into (1) D_v : the set of removed nodes; (2) $V_{\text{singleton}}$: the set of SCCs whose sizes are one, that is, each SCC has only one node; and (3) $V_{\text{connected}}$: the set of remaining SCCs whose sizes are at least two, denote $V_{\text{connected}} = \bigcup_{i=1}^l C_i, |C_i| \geq 2$. Vertices in $V_{\text{connected}}$ belong to at least one cycle in G , whereas vertices in V_{single} are all singleton.

We have the following corresponding SCCs in $G'[E' \setminus D'_e]$:

1. $v \in D_v \Leftrightarrow$ SCCs $\{v^+\}$ and $\{v^-\}$ in $G'[E' \setminus D'_e]$. Because after removing $(v^- \rightarrow v^+)$, v^+ does not have incoming edges and v^- does not have outgoing edges.
2. $v \in V_{\text{singleton}} \Leftrightarrow$ SCCs $\{v^+\}$ and $\{v^-\}$. Assume v^+ belong to some SCC of size at least 2, that is, v^+ lies on some cycle in G' . Because the only incoming edge to v^+ is from v^- , it follows that v^- is preceding v^+ on that cycle. Let u^- and u^+ be the successive vertices of v^+ on that cycle. Then u and v should belong to the same SCC in G which yields a contradiction as $v \in V_{\text{singleton}}$. Similarly, v^- cannot lie on any cycle in G' .
3. SCC $C_i \subset V_{\text{connected}} \Leftrightarrow$ SCC $C'_i = \{v^-, v^+ \mid v \in C_i\}$. This can be shown using a similar argument as above.

Since D'_e is a $\tilde{\beta}$ -separator, the sizes of SCCs in $G'[E' \setminus D'_e]$ are at most $\tilde{\beta} 2n$. It follows that the sizes of SCCs in $G[V \setminus D_v]$ are bounded by $\tilde{\beta} n$.

Denote the set of SCCs in $G[V \setminus D_v]$ by \mathcal{C} with the convention that vertices in D_v become singleton SCC in $G[V \setminus D_v]$. Therefore, we have

$$\begin{aligned} \mathcal{P}(G[V \setminus D_v]) &= \sum_{C_i \in \mathcal{C}} \binom{|C_i|}{2} = \frac{1}{2} \left(\sum_{C_i \in \mathcal{C}} |C_i|^2 - |V| \right) \\ &\leq \frac{1}{2} \left(\sum_{C_i \in \mathcal{C}} \tilde{\beta} |V| |C_i| - |V| \right) \\ &= \frac{1}{2} \left(\tilde{\beta} |V|^2 - |V| \right) \leq \tilde{\beta} \binom{|V|}{2} < \beta' \binom{|V|}{2} \end{aligned}$$

This guarantees that the binary search always finds a β' -vertex disruptor and completes the proof. \square

Theorem 11 *Algorithm 3* achieves a pseudo-approximation ratio of $O(\log n \log \log n)$ for the β -vertex disruptor problem.

Proof We will show that [Algorithm 3](#) always finds a β' -vertex disruptor whose size is at most $O(\log n \log \log n)$ times the optimal β -vertex disruptor for $\beta'^2 > \beta > 0$. First, it follows from the [Lemma 8](#) that [Algorithm 3](#) returns a β' -vertex disruptor D_v . At some step, the size of D_v equals to the cost of $\tilde{\beta}$ -separator D'_e in G' where $\tilde{\beta}$ is at least $\beta' - \epsilon$ according to [Lemma 8](#) and the binary search scheme. The cost of the separator is at most $O(\log n \log \log n)$ times the $Opt_{(\tilde{\beta}-\epsilon)}$ -separator using the algorithm in [25].

Consider an optimal $(\beta'^2 - 9\epsilon)$ -vertex disruptor D'_v of G and its corresponding edge disruptor D'_e in G' . Denote the cost of that optimal vertex disruptor by $Opt_{(\beta'^2-9\epsilon)}\text{-VD}$. If there exists in $G[V \setminus D_v]$ a SCC C_i so that $|C_i| > (\beta' - 2\epsilon)n$, then

$$\mathcal{P}(G[V \setminus D_v]) > \frac{1}{2}((\beta' - 2\epsilon)n - 2)((\beta' - 2\epsilon)n - 1) > (\beta'^2 - 9\epsilon) \binom{n}{2}$$

when $n > \frac{20(\beta'+1)}{\epsilon}$. Hence, every SCC in $G'[V \setminus D'_v]$ has size at most $(\beta' - 2\epsilon)(2n)$, that is, D'_e is an $(\beta' - 2\epsilon)$ -separator in G' . It follows that $Opt_{(\beta'^2-9\epsilon)}\text{-VD} \geq Opt_{(\beta'-2\epsilon)}$ -separator in G' .

Because $\tilde{\beta} - \epsilon \geq \beta' - 2\epsilon$, we have

$$Opt_{(\tilde{\beta}-\epsilon)}\text{-separator} \leq Opt_{(\beta'-2\epsilon)}\text{-separator} \leq Opt_{(\beta'^2-9\epsilon)}\text{-VD}$$

The size of the vertex disruptor $|D_v| = |D'_e|$ is at most $O(\log n \log \log n)$ times $Opt_{(\tilde{\beta}-\epsilon)}$ -separator. Thus, the size of found β' -vertex disruptor D_v is at most $O(\log n \log \log n)$ times the optimal $(\beta'^2 - 9\epsilon)$ -vertex disruptor. As an arbitrary small ϵ can be chosen, setting $\beta = \beta'^2 - 9\epsilon$ completes the proof. \square

5 A Second Look

Another look at the solutions to β -ED and β -VD in order to obtain a better algorithm is discussed in this section. As can be seen earlier, a c -balance cut for a tree decomposition is used to solve the β -ED problem. This results into a $\sqrt{\log n}$ ratio for a c -balance cut and another $\log n$ for the height of the decomposition tree, leading to a $\log^{1.5} n$ ratio. If a better cut without a need of decomposing G into a tree is devised, a $\log n$ factor can be saved, thus obtaining a $\sqrt{\log n}$ ratio. In order to do so, let us first describe the following definitions which are the key concepts to a better algorithm by approximating the best “local” cut at each step:

Cut Ratio. Given a graph $G = (V, E)$, for any cut $\langle S, \bar{S} \rangle$ where $S \subseteq V$ and $\bar{S} = V \setminus S$, the *cut ratio* of $\langle S, \bar{S} \rangle$, denoted by $\alpha(S)$, is defined as

$$\alpha(S) = \frac{c(S, \bar{S})}{|S||\bar{S}|}, \quad (3)$$

where $c(S, \bar{S})$ is the total cost of edges in the cut.

The cut ratio metric intuitively allows to find “natural” partitions: The numerator captures the minimum cost criterion, while the denominator favors a balanced partition. Assume that G is connected, the cut disrupts at least $|S||V \setminus S|$ pairs, those with exact one endpoint in S ; hence, $\alpha(S)$ can also be seen as the average cost to disrupt pairs.

Sparsest Cut. The sparsest cut is a cut with the smallest cut ratio. Let $\alpha(G)$ denote the $\min_{S \subset V} \alpha(S)$, the minimum cut ratio of all cuts in G . Thus, the sparsest cut obtains a cut with the cut ratio $\alpha(G)$. As expected, finding the sparsest cut is also an NP-hard problem [26].

5.1 $O(\sqrt{\log n})$ Pseudo-approximation for β -Edge Disruptor

As the cut ratio can be seen as the average cost to disrupt the pairwise connectivity, iteratively finding and applying the sparsest cut until obtaining a β -edge separator may result in a small cost β -edge disruptor. We describe a new algorithm using the sparsest cut in [Algorithm 4](#) and show this algorithm is indeed a $\sqrt{\log n}$ pseudo-approximation algorithm for the β -ED problem.

The *recursive bisection algorithm* (RBA) iteratively selects a connected component in the graph and calls a subroutine SPARSEST_CUT to cut the component into two smaller ones, until the pairwise connectivity in the graph is no more than $\beta \binom{n}{2}$. The subroutine SPARSEST_CUT function works as follows: Assume that it takes a *connected* graph $G' = (V', E')$ as the input it will find a small ratio cut S' in G' , and returns the pair of $(\langle S', \bar{S}' \rangle, \alpha(S'))$, that is, the edges in the cut and the cut ratio. At each iteration, a component C^* in G that has the minimum cut ratio is selected, and the edges in the sparsest cut of C^* are removed from G . After that, C^* is no longer a component of G , and new components are introduced into G . The SPARSEST_CUT is used again

Algorithm 4 Recursive bisection algorithm (RBA)

```

 $E_\beta \leftarrow \emptyset$ 
for each connected component  $C$  in  $G$ 
   $(C_E, C_\alpha) \leftarrow \text{SPARSEST\_CUT}(C)$  [27]
while  $\mathcal{P}(G) > \beta \binom{n}{2}$ 
  Find a component  $C^*$  of  $G$  with minimum cut ratio  $C_\alpha^*$ 
   $E_\beta \leftarrow E_\beta \cup C_E^*$ 
  Remove edges in  $C_E^*$  from  $G$ 
  for each new component  $C'$  in  $G$ 
     $(C'_E, C'_\alpha) \leftarrow \text{SPARSE\_CUT}(C')$ 
return  $E_\beta$ 

```

to find cuts and the corresponding cut ratios for the newly created components. This procedure is repeated until the pairwise connectivity in G is no more than $\beta \binom{n}{2}$.

Clearly, the performance of the SPARSEST_CUT subroutine directly impacts on the performance of RBA. Here the SPARSEST_CUT is selected as the algorithm that guarantees the best theoretical result in literature for the min ratio cut problem [27]. The result in [27] gives us a polynomial-time algorithm to find a cut (S, \bar{S}) given a graph $G = (V, E)$ with the cut ratio at most $O(\sqrt{\log n})\alpha(G)$. This selection yields an $O(\sqrt{\log n})$ pseudo-approximation algorithm for the β -edge disruptor problem as analyzed below.

Lemma 9 *Given a graph $G = (V, E)$ and a subset of edges $M_\omega \subseteq E$, if $\omega = \mathcal{P}(G) - \mathcal{P}(G[E \setminus M_\omega]) > 0$, then $\frac{c(M_\omega)}{\omega} \geq \alpha_{\min}(G)$, where*

$$\alpha_{\min}(G) = \min\{\alpha(C) \mid C \text{ is a connected component of } G\}.$$

Proof We first prove for the case G is connected, that is, $\alpha_{\min}(G) = \alpha(G)$ and $\mathcal{P}(G) = \binom{n}{2}$. Let C_1, C_2, \dots, C_k be connected components in $G[E \setminus M_\omega]$ and let $C_i(V)$ denote the set of vertices in component C_i . By definition of $\alpha(G)$, we have $\alpha(G) \leq \alpha(C_i(V))$. Thus,

$$c(C_i(V), \overline{C_i(V)}) \geq \alpha(G)|C_i(V)||V \setminus C_i(V)|$$

Take the sum over all components C_i , we have

$$\sum_i c(C_i(V), \overline{C_i(V)}) \geq \alpha(G) \sum_i |C_i(V)|(n - |C_i(V)|)$$

Simplify both sides and note that $\sum_i |C(V_i)| = n$, we have

$$\begin{aligned} 2c(M_\omega) &\geq \alpha(G) \left(n \sum_i |C(V_i)| - \sum_i |C(V_i)|^2 \right) \\ &\geq 2\alpha(G) \left(\binom{n}{2} - \sum_i \mathcal{P}(C_i) \right) \geq 2\alpha(G) \omega \end{aligned}$$

Hence, the lemma holds when G is connected.

Now, if G is not connected, let T_1, T_2, \dots, T_l be connected components of G , $M_\omega^{(j)}$ be the intersection of M_ω and the edges in T_j , and T'_j be the subgraphs obtained from T_j after removing $M_\omega^{(j)}$. Applying the above results to the case that the graph is connected on each connected component, we have

$$\begin{aligned}
c(M_\omega) &= \sum_j c(M_\omega^{(j)}) \geq \sum_j \alpha(T_j) (\mathcal{P}(T_j) - \mathcal{P}(T'_j)) \\
&\geq \alpha_{\min}(G) \sum_j (\mathcal{P}(T_j) - \mathcal{P}(T'_j)) \\
&= \alpha_{\min}(G) (\mathcal{P}(G) - \mathcal{P}(G[E \setminus M_\omega]))
\end{aligned}$$

Thus, the lemma holds for every graph G . \square

Theorem 12 *If SPARSEST_CUT is an approximation algorithm with a factor $f(n)$ for the min cut ratio problem, then RBA returns a β -edge disruptor of cost at most $f(n) \text{OPT}_{\beta'}^e$, for any $0 < \beta' < \beta$, where $\text{OPT}_{\beta'}^e$ denotes the cost of a minimum β' -edge disruptor.*

Proof By Lemma 9, if removing a set of edges $M_\omega \subseteq E$ from G disrupts ω pairs of vertices, then $\frac{c(M_\omega)}{\omega} \geq \alpha_{\min}(G)$. Thus, at any round in the while loop of RBA, since a set of edges $E_{\beta'}^*$ in a minimum β' -edge disruptor, for some $0 < \beta' < \beta$, can disrupt at least $(\beta - \beta') \binom{n}{2}$ more pairs in G , we have

$$\frac{\text{OPT}_{\beta'}^e}{(\beta - \beta') \binom{n}{2}} \geq \alpha_{\min}(G). \quad (4)$$

From the hypothesis that SPARSE_CUT is an $f(n)$ factor approximation algorithm for the min cut ratio problem, the average cost to disrupt a pair by removing C_E^* is upper bounded by $f(n)\alpha_{\min}(G)$. By (4), the average cost to disrupt pairs in the graph at any step is at most

$$f(n) \frac{\text{OPT}_{\beta'}^e}{(\beta - \beta') \binom{n}{2}}$$

Therefore, even when E_β disrupt all $\binom{n}{2}$ pairs in G , the total cost is no more than

$$f(n) \frac{\text{OPT}_{\beta'}^e}{(\beta - \beta') \binom{n}{2}} \binom{n}{2} \leq \frac{f(n)}{\beta - \beta'} \text{OPT}_{\beta'}^e.$$

Hence, the theorem follows. \square

Remarks If the underlying graph is directed, the directed sparsest cut algorithm in [24] can be used in the place of the sparsest cut algorithm in [27] to obtain a pseudo-approximation algorithm with the same ratio. Note that for directed graphs, a pair of vertices (u, v) is said to be connected if there exists a path from u to v and from v to u (i.e., connected in both directions).

5.2 $O(\sqrt{\log n})$ Pseudo-approximation for β -Vertex Disruptor

For the β -vertex disruptor problem, the first phase – vertex conversion – as discussed in Sect. 4 still can be used. However, in order to obtain an $O(\sqrt{\log n})$ pseudo-approximation, a relationship between β -VD and β -ED needs to be defined in order to take advantage of Algorithm 4 instead of using the phase two – size constraint cut. Recall that given a directed graph $G = (V, E)$ for which we want to find a small β -VD, after the vertex conversion, we should obtain a directed graph $G' = (V', E')$ which will have twice the number of vertices in G , that is, $|V'| = 2|V| = 2n$.

Consider a directed edge disruptor set $D'_e \subset E'$ that contains only edge in E'_V . There is a one-to-one correspondence between D'_e to a set $D_v = \{v \mid (v^- \rightarrow v^+) \in D'_e\}$ in $G(V, E)$ which is a vertex disruptor set in G . Since G and G' have different maximum pairwise connectivity, $\frac{(n-1)n}{2}$ for G and $\frac{(2n-1)2n}{2}$ for G' , the fractions of pairwise connectivity remaining in G and G' after removing D_v and D'_e are, however, not exactly equal to each other.

Lemma 10 *A β -edge disruptor set in the directed graph G' induces the same cost β -vertex disruptor set in G .*

Proof Let us denote D_v and D'_e for vertex disruptor in G and edge disruptor in G' .

Given $\mathcal{P}(G'[E' \setminus D'_e]) \leq \beta \binom{2n}{2}$ we need to prove that: $\mathcal{P}(G_{[V \setminus D_v]}) \leq \beta \binom{n}{2}$ where $n = |V|$.

Assume $G_{[V \setminus D_v]}$ has l SCCs of size at least 2, say $C_i, i = 1 \dots l$. The corresponding SCCs in $G'[E' \setminus D'_e]$ will be $C'_i, i = 1 \dots l$ where $|C'_i| = 2|C_i|$.

Since $\frac{\binom{2k}{2}}{\binom{2n}{2}} - \frac{\binom{k}{2}}{\binom{n}{2}} = \frac{k(n-k)}{(n-1)n(2n-1)} \geq 0$, for all $0 \leq k \leq n$. We have

$$\frac{\mathcal{P}(G_{[V \setminus D_v]})}{\binom{n}{2}} = \sum_{i=1}^l \frac{\binom{|C_i|}{2}}{\binom{n}{2}} \leq \sum_{i=1}^l \frac{\binom{|C'_i|}{2}}{\binom{2n}{2}} \leq \beta \quad \square$$

Lemma 11 *A β -vertex disruptor set in G induces the same cost $(\beta + \epsilon)$ -edge disruptor set in G' for any $\epsilon > 0$.*

Proof The same notations in the proof of Lemma 10 are used here. Given $\mathcal{P}(G_{[V \setminus D_v]}) \leq \beta \binom{n}{2}$ we need to prove that $\mathcal{P}(G'[E' \setminus D'_e]) \leq (\beta + \epsilon) \binom{2n}{2}$. We have

$$\begin{aligned} & \frac{\mathcal{P}(G'[E' \setminus D'_e])}{\binom{2n}{2}} \\ &= \sum_{i=1}^l \frac{|C_i|(n - |C_i|)}{(n-1)n(2n-1)} + \frac{\mathcal{P}(G_{[V \setminus D_v]})}{\binom{n}{2}} \end{aligned}$$

$$\begin{aligned}
&= \frac{\mathcal{P}(G_{[V \setminus D_v]})}{\binom{n}{2}} \left(1 - \frac{1}{2n-1}\right) + \frac{\sum_{i=1}^l |C_i|}{n(2n-1)} \\
&< \beta + \frac{1}{2n-1} < \beta + \epsilon
\end{aligned} \tag{5}$$

when $n \geq \lfloor \frac{1+\epsilon}{2\epsilon} \rfloor + 1$. \square

We now prove the main theorem for conversion from directed edge disruptor to vertex disruptor.

Theorem 13 *Given a factor $f(n)$ polynomial-time bicriteria approximation algorithm for β -edge disruptor in directed graphs, there exists a factor $f(n)$ polynomial-time bicriteria approximation algorithm that finds a $(\beta + \epsilon)$ -vertex disruptor whose cost at most $f(n)$ time the cost of the optimal β -vertex disruptor where $\epsilon > 0$ is an arbitrary small constant.*

Proof Let G be a directed graph with uniform vertex costs in which we wish to find a β -vertex disruptor. Construct G' as described at the beginning of this section.

For $\beta' < \beta$, apply the given approximation algorithm to find in G' a β -edge disruptor, denoted by D'_e , with the cost at most $f(n) \cdot \text{Opt}_{\beta'-\text{ED}}(G')$, where $\text{Opt}_{\beta'-\text{ED}}(G')$ is the cost of a minimum β -edge disruptor in G' . From Lemma 10, D'_e induces in G a β -vertex disruptor D_v of the same cost. We shall prove that

$$\text{Opt}_{\beta'-\text{ED}}(G') \leq \text{Opt}_{\beta'-\text{VD}}(G) + \gamma_0,$$

where $\text{Opt}_{\beta'-\text{VD}}(G)$ is the cost of a minimum β' -vertex disruptor in G and γ_0 is some positive constant. It follows that the cost of D_v will be at most

$$f(n) \cdot (\text{Opt}_{\beta'-\text{VD}}(G) + \lambda_0) \leq (1 + \epsilon) f(n) \text{Opt}_{\beta'-\text{VD}}(G)$$

Here, assume that $\text{Opt}_{\beta'-\text{VD}}(G) > \frac{\gamma_0}{\epsilon}$; otherwise, $\text{Opt}_{\beta'-\text{VD}}(G)$ can be found in time $O(n^{\frac{\gamma_0}{\epsilon}+2})$ (polynomial time).

From an optimal β -vertex disruptor of G , construct its corresponding edge disruptor D_e^* in G' . If $\mathcal{P}(G'[E \setminus D_e^*] \leq \beta \binom{2n}{2}$, then $\text{Opt}_{\beta-\text{ED}}(G') \leq \text{Opt}_{\beta-\text{VD}}(G)$, and we yield the proof. Thus, only the case $\mathcal{P}(G'[E \setminus D_e^*] > \beta \binom{2n}{2})$ is considered.

Among SCCs of $G'[E \setminus D_e^*]$, there must be a SCC of size at least $\beta 2n$ or else $G'[E \setminus D_e^*] \leq \beta^{-1} \binom{\beta 2n}{2} \leq \beta \binom{2n}{2}$ (contradiction). Remove $\gamma_0 = \lceil \frac{1}{\beta} \rceil$ vertices from that SCC. The pairwise connectivity in $G'[E \setminus D_e^*]$ will decrease at least $(\beta 2n - \frac{1}{\beta}) \frac{1}{\beta} = 2n - \frac{1}{\beta^2} \geq n$ for sufficient large n . From Lemma 11, the pairwise connectivity after removing vertices will be less than

$$\left(\beta + \frac{1}{2n-1}\right) \binom{2n}{2} - n \leq \beta \binom{2n}{2}$$

Therefore, after removing at most γ_0 vertices from D_e^* , a β -edge disruptor is obtained. Hence,

$$\text{Opt}_{\beta-\text{ED}}(G') \leq \text{Opt}_{\beta-\text{VD}}(G) + \gamma_0.$$

From the above theorem and the $O(\sqrt{\log n})$ pseudo-approximation algorithm for directed β -edge disruptor (shown in [Algorithm 4](#)), we have the following result: \square

Theorem 14 *For any $0 \leq \beta' < \beta$, there is an algorithm that finds a β -vertex disruptor of cost at most $O(\sqrt{\log n})\phi(\text{OPT}_{\beta'}^v)$, where $\text{OPT}_{\beta'}^v$ is the optimal β -vertex disruptor.*

6 Literature

Several existing works on network vulnerability and survivability have been investigated, roughly categorized into two periods. Researches during the early period mainly focused on investigating the node's centrality and prestige, using functions of node degree [3, 5, 28, 29] as the only measure. The main measures of centrality can be classified as degree centrality, betweenness, closeness, and eigenvector centrality. Readers are referred to [30] to find more details about this centrality measurement.

As wireless ad hoc networks came forth, several recent studies have aimed to discover the critical nodes whose removal causes the network disconnected, regardless of how fragmented it is! Several centralized, distributed, and localized heuristics have been proposed. Some representatives are centralized DFS-based search [7–9, 31], distributed disjoint path [10, 32], and localized k -critical [11]. Most of these algorithms suffer from high communication overhead to discover the network partition and could not efficiently locate the critical nodes. In addition, none of these methods have been proven theoretically.

Unfortunately, none of the above work reveals the global damage done on the network in the case of multiple nodes/links failing simultaneously, thus inaccurately assessing the network vulnerability. None of these methods prove the performance bound of their solutions either.

This chapter presents a novel paradigm via two new optimization models for quantitatively characterizing the vulnerability of networks. The proposed approaches *aim to identify the key nodes* who play a vital role in the network overall performance, such as whose removal *maximizes the network fragmentation*. This study defines the objective function differently in terms of the connected components rather than a traditional direct measure of algebraic connectivity, thereby providing an excellent way to assess the network vulnerability.

7 Conclusion

This chapter presents two models along with their complexity hardness and solutions to the network vulnerability. There are a couple of notes that we would like to discuss further as follows:

It is easy to see that when k is large enough, the CVD problem cannot be approximated within a factor of $\alpha(n)$ for any polynomial-time computable function $\alpha(n)$ unless $\mathbf{P} = \mathbf{NP}$ by reducing from the vertex cover problem. To avoid the case of the optimal total pairwise connectivity after deleting S equal to 0, k can be set as $k < |E|/\Delta$ where Δ is the maximum degree of a given graph G . Approximation solutions to this problem are still open.

The two optimization models can be modified to further assess the network vulnerability under other objective functions. For example, in the context of networks, QoS (quality of services) is an important concept. Therefore, we can consider maximizing the QoS instead of total pairwise connectivity. Other objective functions include the following: minimize the number of pairwise nodes such as their shortest paths in $G[V \setminus S] \leq d$ for some distance d minimize the *connected* vertex disruptor. All these problems can be studied on a probabilistic graph $G = (V, E)$ where each edge $e \in E$ has a failure probability $p_e \in [0, 1]$, which models a dynamic network.

As many complex networks such as the Internet, WWW, biological networks, and social networks can specifically be modeled as power-law graphs, where the number of nodes of degree i is $\lfloor e^\alpha / i^\beta \rfloor$ for some constants α and β , it would be interesting to investigate the proposed problems (β -ED, β -VD, CVD, and CED) in power-law networks. As shown early, these problems still remain NP-complete on power-law graphs. Even though, does the power-law distribution play any key factor on the inapproximability? Are we able to obtain a smaller such as a constant approximation algorithm for these problems on power-law graphs?

Abstract

In job shop scheduling problem (JSSP), deadlock-free design and scheduling optimization are important issues, which are difficult to tackle in the JSSP having multiple shared resources. To deal with these issues, this chapter introduces a modular-based system design method for modeling and optimizing JSSP. Several operators are presented for handling the combination of JSSP modules and

resource sharing. For handling deadlock issues with multi-resources sharing, the conditions on “dead transitions” and “circular waiting” are considered. Based on a transitive matrix, deadlock detection and deadlock recovery algorithms are developed in order to get a deadlock-free system. For each operator, the partial schedule and makespan of each module are obtained. The optimal scheduling of JSSP can be derived from these theoretical results step by step. With the modular-based system design method, one cannot only design a correct system model which is live, bounded, reversible, and deadlock-free and terminate properly but also find the optimal scheduling of JSSP in a formal way. For handling large-scale JSSP, the traditional optimization technologies such as genetic algorithm, branch and bound method, hybrid methods, and rule-based methods can be applied together with the modular-based approach in this chapter. Based on the Petri net model, a genetic algorithm is also introduced here.

1 Introduction

The job shop scheduling problem (JSSP) considered in this chapter can be stated as follows: There are a finite set of n jobs, each of which consists of a chain of operations, and a finite set of m machines, which are able to process at most one operation at a time. Each operation must be processed during an uninterrupted time on some given machine, and the purpose is to find a schedule to allocate the resources rationally and finish the task in time. The allocation of resources, such as machines, robots, workers, and AGVs, has to be considered for the modeling and functioning of JSSP, which is a challenge for a system designer. Among others, a JSSP design has the following characterizations and challenges:

- *Heavy reliance on resource sharing and deadlock avoidance.* In a JSSP, resources such as robots, machines, assembly lines, and buffers are sometimes shared by several processes. Therefore, handling resource sharing becomes an important aspect during JSSP design. It is noteworthy that “sharing” does not imply simultaneous usage while simultaneous usage can be handled by re-enterable codes in software systems, which is not allowed in JSSP, and “sharing” requires a resource to be occupied by some part(s) exclusively during utilization and to be released afterward. In single resource-sharing scheduling, if a resource is occupied by others, the job has no other choice but waits until the resource is released. For multiple resources systems, a wrong order of resource allocation, when the resources are limited or distributed unreasonably, deadlocks, or overflows may occur. In a JSSP, deadlock may be the state of “circular waiting” which occurs unexpectedly. Thus, deadlocks must be detected and prevented during system design. In this chapter, handling deadlock issues will be discussed in Sect. 2.
- *Strong tendency toward component-based architecture.* The processes and resources of a JSSP are modeled, built, or owned by different unrelated parties, at different times, and under different environments. Therefore, in order not to have severe interference in their individual developments, it is better for a JSSP to adopt a modular-based architecture. The architecture enlarges the reusability

of the system modules and increases the system running speed. However, it faces many difficulties during integration, including operation system, interfaces, and communication. In the literature, net-based approaches concerning integration include place merging, transition merging, path merging, and modular synthesis. The related references can be found in [1, 2]. This chapter handles the integration problem by applying property-preserving composition operators [3–6] such as enable, choice, interleaving, and iteration. For each operator, the partial schedule and makespan of each module are obtained. The optimal scheduling of JSSP can be derived from these theoretical results step by step. With the modular-based system design method, one cannot only design a correct system model which is live, bounded, and reversible and terminate properly but also find the optimal scheduling of JSSP in a formal way. The technical details concerning modular-based design of JSSP with Petri net will be introduced in Sect. 3.

In the literature, much work involved the research on the above features. The description of the related approaches and a brief review can be found in Deniz K. Terry's PhD thesis [7].

2 Deadlock-Free Design of JSSP with Petri Nets

Petri nets are suitable for modeling sequence, concurrency, choice, and mutual exclusion in discrete event systems, and they have been extensively used to model and analyze the JSSP [8–12]. Further, they are useful for allocating resources and detecting or preventing unexpected system behaviors, such as deadlock and capacity overflow. Motivated by the features of Petri nets, this chapter uses timed Petri nets (TPNs) to model the JSSP, while deadlock detection and recovery are performed by considering the transitive matrix of Petri net model [13].

In the literature, Petri net-based deadlock-free design for JSSP considers the following three types of approaches. The first one is relying on the techniques concerning siphons and traps. Elementary siphon invariants in Petri net structure are useful for analyzing deadlock in flexible manufacturing system (FMS) [14–17]. The deadlock-free method is addressed by adding a monitor or controller to avoid deadlock structure [16–18]. Recently siphons, traps, and invariants have been extensively studied to prevent deadlock and analyze the properties of Petri nets. However, deadlock analysis for compositional system that shares common resources could not grab much attention of the researchers because the number of siphons grows rapidly with the size of final composite net.

The second is about heuristic scheduling algorithm, such as genetic algorithm, used to get an optimum and deadlock-free scheduling of FMS, for example, in [19, 20]. This method is limited to some special problems in JSSP with the given system model; it is not suitable for general cases.

The last one is based on the transitive matrix, which is driven from the directed graph in [13]. The place transitive matrix describes the transferring relation from one place to another place through transitions. The analysis of the cyclic scheduling for the determination of the optimal cycle time is studied, and transitive matrix

has efficiently been used to slice off some subnets from the original net in [21]. Deadlock-free conditions are given in [22, 23] based on transitive matrix, and an algorithm for finding deadlock is given in [24] by using the place transitive matrix.

In this chapter, JSSP is studied by using the TPNs. Further, modular-based architecture is adopted and transitive matrix-based deadlock detection and recovery algorithms are presented. Firstly, each job is modeled by a “small” Petri net, and then these “small” Petri nets, representing different jobs to be completed, are merged together by fusing the common resource places. In multi-resources sharing, an efficient algorithm based on place transitive matrix is presented to detect deadlock for each two jobs of JSSP. In addition, a deadlock recovery method is introduced to give the deadlock-free schedule. Finally, a deadlock-free method for system design is obtained based on these two algorithms. A case study is presented to illustrate the efficiency of the given methods.

2.1 Terminology About Petri Nets

In this subsection, the basic definitions about Petri net and its structural classification are presented for completeness. The related terminology is mostly taken from [13, 25–29].

Definition 1 (Petri Net) A *Petri net* (N, M_0) is a net $N = (P, T, F, W)$ with an initial marking M_0 where, P is a finite set of *places*; T is a finite set of *transitions* such that $P \cap T = \emptyset$ and $P \cup T \neq \emptyset$; $F \subseteq (P \times T) \cup (T \times P)$ is the *flow relation*; and W is a *weight function* such that $W(x, y) \in N^+$ if $(x, y) \in F$ and $W(x, y) = 0$ if $(x, y) \notin F$. M_0 is a function $M_0: P \rightarrow N$ such that $M_0(p)$ represents the number of *tokens* in place $p \in P$.

Definition 2 (Pre-set and Post-set) For $x \in P \cup T$, $\bullet x = \{y \mid (y, x) \in F\}$ and $x^\bullet = \{y \mid (x, y) \in F\}$ are called the *pre-set (input set)* and *post-set (output set)* of x , respectively. For a set $X \subseteq P \cup T$, $\bullet X = \bigcup_{x \in X} \bullet x$ and $X^\bullet = \bigcup_{x \in X} x^\bullet$.

Definition 3 (Marking) A *marking* $M(k) = [p_1(k), p_2(k), \dots, p_m(k)]^T$ is an m -vector of nonnegative integer, where $p_i(k)$ is the number of tokens in place p_i immediately after firing the k th transition in a firing sequence. Especially, $M(0)$ denotes the initial marking; it is the same as M_0 .

Definition 4 (Incidence Matrix) B^- is an $m \times n$ matrix of input function, where the entry of row i column j is $B^-[i, j] = W(p_i, t_j)$; B^+ is an $m \times n$ matrix of output function, where the entry in row i column j is $B^+[i, j] = W(t_j, p_i)$. $B = B^+ - B^-$ is called *incidence matrix*.

Definition 5 (Transitive Matrix) Let L_P be *place transitive matrix*, and let L_V be *transition transitive matrix* with m rows and m columns, where $L_P = B^-(B^+)^T$

and $L_V = (B^+)^T B^-$. The *labeled place transitive matrix* L_{VP} is an $m \times m$ matrix satisfying $L_{VP} = B^- \text{diag}(t_1, t_2, \dots, t_n) (B^+)^T$, where the elements of L_{VP} describe the direct transferring relation from one place to another through one or more transitions.

Definition 6 (Weighted Place Transitive Matrix) The *Weighted place transitive matrix* is denoted as L_{VP}^* which is a transformation from L_{VP} : If a transition t_k appears s times in the same column of L_{VP} , then replace t_k in L_{VP} by t_k/s in L_{VP}^* ; otherwise the elements in L_{VP}^* are the same as L_{VP} .

Definition 7 (Path) For a Petri net $(N, M_0) = (P, T, F, M_0)$, a *path* $\sigma = x_1 x_2 \dots x_n$ is a sequence of places and transitions such that $(x_i, x_{i+1}) \in F$, $1 \leq i \leq n$; $\sigma = x_1 x_2 \dots x_n$ is said to be *elementary* if $\forall x_i, x_j \in \sigma, i \neq j \Rightarrow x_i \neq x_j$.

Definition 8 (Transition (Resp., Place) Path) For an elementary path $\sigma = x_1 x_2 \dots x_{2n}$ in a Petri net $N = (P, T, F, M_0)$, $\sigma' = x_1 x_3 \dots x_{2n-1}$ is said to be a *transition (resp., place) path* of σ if $x_i \in T$ (resp., $x_i \in P$), $i=1, 3, \dots, 2n-1$.

Definition 9 (Timed Petri Net) A *TPN* (N, M_0) is a Petri net with a time parameter. That is $N = (P, T, F, \tau)$, where P, T, F , and M_0 are the same as given in [Definition 1](#) and τ is a time function $\tau: T \rightarrow N$ (set of positive integers) associated to transitions such that for $t \in T$, $\tau(t)$ represents the time duration of firing t .

Definition 10 (State Machine, Augmented State Machine) A Petri net (PN) is said to be a *state machine* (SM) if and only if $\forall t \in T: |t| = |\dot{t}| = 1$. An *augmented state machine* (ASM) is a Petri net $(N, M_0) = (P \cup R, T, I, O, M_0)$ whose places consist of two disjoint subsets P and R such that the following conditions hold:

1. The net N obtained by removing all the resource places in R is a state machine.
2. Each resource place $r \in R$ is associated with k pairs of transitions (t_i, t_j) , $i, j = 1, 2, \dots, k$, where $r^\cdot = \{t_i | i = 1, 2, \dots, k\}$, $r^\cdot = \{t_j | j = 1, 2, \dots, k\}$.
3. Initially, the place in P without input transitions are marked by M_0 and other places are not marked.
4. $M_0(p) = 1, \forall p \in R$.

Definition 11 (Place Fusion) Consider two Petri nets $(N_1, M_{10}) = (P_1, T_1, F_1, M_{10})$ and $(N_2, M_{20}) = (P_2, T_2, F_2, M_{20})$, where $P_1 \cap P_2 = R \neq \emptyset$. Let $(N, M_0) = (P, T, F, M_0)$ be composed from (N_1, M_{10}) and (N_2, M_{20}) by operation *place fusion*. Then the elements in (N, M_0) are defined as follows: $P = P_1 \cup P_2$, $T = T_1 \cup T_2$, $F = F_1 \cup F_2$, and

$$M_0(p) = \begin{cases} M_{10}(p) & p \in P_1 \\ M_{20}(p) & p \in P_2 \\ \max\{M_{10}(p), M_{20}(p)\} & p \in R \end{cases}$$

Definition 12 (Place Invariant and Minimal Place Invariant) For a Petri net (N, M_0) , a place invariant is an m -vector $y \geq 0$ such that $B^T \cdot y = 0$, where B is $m \times n$ incidence matrix. It is represented by nonzero entries of vector $y \geq 0$, which is called the support of place invariant. Place invariant is said to be *minimal* if no proper subset of the support is also a support.

Definition 13 (Siphon and Minimal Siphon) A set of places $S \subseteq P$ is called a *siphon* if $\bullet S \subseteq S^\bullet$, and a siphon S is called *minimal* if there does not exist S' such that $S' \subset S$.

2.2 Petri Net Modeling of JSSP

In this subsection, JSSP is described, and its modeling through TPN is explained.

Problem Description. JSSP discussed in this chapter can be stated as follows:

- $J = \{J_1, J_2, \dots, J_n\}$ is a finite set of n jobs.
- $O = \{O_1, O_2, \dots, O_n\}$ is a set of operations for the jobs, and $O_i = \{O_{i1}, O_{i2}, \dots, O_{ik}\}$ is a chain of operations for job J_i , $1 \leq i \leq n$.
- $M = \{M_1, M_2, \dots, M_m\}$ is a finite set of m machines.
- Each machine can handle at most one operation at a time.
- $\{\tau_{i1}, \tau_{i2}, \dots, \tau_{ik}\}$ is the uninterrupted period of a given length for each operation processed in one or some given machines.
- The resources in JSSP may be workers, who are responsible for operating the machines, robots, or other equipments.
- The purpose of JSSP is to find a schedule, that is, a reasonable allocation of the operations to time intervals and machines or other resources such that the makespan is minimized.

In this chapter, TPN is used to model the JSSP, and there are two types of places, that is, *operation places* and *resource places*. First of all, take no account of resources in JSSP, the predefined sequence of operations in each job is formulated as the transition sequence $t_{i1} t_{i2} \dots t_{ik}$. Then add a set of places P to connect these transitions together, such that p_{i1} is the input place of t_{i1} and initially marked with one token. Generally, for each transition t_{ij} , its output place $p_{i(j+1)}$ is the input place of $t_{i(j+1)}$, $j = 1, 2, \dots, k$, and $i = 1, 2, \dots, n$. As a result, each job in the problem is modeled as n state machines with the unique path $p_{i1} t_{i1} p_{i2} t_{i2} \dots p_{ij} t_{ij} \dots p_{ik} t_{ik} p_{i(k+1)}$ ($i = 1, 2, \dots, n$), and each net has an initial marking M_{i0} and a final marking M_{if} .

Now, consider the set of resources R . Each resource here is denoted as a resource place r_i initially marked with a token. When an operation t_{ij} requires some resource r_i , the output of r_i is t_{ij} . Moreover, resources' release follows the "hold while waiting" property: Suppose the resource r_j is needed by operation t_{ij} of job J_i , after operation t_{ij} is finished, if the next operation $t_{i(j+1)}$ of job J_i also needs r_j ,

then r_j continue to be held by operation $t_{i(j+1)}$ of job J_i ; otherwise the resource r_j is released. After adding resource place, the model of each job is an ASM.

When some operations are ready to execute, there will be one token in the operation places, which is called *operation enabled*, and if the resources are available to use, there will be one token in the resource places, which is called *resource enabled*. A transition t_i can be fired only when its operation place and resource place are both enabled.

Property 1 Every ASM for an individual job is executable.

Proof Every ASM without resource places is a sequence of operations represented by the transitions in the form of a state machine. Such type of state machine is executable in sequence if the input place of first operation in sequence is marked by a token. Since marked resource places are added to the transitions in such a way that they become output and/or input places of transitions in the form of ASM, furthermore, resources are used exclusively and follow the “hold while waiting” property, every ASM is executable in sequence.

Property 2 For every ASM of an individual job, the final marking is reachable.

Proof The [Property 2](#) is the consequence of the [Property 1](#).

Property 3 For each $r \in R$, which is not on self-loop in the ASM of an individual job, there exists a minimal place invariant with only marked place $r \in R$.

Proof Each resource place, which is not on a self-loop, represents a resource utilized by the sequence of operations. Further, each such type of resource place is added to the sequence of transitions representing the chain of operations in such a way that it become input place for the first transition and output place for last transition in that sequence. Therefore, allocation of each resource place to the chain of operations is represented by the directed cycle with only marked place $r \in R$ representing the availability of a resource. Hence, allocation of resources imposes the existence of minimal place invariant for each $r \in R$ which is not on a self-loop.

Property 4 Every place invariant in the ASM of an individual job is a minimal siphon with only one marked place $r \in R$.

Proof From [Property 3](#), since place invariants in ASM are the only directed cycles, each place invariant stands for a minimal siphon with only marked place $r \in R$.

The cost of the implementation of operation is described as time function $\tau(t)$ in TPN for transition t . As described above, each job is modeled as an ASM. Since there are identical shared resources in each ASM, these ASM can be merged

together by applying place fusion operator, and a compositional net is built for modeling the whole JSSP. Thus, the scheduling purpose is to find a firing sequence in the resultant Petri net model from the initial marking M_0 to the final marking M_f and to get a minimum makespan. If there is no common resource in two jobs, the makespan is the maximal one of these two sub-models since the two jobs can be processed in parallel.

Property 5 The compositional net, obtained by merging the ASMs of individual jobs, is an ASM.

Proof Since the compositional net fulfills the conditions of ASM described in [Definition 10](#), which are given below:

1. The net N obtained by removing all the resource places in R is a state machine.
2. Each resource place $r \in R$ is associated with k pairs of transitions (t_i, t_j) , $i, j = 1, 2, \dots, k$, where $\dot{r} = \{t_i | i = 1, 2, \dots, k\}$, $\dot{r} = \{t_j | j = 1, 2, \dots, k\}$.

Therefore, the compositional net, which is obtained by merging the independent ASMs modeling different jobs to be completed in JSSP, is again an ASM.

Property 6 Every cycle in the compositional ASM is marked.

Proof R is the only set of marked places in ASM. From [Property 3](#), by removing every place $r \in R$, there will be no place invariant and consequently no directed cycle in ASM. Thus, every cycle in compositional ASM contains a place from R , which is marked.

Property 7 For a compositional ASM, for every $r \in R$, there exists a minimal siphon which contains only one marked place r .

Proof According to [Property 6](#), every cycle contains a place from R . From [Property 4](#), every minimal siphon in ASM contains a cycle. Therefore, every siphon in the compositional ASM, which contains at least one minimal siphon, is marked with $r \in R$.

[Figure 1](#) is an example of two jobs of JSSP sharing two machines. Each job contains two operations which are associated with time functions $\tau(t_1), \tau(t_2), \tau(t_3)$, and $\tau(t_4)$ respectively. The operations t_1, t_2 in Job1 are both processed on machine r_1 , and operations t_3, t_4 in Job2 are processed on machines r_1 and r_2 , respectively. The original states of Job1 and Job2 are $M_{10} = (1, 0, 0, 1)^T$ and $M_{20} = (1, 0, 0, 1, 1)^T$, respectively, and the final states are $M_{1f} = (0, 0, 1, 1)^T$ and $M_{2f} = (0, 0, 1, 1, 1)^T$, respectively. Since machine r_1 is occupied by both jobs, these two sub-models are merged together by place fusion, and the resultant Petri net model is shown in [Fig. 2](#). Then the scheduling problem is to find a firing sequence in the resultant Petri net,

Fig. 1 Timed Petri net models for two jobs of JSSP

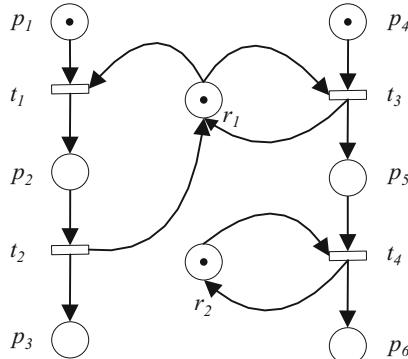

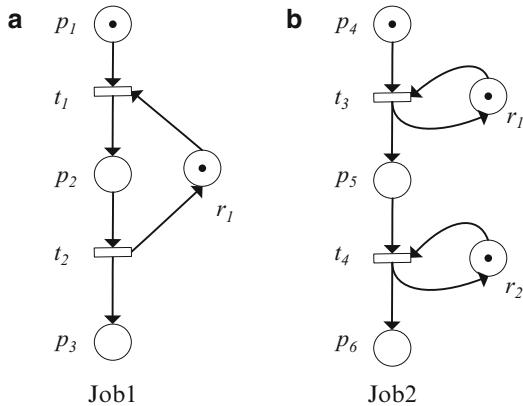

Fig. 2 The merging model of JSSP

from the initial marking $M_0 = (1, 0, 0, 1, 0, 0, 1, 1)^T$ to the final marking $M_f = (0, 0, 1, 0, 0, 1, 1, 1)^T$ such that the makespan is minimized.

2.3 Deadlock-Free Design for JSSP with Multi-resources Sharing

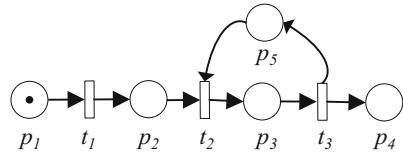

Deadlock is an unexpected state. In a multi-resource-sharing system, deadlock may occur when the resources are limited or distributed unreasonably. In this section, an algorithm is presented to detect deadlock and describe a method to recover deadlock for multi-resource-sharing systems.

2.3.1 Basics of Deadlock

• Dead Marking

In JSSP model, a marking M is said to be a *dead marking* if M is not the final marking M_f , and there is no transition which can be fired at this marking M . Formally, the dead marking can be expressed as $\forall M \in R(N, M_0)$, if $M \neq M_f$ and $\forall t \in T : \neg M[t >]$, then M is a *dead marking*.

Fig. 3 An example to illustrate dead transition

- *Dead Transition*

In JSSP model, a transition t is said to be a *dead transition* if t is operation enabled but not resource enabled. In this chapter, dead transition always appears in the post-set of the operation place with tokens in dead marking.

[Figure 3](#) illustrates the dead transition in a Petri net model. The initial marking is $M_0 = (1, 0, 0, 0, 0)^T$ and the final marking is $M_f = (0, 0, 0, 1, 0)^T$. In this model, after t_1 fires, the marking $M_1 = (0, 1, 0, 0, 0)^T \neq M_f$. Since there are no tokens in p_5 , t_2 cannot be fired and there is no reachable marking for M_1 . Then marking M_1 is a dead marking and transition t_2 is a dead transition.

- *Circular Waiting*

In manufacturing system, “*circular waiting*” is the state that for two or more tasks, each of them holds a machine, but all of them are waiting for each other to release the machine. In this chapter, the state of two tasks is considered. It is one of the inducements of deadlock in manufacturing system.

In Petri net, “*circular waiting*” can be demonstrated as follows: for Petri nets N_i ($i = 1, 2$), r_1 and r_2 are resource places in N_i , and $t_{ia} t_{ib} t_{ic} t_{id}$ ($i = 1, 2$) is a transition path associated with resource place. In N_1 , r_1 is associated with the pairs of transitions (t_{1a}, t_{1c}) , and r_2 is associated with the pairs of transitions (t_{1b}, t_{1d}) ; in addition, $\dot{r}_1 = t_{1a}$, $\dot{r}_1 = t_{1c}$ and $\dot{r}_2 = t_{1b}$, $\dot{r}_2 = t_{1d}$. in N_2 , r_1 is associated with the pairs of transitions (t_{2a}, t_{2c}) , and r_2 is associated with the pairs of transitions (t_{2b}, t_{2d}) ; in addition, $\dot{r}_1 = t_{2b}$, $\dot{r}_1 = t_{2d}$ and $\dot{r}_2 = t_{2a}$, $\dot{r}_2 = t_{2c}$.

[Figure 4](#) is a model of “*circular waiting*” which satisfies $\dot{r}_1 = \{t_{1a}, t_{2b}\}$, $\dot{r}_1 = \{t_{1c}, t_{2d}\}$ and $\dot{r}_2 = \{t_{1b}, t_{2a}\}$, $\dot{r}_2 = \{t_{1d}, t_{2c}\}$.

- *Deadlock*

Based on the place fusion in JSSP, *deadlock* occurs when there are dead transitions that cause “*circular waiting*” in the system.

- *Deadlock-Free*

A Petri net system is said to be *deadlock-free* if there is at least one firing sequence from the initial marking M_0 to the final marking M_f ; otherwise it is said that the system contains *deadlock*.

- *Marking Transformation*

The *transformation of marking* is defined as $M_R(k+1)^T = M(k)^T L_{VP}^*$, where $M_R(k+1)$ is an m -vector of nonnegative integer and is a marking calculated from reachable marking $M(k) = [p_1(k), p_2(k), \dots, p_m(k)]^T$ and L_{VP}^* is the weighted place transitive matrix ([Definition 6](#)) [13].

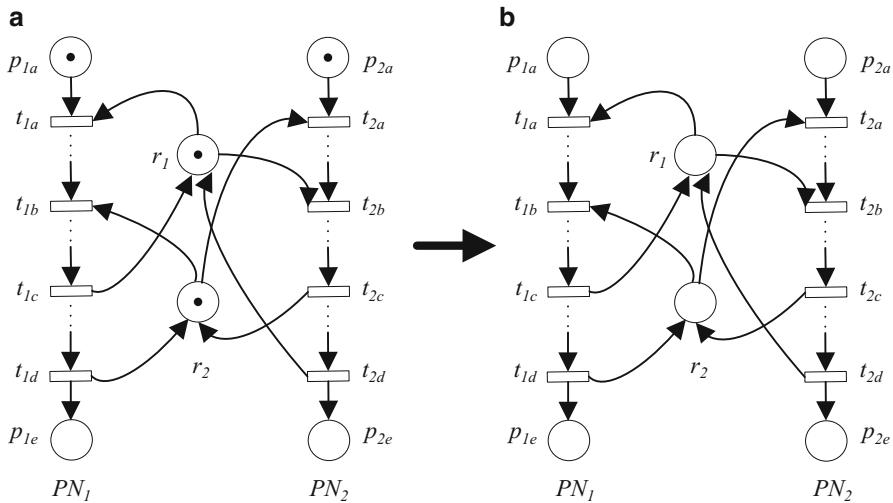

Fig. 4 Circular waiting

The transformation equation shows the flow relation of a token in $p_i(k)$ from $M(k)$ to $M_R(k+1)$ by the weighted place transitive matrix. In this equation, if the coefficient of t_i in the function $\sum_i p_i L_{VP_{ij}}^*$ is an integer, then let $\sum_i p_i L_{VP_{ij}}^* = 1$, which means tokens in $p_i(k)$ can be transferred from $M(k)$ to $M_R(k+1)$; otherwise, let $\sum_i p_i L_{VP_{ij}}^* = 0$, which means tokens in $p_i(k)$ cannot be transferred from $M(k)$ to $M_R(k+1)$.

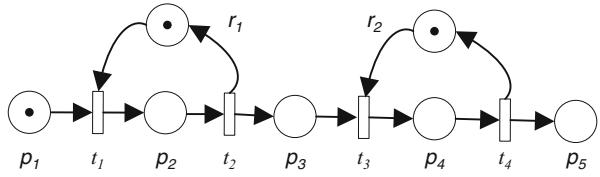

However, $M_R(k+1)$ only presents the flow relation of tokens; it may not correspond to a reachable marking $M(k+1)$. In order to improve this situation, some constrained conditions are added to this equation:

Condition (1) When the coefficient of t_i in the function $\sum_i p_i L_{VP_{ij}}^*$ is an integer, for example, $\sum_i p_i L_{VP_{ij}}^* = 1$ in $M_R(k+1)$, and the tokens in these places appearing in this function are consumed, then these tokens can be transferred from $M(k)$ to $M(k+1)$.

Condition (2) When the coefficient of t_i in the function $\sum_i p_i L_{VP_{ij}}^*$ is not an integer and the tokens in the corresponding places of this entry are not previously consumed, then the tokens in these places are preserved; otherwise let $\sum_i p_i L_{VP_{ij}}^* = 0$ in $M(k+1)$.

From this calculation, a series of reachable marking can be found from M_0 . In addition, if there is no marking reachable from M_i , then there are dead transitions at M_i . Thus, the system contains deadlock. [Figure 5](#) is an

Fig. 5 An example to explain these conditions

example to illustrate these conditions. The initial marking of Fig. 5 is $M_0 = (1, 0, 0, 0, 0, 1, 1)^T$, and the weighted place transitive matrix is $L_{VP}^* =$

$$\begin{array}{l} p_1 \\ p_2 \\ p_3 \\ p_4 \\ p_5 \\ r_1 \\ r_2 \end{array} \left[\begin{array}{cccccc} 0 & t_1/2 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & t_2 & 0 & 0 & t_2 & 0 \\ 0 & 0 & 0 & t_3/2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & t_4 & 0 & t_4 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & t_1/2 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & t_3/2 & 0 & 0 & 0 \end{array} \right].$$

$$M_R(k+1)^T = M(k)^T L_{VP}^* = [0, t_1(p_1(k) + r_1(k))/2, t_2(p_2(k)), t_3(p_3(k) + r_2(k))/2, t_4(p_4(k)), t_2(p_2(k)), t_4(p_4(k))]^T.$$

Since $p_1(0) = 1$, $r_1(0) = 1$ and $r_2(0) = 1$ in the initial marking M_0 , $M_R(1) = M(0)L_{VP}^* = M_0L_{VP}^* = [0, t_1(1+1)/2, t_2*0, t_3(0+1)/2, t_4*0, t_2*0, t_4*0]^T = [0, t_1, 0, t_3/2, 0, 0, 0]^T$.

The second element in $M_R(1)$ is t_1 and the coefficient of t_1 is an integer; at the same time, the tokens in $p_1(0)$ and $r_1(0)$ are consumed, and by Condition (1), the corresponding value in reachable marking M_2 is 1. On the other side, the coefficient of t_3 is 1/2 and the corresponding place is $r_2(0)$ whose tokens are not consumed previously; by Condition (2), the tokens in $r_2(0)$ are preserved. Consequently, the reachable marking of M_0 is $M_1 = (0, 1, 0, 0, 0, 0, 1)^T$. Based on the two constraints, a reachable marking can be obtained by calculating the transformation of marking.

2.3.2 Deadlock Detection

In this subsection, the transformation equation is applied to identify the dead transitions in two Petri nets. Based on the dead transition and the conditions of “circular waiting,” a deadlock detection algorithm is proposed to find out whether there is deadlock or not in the compositional system.

2.3.3 Deadlock Recovery

When there is a deadlock in the net, the system falls into the local deadlock state and even stops running. Therefore, deadlock recovery is important for system design. In this subsection, an efficient method is presented to recover a deadlock for the composition of two Petri nets.

Since the deadlock is caused by “circular waiting” and by removing it, deadlock can be removed. In the following, the recovery method is proposed based on the definition of “circular waiting” and “self-loop” in Petri net.

Algorithm 1: Deadlock detection

Input: $N_1 = (P_1, T_1, F_1, M_{10}, \tau_1)$, $N_2 = (P_2, T_2, F_2, M_{20}, \tau_2)$ (where $P_1 \cap P_2 = R = \{r_1, r_2\}$), the initial marking M_{10} , M_{20} , and the final marking M_{1f} , M_{2f}

Output: Deadlock or deadlock-free

- Step 1: Do place fusion on N_1 and N_2 , and then generate a net N with the initial marking M_0 and the final marking M_f .
- Step 2: Construct the weighted place transitive matrix- L_{VP}^* for compositional net N .
- Step 3: For $k = 0, k < n, k++$:
 - Calculate the next marking $M_R(k+1)$ from the marking $M(k)$ by $M_R(k+1)^T = M(k)^T L_{VP}^*$.
 - If $M_R(k+1) = M_f$, stop and output “there is no deadlock in the net.”
 - Else if there are dead transitions in the net and they form a “circular waiting,” then output “there is a deadlock.”
 - Else output is “there is flaw in the system model.”

Algorithm 2: Deadlock recovery

Input: Dead transitions which cause deadlock (suppose they are t_{1b} and $t_{1b'}$)

Output: A deadlock-free model

- Step 1: Compare #($t_{10}t_{11} \dots t_{1(a-1)}$) and #($t_{20}t_{21} \dots t_{2(a-1)}$), and find out the larger quantity, without loss of generality, suppose it is #($t_{10}t_{11} \dots t_{1(a-1)}$).
 - Step 2: Add two new arcs ($t_{1(b-1)}, r_1$) and (r_1, t_{1b}) into the model, and then the pair (t_{1a}, t_{1c}) is decomposed as ($t_{1a}, t_{1(b-1)}$) and (t_{1b}, t_{1c}) which are both associated with r_1 .
 - Step 3: Detect deadlock by [Algorithm 1](#).
- If output is “there is a deadlock,” do the recovery again by repeating Steps 1 and 2.
Else, output is “there is no deadlock in the net.”

Let N_1 and N_2 be two Petri net sub-models, with two kinds of common resource places r_1 and r_2 . They satisfy the “circular waiting” conditions mentioned in [Sect. 2.3.1](#). Suppose $\sigma_i = t_{i0} t_{i1} \dots t_{im}$ is a transition path in N_i , $\sigma'_i = t_{ia} t_{ib} t_{ic} t_{id}$ is a sub-path of σ_i ($i = \{1, 2\}$), and #($t_{i0} t_{i1} \dots t_{i(a-1)}$) is the makespan of $t_{i0} t_{i1} \dots t_{i(a-1)}$.

After the recovery given above, the subsystem becomes deadlock-free. The method proposed above only changes the input and output of one resource place in one Petri net sub-model. If the complexity of the model is not considered, the similar change is done in the second Petri net sub-model. After this change, the Petri net model can be live and the makespan can also be minimized.

2.3.4 Deadlock-Free Design

Based on the algorithms given above, a compositional deadlock-free model for a multitasking JSSP can be constructed. The detailed process is as shown in [Algorithm 3](#).

Algorithm 3: Deadlock-free design**Input:** n Petri nets**Output:** A compositional deadlock-free model for these n Petri nets

- Step 1: For each pair of Petri nets which have common resource places, run [Algorithm 1](#) to detect deadlock.
- Step 2: If there is a deadlock in any two Petri nets, run [Algorithm 2](#) to recover deadlock, and go to Step 3. Else, if all of these pairs are deadlock-free, go to Step 3.
- Step 3: Merge these n nets together by place fusion to get a deadlock-free model for this JSSP.

2.4 A Case Study

A JSSP example with four jobs and two kinds of resources (e.g., machines and a worker) is shown in [Table 1](#). J_1, J_2, J_3 , and J_4 are four jobs; O_1, O_2, O_3 , and O_4 are operations of each job; M_1 , and M_3 are machines and M_2 is the worker; and the integers following M_i represent the processing time of each operation. The second and the third operations of each job need both machine and worker to process, but the first and the fourth operations of each job need only one resource. In order to obtain a schedule, this problem is illustrated step by step:

Step 1: Construct the model for this JSSP:

- According to [Sect. 2.3](#), the Petri nets (ASMs) for four jobs are depicted in [Fig. 6](#), and $t_{i1}, t_{i2}, t_{i3}, t_{i4}$ are corresponding to the four operations in job i ($i = \{1, 2, 3, 4\}$); r_1, r_2 , and r_3 are corresponding to three resources.
- When there are more than two shared resources in two jobs, deadlock may occur. Therefore, after the system model is built, deadlock detection should be done to make sure the system is deadlock-free. Deadlock detection is performed for each compositional ASM obtained by merging the pair of ASMs of individual jobs. Since there are four Petri nets (ASMs for individual jobs), totally there are six detections.

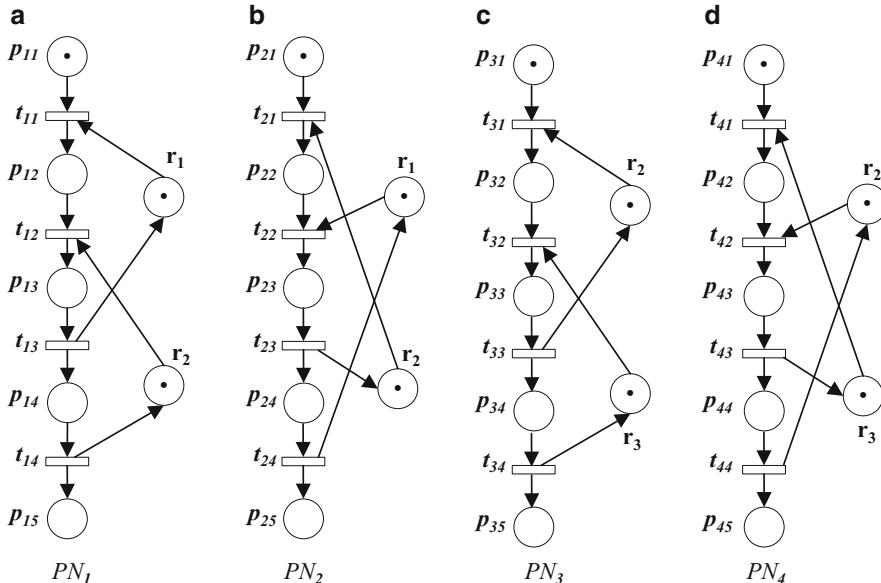

Step 2: Choose two Petri nets with shared resources and detect deadlock; if there exists a deadlock, recover it:

- Consider Petri nets N_1 and N_2 . [Figure 7](#) is the compositional system for N_1 and N_2 . In the model N_{12} , $M(k) = [p_{11}(k), p_{12}(k), p_{13}(k), p_{14}(k), p_{15}(k), p_{21}(k), p_{22}(k), p_{23}(k), p_{24}(k), p_{25}(k), r_1(k), r_2(k)]^T$, the initial marking $M(0) = M_0 = (1, 0, 0, 0, 0, 1, 0, 0, 0, 0, 1, 1)^T$ and the final marking $M_f = (0, 0, 0, 0, 1, 0, 0, 0, 0, 1, 1, 1)^T$.
- Construct the weighted place transitive matrix- L_{VP}^* for [Fig. 7](#): [Table 2](#) is the weighted place transitive matrix, $M(k) = [p_{11}(k), p_{12}(k), p_{13}(k), p_{14}(k), p_{15}(k), p_{21}(k), p_{22}(k), p_{23}(k), p_{24}(k), p_{25}(k), r_1(k), r_2(k)]^T$, and the initial marking is $M_0 = (1, 0, 0, 0, 0, 0, 1, 0, 0, 0, 0, 1, 1)^T$.
- Calculate the reachable marking by $M_R(k+1)^T = M(k)^T L_{VP}^*$, and get the next reachable marking:

$$M_R(k+1)^T = M(k)^T L_{VP}^* = [0, t_{11}(p_{11}(k)+r_1(k))/2, t_{12}(p_{12}(k)+r_2(k))/2, t_{13}(p_{13}(k)+r_3(k))/2, t_{14}(p_{14}(k)+r_3(k))/2, t_{15}(p_{15}(k))/2, t_{21}(p_{21}(k)+r_2(k))/2, t_{22}(p_{22}(k)+r_1(k))/2, t_{23}(p_{23}(k))/2, t_{24}(p_{24}(k))/2, t_{25}(p_{25}(k))/2, r_1(k)t_{21}, r_2(k)t_{22}, r_3(k)t_{23}]^T.$$

Table 1 A job shop scheduling problem

	J_1	J_2	J_3	J_4
O_1	$M_1: 7$	$M_2: 3$	$M_2: 5$	$M_3: 6$
O_2	$M_1, M_2: 4$	$M_1, M_2: 5$	$M_2, M_3: 3$	$M_3, M_2: 4$
O_3	$M_1, M_2: 3$	$M_1, M_2: 4$	$M_2, M_3: 5$	$M_3, M_2: 5$
O_4	$M_2: 4$	$M_1: 3$	$M_3: 4$	$M_2: 3$

**Fig. 6** The Petri net models of the JSSP

$M_R(1) = M(0)L_{VP}^* = [0, t_{11}(p_{11}(k) + r_1(k))/2, t_{12} r_2(k)/2, 0, 0, 0, t_{21}(p_{21}(k) + r_2(k))/2, t_{22} r_1(k)/2, 0, 0, 0, 0]^T$, based on the two conditions presented in Sect. 2.3.1, $M(1) = [0, 1, 0, 0, 0, 0, 1, 0, 0, 0, 0, 0]^T$.

- Analyze if there exists a deadlock or not: in $M(2)$, transitions t_{12} and t_{22} are dead transitions. Since r_1 and r_2 are associated with transitions t_{12} and t_{22} , which involve in “circular waiting”, the system is confronted a deadlock.
- Recover the deadlock for N_1 and N_2 :
 - Since ($\# t_{11} = 7$) is greater than ($\# t_{21} = 3$), then the first sub-model should be modified.
 - Add two arcs t_{11}, r_1 and (r_1, t_{12}) , and then (t_{11}, t_{11}) and (t_{12}, t_{13}) are the new transition pairs associated with resource r_1 (Fig. 8 is the model after deadlock recovery).
 - Detect deadlock again; since there is no deadlock, stop.

Fig. 7 The model after place fusion

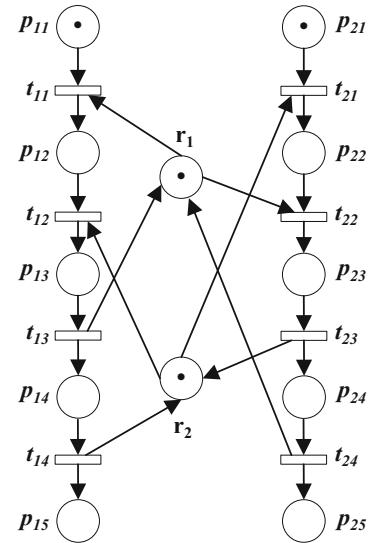

Table 2 Place transitive matrix of Petri net in Fig. 7

$$L_{VP}^* = \begin{bmatrix} p_{11} & 0 & t_{11}/2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ p_{12} & 0 & 0 & t_{12}/2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ p_{13} & 0 & 0 & 0 & t_{13} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & t_{13} \\ p_{14} & 0 & 0 & 0 & 0 & t_{14} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & t_{14} \\ p_{15} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ p_{21} & 0 & 0 & 0 & 0 & 0 & 0 & t_{21}/2 & 0 & 0 & 0 & 0 & 0 & 0 \\ p_{22} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & t_{22}/2 & 0 & 0 & 0 & 0 & 0 \\ p_{23} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & t_{23} & 0 & 0 & 0 & t_{23} \\ p_{24} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & t_{24} & t_{24} & 0 & 0 \\ p_{25} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ r_1 & 0 & t_{11}/2 & 0 & 0 & 0 & 0 & 0 & t_{22}/2 & 0 & 0 & 0 & 0 & 0 \\ r_2 & 0 & 0 & t_{12}/2 & 0 & 0 & 0 & t_{21}/2 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

Step 3: Choose other pairs of Petri nets and do the same work like Step 2:

- The Petri net pairs are (N_1, N_3) , (N_1, N_4) , (N_2, N_3) , (N_2, N_4) , and (N_3, N_4) .
- For the pairs (N_1, N_3) , (N_1, N_4) , (N_2, N_3) , and (N_2, N_4) , there is no deadlock in each of them. However, there is deadlock in integrating N_3 and N_4 .
- Through analyzing the transformation equation $M_R(k+1)^T = M(k)^T L_{VP}^*$, the dead transitions t_{32} and t_{42} are found, which cause deadlock.
- Recover deadlock on transition t_{32} and t_{42} , and the resultant model is similar to Fig. 8.

Fig. 8 The recovery model for N_1 and N_2

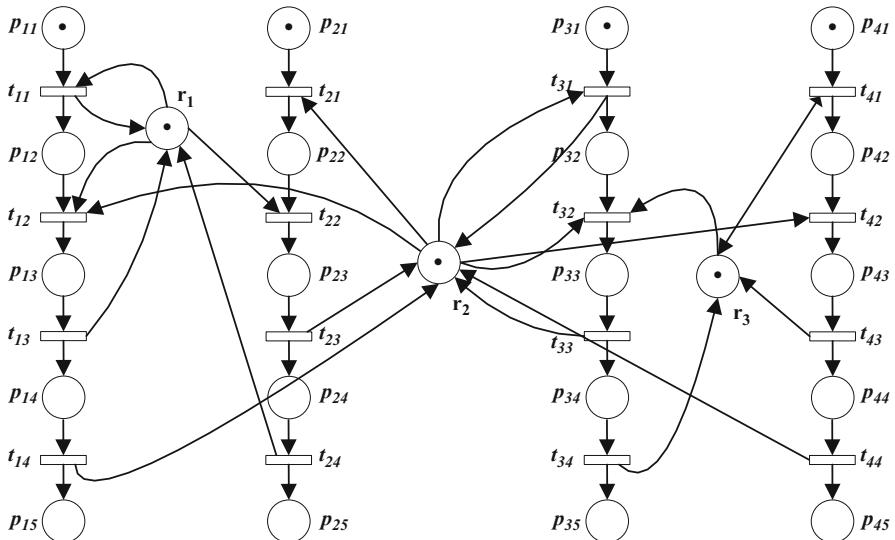

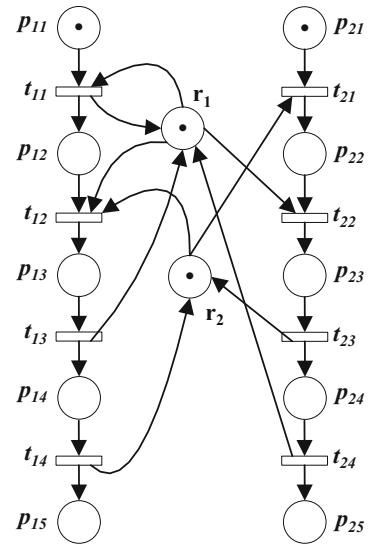

Fig. 9 The deadlock-free model of the given JSSP

Step 4: Deadlock-free design for JSSP

After deadlock detection and recovery, there is no deadlock in each two sub-models. By [Algorithm 3](#), do place fusion on these four Petri nets and a deadlock-free model is obtained ([Fig. 9](#)).

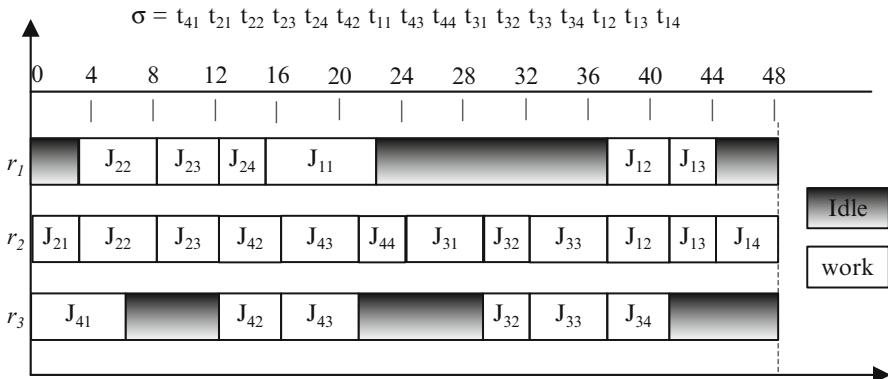

Fig. 10 The Gantt chart of the given JSSP

Step 5: Scheduling solution

Since it is deadlock-free, a scheduling solution for this JSSP can be obtained. Here CPN Tool [30] is applied to simulate the resolutions and choose a best one. The minimum makespan in the report is 48, and one optimal schedule is given in Fig. 10.

3 Modular-Based JSSP Design and Makespan Calculation

In this section, several operators for the design specification of JSSP are presented. For each operator, the property about the makespan calculation is also provided. Based on these operators and properties, a larger and more complex module, even for the whole system, can be deduced from the smaller ones step by step, and the schedule of larger modules can also be calculated.

As a component of a variety of methodologies developed to generate JSSP schedules, Petri net is very powerful for modeling the concurrent processing, resource sharing, routing flexibility, sequential steps, concurrent use of multiple resources, machine setup times, job batch sizes, and so on in JSSP [31–34]. As for schedule optimization, there are two types of Petri net-based methodologies for JSSP: (1) heuristic searching algorithms based on reachability graph of Petri net models [35–37] and (2) GA algorithms for optimizing scheduling [38–40]. Petri nets are attracting the attention of many researchers for the design of JSSP and the optimization of the scheduling of the system [41–43].

However, current Petri net-based methodologies have the following shortages: (1) the Petri net models are put forward by researchers for solving their specified problems. Therefore, the effect of Petri nets cannot be explored efficiently. Although it is good for obtaining better optimization results, they cannot be applied for general problems. (2) the real-time JSSP is usually quite complex and large; consequently,

the size of the Petri net model will be quite large. The current Petri net analysis methods are not applicable because of the state exploding problem of Petri nets.

In order to overcome the hardship mentioned, this chapter handles JSSP problem from two aspects: system design and scheduling optimization. On system design aspect, this chapter applies a modular-based approach for JSSP design specification and verification. The basic module model is an extended Petri net process (EPNP) similar to the Petri net process (PNP) discussed in [2–4]. The difference is that EPNP is an extended Petri net while PNP is a general Petri net. Hence, all the results on property-preserving Petri net process algebra (PPPA) [3–6] will also be true for the JSSP design in this chapter. With modular-based approach, the JSSP is correct from the viewpoint that the system contains some desired properties such as liveness, boundedness, reversibility, and proper termination.

As for system scheduling optimization, based on EPNP, this chapter provides some information on finding the possible schedule (the firing sequences of the Petri net model) and makespan of the composite modules from the constituent modules for the integration operators in PPPA. In order to handle resource-sharing problem, the place-merging operator and the integration operators are combined for system modeling. The firing sequences and the upper bound of the makespan for these combined operators are concluded. The algorithm for finding the makespan and its corresponding scheduling is also presented for the combined operators. With the modular-based method for system design and scheduling optimization, the schedule and makespan of the composite modules can be calculated based on their constituent modules. In order to reduce the calculation time, traditional algorithms such as GAs and branch-and-bound methods can be applied together with the algorithms presented in this chapter for optimizing the schedule of JSSP. For completeness, a GA algorithm based on Petri net model will be introduced in Sect. 4.

The readers are supposed to have some Petri net-related foundations. Most of the terminologies can be found in [3, 4, 45]. The results in this section are mainly derived from [44].

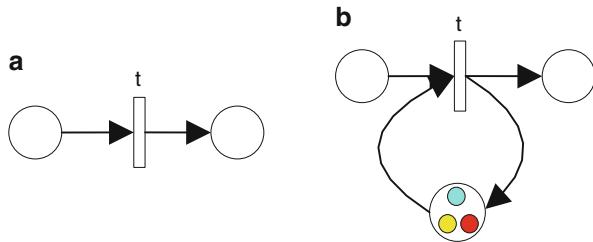

3.1 Operators and Makespan Optimization

Definition 14 An EPNP $B = (N, p_e, p_x)$, where $N = (P, T, F, M_c, C, W, D)$ is a colored TPN (called extended Petri net), p_e is the entry place, and p_x is the exit place of EPNP.

The performance and characteristics, for example, proper initialization, proper termination, and handling resource sharing, of EPNP similar to PNP defined in [3, 4]; the difference is that in EPNP, N is an extended Petri net, while in PNP, N is a general Petri net. Hence, all the theoretical results in [3–6] are also true for EPNP and can be applied to design a correct job shop scheduling system.

Note that since the design specification and verification are similar to [2–4], this chapter will pay much more attention to the design specification and optimization of JSSP.

Fig. 11 The extended Petri net model for operations in JSSP

In job shop scheduling systems, operations either do not need any resources or need resources such as machines, robots, and workers. Hence, the corresponding models for the operations in a JSSP have two different forms.

For the first case, a transition t represents an operation; t has a single input place representing the beginning of the operation and a single output place representing the end of the operation (Fig. 11a). For the second case, one more place representing the resources should be associated to t and a self-loop is formed. Initially, there are some tokens assigned to the resource place. Tokens with different colors are used to represent different resources (Fig. 11b).

Based on the relationship of the operations and the control flow of JSSP, some operators are defined to combine these operations in JSSP.

In this chapter, the basic model is the EPNP. Although EPNP and the general PNP [3, 4] have different structural and behavioral properties and firing rules, the pictorial representation of these operators will be the same as that in [3]. Hence, in this chapter, the same definition and the same pictorial representation as that in Mak's thesis [3] and Huang's thesis [4] are used for the definition of all the operators, that is, action prefix, iteration, enable, choice, interleave, parallel, disable, disable-resume, place merging, and the mix operators.

In the following definition, notation $B = (N, p_e, p_x)$ (resp., $B_i = (N_i, p_{ie}, p_{ix})$) represents an EPNP, where $N = (P, T, F, M_c, C, W, D)$ (resp., $N_i = (P_i, T_i, F_i, M_{ic}, C_i, W_i, D_i)$) is an extended Petri net with an initial static marking M_c , p_e , and p_x (resp., M_{ic} , p_{ie} , and p_{ix}) are the entry and exit places of the process, respectively. The initial marking of B (resp., B_i) is $M_e = p_e + M_c$ (resp., $M_{ie} = p_{ie} + M_{ic}$), and the exit marking of B (resp., B_i) is $M_x = p_x + M_c$ (resp., $M_{ix} = p_{ix} + M_{ic}$).

For each operator defined in this chapter, the firing sequence and the potential partial schedule in the composite process will be concluded based on the possible firing sequences of the constituent processes. These conclusions will be presented as properties. Since the results are trivial, the details of the proof will be omitted. The conclusions can be used to find the optimal scheduling solutions. Some property-preserving results can also be obtained for these operators. Since most property-preserving results can refer to the related results in [3, 4], the behavioral property-preserving results will be omitted in this chapter. While the property-preserving results can be used to specify and verify the JSSP, the work

related to the application of property-preserving technology for system specification and verification can be found in [2, 4].

In JSSP, before processing some operations, a preparation work is usually needed. For example, after a batch of pieces has finished processing, the machine may need repairing before handling the next batch of pieces. In the system modeling, the following formally defined *action prefix* operator is used to combine the preparation action and the operation process. It is a special case of operator *enable* which will be introduced later.

Definition 15 (Action prefix) For a process $B = (N, p_e, p_x)$ and a transition $b \notin T$ representing an action, the operator *action prefix* applied to B , in notation $b; B$, is defined as the process $B' = (N', p_{e'}, p_{x'})$, where $p_{e'}$ is the new entry place, $p_{x'} = p_x$, $P' = P \cup \{p_{e'}\}$, $T' = T \cup \{b\}$, $F' = F \cup \{(p_{e'}, b), (b, p_e)\}$, $M_c' = M_c$, $C' = C$, $W' = W \cup \{w(p_{e'}, b), w(b, p_e)\}$, $D' = D \cup \{d(b)\}$.

Property 8 Suppose $(B', M_{e'})$ is induced from (B, M_e) by applying the operator action prefix. If $M_e[\sigma > M_x]$ in (B, M_e) , then $M_{e'}[b\sigma > M_{x'}]$ in $(B', M_{e'})$. If σ has the minimum makespan in (B, M_e) , then $b\sigma$ has the minimum makespan in $(B', M_{e'})$.

Definition 16 (Iteration) For a process $B = (N, p_e, p_x)$, an operator *iteration* applied to B , in notation B' , is defined as the process $B' = (N', p_{e'}, p_{x'})$, where $P' = P \cup \{p_{e'}, p_{x'}\}$; $T' = T \cup \{\varepsilon_1, \varepsilon_2, \varepsilon_3\}$; $F' = F \cup \{(p_{e'}, \varepsilon_1), (\varepsilon_1, p_e), (\varepsilon_2, p_e), (p_x, \varepsilon_2), (p_x, \varepsilon_3), (\varepsilon_3, p_{x'})\}$, $M_c' = M_c$, $C' = C$, $W' = W \cup \{w(p_{e'}, \varepsilon_1), w(\varepsilon_1, p_e), w(\varepsilon_2, p_e), w(p_x, \varepsilon_2), w(p_x, \varepsilon_3), w(\varepsilon_3, p_{x'})\}$, $D' = D \cup \{d(\varepsilon_1), d(\varepsilon_2), d(\varepsilon_3)\}$.

Iteration modifies a process in such a way that it can be executed repetitively while preserving the option of exiting after any iteration. For example, in JSSP, iteration operator can be used to model the case of processing a batch of pieces in a machine.

Property 9 Suppose $(B', M_{e'})$ is induced from (B, M_e) by applying iteration operator. If $M_e[\sigma > M_x]$ in (B, M_e) , then $M_{e'}[\varepsilon_1 \sigma \varepsilon_2 \sigma \varepsilon_3 \dots \sigma \varepsilon_2 \sigma \varepsilon_3 > M_{x'}]$ in $(B', M_{e'})$. If σ has the minimum makespan in (B, M_e) , then $\varepsilon_1 \sigma \varepsilon_3$ has the minimum makespan in $(B', M_{e'})$.

Definition 17 (Enable) For two processes $B_i = (N_i, p_{ie}, p_{ix})$, $i = 1, 2$, their composition by *enable*, in notation $B_1 \gg B_2$, is defined as the process $B = (N, p_e, p_x)$, where $P = P_1 \cup P_2$, with $p_e = p_{1e}$ and $p_x = p_{2x}$; $T = T_1 \cup T_2 \cup \{\varepsilon\}$; $F = F_1 \cup F_2 \cup \{(p_{1x}, \varepsilon), (\varepsilon, p_{2e})\}$, $M_c = M_{1c} \cup M_{2c}$, $C = C_1 \cup C_2$, $W = W_1 \cup W_2 \cup \{w(p_{1x}, \varepsilon), w(\varepsilon, p_{2e})\}$, $D = D_1 \cup D_2 \cup \{d(\varepsilon)\}$.

Enable $B_1 \gg B_2$ models the execution of two processes B_1 and B_2 in sequence. That is, B_1 is firstly executed and B_2 is executed after the successful termination of B_1 . However, if B_1 does not exit successfully, B_2 will never be activated.

Property 10 Suppose (B, M_e) is induced from (B_1, M_{1e}) and (B_2, M_{2e}) by applying the operator enable. If $M_{1e}[\sigma_1 > M_{1x}]$ in (B_1, M_{1e}) and $M_{2e}[\sigma_2 > M_{2x}]$ in (B_2, M_{2e}) , then $M_e[\sigma_1 \circ \sigma_2 > M_x]$ in (B, M_e) . If σ_1 has the minimum makespan in (B_1, M_{1e}) and σ_2 has the minimum makespan in (B_2, M_{2e}) , then $\sigma_1 \circ \sigma_2$ has the minimum makespan in (B, M_e) .

Definition 18 (Choice) For two processes $B_i = (N_i, p_{ie}, p_{ix})$, $i = 1, 2$, their composition by *choice*, in notation $B_1 [] B_2$, is defined as the process $B = (N, p_e, p_x)$, where $P = (P_1 \cup P_2 - \{p_{1x}, p_{2x}\}) \cup \{p_e, p_x\}$, where p_x is the place merging p_{1x} and p_{2x} ; $T = T_1 \cup T_2 \cup \{\varepsilon_1, \varepsilon_2\}$; $F = F_1' \cup F_2' \cup \{(p_e, \varepsilon_1), (p_e, \varepsilon_2), (\varepsilon_1, p_{1e}), (\varepsilon_2, p_{2e})\}$, where $F'_i = F_i - \{(t, p_{ix}) | t \in {}^* p_{ix}\} \cup \{(t, p_x) | t \in {}^* p_{ix}\}$, $i = 1, 2$, $M_c = M_{1c} \cup M_{2c}$, $C = C_1 \cup C_2$, $W = W_1(F'_1) \cup W_2(F'_2) \cup \{w(p_e, \varepsilon_1), w(p_e, \varepsilon_2), w(\varepsilon_1, p_{1e}), w(\varepsilon_2, p_{2e})\}$, $D = D_1 \cup D_2 \cup \{d(\varepsilon_1), d(\varepsilon_2)\}$.

Choice $B_1 [] B_2$ models the selection for execution between two processes B_1 and B_2 .

Property 11 Suppose (B, M_e) is induced from (B_1, M_{1e}) and (B_2, M_{2e}) by applying the operator choice. If $M_{1e}[\sigma_1 > M_{1x}]$ in (B_1, M_{1e}) or $M_{2e}[\sigma_2 > M_{2x}]$ in (B_2, M_{2e}) , then $M_e[\varepsilon_1 \sigma_1 > M_x]$ and $M_e[\varepsilon_2 \sigma_2 > M_x]$ in (B, M_e) . If σ_1 has the minimum makespan in (B_1, M_{1e}) and σ_2 has the minimum makespan in (B_2, M_{2e}) , then the firing sequence with the minimum makespan in (B, M_e) is $\min\{\varepsilon_1 \sigma_1, \varepsilon_2 \sigma_2\}$.

Definition 19 (Interleave) For two processes $B_i = (N_i, p_{ie}, p_{ix})$, $i = 1, 2$, their composition by *interleave*, in notation $B_1 ||| B_2$, is defined as the process $B = (N, p_e, p_x)$, where $P = P_1 \cup P_2 \cup \{p_e, p_x\}$; $T = T_1 \cup T_2 \cup \{\varepsilon_1, \varepsilon_2\}$; $F = F_1 \cup F_2 \cup \{(p_e, \varepsilon_1), (\varepsilon_1, p_{1e}), (\varepsilon_1, p_{2e}), (p_{1x}, \varepsilon_2), (p_{2x}, \varepsilon_2), (\varepsilon_2, p_x)\}$, $M_c = M_{1c} \cup M_{2c}$, $C = C_1 \cup C_2$, $W = W_1 \cup W_2 \cup \{w(p_e, \varepsilon_1), w(\varepsilon_1, p_{1e}), w(\varepsilon_1, p_{2e}), w(p_{1x}, \varepsilon_2), w(p_{2x}, \varepsilon_2), w(\varepsilon_2, p_x)\}$, $D = D_1 \cup D_2 \cup \{d(\varepsilon_1), d(\varepsilon_2)\}$.

Interleave $B_1 ||| B_2$ models the concurrent but independent execution of two processes B_1 and B_2 with synchronized exit.

Property 12 Suppose (B, M_e) is induced from (B_1, M_{1e}) and (B_2, M_{2e}) by applying the operator interleave. If $M_{1e}[\sigma_1 > M_{1x}]$ in (B_1, M_{1e}) and $M_{2e}[\sigma_2 > M_{2x}]$ in (B_2, M_{2e}) , then $M_e[\varepsilon_1 \circ \sigma_2 > M_x]$ in (B, M_e) , where σ is a transition sequence consisting of all of the transitions in σ_1 and σ_2 such that the appearance order of the transitions conforms to the order in σ_1 and in σ_2 (i.e., the appearance order is preserved). If σ_1 has the minimum makespan in (B_1, M_{1e}) and σ_2 has the minimum makespan in (B_2, M_{2e}) , then σ has the minimum makespan in (B, M_e) and $\#\sigma = \max\{\#\sigma_1, \#\sigma_2\}$, where the notation $\#\sigma$ is the makespan value of the firing sequence σ .

For example, suppose $\sigma_1 = abc$ and $\sigma_2 = de$. Then σ can be any one of the following ten sequences: $deabc, daebc, dabec, dabce, adebc, adbec, adbce, abdec, abdce, and abcde.$

Definition 20 (Composition by the Operator Parallel) For two processes $B_i = (N_i, p_{ie}, p_{ix})$, $i = 1, 2$ with a “common” set of transitions $G = T_1 \cap T_2$ to be synchronized, their composition by *Parallel*, in notation $B_1|G|B_2$, is defined as the process $B = (N, p_e, p_x)$ where $P = P_1 \cup P_2 \cup \{p_e, p_x\}$; $T = T_1 \cup T_2 \cup \{\varepsilon_1, \varepsilon_2\}$, where $T_1 \cap T_2 \neq \emptyset$; $F = F_1 \cup F_2 \cup \{(p_e, \varepsilon_1), (\varepsilon_1, p_{1e}), (\varepsilon_1, p_{2e}), (p_{1x}, \varepsilon_2), (p_{2x}, \varepsilon_2), (\varepsilon_2, p_x)\}$, $M_c = M_{1c} \cup M_{2c}$, $C = C_1 \cup C_2$, $W = W_1 \cup W_2 \cup \{w((p_e, \varepsilon_1), w(\varepsilon_1, p_{1e}), w(\varepsilon_1, p_{2e}), w(p_{1x}, \varepsilon_2), w(p_{2x}, \varepsilon_2), w(\varepsilon_2, p_x))\}$, $D = D_1 \cup D_2 \cup \{d(\varepsilon_1), d(\varepsilon_2)\}$.

Parallel $B_1|G|B_2$ models the concurrent execution of two processes B_1 and B_2 while they have to be synchronized at some points and at their exit points. Synchronization has been one of the most complicated problems in the research of concurrent systems.

Property 13 Suppose (B, M_e) is induced from (B_1, M_{1e}) and (B_2, M_{2e}) by applying the operator parallel. If $M_{1e}[\alpha_1 \tau \beta_1 > M_{1x}$ in (B_1, M_{1e}) and $M_{2e}[\alpha_2 \tau \beta_2 > M_{2x}$ in (B_2, M_{2e}) , then $M_e[\varepsilon_1 \alpha \pi \beta \varepsilon_2 > M_x$ in (B, M_e) , where α is a transition sequence consisting of all of the transitions in α_1 and in α_2 , and β is a transition sequence consisting of all of the transitions in β_1 and β_2 such that the appearance order of the transitions in α conforms to the order in α_1 and in α_2 , and β is a transition sequence consisting of all of the transitions in β_1 and β_2 such that the appearance order of the transitions in β conforms to the order in β_1 and in β_2 . If $\sigma_1 = \alpha_1 \tau \beta_1$ has the minimum makespan in (B_1, M_{1e}) and $\sigma_2 = \alpha_2 \tau \beta_2$ has the minimum makespan in (B_2, M_{2e}) , then $\sigma = \varepsilon_1 \alpha \pi \beta \varepsilon_2$ has the minimum makespan in (B, M_e) and $\#\sigma = \max \{\#\alpha_1, \#\alpha_2\} + \#\tau + \max \{\#\beta_1, \#\beta_2\}$.

Definition 21 (Disable) For two processes $B_i = (N_i, p_{ie}, p_{ix})$, $i = 1, 2$, their composition by *disable*, in notation $B_1 [] B_2$, is defined as the process $B = (N, p_e, p_x)$, where $P = (P_1 - \{p_{1x}\}) \cup (P_2 - \{p_{2x}\}) \cup \{p_e, p_x, p_d\}$, where $p_x = p_{1x} = p_{2x}$; $T = T_1 \cup T_2 \cup \{\varepsilon, t_d\}$; $F = F_1' \cup F_2' \cup \{(p_e, \varepsilon), (\varepsilon, p_{1e}), (\varepsilon, p_{2e}), (p_d, t_d), (t_d, p_{2e})\} \cup \{(p_{2e}, t) | t \in T_1\} \cup \{(t, p_d) | t \in T_1 - \bullet p_{1x}\}$, where $F_i' = F_i - \{(t, p_{ix}) | t \in \bullet p_{ix}\} \cup \{(t, p_x) | t \in \bullet p_{ix}\}$, $i = 1, 2$, $M_c = M_{1c} \cup M_{2c}$, $C = C_1 \cup C_2$, $W = W_1(F_1') \cup W_2(F_2') \cup \{w(p_e, \varepsilon), w(\varepsilon, p_{1e}), w(\varepsilon, p_{2e}), w(p_d, t_d), w(t_d, p_{2e})\} \cup \{w(p_{2e}, t) | t \in T_1\} \cup \{w(t, p_d) | t \in T_1 - \bullet p_{1x}\}$, $D = D_1 \cup D_2 \cup \{d(\varepsilon), d(t_d)\}$.

Disable $B_1 [] B_2$ models a potential interruption of process B_1 by another process B_2 during execution. According to LOTOS, there are three possibilities: (1) If B_2 never begins, B_1 will continue until termination. (2) If B_2 begins while B_1 is executing, B_1 will be stopped and B_2 continues its execution. (3) If B_2 begins first, B_1 will never begin and B_2 will continue its execution until termination. One application of disable is to model task interruption in a JSSP. Although an operation

will not be interrupted during execution, a process may be interrupted since it consists of several operations.

If all initial transitions of B_2 (i.e., outgoing transitions of p_{2e}) are never fired, B_1 will execute until completion. If any initial transition of B_2 is fired when B_1 is executing, B_1 is stopped because any transition of B_1 cannot be fired without a token in p_{2e} and B_2 will execute to completion. If B_2 begins first, the token in p_{2e} will immediately be removed. Then, it is obvious that B_1 can never begin.

Property 14 Suppose (B, M_e) is induced from (B_1, M_{1e}) and (B_2, M_{2e}) by applying the operator disable. If $M_{1e}[\sigma_1 > M_{1x}]$ in (B_1, M_{1e}) and $M_{2e}[\sigma_2 > M_{2x}]$ in (B_2, M_{2e}) , then $M_e[\varepsilon\sigma > M_x]$ in (B, M_e) , where σ satisfies the following: (1) $\sigma = \sigma_1$, (2) $\sigma = \sigma_2$, and (3) σ is a transition sequence consisting of the transitions in a firing sequence α of B_1 and σ_2 ; the appearance order is preserved and $p_{2e} \cdot \cap \alpha = \phi$. If σ_1 has the minimum makespan in (B_1, M_{1e}) and σ_2 has the minimum makespan in (B_2, M_{2e}) , then σ has the minimum makespan in (B, M_e) and $\#\sigma$ equals to one of $\#\sigma_1$, $\#\sigma_2$, and $\#\alpha + \#\sigma_2$.

Definition 22 (Disable-Resume) For two processes $B_i = (N_i, p_{ie}, p_{ix})$, $i = 1, 2$, their composition by the operator *disable-resume*, in notation $B_1 [r] B_2$, is defined as the process $B = (N, p_e, p_x)$, where $P = (P_1 \cup P_2) \cup \{p_e, p_d\}$, where $p_x = p_{1x}$, $T = T_1 \cup T_2 \cup \{\varepsilon_1, \varepsilon_2, t_d\}$; $F = F_1 \cup F_2 \cup \{(p_e, \varepsilon_1), (\varepsilon_1, p_{1e}), (\varepsilon_1, p_{2e}), (p_{2x}, \varepsilon_2), (\varepsilon_2, p_{2e}), (p_d, t_d), (t_d, p_{2e})\} \cup \{(p_{2e}, t) | t \in T_1\} \cup \{(t, p_d) | t \in T_1 - \bullet p_{1x}\}$, $M_c = M_{1c} \cup M_{2c}$, $C = C_1 \cup C_2$, $W = W_1 \cup W_2 \cup \{w(p_e, \varepsilon_1), w(\varepsilon_1, p_{1e}), w(\varepsilon_1, p_{2e}), w(p_{2x}, \varepsilon_2), w(\varepsilon_2, p_{2e}), w(p_d, t_d), w(t_d, p_{2e})\} \cup \{w(p_{2e}, t) | t \in T_1\} \cup \{w(t, p_d) | t \in T_1 - \bullet p_{1x}\}$, $D = D_1 \cup D_2 \cup \{d(\varepsilon_1), d(\varepsilon_2), d(t_d)\}$.

Disable-resume $B_1 [r] B_2$ functions the same as the disable operator $B_1 [] B_2$ except that if B_2 is ever executed and completed, then there will be three options: (1) The entire process terminates. (2) Execution on B_1 resumes from wherever it is left. (3) B_2 is repeated. Similar to the operator disable, there is also a non-pure version of disable-resume.

Property 15 Suppose (B, M_e) is induced from (B_1, M_{1e}) and (B_2, M_{2e}) by applying the operator disable-resume. If $M_{1e}[\sigma_1 > M_{1x}]$ in (B_1, M_{1e}) and $M_{2e}[\sigma_2 > M_{2x}]$ in (B_2, M_{2e}) , then $M_e[\varepsilon_1\sigma > M_x]$ in (B, M_e) , where σ satisfies the following: (1) $\sigma = \sigma_1$, (2) Suppose $\sigma_1 = \alpha\beta$, $p_{2e} \cdot \cap \alpha = \phi$ and $p_{2e} \cdot \cap \beta \neq \phi$. Then $\sigma = \gamma\beta$, where γ is a transition sequence consisting of transitions in α and $\sigma_2\varepsilon_2$ such that the appearance order is preserved. If σ_1 has the minimum makespan in (B_1, M_{1e}) and σ_2 has the minimum makespan in (B_2, M_{2e}) , then σ has the minimum makespan in (B, M_e) and $\#\sigma$ equals to one of $\#\sigma_1$, and $\#\sigma_1 + c \#\sigma_2$, where c is a constant number.

In JSSP, resource sharing is quite necessary; after the composition of the modules, sharing resource should be considered. Therefore, place-merging operator is applied for modeling and analyzing the resource-sharing problem.

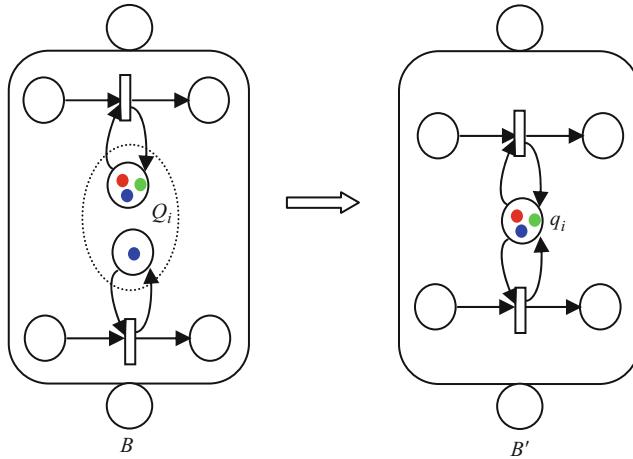

Fig. 12 $B(Q_i \rightarrow q_i)$: the operator place merging in a single process

Definition 23 (Place Merging (Fig. 12)) For a process $B = (N, p_e, p_x)$, suppose $N = (P_0 \cup Q_1 \cup \dots \cup Q_k, T, F, M_c, C, W, D)$ is an extended net satisfying the condition: $\forall i, j \in \{1, 2, \dots, k\}$ and $i \neq j$, $P_0 \cap Q_i = \emptyset$ and $Q_i \cap Q_j = \emptyset$. Let $B' = (N', p_e', p_x')$, denoted as $B(Q_i \rightarrow q_i)$, where $N' = (P_0 \cup Q_0, T', F', M_c', C', W', D')$ and $Q_0 = \{q_1, q_2, \dots, q_k\}$, be obtained from (B, M_e) by merging the places of each Q_i into q_i as follows: $T' = T$; F' is obtained from F by replacing each set of arcs of the form $\{(t, p) | p \in Q_i\}$ with (t, q_i) (resp., $\{(p, t) | p \in Q_i\}$ with (q_i, t))

$$M'_c(p) = \begin{cases} M_c(p) & p \in P_0 \\ \max_{p \in Q_i} \{M_c(p)\} & p = q_i \in Q_0, i = 1, 2, \dots, k \end{cases}$$

$$C' = C, W' = W, D' = D.$$

Property 16 Let (B, M_e) and (B', M_e') be defined in [Definition 10](#). If $M_e[\sigma > M_x]$ in (B, M_e) , then $M_e'[\sigma > M_x']$ in (B', M_e') .

Note that by the modeling technology, each transition t representing an operation forms a self-loop with the corresponding resource places. In such a case, [Property 16](#) is true.

Up to now, several integration operators, including the place-merging operators, are introduced. However, for the place-merging operators, the makespan of the resulted process cannot be obtained from the makespan of the original processes very easily. In order to simplify the computing process and get an exact makespan value, place-merging operator will be applied together with other integration operators if there exists resource sharing in the composition process. For example,

when two processes are composed by *enable* operator, if some operations in these two processes share some common resources, *place-merging* operator will be applied together with *enable* operator. Notations *M-enable*, *M-choice*, *M-interleave*, etc. denote these mixed operators.

Property 17 Suppose $M_{1e}[\sigma_1 > M_{1x}$ in (B_1, M_{1e}) and $M_{2e}[\sigma_2 > M_{2x}$ in (B_2, M_{2e}) . (B, M_e) is resulted from B_1 and B_2 by applying mixed operators and $M_e[\sigma > M_x$ in (B, M_e) . (1) For operator *M-enable*, if σ_1 has the minimum makespan in (B_1, M_{1e}) , and σ_2 has the minimum makespan in (B_2, M_{2e}) , then $\sigma = \sigma_1 \varepsilon \sigma_2$ has the minimum makespan in (B, M_e) and $\#\sigma = \#\sigma_1 + \#\sigma_2$. (2) for *M-choice*, if σ_1 has the minimum makespan in (B_1, M_{1e}) and σ_2 has the minimum makespan in (B_2, M_{2e}) , then the firing sequence with the minimum makespan in (B, M_e) is $\min\{\varepsilon_1 \sigma_1, \varepsilon_2 \sigma_2\}$. (3) for *M-interleave*, denote $\sigma_1 = \alpha_1 t_1 \alpha_2 t_2 \dots \alpha_{k-1} t_{k-1} \alpha_k$ and $\sigma_2 = \beta_1 t'_1 \beta_2 t'_2 \dots \beta_{m-1} t'_{m-1} \beta_m$, where t_1, t_2, \dots, t_{k-1} and $t'_1, t'_2, \dots, t'_{m-1}$ are the transitions sharing some resources in the operators, and α_i and β_j ($i = 1, 2, \dots, k$, $j = 1, 2, \dots, m$) are partial firing sequences. Suppose $\#\sigma_1 \geq \#\sigma_2$. Then the upper bound for the makespan of (B, M_e) is $\#\sigma_2 + \sum_{i=1}^{k-1} \#t_i$.

The proofs for **Property 17** (1) and (2) are trivial. For **Property 17** (3), the worst case would be that when some resources are shared, it is always process B_2 which waits.

By **Properties 12** and **16**, for the mixed operator *M-interleave*, the firing sequence σ of (B, M_e) is a transition sequence consisting of all of the transitions in σ_1 and σ_2 such that the appearance order of the transitions conforms to the order in σ_1 and in σ_2 . Below, an algorithm is introduced for generating a firing sequence σ of (B, M_e) based on σ_1 and σ_2 with the minimum makespan.

Makespan Generating Algorithm for M-Interleave Operator

Input: Two firing sequences $\sigma_1 = \alpha_1 t_1 \alpha_2 t_2 \dots \alpha_{k-1} t_{k-1} \alpha_k$ and $\sigma_2 = \beta_1 t'_1 \beta_2 t'_2 \dots \beta_{m-1} t'_{m-1} \beta_m$ of (B_1, M_{1e}) and (B_2, M_{2e}) , respectively

Output: A firing sequence σ and the corresponding minimum makespan $\#\sigma$ of (B, M_e)

Step 1: Let $\sigma_1 = \alpha_1 t_1 \alpha_2 t_2 \dots \alpha_{k-1} t_{k-1} \alpha_k$, $\sigma_2 = \beta_1 t'_1 \beta_2 t'_2 \dots \beta_{m-1} t'_{m-1} \beta_m$, $\sigma = \phi$, and $\#\sigma = 0$.

Step 2: For $i = 1, i < k$; $j = 1, j < m$,

if there exists a leftmost subsequence $\sigma_i = \alpha_i t_i \dots \alpha_p t_p$ of σ_1 and a leftmost subsequence $\sigma_j = \beta_j t'_j \dots \beta_q t'_q$ of σ_2 satisfying $\#\sigma_i - \#t_p \leq \#\sigma_j - \#t'_q \leq \#\sigma_i$, then $\sigma = \sigma \circ (\beta_j t'_j \dots \beta_q t'_q)$ and $\#\sigma = \#\sigma + \#\sigma_i + \#t'_q$.

If there exists a leftmost subsequence $\sigma_i = \alpha_i t_i \dots \alpha_p t_p$ of σ_1 and a leftmost subsequence $\sigma_j = \beta_j t'_j \dots \beta_q t'_q$ of σ_2 satisfying $\#\sigma_j - \#t'_q \leq \#\sigma_i - \#t_p \leq \#\sigma_j$, then $\sigma = \sigma \circ (\alpha_i t_i \dots \alpha_p t_p)$ and $\#\sigma = \#\sigma + \#\sigma_j + \#t_p$.

Let $\sigma_1 = \sigma_1 - \sigma_i$, $\sigma_2 = \sigma_2 - \sigma_j$, $i = p$ and $j = q$, $i++$, $j++$

Step 3. $\sigma = \max\{\sigma, \sigma_1, \sigma_2\}$ and $\#\sigma = \#\sigma + \max\{\#\sigma_1, \#\sigma_2\}$.

The above algorithm can also be applied to generate the firing sequence and compute the makespan for the mixed operators *M-parallel*, *M-disable*, and *M-disable-resume*. In the case of more than two composition processes, the algorithm can be improved easily such that the input is more than two firing sequences and the comparison is between more than two leftmost subsequences.

3.2 Modular-Based Design and Optimization: A Case Study

This section shows how to apply the composition operators for designing JSSP and finding the optimal scheduling. In order to illustrate the technology more precisely, a real-time JSSP design will be explained as an example.

Suppose there are three jobs to be processed in three workshops. Each job has two or three operations which will be processed in three workshops in a given sequence. In each workshop some machines can be used, and each operation only chooses one machine for processing. Four workers are responsible for these six machines in the three workshops. The details of the operation distribution, the processing time of each operation in different machines, and the worker distribution are shown in [Table 3](#).

3.2.1 System Design

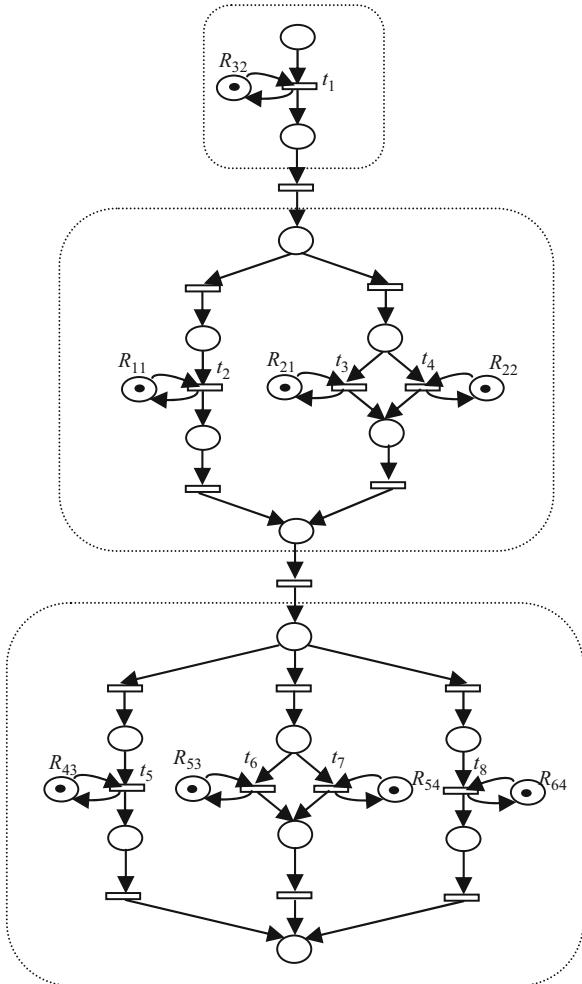

For simplicity, in the figures of Petri net model, only those transitions representing the operations are labeled, and the resource places R_{ij} represent machine M_i which are sponsored by worker W_j .

By the requirement analysis, Job 1 has three operations. In operation 1, machine M_3 is occupied which is sponsored by worker W_2 . Hence, transition t_1 , representing the operation 1, is associated with a resources place R_{32} in the Petri net model ([Fig. 13](#)). For operation 2, it can be processed either in machine M_1 sponsored by worker W_1 or in machine M_2 sponsored by worker W_1 or W_2 . *Choice* operators are applied twice in this model, one is used for choosing machines (M_1 and M_2), and

Table 3 Processing information of jobs

Job	Operation	Workshop	(Machine, time)	W_1	W_2	W_3	W_4
1	1	II	(M_3 , 12)	M_1	O		
	2	I	(M_1 , 9), (M_2 , 10)	M_2	O	O	
	3	III	(M_4 , 5), (M_5 , 6), (M_6 , 8)	M_3		O	
2	1	II	(M_3 , 6)	M_4		O	
	2	III	(M_4 , 6), (M_5 , 9), (M_6 , 8)	M_5		O	O
	3	I	(M_1 , 4), (M_2 , 5)	M_6			O
3	1	I	(M_1 , 5), (M_2 , 4)	<i>Note:</i> “O” means that the worker in the corresponding column is responsible for the machine in the corresponding row			
	2	III	(M_4 , 8), (M_5 , 10), (M_6 , 9)				

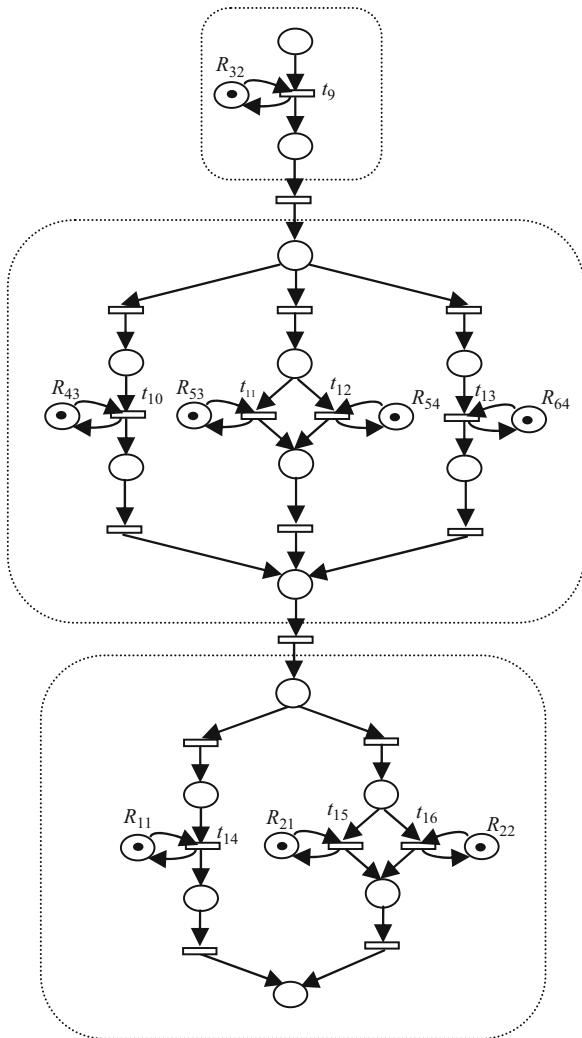

Fig. 13 Petri net model for Job 1

another is used for choosing workers (W_1 and W_2). Similarly, for operation 3, three machines M_4 , M_5 , and M_6 will be chosen, and machine M_5 has a choice between the workers W_3 and W_4 . Since the three operations are in a sequence order, the three modules will be integrated by applying *enable* operator (Fig. 13).

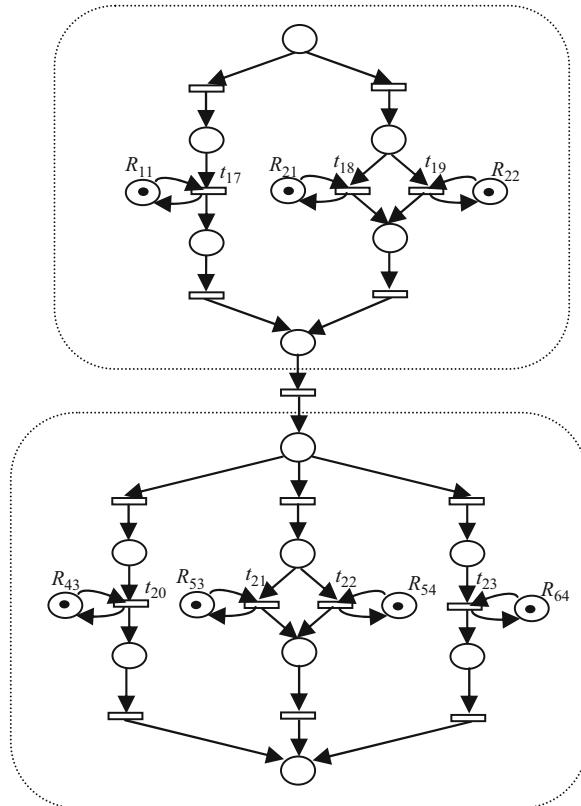

Similarly, the Petri net models for Jobs 2 and 3 can also be obtained (Figs. 14 and 15).

Fig. 14 Petri net model for Job 2

By Properties 8 and 9, the three jobs have the possible firing sequences listed in Fig. 16. In order for simplicity and clarity, only the transitions representing the operations are listed. The processing time and the resources for each operation are assigned to the corresponding transitions. By observing, there are 12 firing sequences for each Petri net model.

Fig. 15 Petri net model for Job 3

Since these three jobs are independent, they can be processed in an interleave relationship. In the three Petri net models, the resource places with the same labels represent the same resources. Hence, a mixed operator M-interleave is applied for composing these three modules, and the system model is obtained. Since the picture is too complex, it is omitted.

Property 18 The job shop scheduling system design is correct.

A system is correct if it is almost live, almost bounded, and almost reversible and terminates properly. Since each of the primary Petri net modules is correct, by the results in [3, 4], the system model resulted by combining the modules by applying the operators defined in this section is also correct. Hence, the design method can guarantee the correctness of the system.

$$\begin{array}{c}
 \left(\begin{array}{l} t_2(9, R_{11}) \\ t_5(5, R_{43}) \\ t_6(6, R_{53}) \\ t_7(6, R_{54}) \\ t_8(8, R_{64}) \\ t_5(5, R_{43}) \\ t_6(6, R_{53}) \\ t_7(6, R_{54}) \\ t_8(8, R_{64}) \\ t_5(5, R_{43}) \\ t_6(6, R_{53}) \\ t_7(6, R_{54}) \\ t_8(8, R_{64}) \end{array} \right) \times \left(\begin{array}{l} t_{17}(5, R_{11}) \\ t_{21}(10, R_{53}) \\ t_{22}(10, R_{54}) \\ t_{23}(9, R_{64}) \\ t_{20}(8, R_{43}) \\ t_{21}(10, R_{53}) \\ t_{22}(10, R_{54}) \\ t_{23}(9, R_{64}) \\ t_{20}(8, R_{43}) \\ t_{21}(10, R_{53}) \\ t_{22}(10, R_{54}) \\ t_{23}(9, R_{64}) \end{array} \right) \times \left(\begin{array}{l} t_{10}(6, R_{43}) \\ t_{11}(7, R_{54}) \\ t_{12}(7, R_{53}) \\ t_{13}(8, R_{64}) \\ t_{14}(4, R_{11}) \\ t_{15}(5, R_{21}) \\ t_{16}(5, R_{22}) \\ t_{14}(4, R_{11}) \\ t_{15}(5, R_{21}) \\ t_{16}(5, R_{22}) \\ t_{14}(4, R_{11}) \\ t_{15}(5, R_{21}) \\ t_{16}(5, R_{22}) \end{array} \right) \\
 t_1(12, R_{32}) \times t_3(10, R_{21}) \times t_9(6, R_{32}) \\
 t_4(10, R_{22}) \times t_{18}(4, R_{21}) \times t_{19}(4, R_{22})
 \end{array}$$

Fig. 16 The possible firing sequences for the three jobs

3.2.2 Scheduling Optimization

By [Property 12](#) and makespan generating algorithm for M-interleave operator, the minimum makespan and the corresponding firing sequence (i.e., schedule) can be obtained. Theoretically, the algorithm should run totally 12^3 times in order to search for the optimal solution for the example. In practice, quite a lot of firing sequences can be deleted from the list.

In order to illustrate the method, two possible schedule examples are illustrated to run the algorithm. For example, let $\sigma_1 = t_1t_2t_5$, $\sigma_2 = t_9t_{10}t_{14}$, and $\sigma_3 = t_{17}t_{20}$. By makespan generating algorithm for M-interleave operator, the schedule is as shown in [Fig. 17a](#), where machines 1, 3, and 4 are used and workers 1, 2, and 3 are needed to sponsor the machines. R_{ij} means machine i sponsored by worker j . J_{ij} means Job i 's j th operation is being processed in the corresponding time slot. In this case, the number of machines is minimum and the makespan equals 29. In another case, let $\sigma_1 = t_1t_4t_6$, $\sigma_2 = t_9t_{10}t_{14}$, and $\sigma_3 = t_{19}t_{21}$. The schedule is shown in [Fig. 17b](#). In this case, five machines are used and three workers are needed. The makespan is 28. There are some more schedules with makespan 28. For example, the following four firing sequences correspond to the optimal schedule: $t_1t_{19}t_{20}t_2t_9t_{10}t_7t_{14}$, $t_{18}t_1t_{20}t_9t_3t_{10}t_6t_{14}$, $t_{17}t_1t_{23}t_9t_4t_{10}t_6t_{14}$, $t_{19}t_1t_{23}t_9t_2t_{10}t_7t_{14}$.

In order to reduce the time complexity, an upper bound for the makespan is given such that for those partial schedules with the possible makespan exceeding the upper bound, they can be deleted from the firing sequence list. For example, in the above example, the makespan of the system will not exceed 28. Hence, the firing sequences $t_1t_2t_8$, $t_1t_3t_8$, and $t_1t_4t_8$ in the Job 1 ([Fig. 13](#)) will be deleted from the list since their makespan have exceeded 28. As for Job 2 ([Fig. 14](#)), before processing, it will wait for 12 time slots because of resource sharing; except the sequence $t_9t_{10}t_{14}$, the makespan for all of other partial schedule will not be less than 28. If an optimal solution is required, only the single firing sequence $t_9t_{10}t_{14}$ needs to be considered. Hence, very possibly, the algorithm only needs to run no more than 9×12 times.

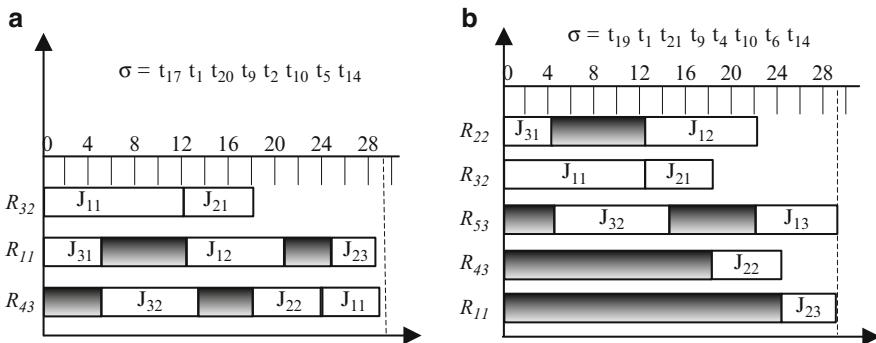

Fig. 17 Some possible schedules

Theoretically, JSSP design method can be applied to find an optimal scheduling and the idea can refer to [2, 4]. In practice, for large and complex systems, the main difficulty is to find the optimal scheduling since there are too many possible partial firing sequences. The makespan generating algorithm should run too many times in order to select the optimal one. In order to reduce the time complexity, one of the possible solutions is to combine the branch and bound method [45] with the algorithm of this chapter. The idea has been introduced in the above example. Another solution is to combine GA algorithm [38] with the algorithm of this chapter, and the idea is as follows: Let the partial firing sequences in each module be genes and the firing sequence of the system be used as the chromosomes. The makespan will be the fitness function and the operators will be newly defined according to the combination operators defined in this article. An efficient GA algorithm is introduced in the next section. The branch and bound method, GA method, and the methods of this chapter can be combined together to find the approximation optimal solution in a much more efficient way.

4 Genetic Algorithm for JSSP

In this section, genetic algorithm is applied to solve JSSP. Different from the existing genetic algorithms, the genetic algorithm applied in this chapter is based on the Petri net model. The chromosomes are composed by sequence of transitions, with crossover and mutation operations based on transition sequences. The experiment result shows that a definite solution to a specific JSSP can be found.

Flexible job shop scheduling problem (FJSSP) is the extension of JSSP, and it is more complex than the classic JSSP. In FJSSP, each operation can be processed on different machines, desiring different period of time. FJSSP is more practical than classic job shop problem and hence attracts much more attentions. There are also many methods used to resolve single-objective flexible job shop problems, such as evolutionary algorithms [46], simulated annealing [47–49], and tabu search [50] which have been proved efficient for solving FJSSP. The combinations of local search and evolutionary algorithm have obtained good solutions for FJSSPs [51].

For both JSSP and FJSSP in a practical application, there are many objectives, e.g., makespan, total tardiness, total earliness, workload of machines, cost, and so on. Sometimes there are conflicts among these objectives; it is nearly impossible to achieve optimization of more objectives simultaneously. Hence, searching for useful methods of finding a counterpoise of the objectives is a challenge and draws many researchers' attention. For instance, Li-Ning Xing and Ying-Wu Chen presented a simulation model to solve the multi-objective FJSSP [52]. The simulation model is proposed for the FJSSP with multi-objectives of minimizing makespan, total workload of machines, and workload of the critical machine [53]. Kazi Shah Nawaz Ripon and Chi-Ho Tsang presented an evolutionary approach for solving multi-objective FJSSP using Jumping Gene Genetic Algorithm that heuristically searches for the near-optimal solutions and optimizes multiple criteria simultaneously [54]. They can achieve near-optimal or optimal solutions to some special problems in their research, but the methods are aimed to solve a given problem, not suitable for the general FJSSP.

In this section, two objectives, that is, makespan and total tardiness, are considered. Firstly, the FJSSP is modeled with Petri nets, and then the problems are solved by a genetic algorithm. As a graphic and mathematic tool, Petri net has been used to model scheduling problems for a long time. Meanwhile, Petri net-based approach will face the state space explosion problem, which may cut down the efficiency of execution.

In order to partially avoid the state explosion problem for Petri net-based approach, genetic algorithm has been used with Petri net to solve scheduling problem. Chung and Fu used timed place Petri net (TPPN) and genetic algorithm to model and schedule FMS [55]. A Petri net with controller is used to model discrete events in flexible job shop scheduling with results obtained based on genetic algorithm and simulated annealing algorithm [56]. Huang et al. applied QCPN (queuing colored Petri net) and GA to model and schedule wafer manufacture [57]. These methods all work effectively, but their encoding related with special case, which sacrificed their general use for good scheduling result. According to the topics talked above, Petri net model is proposed in this section that can visually describe FJSSP. The operations in genetic algorithm such as encode, crossover, and mutation are all operated on elements of Petri net. The method is useful for any FJSSP which can be modeled by Petri net. The results in this section is mainly derived from [58].

4.1 Petri Net-Based Modeling and Problem Formulation

In this section, how to model the scheduling problems with Petri nets is introduced.

The FJSSP is described as follows:

1. $J = \{J_1, J_2, J_3, \dots, J_n\}$ is a set of jobs to be scheduled.
2. Each job consists of a predefined sequence of operations; let O_{ij} be operation j of job i .
3. Each job has a deadline, $D = \{d_1, d_2, d_3, \dots, d_n\}$ is a set of deadline, and d_i is a deadline of job i .

4. $M = \{M_1, M_2, M_3, \dots, M_m\}$ is a set of machines. Each operation is processed on some given machines for a fixed duration without interruption.
5. Each machine can process one operation at a time.

Let $C = \{c_1, c_2, c_3, \dots, c_n\}$ be the set of completion time of jobs, c_i is the completion time of job J_i . Two objectives are considered in this section:

1. Minimization of makespan, $F_1 = \max(c_i | i=1,2,3, \dots, n)$.
2. Minimization of total tardiness, $F_2 = \sum_i \text{tardiness}(i), i=1,2,3,\dots,n$

$$\text{tardiness}(i) = \begin{cases} 0, & c_i \leq d_i \\ c_i - d_i, & c_i > d_i \end{cases}$$

The task is to find a solution which is better than any others when both the objectives are considered. FJSSP, as one of the most difficult problems in combinational optimization, has been proved to be NP-hard problem [59]. Modeling the job shop problem with Petri nets can make the complex scheduling problem visualized. The scheduling problems can be modeled with Petri nets and the rules are as follows:

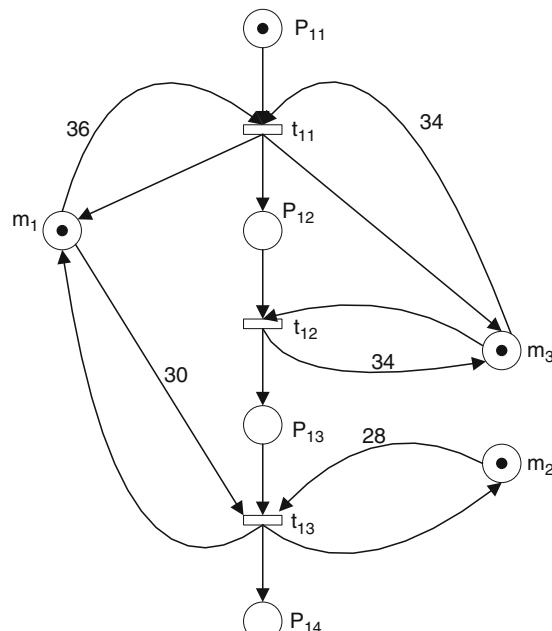

1. Each transition denotes an operation, and the input (resp., output) place of the transition can be interpreted as the beginning (resp., end) of the operation.
2. There are some initially marked places, called resource places, which denote machines. Each resource place is associated with some transitions when the operation is processed on this machine.
3. Each job can be modeled with a small Petri net, where machines are models as resource places in the model without sharing. Then all the small Petri nets are composed by merging their identical resource places if the corresponding machines are shared by different jobs.
4. For the Petri net model with m places and n transitions, an m -by- n matrix is generated as follows: Row i corresponds to place p_i ; column j corresponds to transition t_j ; if p_i is the input place of t_j , then the element in row i column j is -1 ; if p_i is the output place of t_j , then the element in row i column j is 1 ; otherwise, the element in row i column j is 0 ; if p_i is a resource place connecting to t_j , then the element in row i column j is the time pieces that the operation needs to be processed on the machine p_i ; otherwise, the element in row i column j is $1,000$.

At the beginning, tokens only exist in the first place of each job and all the resource places. After firing a sequence of transitions in turn, the tokens are transferred to the last place of each job and resource places, which represents that the job has been finished.

The following is a FJSSP example: three jobs (J_1, J_2, J_3) are to be processed on three machines (M_1, M_2, M_3). Each job consists of three operations (O_1, O_2, O_3), and each operation can be processed on some given machines. Meanwhile, there is a deadline of each job, and if a job is completed after the deadline, extra cost must be charged (Table 4). For example, the first operation (O_1) of J_1 can be operated on machine M_1 for 36-unit time or on machine M_3 for 34-unit time. The second operation (O_2) of J_1 can be operated on machine M_3 for 34-unit time. The third operation (O_3) of J_1 can be operated on machine M_2 for 28-unit time or on machine M_1 for 30-unit time. The deadlines of the three jobs are 98, 84, and 92, respectively.

Table 4 The job shop scheduling problem

	J_1	J_2	J_3
O_1	$M_1(36)/M_3(34)$	$M_2(35)$	$M_3(33)$
O_2	$M_3(34)$	$M_1(29)/M_3(26)$	$M_3(34)$
O_3	$M_2(28)/M_1(30)$	$M_3(22)$	$M_1(28)/M_2(30)$
Deadline	98	84	92

**Fig. 18** Petri net model for J_1

According to the rules of modeling, this section gets the Petri net model for each job and then merges the small Petri nets by sharing machines. Figures 18–20 are the Petri net model of J_1 , J_2 , and J_3 , respectively. After merging the three small Petri nets by sharing machines, the whole Petri net (Fig. 21) is obtained. Take J_1 as an example; t_{11} , t_{12} , and t_{13} are the three predefined operations of J_1 . Add four places to connect the transitions such that except the first place, each place represents the completion state of the last operation and the beginning state of next operation. The first place of a job represents the beginning state of the job. M_1 , M_2 , and M_3 are resource places. If an operation can be processed on a machine, there is an arc from the resource place to corresponding transition and also an arc from transition to the resource place. For instance, operation t_{11} can be operated on machine M_1 for 36-unit time or on machine M_3 for 34-unit time. So there is an arc from M_1 to t_{11} and also an arc from t_{11} to M_1 , both weights are 36, and there is an arc from M_3 to t_{11} and also an arc from t_{11} to M_3 , both weights are 34. If there are tokens in all the input places of an operation, the operation is ready to be processed. And if there are

Fig. 19 Petri net model for J_2

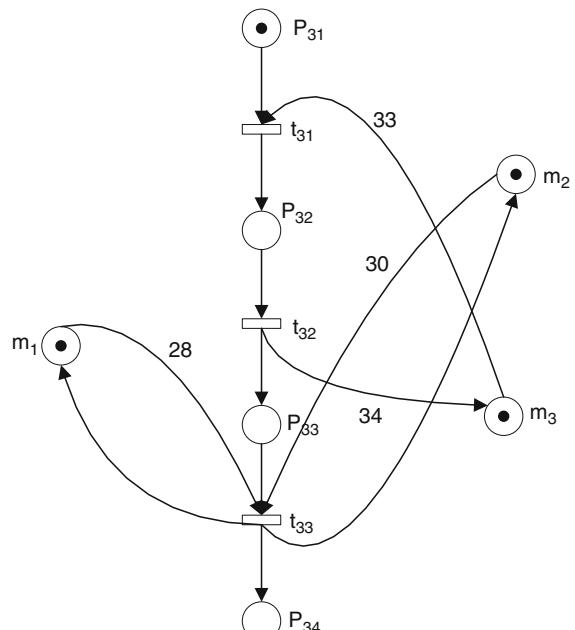

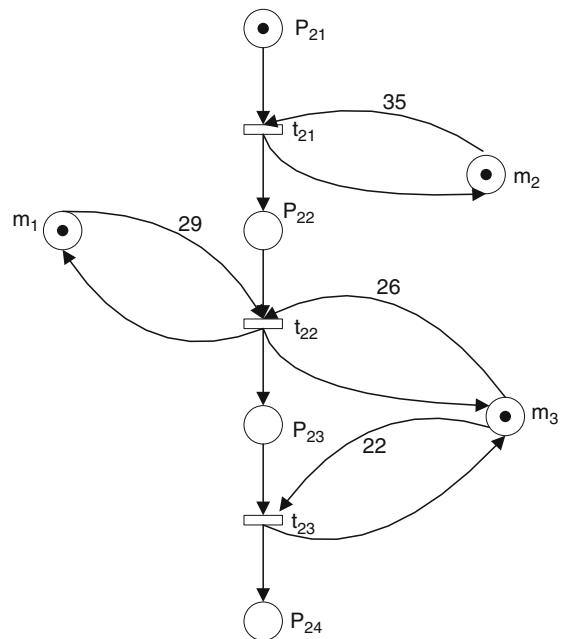

Fig. 20 Petri net model for J_3

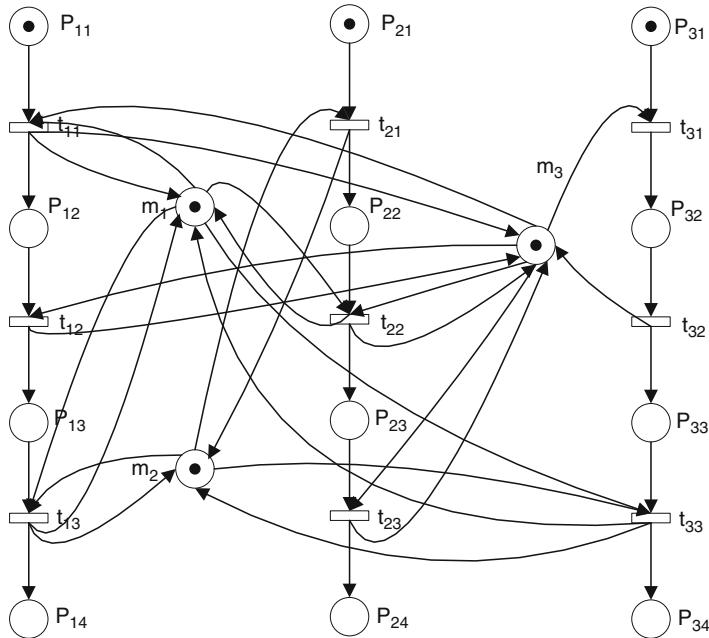

Fig. 21 Petri net model for the FJSSP

tokens in output place of an operation, the operation has been operated. As shown in Fig. 18, operation t_{11} is ready to be operated. With the same method, J_2 and J_3 are modeled.

For a Petri net model, a transition sequence is obtained by their firing time, which corresponds to a solution of the scheduling problem (e.g., $t_{11}t_{21}t_{31}t_{32}t_{22}t_{33}t_{12}t_{13}t_{23}$).

4.2 Genetic Algorithm for FJSSP

Genetic algorithm (GA) has received much attention since it had been introduced, and it has been a powerful tool of solving some NP problems in many areas.

This section uses Petri net to model the scheduling problem. Genetic algorithm is designed on the Petri net model, and a firing sequence as a chromosome, corresponding to a feasible solution.

Chromosome Encoding

For a Petri net model, if there is a firing transition sequence $\tau = t_1 t_2 t_3 \dots t_n$ such that $M_0[N, \tau] M_f$ (M_0 is initial marking and M_f is final marking), then τ is regarded as a chromosome.

Fitness function

The objectives are makespan and total tardiness, which are measured by time. For a chromosome τ , the makespan and the total tardiness of it are computed. Since the importance of the two objectives is equal, the weights are 0.5 and 0.5, respectively.

$$F_1 = \max(c_i | i=1,2,3,\dots,n)$$

$$F_2 = \sum_i \text{tardiness}(i), i = 1, 2, 3, \dots, n$$

$$\text{tardiness}(i) = \begin{cases} 0, & c_i \leq d_i \\ c_i - d_i, & c_i > d_i \end{cases}$$

The fitness function can be denoted as

$$F = 0.5F_1 + 0.5F_2$$

Initial population

Generally, the initial population is randomly produced. The initial population has great influence on finding final solution of JSSP using genetic algorithm. So the proper initial population should be selected in order to guarantee the quality of the final solution.

Since there are orders among the operations of the same job, and unfeasible solutions may be generated when the initial population is generated, the illegal solutions can become feasible by changing some transitions' positions.

Selection operation

Roulette Selection algorithm [60] is used to select parent chromosome to produce chromosome of the next generation by crossover and mutation operations.

Crossover operation

Crossover operation is vital for the genetic algorithm, and the possibility of it has a great influence on the final result. The process of crossover operation is as follows (Fig. 22):

1. Select two chromosomes $\tau_1 = t_1 t_2 t_3 \dots t_i t_{i+1} \dots t_{j-1} t_j \dots t_n$, and $\tau_2 = t'_1 t'_2 t'_3 \dots t'_i t'_{i+1} \dots t'_{j-1} t'_{j+1} \dots t'_n$, and then fire the transitions one by one in both chromosomes. Suppose $M_i[N, t_i] M_{i+1}$ and $M'_i[N, t'_i] M'_{i+1}$, $i = 1, 2, \dots, n$. Then, generate many corresponding temporary markings and get

$$\sigma_1 = \frac{t_1}{M_1} \frac{t_2}{M_2} \frac{t_3}{M_3} \dots \frac{t_i}{M_i} \frac{t_{i+1}}{M_{i+1}} \dots \frac{t_{j-1}}{M_{j-1}} \frac{t_j}{M_j} \dots \frac{t_n}{M_n}$$

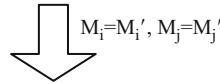

and

$$\sigma_2 = \frac{t'_1}{M'_1} \frac{t'_2}{M'_2} \frac{t'_3}{M'_3} \dots \frac{t'_i}{M'_i} \frac{t'_{i+1}}{M'_{i+1}} \dots \frac{t'_{j-1}}{M'_{j-1}} \frac{t'_{j+1}}{M'_{j+1}} \dots \frac{t'_n}{M'_n}$$

$$\begin{aligned}\tau_1 &= t_1 t_2 t_3 \dots t_i t_{i+1} \dots t_{j-1} t_j \dots t_n \\ \tau_2 &= t_1' t_2' t_3' \dots t_i' t_{i+1}' \dots t_{j-1}' t_j' \dots t_n'\end{aligned}$$

$$\sigma_1 = \frac{t_1}{M_1} \quad \frac{t_2}{M_2} \quad \frac{t_3}{M_3} \quad \dots \quad \frac{t_i}{M_i} \quad \frac{t_{i+1}}{M_{i+1}} \quad \dots \quad \frac{t_{j-1}}{M_{j-1}} \quad \frac{t_j}{M_j} \quad \dots \quad \frac{t_n}{M_n}$$

$$\sigma_2 = \frac{t_1'}{M_1'} \quad \frac{t_2'}{M_2'} \quad \frac{t_3'}{M_3'} \quad \dots \quad \frac{t_i'}{M_i'} \quad \frac{t_{i+1}'}{M_{i+1}'} \quad \dots \quad \frac{t_{j-1}'}{M_{j-1}'} \quad \frac{t_j'}{M_j'} \quad \dots \quad \frac{t_n'}{M_n'}$$

$$\sigma_1' = \frac{t_1}{M_1} \quad \frac{t_2}{M_2} \quad \frac{t_3}{M_3} \quad \dots \quad \frac{t_i}{M_i} \quad \frac{t_{i+1}'}{M_{i+1}''} \quad \dots \quad \frac{t_{j-1}'}{M_{j-1}''} \quad \frac{t_j}{M_j} \quad \dots \quad \frac{t_n}{M_n}$$

$$\sigma_2' = \frac{t_1'}{M_1'} \quad \frac{t_2'}{M_2'} \quad \frac{t_3'}{M_3'} \quad \dots \quad \frac{t_i'}{M_i'} \quad \frac{t_{i+1}''}{M_{i+1}'''} \quad \dots \quad \frac{t_{j-1}''}{M_{j-1}'''} \quad \frac{t_j'}{M_j'} \quad \dots \quad \frac{t_n'}{M_n'}$$

$$\tau_1' = t_1 t_2 t_3 \dots t_i t_{i+1} \dots t_{j-1} t_j \dots t_n$$

$$\tau_2' = t_1' t_2' t_3' \dots t_i' t_{i+1}' \dots t_{j-1}' t_j' \dots t_n'$$

Fig. 22 Process of crossover

$$\begin{aligned}\tau &= t_1 t_2 t_3 \dots t_i \dots t_j \dots t_n \\ \tau' &= t_1 t_2 t_3 \dots t_j \dots t_i \dots t_n\end{aligned}$$

Fig. 23 Process of mutation

2. Search for the identical markings in σ_1 and σ_2 such that $M_i = M'_i$, randomly select two pairs such as $M_i = M'_i$, $M_j = M'_j$, then exchange the gene piece $t_i t_{i+1} \dots t_{j-1} t_j$ of σ_1 and gene piece $t'_i t'_{i+1} \dots t'_{j-1} t'_j$ of σ_2 , and get two child sequences σ'_1 and σ'_2 . At last two child chromosomes τ'_1 and τ'_2 are obtained.

Mutation operation

Mutation operation is used to maintain the variety of populations, and it is operated on some genes of a chromosome. Mutation operation can renovate and make up genes that are lost in the selection and crossover operation. Crossing over mutation is applied to change two gene positions of a chromosome (e.g., exchange positions t_i and t_j in Fig. 23).

For the chromosome τ , positions of t_i and t_j can be interchanged only when the two operations can be processed on the same machine, and they do not belong to the same job.

4.3 Simulation Experiment

According to the topics talked above, the whole process of genetic algorithm is as follows:

- Step 1: Encode with the firing transition sequence.
- Step 2: Initialize the populations.
- Step 3: Calculate the fitness value of each chromosome of the population.
- Step 4: Judge whether the population meets the given condition: YES, go to Step 5; NO, go to Step 7.
- Step 5: Run roulette selection algorithm to select parent chromosome. Take crossover operation with a possibility and obtain a new population.
- Step 6: Take mutation operation on the population achieved in Step 5, to optimize the population, and then go to step 3.
- Step 7: Output the best solution.

For the example discussed in Sect. 4.1, firstly the Petri net model is transferred to a matrix F below (Fig. 24), and then all the genetic algorithm operations are all taken on the matrix. According to Table 4, there are three jobs and three machines and each job has three operations. So there are 9 transitions and 15 places (12 places and 3 resource places). A 15×9 matrix F is constructed. The elements of matrix F are defined as follows:

$F(p, t) = 1$, there is an arc from p to t ; $F(p, t) = -1$, there is an arc from t to p ; $F(p, t) = 0$, there is no arc between p and t ; $F(m, t) = T$, operation t can be processed on machine m for T -unit time; $F(m, t) = 1,000$, operation t cannot be processed on machine m .

Set the size of population 100 and the number of generation 50. Crossover possibility is 0.4 and mutation possibility is 0.2. The objective is to schedule

the three jobs on the three machines to minimize makespan and total tardiness. **Figure 25** is the solution for the 3-job-3-machine FJSSP.

There is another case in **Table 5**: five jobs (J_1, J_2, J_3, J_4, J_5) (each has three operations (O_1, O_2, O_3)) are scheduled on four machines (M_1, M_2, M_3, M_4), each job has a deadline. The numbers in brackets are time needed on related machines. The objective is to complete the jobs before their deadline and minimize the makespan. The parameters stay the same as last example. Since genetic algorithm has randomicity, the experiment carried out 30 times, and there are 20 times such

that the objective value is smaller than 70. The objective value of the optimal solution is 68. The final schedule is shown in Fig. 26.

5 Conclusion

Traditionally, Petri net-based methodologies for JSSP focused on two aspects: One is to model the system with Petri nets and then find the possible schedule by simulation. Another one is based on Petri net model, searching for algorithms for the optimization of the schedule. The common point of current methods is that the Petri net model is assumed to exist. For a real-time complex and large JSSP, generating the Petri net model is in fact a hard work. How to design a correct Petri net model such that it satisfies the requirement by itself is a research topic. Even when the model is given, the simulation and approximation algorithms are not applicable since the state space would be quite large.

This chapter introduces a modular-based approach for JSSP design and optimization. It applies the operators in PPPA for specifying and verifying the JSSP such that a correct Petri net model is generated. Based on the approach, a deadlock-free JSSP is designed. Furthermore, the scheduling of a composite module can be induced from the partial scheduling of the constituent modules. Hence, the schedule of the whole system can be induced from the original modules step by step.

Theoretically, the modular-based approach can be used to find the optimal solution for JSSP in a formal way. For real-time systems, due to its complexity, the algorithm may have a very large time complexity. In order to reduce the time complexity and to find an approximation optimal solution, the traditional optimization technologies such as GAs, branch and bound methods, hybrid methods, and rule-based methods can be applied together with the modular-based approach in this chapter. Based on the Petri net model, a genetic algorithm is introduced in this chapter to solve the problems. The firing sequence of transitions is regarded as a chromosome; genetic operations such as crossover and mutation are based on the elements of the Petri net model.

In order to solve more general JSSP, more integration operators should be considered, and the conclusions about the scheduling-preservation and makespan calculation should also be considered in the future research.

Abstract

In the applications where a group of people share some service such as teleconferencing and online TV, the most important security problem is to ensure that only the authorized users can enjoy the service. One popular way to enforce the security is to encrypt the service content using a group key and update it whenever users leave or join. The key tree model is proposed for the purpose of managing key updates. Sometimes, the system manager knows the user behavior related to the group and therefore hopes to reduce the number of encryptions needed to update keys. For example, in applications where the resource is limited and there are always users waiting to join the group, the system manager may

M. Li

e-mail: minmli@cs.cityu.edu.hk

decide to update the keys whenever k users leave (and hence k new users join) the group. There are also scenarios where there are some users who never leave the group (loyal users), but others will leave the group with a certain probability before the system manager decides to rekey. In all these and other similar scenarios, finding a tree which requires minimum number of encryptions to update the keys will be of great interest to the system manager because encryptions usually take quite some time. In this chapter, the relevant results in this area will be surveyed.

1 Introduction

Secure group communication is one of the major problems in wireless security. How to distribute the keys over insecure wireless channels is quite a challenging problem. There are several fundamentally different approaches to dealing with key management.

Key pre-distribution schemes refer to methods where a trusted authority distributes secret information to users so that only privileged users can get the group key. The concept of probabilistic key pre-distribution was proposed by Eschenauer and Gligor in their pioneering work [13]. Chan et al. [7] generalized this idea by considering q -compositeness, increasing the security and robustness against node loss. Liu and Ning [23], extending the ideas of [7, 13], later designed a polynomial-based framework by using random subsets and grids. Zhu et al. [46] designed LEAP protocol which uses different methods for different types of transmission.

Contributory group key agreement schemes require that each member contribute an equal share of the group key. The Diffie-Hellman key exchange protocol [11] is the first important contributory key management protocol, and is also the pioneer of every other subsequent protocol of this kind. Later, the following generalizations are proposed. Ingemarsson et al. [19], Burmester and Desmedt [5], and Steiner et al. [34–36] arrange users in a logical ring or chain structure and accumulate the keying material while traversing group members one by one. Ateniese et al. [1] and Becker and Wille [3] also ask each node to contribute an input to establish a common secret through successive pairwise message exchanges among the nodes in a secure manner using two-party D-H exchange [11]. In [12, 39, 40], logical tree structures are introduced, and the number of rounds for establishing the group key is reduced to the logarithm of the group size.

Group key management schemes use a trusted third party to perform all bookkeeping tasks, and only one group key is maintained and used by everybody. Regarding functionalities, they can be further divided into two types: broadcast encryption, in which join is not supported, and group key distribution, in which both join and leave are supported.

Broadcast encryption schemes are created by Fiat and Naor [14] to handle dynamic membership changes in secure communication groups. Naor et al. [27] later designed an efficient stateless broadcast encryption scheme SD. SD users' storage requirement $O(\log^2 n)$ was reduced by Halevy et al. [17], making the scheme more practical to large-scale networks. Aside from them, perfect hash families were also used to construct different broadcast encryption schemes, such as the work of Safavi-Naini et al. [30] and Fiat and Naor [14].

Group key distribution protocols are mainly built on top of logical trees. We give more details below since it is the focus of the chapter. Other variants can be found in [2, 4, 6, 24–26, 29, 33, 37, 38].

In the group key distribution problem, there are n subscribers and a group controller (GC) that periodically broadcasts messages (e.g., a video clip) to all the subscribers over an insecure channel. To guarantee that only the authorized users can decode the contents of the messages, the GC will dynamically update the group key for the whole group. Whenever some user leaves or joins, the GC will generate a new group key and in some way notify the remaining users in the group. The update of keys basically provides two kinds of securities. One is *Future Security* which prevents a deleted user from accessing the future content; the other is *Past Security* which prevents a newly joined user from accessing the past content.

Key tree model, which was proposed by Wong et al. [42] and Wallner et al. [41], is one of the most popular models used to achieve the goal above. In the key tree model, the group controller (GC) maintains a tree structure for the whole group. The root of the tree stores a Traffic Encryption Key (TEK) which is used to encrypt the content that should be broadcast to the authorized users. Every leaf node of the key tree represents a user and stores his individual key. Every internal node stores a Key Encryption Key (KEK) shared by all leaf descendants of the internal node. Every user possesses all the keys along the path from the leaf node (representing the user) to the root node. To prevent revoked users from knowing future message contents and also to prevent new users from knowing past message contents, the GC updates a set of keys, whenever a new user joins or a current user leaves, as follows. So long as there is a user change among the leaf descendants of an internal node v , the GC will (1) replace the old key stored at v with a new key and (2) broadcast (to all users) the new key encrypted with the key stored at each child node of v . Note that only users represented by leaf descendants of v can get useful information from the broadcast. Furthermore, this procedure must be done in a bottom-up fashion (i.e., starting with the lowest v whose key must be updated.) to guarantee that a revoked user will not know the new keys. The cost of the above procedure counts the number of encryptions used in step 2 (or equivalently, the number of broadcasts made by the GC).

Because updating keys for each user change is too frequent in some applications, [21] proposed *batch rekeying model* where keys are only updated after a certain period of time. A good survey for key tree management can be found in [15]. In this chapter, only optimization problems in batch updating scenario will be considered. Other works can be found in [8, 18, 20, 31], etc.

2 Batch Update with Probability on Membership Change

When the service is not so frequently broadcasted but the user change is frequent, updating keys after every user change will be too costly and unnecessary. Thus, a batch rekeying strategy was proposed in [21] whereby rekeying is done only periodically instead of immediately after each member change. They designed a

marking algorithm for processing the batch updates. It was shown by simulation that, using their algorithm, among the totally balanced key trees (where internal nodes of the tree have branching degree 2^i), degree 4 is the best when the number of requests (leave/join) within a batch is not large. For large number of requests, using a star (a tree of depth 1) to organize the users outperforms all the balanced key trees mentioned above in their simulation. According to how users behave, the following three scenarios are discussed here: uniform probability, loyal user, and heterogeneous probability.

2.1 Uniform Probability

Zhu et al. [45] proposed the uniform probability model where each of the n positions has the same probability p to independently experience subscriber change during a batch rekeying period. In this model, an internal node v with N_v leaf descendants will have probability $1 - q^{N_v}$ that its associated key k_v requires updating, where $q = 1 - p$. The updating incurs $d_v \cdot (1 - q^{N_v})$ expected broadcast messages by the procedure described above. Thus, the expected updating cost $C(T)$ of a key tree T is defined by $C(T) = \sum_v d_v \cdot (1 - q^{N_v})$ where the sum is taken over all the internal nodes v of T . $C(T)$ can also be viewed as an edge weight summation: For each tree edge $e = (u, v)$ where u is a child of v , its edge weight is defined to be $1 - q^{N_v}$. The optimization problem can be formulated as follows.

Given two parameters $0 \leq p \leq 1$ and $n > 0$, let $q = 1 - p$. For a rooted tree T with n leaves and edge set E , define a weight function $c(e)$ on the tree edges as follows. For every edge $e = (u, v)$ where u is a child of v and v has N_v leaf descendants, let $c(e) = 1 - q^{N_v}$. Define the cost of T as $C(T) = \sum_{e \in E} c(e)$. Find a T for which $C(T)$ is minimized. We say that such a tree is (p, n) -optimal and denotes its cost by $OPT(p, n)$.

Zhu et al. [45] characterized the optimal tree with the restriction that each internal node on level i has 2^{a_i} children and the total number of users is 2^k . Graham et al. [16] extend the search of the optimal key tree for batch updates from restricted classes of trees to all trees.

Below are some results and observations from [16]. The main idea of the algorithm to find the optimal tree is to prove some properties of the optimal tree by changing the structure of an arbitrary tree to one with better properties without increasing the total cost. This way, search space can be greatly reduced and make polynomial-time algorithm possible.

2.1.1 When the Star Is Optimal

First, several definitions are given. A tree is of *depth k* if the longest leaf-root path consists of k edges. A tree of depth 2 is also referred to as a *two-level tree*. A tree of depth 1 is called a *k-star* if it has k leaves. A tree edge (u, v) where u is a child of v is said to be at *depth k* if the path from u to the root consists of k edges. The *branching degree* of a node v is the number of children of v ; the *subtree size* of v , denoted by N_v , refers to the number of leaf descendants of v .

Lemma 1 If the n -star can achieve $OPT(p, n)$, then the $(n-1)$ -star can also achieve $OPT(p, n-1)$.

Proof The lemma can be proved by contradiction. Suppose the $(n-1)$ -star cannot achieve $OPT(p, n-1)$. Let the degree of the root in a $(p, n-1)$ -optimal tree be k where $k < n-1$. Write the optimal cost as $OPT(p, n-1) = k(1-q^{n-1}) + C$, where C represents the contribution to the cost by edges at depth ≥ 2 . Thus, $(n-1)(1-q^{n-1}) > k(1-q^{n-1}) + C$, which implies $n(1-q^n) > (k+1)(1-q^n) + C$. This means the cost of $OPT(p, n)$ can be reduced by adopting the same structure of the $(p, n-1)$ -optimal tree but with root degree $k+1$, a contradiction. \square

Lemma 2 When $0 \leq q \leq 3^{-1/3}$, the n -star is strictly better than any two-level tree.

Proof A two-level tree can be obtained from a star by successively grouping certain nodes together to form a subtree of the root. To prove the lemma, one only needs to show that the above operation always increases the cost of the tree, i.e., for any grouping size k where $1 < k < n$, one needs to show that $1-q^n < \frac{1}{k}(1-q^n) + 1-q^k$. This is trivially true when $k=1$ or $q=0$, so one can assume that $k \geq 2$ and $q > 0$.

With fixed $q > 0$, define $f(k)$ for integer k by $f(k) = k \log_k(1/q)$. Notice that for any fixed q where $0 < q < 1$, the value of $f(k)$ is minimized when $k=3$. Thus, when $0 < q \leq 3^{-1/3}$, one has $k \log_k(1/q) \geq 1$ which implies $kq^k \leq 1$. Hence, for $0 < q \leq 3^{-1/3}$, the following deductions are correct:

$$\begin{aligned} 1 - q^n - \left(\frac{1}{k}(1 - q^n) + 1 - q^k \right) &= \frac{1}{k}(kq^k - 1 - (k-1)q^n) \\ &< \frac{1}{k}(kq^k - 1) \\ &\leq 0. \end{aligned}$$

\square

Lemma 3 Let p and n be given. Suppose that the n -star is strictly better than any two-level tree, then the n -star is the (p, n) -optimal tree.

Proof If the n -star is not a (p, n) -optimal tree, then one can transform the (p, n) -optimal tree from the bottom up, every time combining two levels into a star. By Lemma 1, the m -star is strictly better than any two-level tree for $1 < m < n$ and p . Since one level is always better than two levels, one can eventually transform the optimal tree into the n -star without increasing the cost. \square

Theorem 1 When $1 \geq p \geq 1 - 3^{-1/3}$, the n -star is the (p, n) -optimal tree for any n . For $2 \leq n \leq 4$, the n -star is the (p, n) -optimal tree for any $p > 0$.

Proof The first part of the theorem follows from Lemmas 2 and 3. The cases of $2 \leq n \leq 4$ can be verified easily. \square

2.1.2 Properties of an Optimal Tree

By [Theorem 1](#), the structure of an (p, n) -optimal tree is uniquely determined for $0 \leq q \leq 3^{-1/3} \approx 0.693$ (or $1 \geq p \geq 0.307$). In the following, some properties of the optimal trees will be derived which will be used for constructing an (p, n) -optimal tree in the remaining range $1 \geq q > 3^{-1/3}$. Note that the following [Lemmas 4](#) and [5](#) as well as [Theorem 2](#) are true for all (p, n) -optimal trees where $0 \leq p \leq 1$ and $n > 0$.

For a tree T , associate a value $t_v = q^{N_v}$ with every node v (thus, $t_v = q$ if v is a leaf). The subtree rooted at u is denoted by T_u . T_u is called a subtree of v if u is a child of v .

Lemma 4 *For a non-root internal node v with branching degree k in a (p, n) -optimal tree, every child u of v satisfies $t_u \geq \frac{k-1}{k}$.*

Proof If $t_u < \frac{k-1}{k}$, one can move u up to become a sibling of v , as shown in [Fig. 1](#). In this way, the total cost of the tree is increased by

$$\begin{aligned}\Delta C &= (1 - q^{N_w}) + (k - 1)(1 - q^{N_v - N_u}) - k(1 - q^{N_v}) \\ &< 1 + (k - 1)(1 - q^{N_v - N_u}) - k(1 - q^{N_v - N_u} t_u) \\ &= q^{N_v - N_u} (k t_u - (k - 1)) \\ &< 0\end{aligned}$$

where w is the parent of v and N_v represents the value before the transformation. This contradicts the cost optimality of the original tree. \square

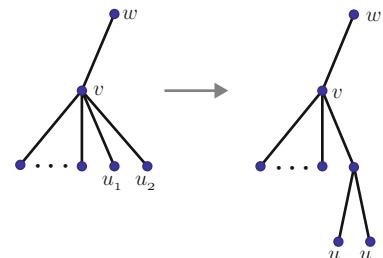

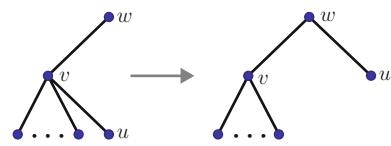

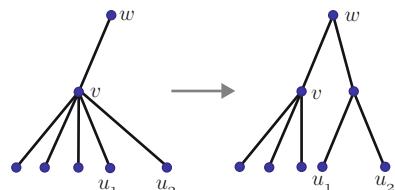

Lemma 5 *Every non-root internal node in a (p, n) -optimal tree has branching degree ≤ 5 .*

Proof By [Lemma 4](#), if a non-root internal node v in the optimal tree has branching degree $k \geq 6$, then $t_u \geq \frac{k-1}{k}$ for any child u of v . One can group together two children of v , with the largest and the second largest t_u values, to form a single subtree of v as shown in [Fig. 2](#). By this transformation, the total cost is increased by

$$\begin{aligned}\Delta C &= 2(1 - t_{u_1} t_{u_2}) - (1 - t_v) \\ &= t_v - 2t_{u_1} t_{u_2} + 1.\end{aligned}$$

Note that t_v is the product of t_u over all children u of v . Thus, $t_v < (t_{u_1} t_{u_2})^{k/2}$, which implies $\Delta C < z^k - 2z^2 + 1$ where $\frac{k-1}{k} \leq z \leq 1$.

It is easy to verify that $z^6 - 2z^2 + 1 < 0$ for $5/6 \leq z \leq 1$. Because the value of $z^k - 2z^2 + 1$ decreases with k for fixed z , the inequality $\Delta C < 0$ holds for any $k \geq 6$ and $\frac{k-1}{k} \leq z \leq 1$, which proves the lemma. \square

Fig. 1 Tree transformation 1**Fig. 2** Tree transformation 2**Fig. 3** Tree transformation 3

Theorem 2 *In an (p, n) -optimal tree:*

1. *Any internal node other than the root must have branching degree ≤ 4 .*
2. *The size of any subtree T_v , where v is a child of the root, must be upper bounded by $\max\{4 \log_q \frac{1}{2}, 1\}$.*

Proof By using Lemma 5, to prove property 1, it is sufficient to show that the optimal tree does not have any internal node with branching degree 5.

Assume that there is a non-root internal node v with five children u_1, \dots, u_5 . For simplicity, write t_{u_i} as t_i and assume $t_1 \geq \dots \geq t_5$. First observe that $z^5 - 2z^2 + 1 < 0$ when $z \geq 0.86$. According to Lemma 4 and the proof of Lemma 5, both conditions $t_1 t_2 < (0.86)^2 = 0.7396$ and $0.8 \leq t_i < 0.86$ for $2 \leq i \leq 5$ must hold. One can now prove that under these conditions, another tree transformation will reduce the total cost which contradicts the tree's optimality. The optimal tree can be transformed into tree T' as shown in Fig. 3. By doing so, the total cost is increased by

$$\begin{aligned}\Delta C &= 3(1 - t_3 t_4 t_5) + 2(1 - t_1 t_2) + (1 - t_w) - 5(1 - t_v) \\ &< -2t_1 t_2 - 3t_3 t_4 t_5 + 5t_v + 1 \\ &= (5t_3 t_4 t_5 - 2)t_1 t_2 - (3t_3 t_4 t_5 - 1)\end{aligned}$$

where t_v represents the value before transformation. By using the fact that $t_i \geq 0.8$ for $1 \leq i \leq 5$ and $t_1 t_2 < 0.7396$, it can be verified that $\Delta C < 0$. This completes the proof of property 1.

For property 2, as is shown in [Lemma 4](#), any child u of v satisfies $q(u) = q^{N_u} > 1/2$. Thus, $N_u < \log_q \frac{1}{2}$. Since v has branching degree at most 4 by property 1 and also $N_v \geq 1$, one has $N_v \leq \max\{4 \log_q \frac{1}{2}, 1\}$. This completes the proof of the theorem. \square

2.1.3 Algorithm for Constructing the Optimal Tree

A (p, n) -optimal tree can be constructed by assembling a forest of suitable subtrees. Firstly, the cost function needs to be generalized from trees to forests as follows.

Definition 1 For $L \leq n$, define a (p, n, L) -forest to be a forest of key trees with L leaves in total. The cost of the tree edges in the forest is defined as before, while the cost of the forest is the sum of individual tree costs plus $k \cdot (1 - q^n)$, where k is the number of trees in the forest. The (p, n, L) -forest with minimum cost is referred to as the optimal (p, n, L) -forest, and the corresponding minimum cost is denoted by $F(p, n, L)$.

Theorem 3 For any fixed p , [Algorithm 1](#) computes the (p, n) -optimal tree cost in $O(n)$ time.

Proof By [Theorem 2](#), in a (p, n) -optimal tree, any subtree T_v where v is a child of the root satisfies (1) its size is at most $\max\{4 \log_q \frac{1}{2}, 1\}$ and (2) the branching degree of any internal node in T_v is at most 4. For fixed q , $4 \log_q \frac{1}{2}$ can be viewed as a constant K . For each i where $2 \leq i \leq K$, the minimum cost $R(i)$ of any tree T_v with size i and subject to the degree restriction stated in (2) will be the focus of the calculations. The value of $R(i)$ can be computed in constant time as follows. First, define (k_1, k_2, k_3, k_4) to be an i -quadruple if $k_1 + k_2 + k_3 + k_4 = i$, $0 \leq k_1, k_2, k_3, k_4 \leq i$, and $k^* \geq 2$ where k^* is the number of positive elements in (k_1, k_2, k_3, k_4) . Then, $R(i)$ is the minimum value of $R(k_1) + R(k_2) + R(k_3) + R(k_4) + (1 - q^i) \cdot k^*$ over all i -quadruples (k_1, k_2, k_3, k_4) , and it can be computed in $O(K^3)$ time using dynamic programming. Now, one can obtain the true (p, n) -optimal tree also by dynamic programming, by computing optimal (p, n, L) -forests as subproblems of size L for $1 \leq L \leq n$ as given in [Algorithm 1](#). Thus, the total running time of the algorithm is $O(n \cdot K + K^4)$ which is $O(n)$ for fixed p . [Algorithm 1](#) focuses on computing the optimal tree cost; the tree structure can be obtained by keeping track of the optimal branching at every dynamic programming iteration. \square

2.1.4 Optimal Trees as $p \rightarrow 0$

[Algorithm 1](#) has running time $O(n \cdot K + K^4)$ where K is upper bounded by $4 \log_q \frac{1}{2}$ (and also by n). We can regard $O(K^4)$ as a constant term for fixed value of p , but its value gets large as $p \rightarrow 0$. Therefore, the structure of (p, n) -optimal trees as $p \rightarrow 0$ is worth exploring. The following theorem is proved in [16].

Algorithm 1 Computing optimal key tree

Input: n and p ($0 \leq p \leq 1$)**Output:** Optimal tree cost $OPT(n, p)$

```

 $q = 1 - p$ 
 $K = \min\{4 \log_q \frac{1}{2}, n\}$ 
if  $q \leq 3^{-1/3}$  or  $2 \leq n \leq 4$  then
     $OPT(p, n) \leftarrow n \cdot (1 - q^n)$ 
    Return  $OPT(p, n)$ 
end if
 $R(1) = 0$ 
for  $i = 2$  to  $4$  do
     $R(i) = i * (1 - q^i)$ 
end for
 $i = 5$ 
while  $i < K$  do
    Compute  $R(i)$ , cost of the restricted  $(p, i)$ -optimal tree.
     $i = i + 1$ 
end while
 $F(p, n, 0) \leftarrow 0$ 
for  $L = 1$  to  $n$  do
     $F(p, n, L) \leftarrow \min_{1 \leq j \leq \min\{K, L\}} (R(j) + 1 - q^n + F(p, n, L - j))$ .
end for
 $OPT(n, p) \leftarrow F(p, n, n)$ 
return  $OPT(n, p)$ 

```

Theorem 4 As $p \rightarrow 0$, the (p, n) -optimal tree $T^*(n)$ always has root degree 3 except for n of the form $4 \cdot 3^t$, in which case $T^*(4 \cdot 3^t)$ has root degree 4, and for $n = 2$, when $T^*(2)$ has root degree 2. When $2 \cdot 3^t \leq n \leq 3^{t+1}$, then $T^*(n)$ is as close to a balanced ternary tree with n leaves as possible. Namely, all subtrees (as well as $T^*(n)$ itself) have root degrees 3, except for the very bottom level, where subtrees of size 2 can occur. However, when $3^t \leq n < 2 \cdot 3^t$, $T^*(n)$ can deviate substantially from a balanced ternary tree. For example, $T^*(39)$ has three subtrees of sizes 9, 12, and 18 (see Fig. 4).

It is observed by Graham et al. [16] to be difficult to predict the sizes of the subtrees in the optimal tree $T^*(n)$ for certain values of n . For example, for $n = 1,252$, the sizes are 280, 486, and 486, while for $n = 1,253$, the sizes are 324, 443, and 486.

In [22], the authors studied the approximate optimal tree. They design a simple $O(n)$ algorithm whose approximation ratio is nearly 2. They also design a refined algorithm and show that it achieves an approximation ratio of $1 + \epsilon$.

2.2 Loyal Users

The concept of “loyal users” is first proposed in [28]. They restructure the key tree scheme and design a modified protocol considering the membership duration. Two kinds of users, volatile and permanent members, are separately grouped into two

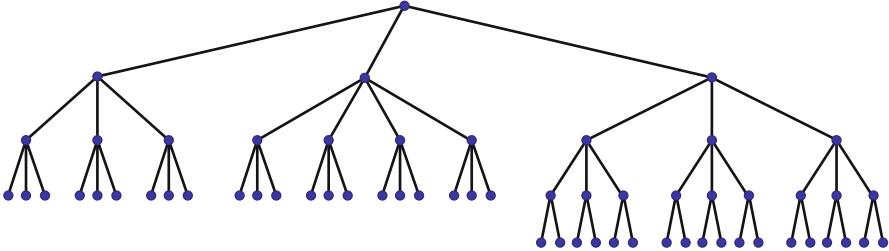

Fig. 4 An optimal $T^*(39)$

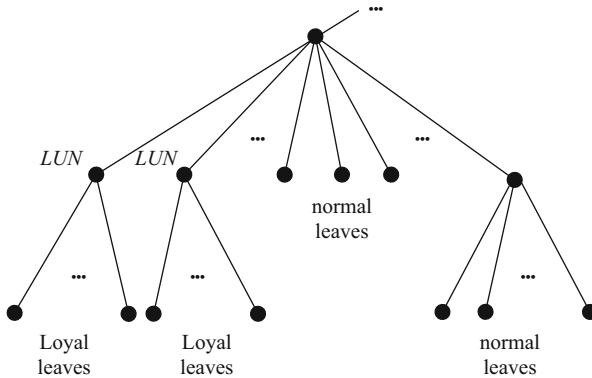

Fig. 5 An example tree with LUN

key trees. The newly joined user is first regarded as a volatile member; once the duration of the user exceeds a threshold, it is moved to the permanent member group. Chan et al. [9] extends the uniform probability batch update key tree model by considering two types of users in the same key tree. Users belonging to the first type have probability p to issue a leave request (the vacant place will be taken by the newly joined user that belongs to this type), while users belonging to the second type are considered loyal (with probability zero to leave the group) to the group. The objective is to theoretically study the optimal key tree structure to minimize expected rekeying cost. Note that loyal users have zero probability to leave the group. To control the tree cost, the loyal users should be appropriately arranged. They define a special internal node, Loyal User Node (LUN), whose children all are loyal users. [Figure 5](#) shows an example.

For a key tree T with n leaves, N_v (and L_v) is used to denote the number of “normal” (and “loyal”) leaf descendants of node v . The normal users have probability p to leave the group, while the loyal users have probability zero. Note that in this new model, the expected updating cost for every internal node v is $d_v \cdot (1 - (1 - p)^{N_v})$. Thus, one can apply the distribution trick again as follows.

Let V be the node set of T , including all internal nodes, normal and loyal leaves. Given p and n and let $q = 1 - p$, the weight $c'(u)$ of node u over V can be defined as

$$c'(u) = \begin{cases} 0 & \text{if } u \text{ is the root} \\ 1 - q^{N_v} & \text{if } u \text{ is a child of internal node } v \end{cases}$$

The cost of T is defined as $C'(T) = \sum_{u \in V} c'(u)$. Accordingly, T is a $(p, n)'$ -optimal tree if $C'(T)$ is minimum among all possible tree structures. The cost of the $(p, n)'$ -optimal tree is denoted as $OPT'(p, n)$. Our objective is to find the structure of $(p, n)'$ -optimal trees.

They first showed the following property of loyal users.

Lemma 6 *For any tree with loyal users, removing loyal leaves strictly decreases the tree cost.*

Proof Consider the subtree T_v rooted at an internal node v which has l_v ($l_v \geq 1$) children to be loyal leaves. Let N_v be the number of normal leaves on T_v . Removing all loyal children from v will decrease the tree cost by $\Delta C = l_v(1 - q^{N_v})$. It is obvious that $\Delta C \geq 0$ as $l_v \geq 1$. The cost on the remaining nodes does not change. This finishes the proof. \square

Let r be the root of the tree T and L_r be the number of loyal leaves ($L_r \geq 1$). One can obtain a tree with no larger cost by doing the following three steps:

1. Arbitrarily remove $L_r - 1$ loyal leaves from T .
2. Replace the last loyal leaf u with a LUN v .
3. Add all loyal leaves removed in step 1 including u to be children of v .

By Lemma 6, step 1 strictly decreases the tree cost. For steps 2 and 3, the new LUN v will not increase the tree cost because all nodes inserted to v are loyal leaves which do not issue any join/leave request. Thus, the transformation does not increase the tree cost. In fact, the newly joined loyal users will be placed under the LUN. This does not make any change to the tree structure excluding the LUN. In other words, the LUN can represent all loyal leaves. Thus, optimal trees can be found by focusing on trees with n normal leaves and one LUN. Similar properties can be proved about the optimal key tree based on the proof paradigm in [16]. The final dynamic programming algorithm to calculate the optimal key tree with loyal users is summarized below.

Theorem 5 *Algorithm 2 computes a $(p, n)'$ -optimal tree in $O(n \cdot K + K^4)$ time where $K = \min\{4(\log q^{-1})^{-1}, n\}$.*

Proof Define a $(p, n, L)'$ -forest to be a forest of key trees with L normal leaves and one LUN. Similarly define (p, n, L) -forest to be a forest of key trees with L normal leaves and no LUN. The cost of the forest of the trees is the cost of the individual trees plus $k(1 - q^n)$ where k is the number of trees. Use $F'(p, n, L)$ to denote the minimum cost of a $(p, n, L)'$ -forest and $F(p, n, L)$ to denote the minimum cost of a (p, n, L) -forest. \square

Algorithm 2 Computing optimal key tree with a LUN

Input: n : Number of normal users ($n \geq 1$)
 p : Probability of normal users to update ($0 < p < 1$)
Output: Cost of $(p, n)'$ -optimal tree $OPT'(p, n)$

```

 $q = 1 - p; K = \min\{4(\log q^{-1})^{-1}, n\}$ 
//Optimal  $(n)'$ -star tree
if  $q \leq 0.57$  then
     $OPT'(p, n) = (n + 1)(1 - q^n)$ 
    return  $OPT'(p, n)$ 
end if
// Optimal tree for  $n \leq 4(\log q^{-1})^{-1}$ 
 $R(0) = R(1) = 0; R(2) = 2(1 - q^2); R'(0) = 0; R'(1) = 2(1 - q); R'(2) = 3(1 - q^2);$ 
 $i = 3;$ 
while  $i \leq K$  do
     $R(i) = \min\{R(k_1) + R(k_2) + R(k_3) + R(k_4) + (1 - q^i)k^*\};$ 
     $R'(i) = \min\{R'(k_1) + R(k_2) + R(k_3) + R(k_4) + (1 - q^i)k^*\};$ 
     $i = i + 1;$ 
end while
if  $n \leq 4(\log q^{-1})^{-1}$  then
    return  $OPT'(p, n) = R'(n).$ 
end if
// Optimal tree when  $n > 4(\log q^{-1})^{-1}$ 
 $F(p, n, L) = 0; F'(p, n, L) = 0;$ 
for  $L = 1$  to  $n$  do
     $F(p, n, L) = \min_{1 \leq j \leq \min\{K, L\}}\{R(j) + 1 - q^n + F(p, n, L - j)\};$ 
     $F'(p, n, L) = \min_{1 \leq j \leq \min\{K, L\}}\{R'(j) + 1 - q^n + F(p, n, L - j)\};$ 
end for
 $OPT'(p, n) = F'(p, n, n)$ 
return  $OPT'(p, n)$ 

```

2.3 Heterogeneous Probability

When a different user has different probability of leaving the group, then the problem becomes much complicated. [Lemmas 4](#) and [5](#) and [Theorem 2](#) are still true. The size limit for each subtree connecting to the root is now only related to the smallest possible probability of leaving. However, with all these good features preserved, one still needs to guess the number of different probabilities in each branch, therefore making polynomial-time algorithm impossible if one still follows the dynamic programming framework.

3 Batch Update with a Fixed Number of Membership Changes

In this section, it is assumed that k users will leave the group during the batch period. A key tree which can minimize the worst case number of encryptions caused during the batch period is the target.

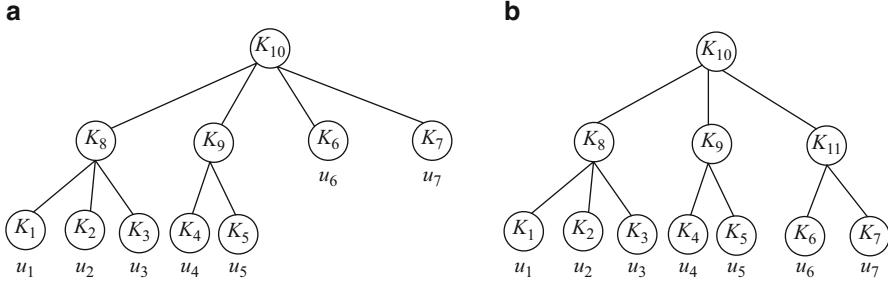

Fig. 6 Two structures of a group with seven users

As shown in Fig. 6a, there are seven users in the group. We take the deletion of user u_4 as an example. Since u_4 knows k_4 , k_9 , and k_{10} , the GC needs to update the keys k_9 and k_{10} (the node that stores k_4 disappears because u_4 is already deleted from the group). GC will encrypt the new k_9 with k_5 and broadcast it to notify u_5 . Note that only u_5 can decrypt the message. Then, GC encrypts the new k_{10} with k_6 , k_7 , and k_8 and the new k_9 , respectively, and then broadcasts the encrypted messages to notify the users. Since all the users and only the users in the group can decrypt one of these messages, the GC can safely notify the users except user u_4 about the new TEK. The deletion cost measured as the number of encryptions is 5 in this example.

In popular servers, since there are always users on the waiting list, the batch rekeying model will update the TEK by replacing constant k revoked users with k waiting users. The newly joined k users will take the k positions which are vacant due to the leave of k users, thus keeping the structure of the tree unchanged for each update. This reduces the update frequency. The updating cost equals the summation of degrees of all ancestors of the k old users (leaves). Thus, the objective is to find an optimal tree where the worst case updating cost incurred by the k -user membership change is minimum. This problem is denoted as *k-replacement problem*. In fact, [32] showed that 2–3 tree is the optimal tree for 1-replacement problem. Wu et al. [43] further denote the problem to find the optimal tree when k users are deleted from the tree as *k-deletion problem*. As shown in Fig. 6b, the tree has a worst case cost 5 for 1-deletion problem and worst case cost 6 for 1-replacement problem.

In the following, a node u is said to have degree/branching degree d if it has d children in the tree.

Wu et al. [43] first define the *k-replacement problem* formally as follows.

Definition 2 Given a tree T , the number of encryptions incurred by replacing u_{i_1}, \dots, u_{i_k} with k new users is denoted as $C_T(u_{i_1}, \dots, u_{i_k}) = \sum_{v \in (\bigcup_{1 \leq j \leq k} ANC(u_{i_j}))} d_v$ where $ANC(u)$ is the set of u 's ancestor nodes and d_v is v 's degree. *k-replacement cost* refers to the maximum cost among all possible combinations and is written as $C_k(T, n) = \max_{i_1, i_2, \dots, i_k} C_T(u_{i_1}, u_{i_2}, \dots, u_{i_k})$.

An optimal tree $T_{n,k,opt}$ (abbreviated as $T_{n,opt}$ if the context is clear) for the k -replacement problem is a tree which has the minimum k -replacement cost over all trees with n leaves, i.e., $C_k(T_{n,opt}, n) = \min_T C_k(T, n)$. This optimal cost is denoted as $OPT_k(n)$. The k -replacement problem is to find the $OPT_k(n)$ and $T_{n,k,opt}$. The k -deletion cost and the k -deletion problem are defined similarly by using the cost incurred by permanently deleting the leaves instead of the cost incurred by replacing the leaves. Note that some keys do not need to be updated if all its leaf descendants are deleted and the number of encryptions needed to update that key is also reduced if some branches of that node totally disappear due to deletion. Notice that the k -deletion problem and the k -replacement problem are not trivially equivalent.

Wu et al. [43] showed that the k -deletion problem can be solved by handling the k -replacement problem. Below are major deductions from [43].

Definition 3 Define a node v to be a pseudo-leaf node if its children are all leaves. In the following two lemmas, t is used to denote the number of pseudo-leaf nodes in a tree T .

Lemma 7 *If $t \leq k$, then the k -deletion cost of T is at least $n - k$.*

Proof When $t \leq k$, in order to achieve k -deletion cost, at least one leaf needs to be deleted from each pseudo-leaf node. Suppose on the contrary there exists one pseudo-leaf node v where none of its children belong to the k leaves deleted. The discussion can be divided into two cases.

First, if each of the k leaves is a child of the remaining $t - 1$ pseudo-leaf nodes, then there exists one pseudo-leaf node u with at least two children deleted. In this case, a larger deletion cost can be achieved if one deletes one child of v while keeping one more child of u undeleted.

Second, if some of the k leaves are not from the remaining $t - 1$ pseudo-leaf nodes, then one can assume that u is one of them whose parent is not a pseudo-leaf. Then there exists one of u 's siblings w that has at least one pseudo-leaf w' (w' can be w itself) as its descendant. If no children of w' belongs to the k leaves, then deleting a child of w' while keeping u undeleted incurs larger deletion cost. If at least one child of w' belongs to the k leaves, then deleting a child of v while keeping u undeleted incurs larger deletion cost.

It can be seen that in the worse case deletion, each pseudo-leaf node has at least one child deleted, which implies that all the keys in the remaining $n - k$ leaves should be used once as the encryption key in the updating process. Hence the k -deletion cost of T is at least $n - k$. \square

Lemma 8 *If $t > k$, then the k -deletion cost is $C_k(T, n) - k$ where $C_k(T, n)$ is the k -replacement cost.*

Proof Using similar arguments as in the proof of Lemma 7, one can prove that when $t > k$, the k -deletion cost can only be achieved when the k deleted leaves are from k different pseudo-leaf nodes. Then it is easy to see that the k -deletion cost is $C_k(T, n) - k$ where $C_k(T, n)$ is the k -replacement cost. \square

Although worst case costs between these two problems do not always differ by a constant k given some tree T , they show that the worst case costs between their optimal tree structures always differ by k .

Theorem 6 *When considering trees with n leaves, the optimal k -deletion cost is $OPT_k(n) - k$ where $OPT_k(n)$ is the optimal k -replacement cost.*

Proof Note that in the tree where all n leaves have the same parent (denoted as one-level tree), the k -deletion cost is $n - k$. By Lemma 7, any tree with the number of pseudo-leaf nodes at most k has the k -deletion cost at least $n - k$. Hence, one only needs to search the optimal tree among the one-level tree and the trees with the number of pseudo-leaf nodes larger than k . Moreover, in the one-level tree T , the k -deletion cost is $n - k = C_k(T, n) - k$ where $C_k(T, n)$ is the k -replacement cost. Further, by Lemma 8, all the trees in the scope for searching the optimal tree have k -deletion cost $C_k(T, n) - k$, which implies that the optimal k -deletion cost is $OPT_k(n) - k$ where $OPT_k(n)$ is the optimal k -replacement cost. \square

The above analysis implies that the optimal tree for the k -deletion problem can be obtained by solving the k -replacement problem. Therefore, one only needs to consider the k -replacement problem in the following.

3.1 1-Replacement

In [32], the authors investigate the optimal tree structure with n leaves where the worst case single-deletion cost is minimum. Their result shows that the optimal tree is a special kind of 2–3 tree defined below.

Definition 4 2–3 tree is a tree with n leaves constructed in the following way:

1. When $n \geq 5$, the root degree is 3 and the number of leaves in three subtrees of the root differs by at most 1. When $n = 4$, the tree is a complete binary tree. When $n = 2$ and $n = 3$, the tree has root degree 2 and 3, respectively. When $n = 1$, the tree only consists of a root.
2. Each subtree of the root is a 2–3 tree defined recursively.

3.2 k -Replacement

The following discussion also comes from [43].

3.2.1 First Step: Loose Degree Bound for the k -Replacement Problem

Given a constant k , k -replacement problem can be computed in polynomial time by deducing a loose degree bound. In the following proofs, the following procedure is often done: First, choose a template tree T and then construct a tree T' by removing from T some leaves together with the exclusive part of leaf-root paths of those leaves. Here, the exclusive part of a leaf-root path includes those edges that are not on the leaf-root path of any of the remaining leaves. In this case, T is called a template tree of T' . By the definition of the k -replacement cost, the following fact holds.

Fact 1 *If T is a template tree of T' , then the k -replacement cost of T' is no larger than that of T .*

Lemma 9 $OPT_k(n)$ is nondecreasing when n increases.

Proof Suppose on the contrary $OPT_k(n_1) > OPT_k(n_2)$ when $n_1 \leq n_2$, then there exist two trees T_1 and T_2 satisfying $C_k(T_1, n_1) = OPT_k(n_1)$ and $C_k(T_2, n_2) = OPT_k(n_2)$. One can take T_2 as a template tree and delete the leaves until the number of leaves decreases to n_1 . The resulting tree T'_2 satisfies $C_k(T'_2, n_1) \leq C_k(T_2, n_2) < OPT_k(n_1)$ by Fact 1, which contradicts the definition of $OPT_k(n_1)$. The lemma is then proved. \square

Lemma 10 $T_{n,opt}$ has root degree upper bounded by $(k + 1)^2 - 1$.

Proof The value of root degree $d \geq (k + 1)^2$ can be divided into two sets, $\{d|(k + t)^2 \leq d < (k + t)(k + t + 1), d, k, t \in N, t \geq 1\}$ and $\{d|(k + t - 1)(k + t) \leq d < (k + t)^2, d, k, t \in N, t \geq 2\}$. Take $k = 2$, for instance, the first set is $\{9, 10, 11, 16, 17, 18, 19, 25, \dots\}$, while the other is $\{12, 13, 14, 15, 20, 21, 22, 23, \dots\}$.

Case 1: $(k + t)^2 \leq d < (k + t)(k + t + 1)$ ($t \geq 1$).

Write d as $(k + t)^2 + r$ where $0 \leq r < k + t$. Given a tree T , one can transform it into a tree with root degree $k + t$ as Fig. 7 shows. In the resulting tree T' , subtrees $T_{u_1}, \dots, T_{u_{k+t}}$ are $k + t$ subtrees where the root u_1, \dots, u_{k+t} are on level one. Among the $k + t$ subtrees, there are r subtrees with root degree $k + t + 1$ and $k + t - r$ subtrees with root degree $k + t$. Suppose that the k -replacement cost of T' is incurred by replacing k_1, k_2, \dots, k_s users from subtrees $T_{i_1}, T_{i_2}, \dots, T_{i_s}$ respectively where $k_1 + k_2 + \dots + k_s = k$ and $s \leq k$. The corresponding cost is $C_k(T', n) = \sum_{j=1}^s C_{k_j}(T_{i_j}, n_{i_j}) + D_0$ where n_{i_j} is the number of leaves in T_{i_j} and D_0 is the cost incurred in the first two levels.

In the original tree T , the corresponding cost for replacing those leaves is $C_k(T, n) = \sum_{j=1}^s C_{k_j}(T_{i_j}, n_{i_j}) + d = \sum_{j=1}^s C_{k_j}(T_{i_j}, n_{i_j}) + (k + t)^2 + r$. In the following, one can show $C_k(T, n) \geq C_k(T', n)$, i.e., $D_0 \leq (k + t)^2 + r$ when $t \geq 1$.

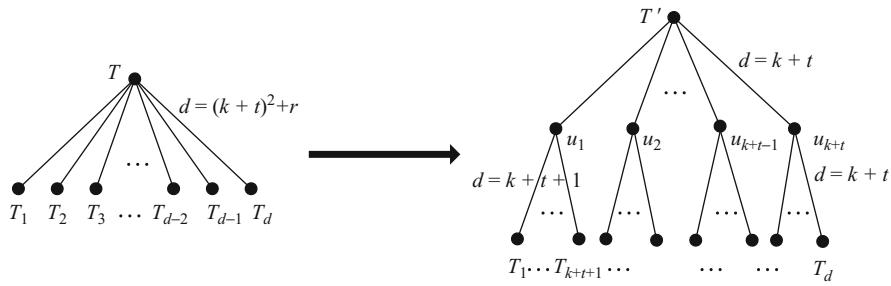

Fig. 7 Transformation of the tree which has root degree $d = (k+t)^2 + r$

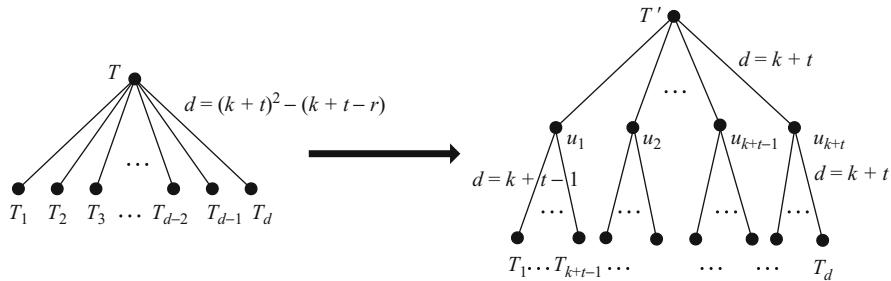

Fig. 8 Transformation of the tree which has root degree $d = (k+t)^2 - (k+t-r)$

Firstly, if $r \leq k$, the cost D_0 is at most $r(k+t+1) + (k-r)(k+t) + k+t$ where there are r users coming from r subtrees with root degree $k+t+1$ and $k-r$ users coming from $k-r$ subtrees with root degree $k+t$. Therefore, one has

$$D_0 \leq (k+t+1)r + (k+t)(k-r) + k+t = (k+t)(k+1) + r \leq (k+t)^2 + r.$$

Secondly, if $r > k$, the cost D_0 is at most $(k+t) + (k+t+1)k$ where the k users are all from k subtrees which have root degree $k+t+1$. Therefore, one has

$$D_0 \leq (k+t) + (k+t+1)k \leq (k+t)(k+1) + k \leq (k+t)^2 + r.$$

Hence, in both situations, the condition $t \geq 1$ ensures that the transformation from \$T\$ to \$T'\$ does not increase the k -replacement cost.

Case 2: $(k+t-1)(k+t) \leq d < (k+t)^2$ ($t \geq 2$).

In this case, d can be written as $(k+t)^2 - (k+t-r)$ where $0 \leq r < k+t$. One can transform \$T\$ into a tree with root degree $k+t$ where there are r subtrees with root degree $k+t$ and $k+t-r$ subtrees with root degree $k+t-1$, as Fig. 8 shows. Similarly for $r \leq k$, one has

$$D_0 \leq (k+t)r + (k+t-1)(k-r) + k + t = (k+t)(k+1) - (k-r) \leq (k+t)^2 - (k+t-r).$$

The last inequality holds because $t \geq 2$.
While for $r > k$, one has

$$D_0 \leq (k+t)k \leq (k+t)^2 - (k+t-r).$$

Thus, $t \geq 2$ ensures that the transformation from T to T' does not increase the k -replacement cost.

Therefore, for any root degree $d \geq (k+1)^2$, through a series of transformations, the original tree can be transformed into a tree with root degree less than $(k+1)^2$ without increasing the k -replacement cost. For example, when $d = 120$ and $k = 2$, since $120 = (k+9)^2 - 1$, firstly one can transform it into a tree with root degree $k+9 = 11$. Since $11 = (k+1)^2 + 2$ is still greater than $(k+1)^2$, one can further transform the resulting tree into a tree with root degree $k+1 = 3$. Because $3 < (2+1)^2$, no further transformation will take place. The lemma is finally proved. \square

[Lemma 10](#) suggests that one can find an optimal tree for the k -replacement problem among trees whose root degree is at most $(k+t)^2 - 1$. Note that the degree bound in [Lemma 10](#) is only for the root. One can also extend this property to all the internal nodes. This leads to a polynomial-time algorithm to compute the optimal k -replacement tree given a constant k .

Theorem 7 *Any internal node in $T_{n,opt}$ has degree upper bounded by $(k+1)^2 - 1$. Given a constant k , the k -replacement problem can be computed in $O(n^{(k+1)^2})$ time.*

Proof Suppose T is an optimal tree and has an internal node v which has degree $d_v \geq (k+1)^2$, as shown in [Fig. 9](#). One can transform the subtree T_v rooted at v into T'_v in the similar way as in [Lemma 10](#) (The resulting tree is denoted by T'). One can prove that the k -replacement cost in the resulting tree T' does not increase. Consider all the three possible relative positions of those k leaves whose membership change achieves k -replacement cost in T' . First, if none of the leaves are from T'_v , then the replacement cost of the corresponding leaves in T will be the same as the replacement cost in T' . If there are m ($m < k$) leaves from T'_v while the others are not, then replacing the corresponding leaves in T incurs no smaller replacement cost compared to that in T' , because replacing m leaves of T_v incurs no smaller cost than replacing the corresponding m leaves in T'_v due to similar analysis shown in [Lemma 10](#). If all the k leaves are from T'_v , then replacing the corresponding leaves in T again incurs no smaller replacement cost than T' by [Lemma 10](#). In all the above three cases, T' has replacement cost no greater than T , which enables us to transform the degree of every internal node to be equal to or less than $(k+1)^2 - 1$ without increasing the k -replacement cost. By enumerating all the possible degrees of the internal node, one can design a $O(n^{(k+1)^2})$ time dynamic programming algorithm to iteratively compute the optimal

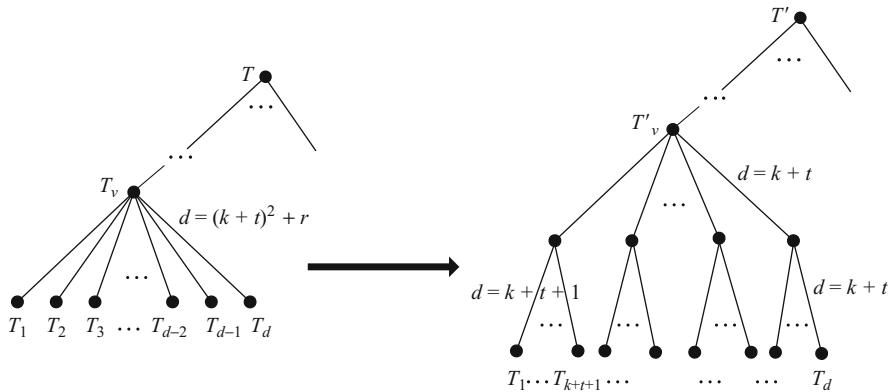

Fig. 9 Transformation of tree T which has an internal node with degree $d \geq (k+t)^2$

k -replacement cost $OPT_k(i)$ ($1 \leq i \leq n$). By keeping the branching information for each iteration, the optimal k -replacement tree can be constructed with the same complexity. \square

3.2.2 Tight Degree Bound for 2-Replacement Problem

From this subsection on, 2-replacement problem will be the major focus.

Definition 5 Denote the maximum cost to delete a single leaf in a tree T as S_T and the maximum cost to delete two leaves in T as D_T , i.e., $S_T = C_1(T, n)$ and $D_T = C_2(T, n)$.

According to [Theorem 7](#), for the 2-replacement problem, $T_{n, \text{opt}}$ has degree upper bounded by 8. Furthermore, root degree $d = 1$ is not possible in the optimal tree because merging the root and its single child into one node can strictly decrease the worst case updating cost.

Fact 2 For the 2-replacement problem, suppose that a tree T has root degree d where $d \geq 2$ and the d subtrees are T_1, T_2, \dots, T_d . One has

$$D_T = \max_{1 \leq i, j \leq d} \{D_{T_i} + d, S_{T_i} + S_{T_j} + d\}.$$

Proof It is easy to see that replacing any two leaves from a subtree T_i will incur a cost at most $D_{T_i} + d$, while replacing two leaves from two different subtrees T_i and T_j will incur a cost at most $S_{T_i} + S_{T_j} + d$. The 2-replacement cost comes from one of the above cases, and therefore the fact holds. \square

Wu et al. [43] further remove the possibility of degree 8 by the following lemma.

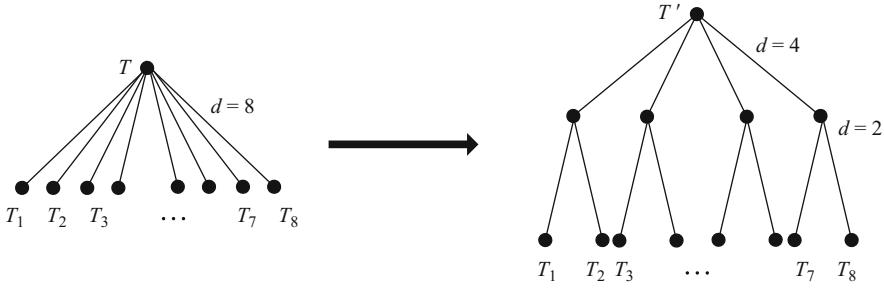

Fig. 10 Transformation of tree T which has an internal node with degree 8

Lemma 11 *For the 2-replacement problem, one can find an optimal tree among the trees with node degrees bounded between 2 and 7.*

Proof By [Theorem 7](#), one only needs to remove the possibility of degree 8 for any internal node. Firstly, any tree with root degree 8 can be transformed into a tree with a smaller root degree and no larger 2-replacement cost. Given a tree T with root degree 8 and subtrees T_1, T_2, \dots, T_8 , one can transform the structure at the root v into degree 4, and each child of v has degree 2, as shown in [Fig. 10](#). In the original tree, 2-replacement cost is $D_T = \max\{D_{T_i} + 8, S_{T_i} + S_{T_j} + 8\}$ ([Fact 2](#)). In the resulting tree T' , the cost of replacing two leaves from different subtrees T_i and T_j is at most $S_{T_i} + S_{T_j} + 8$, and the cost of replacing two leaves from one subtree T_i is at most $D_{T_i} + 6$. Hence, 2-replacement cost in T' is at most $\max\{D_{T_i} + 6, S_{T_i} + S_{T_j} + 8\} \leq D_T$.

Note that the 1-replacement cost of T also does not increase in the transformation. One can then extend this transformation to any internal node as has been shown in the proof of [Theorem 7](#). The lemma is then proved. \square

Based on this bound, the optimal tree can be computed in $O(n^8)$ time by enumerating all possible degrees that are at most 7 using a dynamic programming algorithm. However, $O(n^8)$ is still a bit unaffordable in real computations. Therefore, [43] reduced the complexity to $O(n)$ by accurately determining the structure of the optimal tree. They showed two important properties of the optimal tree (monotone property and 2–3 tree property) and then further remove the possibility of root degree 2 and 3 to reduce the scope of trees within which the optimal tree is searched for.

Lemma 12 (monotone property) *For the 2-replacement problem, suppose a tree T has root degree d where $d \geq 2$ and d subtrees are T_1, T_2, \dots, T_d . Without loss of generality, assume that T has a nonincreasing leaf descendant vector (n_1, n_2, \dots, n_d) , where n_i is the number of leaves in subtree T_i . Then, there exists an optimal tree where $S_{T_1} \geq S_{T_2} \geq \dots \geq S_{T_d}$ and T_i is a template of T_{i+1} for $2 \leq i \leq d - 1$.*

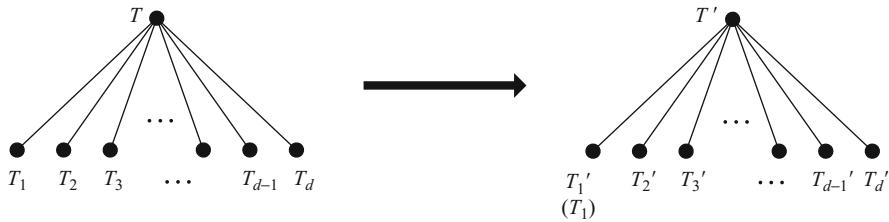

Fig. 11 Transformation of a tree which has $S_{T_1} < S_{T_2}$

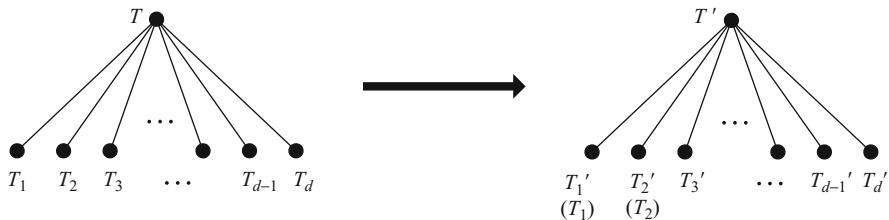

Fig. 12 Transformation of a tree T which has $S_{T_j} < S_{T_{j+1}}$ where $j \geq 2$

Proof If a given optimal tree contradicts the lemma, one can always change this tree into a tree satisfying the monotone property but with equal or less 2-replacement cost.

Case 1: $S_{T_1} < S_{T_2}$.

Let T'_1 be the same as T_1 , and then choose T'_1 to be the template tree and construct a subtree T'_2 by removing $n_1 - n_2$ leaves from T_1 . Similarly, one can construct the subtrees T'_i ($3 \leq i \leq d$) by removing $n_{i-1} - n_i$ leaves from T'_{i-1} , as shown in Fig. 11. Since each subtree T'_i is a template of T'_{i+1} , the final set of new trees satisfies $S_{T'_1} \geq S_{T'_2} \geq \dots \geq S_{T'_d}$ and $D_{T'_1} \geq D_{T'_2} \geq \dots \geq D_{T'_d}$. Then one can prove that 2-replacement cost is not increased in the resulting tree T' . Note that $S_{T'_1} = S_{T_1} < S_{T_2}$ and $D_{T'_1} = D_{T_1}$. Since $D_{T'} = \max_{1 \leq i < j \leq d} \{D_{T'_i} + d, S_{T'_i} + S_{T'_j} + d\} = \max\{D_{T_1} + d, S_{T'_1} + S_{T'_2} + d\}$ and $D_T \geq \max\{D_{T_1} + d, S_{T_1} + S_{T_2} + d\}$, $D_{T'} < D_T$ holds because $S_{T'_1} + S_{T'_2} < S_{T_1} + S_{T_2}$. Hence, the lemma holds in this case.

Case 2: $S_{T_1} \geq S_{T_2} \dots \geq S_{T_j}$ and $S_{T_j} < S_{T_{j+1}}$.

Let T'_1, T'_2 be the same as T_1, T_2 , respectively, and choose T'_2 to be the template tree and construct a subtree T'_3 by removing $n_2 - n_3$ leaves from T_2 . Similarly, one can construct subtrees T'_i ($4 \leq i \leq d$) by removing $n_{i-1} - n_i$ leaves from T'_{i-1} , as shown in Fig. 12. Since each subtree T'_i is a template of T'_{i+1} , the final set of new trees satisfies $S_{T_1} \geq S_{T_2} \geq S_{T'_3} \dots \geq S_{T'_d}$ and $D_{T_2} \geq D_{T'_3} \dots \geq D_{T'_d}$.

Therefore, one has $D_{T'} = \max_{1 \leq i, j \leq d} \{D_{T'_i} + d, S_{T'_i} + S_{T'_j} + d\} = \max\{D_{T_1} + d, D_{T_2} + d, S_{T_1} + S_{T_2} + d\}$, which implies $D_{T'} \leq D_T$.

The 2-replacement cost is not increased in T' in both cases, and therefore the lemma is proved. \square

Fact 3 *For trees satisfying the monotone property (Lemma 12), one has*

$$D_T = \max\{D_{T_1} + d, S_{T_1} + S_{T_2} + d\}.$$

Proof By Fact 2 one has $D_T = \max_{1 \leq i, j \leq d} \{D_{T_i} + d, S_{T_i} + S_{T_j} + d\}$. Lemma 12 further ensures that $\max_{1 \leq i, j \leq d} \{D_{T_i} + d, S_{T_i} + S_{T_j} + d\} = \max\{D_{T_1} + d, D_{T_2} + d, S_{T_1} + S_{T_2} + d\}$. Then $D_{T_2} < 2S_{T_2} \leq S_{T_1} + S_{T_2}$ implies $D_T = \max\{D_{T_1} + d, S_{T_1} + S_{T_2} + d\}$. \square

Lemma 13 (2–3 tree property) *For a tree T satisfying Lemma 12, subtrees T_2, \dots, T_d can be transformed into 2–3 trees without increasing the 2-replacement cost.*

Proof Given a tree T satisfying Lemma 12 and Fact 3, one can transform subtrees T_2, T_3, \dots, T_d into 2–3 trees T'_2, T'_3, \dots, T'_d to get a new tree T' . For $2 \leq i \leq d$, since $S_{T'_i} = OPT_1(n_i)$, one has $S_{T'_d} \leq \dots \leq S_{T'_3} \leq S_{T'_2} \leq S_{T_2}$ (Lemma 9) and $D_{T'_i} \leq 2S_{T'_i} \leq 2S_{T'_2} \leq S_{T_1} + S_{T'_2}$ ($2 \leq i \leq d$). Thus, $D_{T'} = \max\{D_{T_1} + d, D_{T'_2} + d, S_{T_1} + S_{T'_2} + d\} \leq \max\{D_{T_1} + d, S_{T_1} + S_{T_2} + d\} = D_T$, which implies that the transformation does not increase 2-replacement cost. The lemma is then proved. \square

Denote the trees satisfying Lemma 13 as *candidate trees*. By Lemma 13, an optimal tree can be found among all the candidate trees. For a candidate tree T with root degree d , the union of T_i and the edge connecting the root of T with the root of T_i is defined as branch B_i . Branch B_1 is called the *dominating branch* and other branches B_2, \dots, B_d are called *ordinary branches*. To make the discussion self-contained, [43] introduce the following two facts:

Fact 4 *Suppose that $c(u)$ is the ancestor weight of leaf u , i.e., $c(u) = \sum_{v \in ANC(u)} d_v$ where $ANC(u)$ is the set of u 's ancestor nodes and d_v is v 's degree, then the cost of replacing two leaves u_1 and u_2 is $c(u_1, u_2) = c(u_1) + c(u_2) - c(v) - d_v$ where v is the nearest common ancestor of u_1 and u_2 .*

Fact 5 *In a tree T , assume that u_1, u_2 are the two leaves which incur the 2-replacement cost ($c(u_1, u_2) = D_T$) and v is the nearest common ancestor of u_1 and u_2 , then*

1. *One of the leaves satisfies $c(u) = S_T$ (let this leaf be u_1), and therefore $D_T = c(u_1) + c(u_2) - c(v) - d_v = S_T + c(u_2) - c(v) - d_v$.*
2. *$c(u_2) - c(v) - d_v \leq S_T - 1$.*

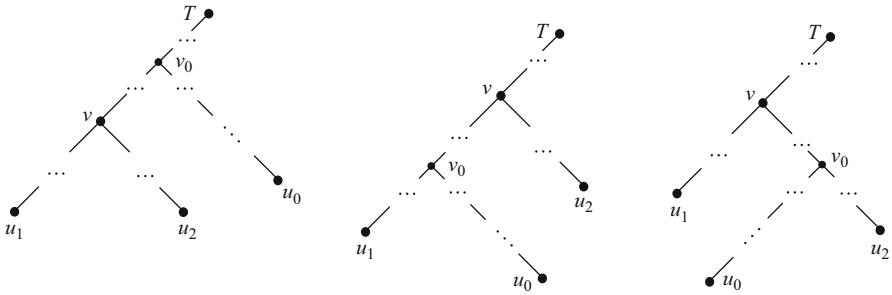

Fig. 13 The three cases of u_0 in the proof of Fact 5

Proof This fact implies that if two-leaf replacement cost in T is maximum, then at least one of the leaves has the maximum ancestor weight S_T . Suppose on the contrary that two leaves u_1, u_2 satisfy $c(u_1, u_2) = D_T$ but $c(u_1) < S_T$ and $c(u_2) < S_T$. Then, for a leaf u_0 which has $c(u_0) = S_T$, one can prove $c(u_0, u_1) > c(u_1, u_2)$ or $c(u_0, u_2) > c(u_1, u_2)$, which contradicts $c(u_1, u_2) = D_T$. Figure 13 shows the transformations for the following three cases:

Case 1: u_0, u_1 's nearest common ancestor $v_0 \in ANC(v)$.

In this case, one has $c(u_0, u_2) = c(u_0) + c(u_2) - c(v_0) - d_{v_0}$, and therefore $c(u_0, u_2) - c(u_1, u_2) = c(u_0) - c(u_1) + c(v) + d_v - c(v_0) - d_{v_0}$. Since $c(u_0) > c(u_1)$ and $c(v_0) + d_{v_0} \leq c(v)$ (v_0 is v_1 's ancestor), one has $c(u_0, u_2) > c(u_1, u_2)$; the lemma is proved in this case.

Case 2: u_0, u_1 's nearest common ancestor $v_0 \in ANC(u_1)$ but $v_0 \notin ANC(v)$.

In this case, one has $c(u_0, u_2) - c(u_1, u_2) = c(u_0) - c(u_1) > 0$.

Case 3: u_0, u_2 's nearest common ancestor $v_0 \in ANC(u_2)$ but $v_0 \notin ANC(v)$.

In this case, one has $c(u_0, u_1) - c(u_1, u_2) = c(u_0) - c(u_2) > 0$.

In all the three cases, either $c(u_0, u_1) > c(u_1, u_2)$ or $c(u_0, u_2) > c(u_1, u_2)$. Therefore, Item (1) of the fact is proved.

Item (2) is correct because $c(u_2) \leq S_T$. □

Through a series of lemmas below, [43] proved the following theorem to further remove the possibility of root degrees 2 and 3 in the optimal tree. While removing large degree $d \geq 8$ is easy, it is comparatively complicated to remove small degrees 2 or 3.

Fig. 14 Transform a tree T where the two subtrees are 2–3 trees into a 2–3 tree T'

Theorem 8 For the 2-replacement problem, a tree T with root degree 2 or 3 can be transformed into a tree with root degree 4 without increasing the 2-replacement cost.

Lemma 14 Given a tree T with root degree 2 where two subtrees T_1, T_2 are both 2–3 trees and $|n_1 - n_2| \leq 1$, when T is transformed into 2–3 tree T' with root degree 3 as shown in Fig. 14, one has $S_T \geq S_{T'}$, $D_T \geq D_{T'}$.

Proof Without loss of generality, assume that $n_1 \geq n_2$. According to the definition and optimality of 2–3 tree, when the 1-replacement cost is r , the maximum possible number of leaves on the tree is $f(\cdot)$ where

$$f(r) = \begin{cases} 3 \cdot 3^{i-1} & \text{if } r = 3i \\ 4 \cdot 3^{i-1} & \text{if } r = 3i + 1 \\ 6 \cdot 3^{i-1} & \text{if } r = 3i + 2 \end{cases}$$

Notice that T_1 and T_2 are 2–3 trees which satisfy function $f(\cdot)$. When $n_1 \in (3 \cdot 3^{i-1}, 4 \cdot 3^{i-1}]$, one has $S_{T_2} \leq S_{T_1} = 3i + 1$ and $S_T = S_{T_1} + 2 = 3i + 3$. Since $n_1 + n_2 \leq 8 \cdot 3^{i-1} < 3 \cdot 3^i$, one has $S_{T'} \leq 3i + 3 = S_T$. Similarly for $n_1 \in (4 \cdot 3^{i-1}, 6 \cdot 3^{i-1}]$, one has $S_T = S_{T_1} + 2 = 3i + 4$ and $S_{T'} \leq 3i + 4$. And for $n_1 \in (6 \cdot 3^{i-1}, 9 \cdot 3^{i-1}]$, one has $S_T = S_{T_1} + 2 = 3i + 5$ and $S_{T'} \leq 3i + 5$. Therefore, the first inequality of the lemma holds.

Suppose that the three subtrees of T' are T'_1, T'_2, T'_3 which are also 2–3 trees and satisfy $S_{T'_1} \geq S_{T'_2} \geq S_{T'_3}$. Since $S_T = S_{T_1} + 2$ and $S_{T'} = S_{T'_1} + 3$, one has $S_{T'_1} \leq S_{T_1} - 1$ and $D_{T'} \leq 2S_{T'_1} + 3 \leq 2S_{T_1} + 1$. Note that one has $S_{T_2} \geq S_{T_1} - 1$ because both subtrees are 2–3 trees with the number of leaves differed by at most 1. Hence, $D_{T'} \leq S_{T_1} + S_{T_2} + 2 \leq D_T$. The lemma is finally proved. \square

Lemma 15 For the 2-replacement problem, a tree T with root degree 2 can be transformed into a tree with root degree 3 or 4 without increasing the 2-replacement cost.

Proof Lemma 13 implies that one can transform T into a candidate tree where T_2 is a 2–3 tree. The discussion can be divided into three cases.

Fig. 15 Transform a tree T from root degree 2 into degree 4

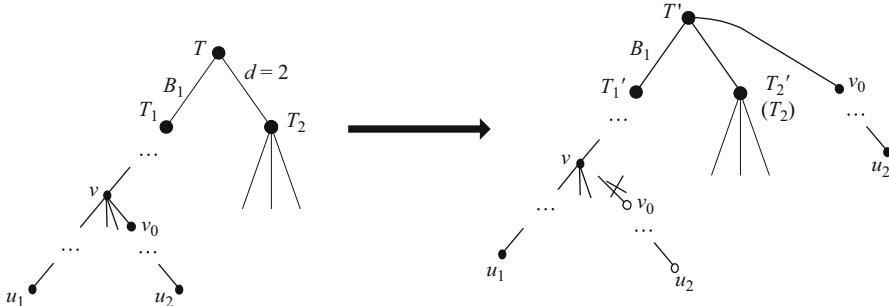

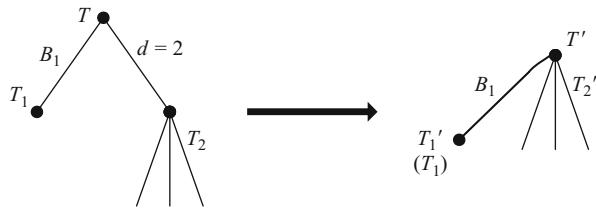

Fig. 16 Transform a tree T from root degree 2 to degree 3

Case 1: $D_{T_1} < S_{T_1} + S_{T_2}$

According to Fact 5, in subtree T_1 , one has $D_{T_1} = S_{T_1} + c(u_2) - c(v) - d_v < S_{T_1} + S_{T_2}$ which implies $c(u_2) - c(v) - d_v \leq S_{T_2} - 1$ where v is the nearest common ancestor of u_1, u_2 . Two subcases are discussed below: $c(u_2) - c(v) - d_v \leq S_{T_2} - 2$ and $c(u_2) - c(v) - d_v = S_{T_2} - 1$.

When $c(u_2) - c(v) - d_v \leq S_{T_2} - 2$, tree T can be transformed into a tree T' which is composed of the dominating branch B_1 and T'_2 (T'_2 is the same as T_2) as shown in Fig. 15. In T' , consider three subcases according to the positions of the two leaves whose replacement cost reaches $D_{T'}$. For the subcase where two leaves are both from T'_2 , one has $D_{T'} = D_{T'_2} + 1 = D_{T_2} + 1 < D_{T_2} + 2 \leq D_T$. For the subcase where one of the leaves is from T'_1 and the other is from T'_2 , one has $D_{T'} = S_{T'_1} + S_{T'_2} + 1 = S_{T_1} + S_{T_2} + 1 < S_{T_1} + S_{T_2} + 2 \leq D_T$. For the subcase where both leaves u_1 and u_2 are from T'_1 , one has $D_{T'} = D_{T'_1} + 4 = D_{T_1} + 4$. Since $c(u_2) - c(v) - d_v \leq S_{T_2} - 2$, one has $D_{T_1} \leq S_{T_1} + S_{T_2} - 2$, which implies $D_{T'} \leq S_{T_1} + S_{T_2} + 2 \leq D_T$.

When $c(u_2) - c(v) - d_v = S_{T_2} - 1$, consider another transformation for T . Notice that $S_{T_1} = c(u_1) - 2 \geq c(u_2) - c(v) = S_{T_2} - 1 + d_v \geq S_{T_2} + 1$, which means $S_{T_2} \leq S_{T_1} - 1$. Assume that T_{v_0} is the subtree of v which contains leaf u_2 , then one can move T_{v_0} to the root to produce a tree T' , as Fig. 16 shows. One also needs to consider three subcases for T' according to the positions of the two leaves whose replacement cost reaches $D_{T'}$. Firstly, if the two leaves are originally from T_1 , then one has $D_{T'} \leq D_{T_1} + 3 \leq S_{T_1} + S_{T_2} + 2 = D_T$. Secondly, if one of the two leaves is originally from T_1 while the other is not, then one can

Fig. 17 u belongs to a leaf descendant of \hat{v}

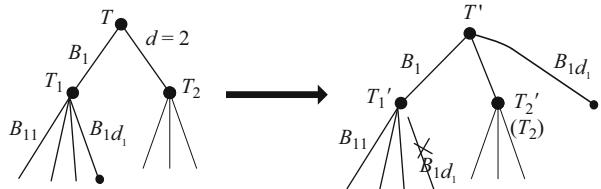

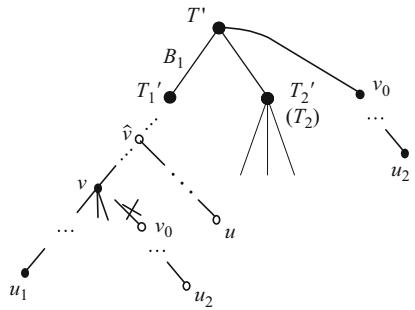

Fig. 18 Transform a tree T from root degree 2 to degree 3

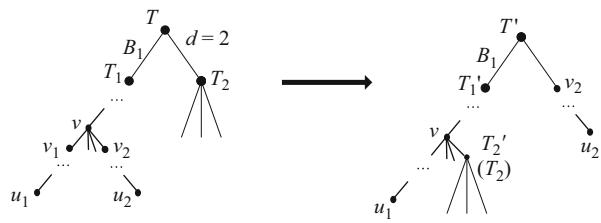

show that replacing a leaf from T'_1 or T_{v_0} incurs cost at most $S_{T_1} - 1$ which implies $D_{T'} \leq (S_{T_1} - 1) + S_{T_2} + 3 = D_T$. Suppose first the leaf u is from subtree $T_v \setminus T_{v_0}$ which is rooted at v . Since d_v decreases by 1 in the resulting tree, the cost to delete u in T'_1 is at most $S_{T_1} - 1$. If the leaf u is from T_{v_0} , then the cost to delete u in T_{v_0} is at most $S_{T_1} - d_v$. Otherwise, if the leaf is not from T_v , then suppose the leaf u is a leaf descendant of \hat{v} where \hat{v} is an ancestor of v , as shown in Fig. 17. Note that $c(u_1) + c(u) - c(\hat{v}) - d_{\hat{v}} \leq c(u_1) + c(u_2) - c(v) - d_v = c(u_1) + S_{T_2} - 1$; thus, one has $c(u) \leq S_{T_2} - 1 + c(\hat{v}) + d_{\hat{v}} \leq S_{T_2} - 1 + c(v) = c(u_2) - d_v \leq c(u_1) - d_v = S_{T_1} + 2 - d_v \leq S_{T_1}$, which implies $c(u) \leq S_{T_1}$. Therefore, replacing u from T'_1 is at most $S_{T_1} - 2$. Finally, if both leaves are originally from T_2 , then one has $D_{T'} < 2S_{T_2} + d + 1 \leq S_{T_1} - 1 + S_{T_2} + d + 1 = S_{T_1} + S_{T_2} + d \leq D_T$.

Hence, when $D_{T_1} < S_{T_1} + S_{T_2}$, one can transform T into a better tree with root degree 3 or 4.

Case 2: $D_{T_1} = S_{T_1} + S_{T_2}$

Suppose the root degree of T_1 is d_1 . One can move a branch B_{1d_1} of T_1 to the root (Fig. 18) to obtain a new tree T' . One can prove that 2-replacement cost of T' does not change compared to that of T . One also needs to consider three subcases for T' according to the positions of the two leaves whose replacement cost reaches $D_{T'}$. If the two leaves are originally from T_1 , one has $D_{T'} \leq D_{T'_1} + d + 1 = D_{T_1} - 1 + d + 1 = D_{T_1} + d \leq D_T$. If one of the leaves is originally from T_1 while the other is not, the cost $D_{T'}$ is $S_{T'_1} + S_{T_2} + d + 1 = S_{T_1} - 1 + S_{T_2} + d + 1 = S_{T_1} + S_{T_2} + d \leq D_T$ or $S_{T'_2} + S_{T_{1d_1}} + d + 1 = S_{T_2} + S_{T_{1d_1}} + d + 1 < S_{T_2} + S_{T_1} + d \leq D_T$. If both leaves are originally from T_2 , the cost $D_{T'}$ is no more than $2S_{T_2} + d + 1$. Furthermore, by Fact 5, $D_{T_1} = S_{T_1} + c(u_2) - c(v) - d_v \leq 2S_{T_1} - 1$. Since $D_{T_1} = S_{T_1} + S_{T_2}$, one

Fig. 19 Exchange two subtrees for the case that $D_{T_1} > S_{T_1} + S_{T_2}$

has $S_{T_2} \leq S_{T_1} - 1$. Therefore, $D_{T'} \leq 2S_{T_2} + d + 1 \leq S_{T_1} - 1 + S_{T_2} + d + 1 = S_{T_1} + S_{T_2} + d \leq D_T$.

Hence, $D_{T'} \leq D_T$.

Case 3: $D_{T_1} > S_{T_1} + S_{T_2}$.

In this case, replacing two leaves from T_1 incurs the cost D_T . First, transform T into a tree satisfying case 1 or case 2. In subtree T_1 , by Fact 5, if $c(u_1, u_2) = D_T$, one can assume $c(u_1) = S_T$. Suppose v is the nearest common ancestor of u_1 and u_2 and v 's children v_1 and v_2 are ancestors of u_1 and u_2 , respectively (v_i can be u_i itself), then $c(u_1) - c(v_1) \geq c(u_2) - c(v_2)$. One can exchange subtree T_{v_2} which is rooted at v_2 with subtree T_2 , as shown in Fig. 19. Because $S_{T_1} + S_{T_2} < D_{T_1} = S_{T_1} + c(u_2) - c(v_2) = S_{T_1} + S_{T_{v_2}}$, T_{v_2} has larger 1-replacement cost than T_2 . After the exchange, one has $D_{T'} \leq D_T$ because replacing one leaf from T_{v_1} and one leaf from T_{v_2} incurs a cost at most $S_{T'_1} + c(u_2) - c(v_2) + d = S_{T_1} + c(u_2) - c(v_2) + d = D_T$; replacing two leaves from T'_2 of T' incurs a cost at most $2S_{T_2} + c(v) + d_v < S_{T_2} + S_{T_{v_2}} + c(v) + d_v \leq S_{T_1} + S_{T_2} + d < D_T$, and other combinations of two replaced leaves in T' incur at most the same cost as that of T correspondingly. Note that T' has degree 2 and belongs to cases 1 or 2. Hence, T' can be further transformed into a tree with degree 3 or 4 according to cases 1 and 2.

Since in all cases, one can transform a tree with root degree 2 into a tree with root degree 3 or 4 without increasing 2-replacement cost; the lemma is finally proved. \square

Lemma 16 For 2-replacement problem, a tree T with root degree 3 can be transformed into a tree with root degree 4 without increasing the 2-replacement cost.

Proof Case 1: $D_{T_1} < S_{T_1} + S_{T_2}$.

Lemma 13 implies that one can transform T into a candidate tree where T_2, T_3 are 2–3 trees without increasing 2-replacement cost. One can then reallocate the leaves in T_2, T_3 so that T_2 is a template tree of T_3 with $0 \leq n_2 - n_3 \leq 1$ and both subtrees are still 2–3 trees as Fig. 20 shows. First, it is easy to see that this transformation will not increase 2-replacement cost. Then one can prove that such a tree can be further transformed into a tree with root degree 4 without increasing 2-replacement cost. Consider T 's two branches B_2 and B_3 (Suppose these two

Fig. 20 Transform a tree T from root degree 3 to root degree 4

branches compose a new tree \tilde{T}) in T ; according to the proof of [Lemma 14](#), one can transform \tilde{T} into tree \tilde{T}' which is a 2-3 tree and denote the whole new tree as T' . The transformation ensures that $S_{\tilde{T}} \geq S_{\tilde{T}'}, D_{\tilde{T}} \geq D_{\tilde{T}'}$. One can prove that the transformation does not increase the 2-replacement cost. One still needs to consider three subcases for T' according to the positions of the two leaves whose replacement cost reaches $D_{T'}$. If two leaves are originally from T_1 , one has $D_{T'} = D_{T'_1} + d + 1 = D_{T_1} + d + 1 \leq S_{T_1} + S_{T_2} + d = D_T$. If one of the leaves is originally from T_1 while the other is from \tilde{T} , one has $D_{T'} = S_{T_1} + S_{\tilde{T}'} + 1 \leq S_{T_1} + S_{\tilde{T}} + 1 = S_{T_1} + S_{T_2} + d = D_T$. If both leaves are from \tilde{T} , one has $D_{T'} = D_{\tilde{T}'} + 1 \leq D_{\tilde{T}} + 1 \leq D_T$. In all the subcases $D_{T'} \leq D_T$.

Case 2: $D_{T_1} = S_{T_1} + S_{T_2}$

The transformation and proof for this case is similar to the case 2 in the proof of [Lemma 15](#). The only difference is that the original tree has root degree $d = 3$ instead of 2 in this case.

Case 3: $D_{T_1} > S_{T_1} + S_{T_2}$

The transformation and proof for this case is similar to the case 3 in the proof of [Lemma 15](#). The only difference is that the original tree has root degree $d = 3$ instead of 2 in this case.

Since, in all cases, the tree with root degree 3 is transformed into a tree with root degree 4 without increasing 2-replacement cost, the lemma is finally proved. \square

3.2.3 Linear Time Algorithm: Balanced Structure of 2-Replacement Problem

Note that the optimal structure can be computed in $O(n^8)$ time by enumerating all possible degrees that are at most 7 by the result of [Sect. 3.2.2](#). Although the possibility of the root degrees 2 and 3 has been removed in [Sect. 3.2.2](#) and the structure of the ordinary branches has been fixed, to exactly compute the optimal structure is still not efficient enough because one needs to enumerate all the possible structures of the dominating branch. In this subsection, [43] showed that among the candidate trees with n leaves, a balanced structure can achieve 2-replacement cost $OPT_2(n)$. This reduces the complexity of the algorithm substantially to $O(n)$.

The basic idea is to first investigate the *capacity* $g(R)$ defined below for candidate trees with 2-replacement cost R ([Theorem 9](#)). Note that the optimal tree

has the minimum 2-replacement cost with n leaves, which reversely implies that if one wants to find a tree with 2-replacement cost R and at the same time has the maximum possible number of leaves, then computing the optimal tree for increasing n until $OPT_2(n) > R$ will produce one such solution. Wu et al. [43] then analyze and calculate the exact value for the capacity (maximum number of leaves) given a fixed 2-replacement cost R ([Theorem 10](#)). Finally, they prove that certain balanced structure can always be the optimal structure that minimizes the 2-replacement cost ([Theorem 11](#)).

Definition 6 Define capacity to be the maximum number of leaves that can be placed in a certain type of trees given a fixed replacement cost. According to [32], function $f(r)$ defined below is the capacity for 1-replacement cost r (among all the possible trees). Wu et al. [43] uses function $g(R)$ to denote the capacity for 2-replacement cost R (among all the possible trees). In other words, when $g(R - 1) < n \leq g(R)$, one has $OPT_2(n) = R$:

$$f(r) = \begin{cases} 3 \cdot 3^{i-1} & \text{if } r = 3i \\ 4 \cdot 3^{i-1} & \text{if } r = 3i + 1 \\ 6 \cdot 3^{i-1} & \text{if } r = 3i + 2 \end{cases}$$

To facilitate the discussion, according to [Fact 3](#), one can divide the candidate trees with 2-replacement cost R and root degree d into two categories as summarized in the following definition.

Definition 7 Candidate trees of category 1: The two leaves whose replacement cost achieves 2-replacement cost are from different branches, i.e., $D_T = S_{T_1} + S_{T_2} + d$, which implies $S_{T_1} + S_{T_2} \geq D_{T_1}$.

Candidate trees of category 2: The two leaves whose replacement cost achieves 2-replacement cost are both from the dominating branch B_1 , i.e., $D_T = D_{T_1} + d$, which implies $S_{T_1} + S_{T_2} < D_{T_1}$.

Correspondingly, denote the capacity of the candidate trees belonging to category 1 with 2-replacement cost R by $g_1(R)$, and denote the capacity of the candidate trees belonging to category 2 with 2-replacement cost R by $g_2(R)$. Note that one can find the optimal tree among the candidate trees according to [Lemma 13](#), which implies that with the same 2-replacement cost R , the best candidate tree can always have equal or larger number of leaves than the general trees. That is, $g(R) = \max\{g_1(R), g_2(R)\}$. Thus, in the following discussions, only the candidate trees will be discussed. On the other hand, because trees with the maximum number of leaves are the targets, it is easy to see that one can assume the numbers of leaves in ordinary branches are all the same (Otherwise, the tree can be bigger without affecting the 2-replacement cost).

In all candidate trees with 2-replacement cost R , by [Fact 3](#), at most one of the two leaves whose replacement cost achieves 2-replacement cost is from an

ordinary branch. Suppose each ordinary branch has 1-replacement cost r^- , and correspondingly T_1 has 1-replacement cost r^+ where $r^+ \leq R - d - r^-$ (otherwise, $D_T \geq r^+ + r^- + d > R$, a contradiction). For fixed cost R , [Lemma 12](#) (monotonous property) implies that $r^+ \geq r^-$. The following capacity bound can be proved.

Theorem 9 $g_i(R) \leq (R - 2r^-) \cdot f(r^-)$ ($i = 1, 2$).

To prove this theorem, it is sufficient to prove $g_1(R) \leq (R - 2r^-) \cdot f(r^-)$ and $g_2(R) \leq g_1(R)$. Wu et al. [43] used critical node defined below to denote a special kind of nodes in the following proofs.

Definition 8 For a selected node u , define the path from u to the root to be a critical path. Correspondingly, u 's ancestor nodes on the path are named critical nodes.

First, investigate the capacity of the candidate tree T in category 1 which has 2-replacement cost R . In [Lemmas 17–20](#), assume that the number of leaves in T is the maximum possible and the goal is to fix the $r_{\max}(\cdot)$ ([Definition 9](#)) of some critical nodes and their siblings to prove the capacity bound $g_1(R)$.

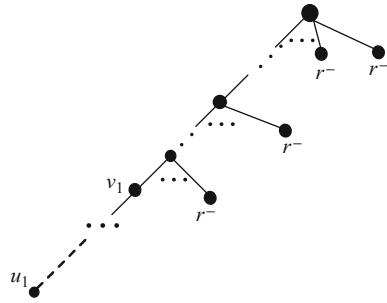

Definition 9 For the subtree T_v rooted at node v , the maximum ancestor weight with respect to T_v is denoted as $r_{\max}(v)$. Correspondingly, the maximum number of leaves T_v can hold given the 1-replacement cost $r_{\max}(v)$ is denoted as $\text{cap}(v)$.

Given a candidate tree in category 1 where $D_T = S_{T_1} + S_{T_2} + d$, there exists at least one leaf $u \in B_1$ satisfying $c(u) = r^+ + d = R - r^-$. Choose such a leaf u to obtain a critical path; correspondingly u 's ancestors are critical nodes. Notice that critical node v has $r_{\max}(v) = R - r^- - c(v)$. Furthermore, without loss of generality, suppose that v_1 is the nearest ancestor of u which satisfies $r_{\max}(v_1) \geq r^-$ (which implies $r_{\max}(v_0) < r^-$ where critical node v_0 is v_1 's child). The following discussions investigate the capacity for the critical node and their siblings.

Lemma 17 *If node v is a critical node, then $r_{\max}(v') = \min\{r^-, r_{\max}(v)\}$ for any sibling v' of v .*

Proof By the definition of r^+ , one has $r_{\max}(v') + c(v') - d \leq r^+ = r_{\max}(v) + c(v) - d$, which implies $r_{\max}(v') \leq r_{\max}(v)$. On the other hand, if one chooses to delete a leaf u in T_v and a leaf w in $T_{v'}$, the replacement cost should be at most R , which means $r_{\max}(v) + r_{\max}(v') + c(v) \leq R$. Note that $r_{\max}(v) = R - r^- - c(v)$. Therefore, $r_{\max}(v') \leq r^-$. The possibility $r_{\max}(v') < \min\{r^-, r_{\max}(v)\}$ can be removed because otherwise the capacity of $T_{v'}$ is not maximum which contradicts the assumption that the number of leaves in T is the maximum possible. In other words, if $r_{\max}(v') < \min\{r^-, r_{\max}(v)\}$, one can enlarge the tree by increasing $r_{\max}(v')$ to $\min\{r^-, r_{\max}(v)\}$ while ensuring that the tree still belongs to candidate trees in category 1 and has 2-replacement cost R . This ends the proof. \square

Fig. 21 $spine(v_1, root)$ that belongs to candidate trees in category 1

Lemma 18 Given a critical node v which is on the path from v_1 to the root, if v' is a sibling of v , then $r_{\max}(v') = r^-$.

Proof Firstly, $r_{\max}(v) = R - r^- - c(v)$ for the critical node v . Furthermore, since v is v_1 's ancestor or v_1 itself, one has $r_{\max}(v) \geq r_{\max}(v_1) \geq r^-$. Hence, the sibling of v has $r_{\max}(v') = \min\{r^-, r_{\max}(v)\} = r^-$ ([Lemma 17](#)). The lemma is proved. \square

Consider the structure composed by the critical nodes on the path from v_1 to the root and the siblings of these critical nodes, as shown in [Fig. 21](#). This structure is denoted as $spine(v_1, root)$ according to the definition below. Suppose that w is a leaf in this structure. The value of $r_{\max}(w)$ is r^- by [Lemma 18](#).

Definition 10 Suppose that v_a and v_b (v_a is a descendent of v_b) are critical nodes on the selected critical path. Denote the structure composed by the critical nodes from v_a to v_b and their siblings as $spine(v_a, v_b)$ (v_b 's siblings are not included).

Consider two cases of $spine(v_1, root)$ for candidate trees in category 1. One can prove $g_1(R) \leq (R - 2r^-) \cdot f(r^-)$ in the following cases:

Case 1: $r_{\max}(v_1) = r^-$.

Case 2: $r_{\max}(v_1) > r^-$.

Lemma 19 $g_1(R) \leq (R - 2r^-) \cdot f(r^-)$ when $r_{\max}(v_1) = r^-$.

Proof In this case, besides node v_1 , any other leaf w of $spine(v_1, root)$ also has $r_{\max}(w) = r^-$ according to [Lemma 18](#).

On the other hand, the total degrees from the parent of v_1 to the root are $c(v_1) = R - r^- - r_{\max}(v_1) = R - 2r^-$, which equals the number of leaves on $spine(v_1, root)$. Therefore, the capacity is bounded by $(R - 2r^-) \cdot f(r^-)$. \square

Lemma 20 $g_1(R) \leq (R - 2r^-) \cdot f(r^-)$ when $r_{\max}(v_1) > r^-$.

Proof Theorem 7 implies that $d_{v_1} \leq 7$; thus, $r_{\max}(v_1) = r_{\max}(v_0) + d_{v_1} \leq r^- + 6$ (because $r_{\max}(v_0) < r^-$).

Similar with the proof in the previous lemma, for any leaf v except v_1 on $\text{spine}(v_1, \text{root})$, one has $\text{cap}(v) \leq f(r^-)$, which results in at most $(R - r^- - r_{\max}(v_1) - 1) \cdot f(r^-)$ leaves. To prove the capacity bound, one only needs to show that $\text{cap}(v_1) \leq (r_{\max}(v_1) + 1 - r^-) \cdot f(r^-)$. If $r_{\max}(v_1)$ is written as $r^- + m$ where $m \leq 6$, then it is equivalent to proving $(m + 1) \cdot f(r^-) - f(r^- + m) \geq 0$. When $1 \leq m \leq 5$, one can verify that $f(r^- + m) < (m + 1)f(r^-)$. When $m = 6$, the above relation does not hold because $f(r^- + 6) = 9f(r^-) > 7f(r^-)$. But when $r_{\max}(v_1) = r^- + m = r^- + 6$, one has $d_{v_1} = 7$. Lemma 17 implies that the sibling u of v_0 has $r_{\max}(u) = \min\{r^-, r_{\max}(v_0)\} = r_{\max}(v_0) = r^- + 6 - 7 = r^- - 1$. Hence, $\text{cap}(v_1) \leq 7f(r^- - 1) \leq 7f(r^-)$. This completes the proof. \square

By Lemmas 19 and 20, the capacity bound of candidate trees in category 1 is proved, i.e., $g_1(R) \leq (R - 2r^-) \cdot f(r^-)$. The following part is to show that candidate trees in category 2 have a capacity no greater than that of category 1.

Note that the following fact holds for candidate trees T in category 2.

Fact 6 Given a candidate tree T in category 2, suppose that u_1, u_2 are the two leaves (from subtree T_1) whose replacement cost equals R , i.e., $c(u_1) + c(u_2) - c(v) - d_v = R$ where v is the nearest common ancestor of u_1, u_2 and $c(u_1) = S_T$. In order to find an optimal tree, among candidate trees in category 2, one only needs to search among those trees satisfying $c(u_2) - c(v) - d_v < OPT_1(n_1)$ where n_1 is the number of leaves in T_1 .

Proof If on the contrary in the optimal tree, one has $c(u_2) - c(v) - d_v \geq OPT_1(n_1)$, then $D_T = c(u_1) + c(u_2) - c(v) - d_v \geq 2OPT_1(n_1) + d$ since $c(u_1) = S_{T_1} + d \geq OPT_1(n_1) + d$. In this case, if T is transformed into T' by replacing subtree T_1 with a 2–3 tree with the same number of leaves, one has $D_{T'} \leq D_T$ because $S_{T'_1} = OPT_1(n_1) \leq S_{T_1}$ and $D_{T'_1} + d < 2OPT_1(n_1) + d \leq c(u_1) + c(u_2) - c(v) - d_v = R$. Notice that T' is either a candidate tree in category 1 or a candidate tree in category 2 satisfying $c(u_2) - c(v) - d_v < OPT_1(n_1)$. Thus, the fact follows. \square

Lemma 21 A candidate tree in category 2 has capacity $g_2(R) \leq g_1(R)$.

Proof Given a candidate tree T in category 2, one has $S_{T_1} + S_{T_2} + d < D_{T_1} + d = R = D_T$. By the monotone property in Lemma 12, the d subtrees satisfy $S_{T_1} \geq S_{T_2} \geq \dots \geq S_{T_d}$. If $S_{T_1} = S_{T_2}$, then $D_{T_1} + d \leq 2S_{T_1} + d = S_{T_1} + S_{T_2} + d$, which leads to a contradiction. Thus, $S_{T_1} \geq S_{T_2} + 1$. Note that the ordinary branches are 2–3 trees; one can do a tree expansion by adding one leaf to each of the ordinary branches (where each resulting subtree is still a 2–3 tree). In this way, one can increase the number of leaves in the tree without affecting the 2-replacement cost.

The resulting subtree's 1-replacement cost will increase by at most 1. Suppose that two leaves in the resulting tree T' whose replacement cost achieves the 2-replacement cost are u_1 and u_2 . We discuss three cases. If u_1, u_2 are both from T_1 ,

then replacing u_1, u_2 incurs a cost $D_{T_1} + d = R$. If one of the two leaves is from T_1 while the other is from T_i , then replacing u_1, u_2 incurs a cost at most $S_{T_1} + S_{T_2} + 1 + d \leq R$. If u_1, u_2 are both from the ordinary branches, then replacing u_1, u_2 incurs a cost at most $2(S_{T_2} + 1) + d \leq S_{T_2} + 1 + S_{T_1} + d \leq R$.

The above tree expansion can be applied until $S_{T_1} + S_{T_i} + d = R$ (The tree becomes a candidate tree of category 1), and the final tree is denoted as T'' . One can prove that T'' is a candidate tree of category 1. To show this, one only needs to prove that in T'' subtree T''_2 has the number of leaves less than T_1 .

This follows because $OPT_1(n''_2) = S_{T''_2} = R - S_{T_1} - d = c(u_2) - c(v) - d_v < OPT(n_1)$ implies $n''_2 < n_1$.

Therefore, with 2-replacement cost R fixed, there is always a candidate tree of category 1 which has more leaves than any candidate tree of category 2. This finishes the proof of $g_2(R) \leq g_1(R)$. \square

Lemma 21 implies that the maximum capacity can always be achieved by the candidate trees in category 1. Thus, the capacity bound is $(R - 2r^-) \cdot f(r^-)$ and **Theorem 9** is then proved.

In the following, among these candidate trees one can study the optimal structure which achieves the maximum capacity for different values of 2-replacement cost R . Only the proof for $R = 6i + 6$ will be elaborated due to the similarity of other proofs. The correctness of other proofs can be referred to in [Table 1](#). The following fact is used in the proofs.

Fact 7

$$(s + 2t) \cdot f(r - t) \leq s \cdot f(r) \text{ when } \begin{cases} r = 3i, t \geq 1, s \geq 4 \\ r = 3i + 1, t \geq 2, s \geq 4 \\ r = 3i + 1, t \geq 1, s \geq 6 \\ r = 3i + 2, t \geq 1, s \geq 4 \end{cases}$$

Proof One only needs to prove $\frac{f(r-t)}{f(r)} \leq \frac{s}{s+2t}$. Since $\frac{s}{s+2t}$ is a monotonously increasing relative to s , thus when $s \geq 4$ it is sufficient to prove $\frac{f(r-t)}{f(r)} \leq \frac{4}{4+2t}$. By the definition of function $f(\cdot)$, one needs to discuss about three cases.

Case 1: $r = 3i$.

$$\frac{f(3i-t)}{f(3i)} = \begin{cases} \frac{f(3i-1-3j)}{f(3i)} = \frac{6 \cdot 3^{i-2}/3^j}{3^i} = \frac{2}{3} \cdot \frac{1}{3^j} \leq \frac{4}{4+2(3j+1)} & \text{if } t = 3j + 1 \\ \frac{f(3i-2-3j)}{f(3i)} = \frac{4 \cdot 3^{i-2}/3^j}{3^i} = \frac{4}{9} \cdot \frac{1}{3^j} < \frac{4}{4+2(3j+2)} & \text{if } t = 3j + 2 \\ \frac{f(3i-3-3j)}{f(3i)} = \frac{3 \cdot 3^{i-2}/3^j}{3^i} = \frac{1}{3} \cdot \frac{1}{3^j} < \frac{4}{4+2(3j+3)} & \text{if } t = 3j + 3 \end{cases}$$

Thus, in this case $(s + 2t) \cdot f(r - t) \leq s \cdot f(r)$ when $s \geq 4$ and $t \geq 1$.

Table 1 Capacity bound for different values of R

R	$d = 7$	$d = 6$	$d = 5$	$d = 4$
6i + 6	$(8 + 2t)f(3i - 1 - t) \leq 8 \cdot f(3i - 1) = 16 \cdot 3^{i-1}$	$(6 + 2t)f(3i - t) \leq 6 \cdot f(3i) = 18 \cdot 3^{i-1}$	$(6 + 2t)f(3i - t) \leq 6 \cdot f(3i) = 18 \cdot 3^{i-1}$	$(4+2t)f(3i+1-t) \leq 4 \cdot f(3i+1) = 16 \cdot 3^{i-1}$
6i + 5	$(7 + 2t)f(3i - 1 - t) \leq 7 \cdot f(3i - 1) = 14 \cdot 3^{i-1}$	$(7 + 2t)f(3i - 1 - t) \leq 7 \cdot f(3i - 1) = 14 \cdot 3^{i-1}$	$(5 + 2t)f(3i - t) \leq 5 \cdot f(3i) = 15 \cdot 3^{i-1}$	$(5 + 2t)f(3i - t) \leq 5 \cdot f(3i) = 15 \cdot 3^{i-1}$
6i + 4	$(8 + 2t)f(3i - 2 - t) \leq 8 \cdot f(3i - 2) = \frac{32}{3} \cdot 3^{i-1}$	$(6 + 2t)f(3i - 1 - t) \leq 6 \cdot f(3i - 1) = 12 \cdot 3^{i-1}$	$(6 + 2t)f(3i - 1 - t) \leq 6 \cdot f(3i - 1) = 12 \cdot 3^{i-1}$	$(4 + 2t)f(3i - t) \leq 4 \cdot f(3i) = 12 \cdot 3^{i-1}$
6i + 3	$(7 + 2t)f(3i - 2 - t) \leq 7 \cdot f(3i - 2) = \frac{28}{3} \cdot 3^{i-1}$	$(7 + 2t)f(3i - 2 - t) \leq 7 \cdot f(3i - 2) = \frac{28}{3} \cdot 3^{i-1}$	$(5 + 2t)f(3i - 1 - t) \leq 5 \cdot f(3i - 1) = 10 \cdot 3^{i-1}$	$(5 + 2t)f(3i - 1 - t) \leq 5 \cdot f(3i - 1) = 10 \cdot 3^{i-1}$
6i + 2	$(8 + 2t)f(3i - 3 - t) \leq 8 \cdot f(3i - 3) = 8 \cdot 3^{i-1}$	$(6 + 2t)f(3i - 2 - t) \leq 6 \cdot f(3i - 2) = 8 \cdot 3^{i-1}$	$(6 + 2t)f(3i - 2 - t) \leq 6 \cdot f(3i - 2) = 8 \cdot 3^{i-1}$	$(4 + 2t)f(3i - 1 - t) \leq 4 \cdot f(3i - 1) = 8 \cdot 3^{i-1}$
6i + 1	$(7 + 2t)f(3i - 3 - t) \leq 7 \cdot f(3i - 3) = 7 \cdot 3^{i-1}$	$(7 + 2t)f(3i - 3 - t) \leq 7 \cdot f(3i - 3) = 7 \cdot 3^{i-1}$	$(5+2t)f(3i-2-t) \leq 5 \cdot f(3i-2) = \frac{20}{3} \cdot 3^{i-1}$	$(5+2t)f(3i-2-t) \leq 5 \cdot f(3i-2) = \frac{20}{3} \cdot 3^{i-1}$

Case 2: $r = 3i + 2$.

$$\frac{f(3i + 2 - t)}{f(3i + 2)} = \begin{cases} \frac{2}{3} \cdot \frac{1}{3^j} \leq \frac{4}{4+2(3j+1)} & \text{if } t = 3j + 1 \\ \frac{1}{2} \cdot \frac{1}{3^j} \leq \frac{4}{4+2(3j+2)} & \text{if } t = 3j + 2 \\ \frac{1}{3} \cdot \frac{1}{3^j} < \frac{4}{4+2(3j+3)} & \text{if } t = 3j + 3 \end{cases}$$

Hence, $(s + 2t) \cdot f(r - t) \leq s \cdot f(r)$ when $s \geq 4$ and $t \geq 1$.

Case 3: $r = 3i + 1$.

$$\frac{f(3i + 1 - t)}{f(3i + 1)} = \begin{cases} \frac{3}{4} \cdot \frac{1}{3^j} < \frac{4}{4+2(3j+1)} & \text{if } t = 3j + 1, t \neq 1 \\ \frac{1}{2} \cdot \frac{1}{3^j} \leq \frac{4}{4+2(3j+2)} & \text{if } t = 3j + 2 \\ \frac{1}{3} \cdot \frac{1}{3^j} < \frac{4}{4+2(3j+3)} & \text{if } t = 3j + 3 \end{cases}$$

In this case, when $s \geq 4, t = 1$, the inequality $(s + 2t) \cdot f(r - t) \leq s \cdot f(r)$ fails. However, one still has $(s + 2t) \cdot f(r - t) \leq s \cdot f(r)$ when $s \geq 4$ and $t \geq 2$. For similar reasons, because

$$\frac{f(3i+1-t)}{f(3i+1)} = \begin{cases} \frac{3}{4} \cdot \frac{1}{3^j} \leq \frac{6}{6+2(3j+1)} & \text{if } t = 3j+1 \\ \frac{1}{2} \cdot \frac{1}{3^j} < \frac{6}{6+2(3j+2)} & \text{if } t = 3j+2 \\ \frac{1}{3} \cdot \frac{1}{3^j} < \frac{6}{6+2(3j+3)} & \text{if } t = 3j+3 \end{cases}$$

one has $(s + 2t) \cdot f(r - t) \leq s \cdot f(r)$ when $s \geq 6$ and $t \geq 1$. \square

Lemma 22 *When $R = 6i + 6$, the maximum capacity is $18 \cdot 3^{i-1}$.*

Proof Only root degree $4 \leq d \leq 7$ needs to be considered according to the root degree bound derived in Sect. 3.2.2. In the following cases, the capacity of candidate trees with the same root degree is firstly compared. One can prove that the tree at certain balance point ($r^+ - r^- \leq 1$) has larger capacity in each case.

Case 1: Candidate trees with root degree $d = 7$.

All these candidate trees have $r^+ \geq r^-$ and $r^+ + r^- + d = 6i + 6$; thus, $1 \leq r^- \leq 3i - 1$. Given such a candidate tree, when writing r^- as $3i - 1 - t$ where $0 \leq t \leq 3i - 1$, one has capacity bound $(R - 2(3i - 1 - t)) \cdot f(3i - 1 - t) = (8 + 2t) \cdot f(3i - 1 - t)$ by Theorem 9. One can prove that this capacity is maximum when $t = 0$. Hence, one only needs to prove $(8 + 2t) \cdot f(3i - 1 - t) \leq 8f(3i - 1)$. Let $r = 3i - 1, s = 8$. Obviously for any $t \geq 1$, Fact 7 implies $(8 + 2t) \cdot f(3i - 1 - t) \leq 8f(3i - 1) = 16 \cdot 3^{i-1}$.

Case 2: Candidate trees with root degree $d = 6$.

All these candidate trees have $r^+ \geq r^-$ and $r^+ + r^- + d = 6i + 6$; thus, $1 \leq r^- \leq 3i$. Given such a candidate tree, when writing r^- as $3i - t$ where $0 \leq t \leq 3i$, one has capacity bound $(R - 2(3i - t)) \cdot f(3i - t) = (d + 2t) \cdot f(3i - t)$. One can prove that this capacity is maximum when $t = 0$. That is, one needs to prove $(6 + 2t) \cdot f(3i - t) \leq 6 \cdot f(3i)$ when $t \geq 1$. Let $r = 3i, s = 6$. Fact 7 implies $(6 + 2t) \cdot f(3i - t) \leq 6 \cdot f(3i)$. Hence, the balance point $t = 0, r^- = 3i, r^+ = 3i$ achieves maximum capacity in this case.

Case 3: Candidate trees with root degree $d = 5$.

In this case $1 \leq r^- \leq 3i$. Write r^- as $3i - t$. Similarly, let $r = 3i, s = 6$. Fact 7 implies $(6 + 2t) \cdot f(3i - t) \leq 6f(3i)$, which further implies that the capacity is maximized to be $18 \cdot 3^{i-1}$ when $t = 0$.

Case 4: Candidate trees with root degree $d = 4$.

In this case $1 \leq r^- \leq 3i + 1$. Let $r = 3i + 1, s = 4$. When $t \geq 2$, Fact 7 implies $(4 + 2t) \cdot f(3i + 1 - t) \leq 4 \cdot f(3i + 1)$. Thus, the capacity of candidate tree which has $r^- = 3i + 1 - t$ and $t \geq 2$ is at most $4f(3i + 1) = 16 \cdot 3^{i-1}$. While for $t = 1$, the inequality fails as $(4 + 2) \cdot f(3i) = 18 \cdot 3^{i-1} > 4 \cdot f(3i + 1) = 16 \cdot 3^{i-1}$. However, in this special case, the capacity $6 \cdot f(3i)$ is equal to that of case 2. Finally, note that when $t = 0$ the capacity bound $4f(3i + 1) = 16 \cdot 3^{i-1}$ is less than that in case 2.

Since in all the four cases the maximum capacity is $18 \cdot 3^{i-1}$, the lemma is proved. \square

Considering other values of R , the following theorem can be proved.

Theorem 10 *For 2-replacement cost R , the maximum capacity is*

$$g(R) = \begin{cases} 6 \cdot 3^{i-1} & \text{if } R = 6i \\ 7 \cdot 3^{i-1} & \text{if } R = 6i + 1 \\ 8 \cdot 3^{i-1} & \text{if } R = 6i + 2 \\ 10 \cdot 3^{i-1} & \text{if } R = 6i + 3 \\ 12 \cdot 3^{i-1} & \text{if } R = 6i + 4 \\ 15 \cdot 3^{i-1} & \text{if } R = 6i + 5 \end{cases}$$

Proof Due to the similarity of the proofs for different values R , [43] put the key inequality and capacity bound in Table 1 for $R = 6i + 1, 6i + 2, 6i + 3, 6i + 4, 6i + 5$. Notice that in all cases, when $t \geq 2$ the inequality holds. In the special case that $t = 1$, when $R = 6i + 6, d = 4$, $R = 6i + 1, d = 5$, or $R = 6i + 1, d = 4$, the inequality fails. The analysis of the case where $R = 6i + 1, d = 5$ or $R = 6i + 1, d = 4$ is similar to that of the case $R = 6i + 6, d = 4$ as shown in the proof of Lemma 22. For example, when $R = 6i + 1, d = 5$, and $t = 1$, the capacity bound $(6i + 1 - 2(3i - 2 - t)) = 7f(3i - 3)$ is the capacity that can be achieved in the case $R = 6i + 1, d = 7$. \square

After obtaining the capacity for the 2-replacement cost R , one can finally prove that among the candidate trees with n leaves, the optimal cost can be achieved by some balanced structure as shown below.

Definition 11 We use the balanced tree to denote a tree with root degree d where each subtree is 2–3 tree and has number of leaves differed by at most 1.

Theorem 11 *Among trees with n leaves,*

1. *When $n \in (15 \cdot 3^{i-1}, 18 \cdot 3^{i-1}]$, the optimal tree is a balanced tree which has root degree 6 and 2-replacement cost $6i+6$.*

2. When $n \in (12 \cdot 3^{i-1}, 15 \cdot 3^{i-1}]$, the optimal tree is a balanced tree which has root degree 5 and 2-replacement cost $6i+5$.
3. When $n \in (10 \cdot 3^{i-1}, 12 \cdot 3^{i-1}]$, the optimal tree is a balanced tree which has root degree 6 and 2-replacement cost $6i+4$.
4. When $n \in (8 \cdot 3^{i-1}, 10 \cdot 3^{i-1}]$, the optimal tree is a balanced tree which has root degree 5 and 2-replacement cost $6i+3$.
5. When $n \in (7 \cdot 3^{i-1}, 8 \cdot 3^{i-1}]$, the optimal tree is a balanced tree which has root degree 6 and 2-replacement cost $6i+2$.
6. When $n \in (6 \cdot 3^{i-1}, 7 \cdot 3^{i-1}]$, the optimal tree is a balanced tree which has root degree 7 and 2-replacement cost $6i+1$.

Proof When $n \in (15 \cdot 3^{i-1}, 18 \cdot 3^{i-1}]$, one has $OPT_2(n) = 6i + 6$. One can prove that the balanced tree with root degree 6 can always achieve this optimal cost. In the balanced tree, each subtree T_j ($1 \leq j \leq 6$) has the number of leaves $n_j = \lceil \frac{n-j+1}{6} \rceil \in [\lfloor \frac{5}{2} \cdot 3^{i-1} \rfloor, 3 \cdot 3^{i-1}]$. By function $f(\cdot)$, one has $S_{T_i} \leq 3i$. Thus, any two leaves from the tree will incur a replacement cost at most $2 \cdot 3i + 6 = 6i + 6$.

When $n \in (12 \cdot 3^{i-1}, 15 \cdot 3^{i-1}]$, one has $OPT_2(n) = 6i + 5$. Then one can prove that the balanced tree with root degree 5 can always achieve the optimal cost. In the balanced tree, each subtree T_j ($1 \leq j \leq 5$) has the number of leaves $n_j = \lceil \frac{n-j+1}{5} \rceil \in [\lfloor \frac{12}{5} \cdot 3^{i-1} \rfloor, 3 \cdot 3^{i-1}]$. By function $f(\cdot)$, one has $S_{T_i} \leq 3i$. Thus, any two leaves from the tree will incur a replacement cost at most $2 \cdot 3i + 5 = 6i + 5$.

When $n \in (10 \cdot 3^{i-1}, 12 \cdot 3^{i-1}]$, one has $OPT_2(n) = 6i + 4$ and $n_j = \lceil \frac{n-j+1}{6} \rceil \in [\lfloor \frac{5}{3} \cdot 3^{i-1} \rfloor, 2 \cdot 3^{i-1}]$. By function $f(\cdot)$, one has $S_{T_i} \leq 3i - 1$. Thus, any two leaves from the tree will incur a replacement cost at most $2 \cdot (3i - 1) + 6 = 6i + 4$.

When $n \in (8 \cdot 3^{i-1}, 10 \cdot 3^{i-1}]$, one has $OPT_2(n) = 6i + 3$ and $n_j = \lceil \frac{n-j+1}{5} \rceil \in [\lfloor \frac{8}{5} \cdot 3^{i-1} \rfloor, 2 \cdot 3^{i-1}]$. By function $f(\cdot)$, one has $S_{T_i} \leq 3i - 1$. Thus, any two leaves from the tree will incur a replacement cost at most $2 \cdot (3i - 1) + 5 = 6i + 3$.

When $n \in (7 \cdot 3^{i-1}, 8 \cdot 3^{i-1}]$, one has $OPT_2(n) = 6i + 2$ and $n_j = \lceil \frac{n-j+1}{6} \rceil \in [\lfloor \frac{7}{6} \cdot 3^{i-1} \rfloor, \frac{4}{3} \cdot 3^{i-1}]$. By function $f(\cdot)$, one has $S_{T_i} \leq 3i - 2$. Thus, any two leaves from the tree will incur a replacement cost at most $2 \cdot (3i - 2) + 6 = 6i + 2$.

When $n \in (6 \cdot 3^{i-1}, 7 \cdot 3^{i-1}]$, one has $OPT_2(n) = 6i + 1$. The balanced tree with root degree 7 where $n_j = \lceil \frac{n-j+1}{7} \rceil \in [\lfloor \frac{6}{7} \cdot 3^{i-1} \rfloor, 3^{i-1}]$ can always achieve the optimal cost. By function $f(\cdot)$, one has $S_{T_i} \leq 3i - 3$. Thus, any two leaves from the tree will incur a replacement cost at most $2 \cdot (3i - 3) + 7 = 6i + 1$. \square

Finally, the structure of the dominating branch is fixed and the optimal tree structure for the 2-replacement problem is obtained. Wu et al. [43] conjecture the general result for the k -replacement problem as follows.

The general form of capacity $G_k(R)$ which denotes the maximum number of leaves that can be placed in a tree given the k -replacement cost R in the k -replacement problem is conjectured to be of the form shown in Eq.(1). They believe such a capacity function is generated by some balanced structure of the trees. Furthermore, if the conjecture is proved to be correct, it is also possible to obtain

the optimal structure in a similar way as in the proof of [Theorem 11](#) and construct the optimal tree in $O(n)$ time:

$$G_k(R) = \begin{cases} (3k + \alpha) \cdot 3^{i-1} & \text{if } R = 3k \cdot i + \alpha, \alpha \in [0, k), \\ (4k + 2(\alpha - k)) \cdot 3^{i-1} & \text{if } R = 3k \cdot i + \alpha, \alpha \in [k, 2k), \\ (6k + 3(\alpha - 2k)) \cdot 3^{i-1} & \text{if } R = 3k \cdot i + \alpha, \alpha \in [2k, 3k). \end{cases} \quad (1)$$

4 Other Variants

4.1 Minimize sequential update cost for a sequence of actions

When the key tree carries out sequential update instead of the batch update, [\[10\]](#) and [\[44\]](#) studied the structure of the optimal trees together with algorithms for computing them. When the user change is n consecutive deletions, [\[10\]](#) prove that there is an optimal tree in which each internal node has at most five children and each internal node with at least one non-leaf child has exactly three children. Based on these characterizations, they present a dynamic programming algorithm that computes an optimal key tree in $O(n^2)$ time. Later in [\[44\]](#), the authors prove a semi-balance property for the optimal tree and use it to reduce the running time to $O(\log n)$ multiplications of $O(\log n)$ —bit integers. Then they study the optimal tree structure when insertion cost is also considered. They show that the optimal tree is such a tree where any internal node has degree at most 7 and children of nodes with degree not equal to 2 or 3 are all leaves. Based on this result, they give a dynamic programming algorithm with $O(n^2)$ time to compute the optimal tree.

4.2 Minimize Cost for the Next Update

Selcuk et al. [\[31\]](#) studied the key tree optimization when the objective is to minimize the expected cost of the next rekey operation (caused by a leave or compromise event). They define the expected cost as $\sum(p_i \cdot d_i)$ where p_i is the probability that member i will be the next to be evicted/compromised and d_i is its depth in the tree. They pointed out that although this objective is the same as data compression trees, there is a major difference. In the key tree, changing a member's location will cause extra cost, while in the data compression tree, such a movement will not cause extra overhead. However, theoretical results on optimization is lacking because of the complicated nature of this objective function.

4.3 Optimization with Underlying Network Structure

If the users themselves have certain underlying network connection, the optimization problem is called key hierarchy problem and defined by Chan et al. [\[8\]](#).

An instance of the key hierarchy problem is given by the tuple (S, w, G, c) , where S is the set of group members, $w : S \rightarrow Z$ is the weight function capturing the update probability of each member, $G = (V, E)$ is the underlying communication network with $V \supseteq S \cup \{r\}$ where r is the group controller (GC), and $c : E \rightarrow Z$ specifies the cost of the edges in G .

For a given instance, a *hierarchy* on a set $X \subseteq S$ is a rooted tree H whose leaves are the elements of X . For a hierarchy T over X , the cost of a member $x \in X$ with respect to T is given by $\sum_{\text{ancestor } u \text{ of } x} \sum_{\text{child } v \text{ of } u} M(T_v)$ where T_v is the set of leaves in the subtree of T rooted at v , and for any set $Y \subseteq S$, $M(Y)$ is the cost of multicasting from root r to Y in G . The cost of a hierarchy T over X is the sum of the weighted costs of all the members of X with respect to T . The goal is to determine a hierarchy of minimum cost.

Within that model, [8] presented a polynomial-time approximation scheme for minimizing the average number of multicast messages needed for an update. They further showed that when routing costs are considered, the problem is NP-hard even if the underlying routing network is a tree (by a reduction from three Partition) or if every member has the same update frequency (by a reduction from 3D matching). Then for the general case when routing network is an arbitrary weighted graph and group members have nonuniform update frequencies, they designed a polynomial-time constant-factor approximation algorithm.

5 Conclusion

This chapter summarizes the recent progress in the key tree optimization problem, especially in the domain of the batch update model. When different batch decisions are adopted based on different user behaviors, optimal solutions can be computed in polynomial time in most of the cases. In the models considered in this chapter, there are quite some open problems to be solved. Firstly, in the model where each user has a certain probability to get replaced, the structural properties of the optimal tree for the uniform probability case when the probability tends to 0 are still well worth exploring. For the heterogeneous probability version, one can try to look for efficient algorithms to calculate the optimal tree. Secondly, when a certain number of users leave the group during the batch period, the conjecture proposed in [43] for the general k is to be verified or disproved. Finally, one can also consider other user patterns and other cost models for the key tree optimization problems.

Abstract

The analysis of nonblocking switching networks often centers around a natural combinatorial optimization problem. The constraints capture the limited physical capacities and/or capabilities of the inputs, outputs, the internal switching components, and their interconnection patterns. The objective of the optimization problem is often to minimize the number of certain switching components.

Recent works have pointed to a simple strategy to derive useful bounds for the optimization objective. The bounds give us sufficient conditions for a switching network design to be nonblocking in some desired sense. The strategy, which applies in a variety of settings, works roughly as follows. The optimization problem is first rewritten as an (integer) linear program. By exploiting the structure of the primal linear program or by specifying a family of dual-feasible solutions, a sufficient condition for the switching network to be nonblocking can quickly be derived.

This chapter illustrates the above analysis technique with many examples on two fundamental switching network topologies: the Clos network and the multilog network. The examples shall cover a wide range of switching network environments: from unicast to multicast, from circuit- to multirate- to optical-switching, and from wide-sense to strictly nonblocking networks. Many known results are derived as direct consequences of these examples.

1 Introduction

The two most important architectures for designing nonblocking switching networks are Clos-type [7] and Banyan-type [16]. The Clos network not only played a central role in classical circuit-switching theory [1, 21] but also was the bedrock of multirate switching [6, 15, 19, 29, 35, 37, 50] (e.g., in time-division switching environments where connections are of varying bandwidth requirements) and photonic-switching [17, 38, 45, 46, 55, 59, 60]. The Banyan network is isomorphic to various other “bit-permutation” networks such as Omega, baseline, etc. [3]; they are called *Banyan-type* networks and have been used extensively in designing electronic and optical switches, as well as parallel processor architectures [12]. In particular, the multilog design which involves the vertical stacking of a number of inverse Banyan planes has been used in circuit- and photonic-switching environments because they have small depth ($\log N$), self-routing capability, and absolute signal loss uniformity [20, 24, 25, 27, 28, 33, 47, 53]. Clos and the multilog networks are formally defined in the next section.

In analyzing Clos networks, the most basic task is to determine the minimum number of middle-stage crossbars so that the network satisfies a given nonblocking condition. This holds true in space-, multirate-, and photonic-switching; in unicast, f -cast and multicast, and broadcast traffic patterns; and in all nonblocking types (strict-sense, wide-sense, and rearrangeable). Similarly, analyzing multilog networks often involves determining the minimum number of Banyan planes so that the network satisfies some requirements.

This chapter aims to illustrate that a simple and effective two-step strategy based on linear programming can be employed in the analysis:

- First, the minimum value being sought (e.g., the number of middle-stage crossbars in a Clos network or the minimum number of Banyan planes in a multilog network) is upperbounded by the optimum value of a linear program (LP) of the form $\max\{\mathbf{c}^T \mathbf{x} \mid \mathbf{A}\mathbf{x} \leq \mathbf{b}, \mathbf{x} \geq \mathbf{0}\}$. The maximization objective often comes from some form of worst-case analysis. For example, one might want the maximum number of middle-stage crossbars in a Clos network which is insufficient to carry a new request. The constraints of the linear program are used to express the fact that no input or output can generate or receive connection requests totaling more than its capacity.
- Second, by specifying *any* feasible solution, say \mathbf{y}^* , to the dual program $\min\{\mathbf{b}^T \mathbf{y} \mid \mathbf{A}^T \mathbf{y} \geq \mathbf{c}\}$ and applying weak duality, the dual-objective value $\mathbf{b}^T \mathbf{y}^*$ can be used as an upperbound for the minimum value being sought.

In some cases, the second step may not be necessary because the primal linear program is small with only a few variables. In most cases, however, the linear program and its dual are very general, dependent on various parameters of the switch design (e.g., number of inputs and switching elements' dimensions). In such cases, it would be difficult to come up with a closed-form primal-optimal solution. Fortunately, by weak duality, a dual-feasible solution can quickly “certify” the bound. In fact, as shall be seen later, it is often the case that a family of dual-feasible solutions is needed and the best one is chosen (i.e., the one giving the smallest objective value) in accordance with the parameters of the problem at hand.

The linear programming duality technique was first used in a recent paper [40] to analyze the (unicast) strictly nonblocking multilog architecture in the photonic-switching case, subject to general crosstalk constraints. This chapter demonstrates that the technique can be applied to a wider range of switching network analysis problems, presenting a subset of follow-up works in [41, 42]. Clos and multilog networks are used as canonical examples to illustrate the analysis technique.

The rest of this chapter is organized as follows. [Section 2](#) presents notations and terminologies. [Section 3](#) illustrates the strength of the LP-duality technique on analyzing several problems on the Clos networks. [Sections 4–7](#) present examples in the multilog architecture. [Section 4](#) is on strictly non-blocking photonic unicast switching under a general crosstalk constraint; [Sect. 5](#) deals with the strictly non-blocking multicast case under the same constraint. [Section 6](#) presents results on the f -cast wide-sense non-blocking case, and [Sect. 7](#) analyzes the crosstalk-free f -cast wide-sense non-blocking multilog networks. Finally, [Sect. 8](#) concludes the chapter with some remarks on open problems.

2 Preliminaries

The following notations will be used throughout this chapter. For any positive integers l, d , let $[l]$ denote the set $\{1, \dots, l\}$, \mathbb{Z}_d denote the set $\{0, \dots, d - 1\}$ which can be thought of as d -ary “symbols,” \mathbb{Z}_d^l denote the set of all d -ary strings of length

l , b^l denote the string with symbol $b \in \mathbb{Z}_d$ repeated l times (e.g., $3^4 = 3333$), $|\mathbf{s}|$ denote the length of any d -ary string \mathbf{s} (e.g., $|31| = 2$), and $\mathbf{s}_{i..j}$ denote the substring $s_i \dots s_j$ of a string $\mathbf{s} = s_1 \dots s_l \in \mathbb{Z}_d^l$. If $i > j$, then $\mathbf{s}_{i..j}$ is the empty string.

2.1 Switching Networks

The reader is referred to [1, 18, 19, 21, 36] for more detailed coverage on switching networks, their practical usage, and related concepts. The discussion on switching network background will be relatively brief.

Roughly, an $N \times N$ switching network is used to interconnect N inputs to N outputs. Figure 1 shows a switching network with 32 inputs and 32 outputs. Depending on the application at hand, the inputs and outputs represent different objects. For example, in the old days, telephone calls are circuit-switched from inputs to outputs simultaneously in a one-to-one fashion. In parallel computer architectures, inputs may be processors, and outputs are memories. Inside a modern Internet router, there often is a switching network (or *switching fabric*) connecting input linecards to output linecards. Internal to the switching network are various types of *switching components* or *switching elements*. For example, in Fig. 1, the most basic switching element is used: 2×2 switching elements. The key functionality of a switching network is to transfer (electronic, optical) signals from the inputs to outputs, realizing as many connection patterns as possible while keeping the hardware cost as low as possible. Hardware cost is often measured by the number of switching components used.

2.1.1 Connection Patterns

The connection patterns to be realized could be one-to-one (*unicast*) or one-to-many (*multicast*). The one-to-all connection pattern is called a *broadcast*. Multicast-capable (photonic)-switching architectures will likely play a central role in the near future because most bandwidth-intensive applications require multicast support. Many current multicast switch designs focus on the broadcast case [13, 26, 57]. Although broadcast switches are certainly capable of supporting multicast with any *fanout* requirements, they are not scalable due to their prohibitively high hardware cost. (The fanout of a multicast request is size of the output set the request asks for.) Moreover, most multicast applications are restricted to a group of users, where broadcasting is rarely required. Hence, allocating expensive broadcast capability to each network switch is cost-inefficient for most practical purposes. Moreover, from the viewpoints of resource fairness and network security (e.g., limiting virus and worm propagation), there are other good reasons to impose a restriction on the maximum fanout of each request. Consequently, there have been many research efforts on designing and analyzing *f*-*cast* switches, in which the maximum fanout of each request is upperbounded by the parameter f [4, 14, 21, 23, 41–43, 54]. An *f*-*cast* switch usually requires significantly lower hardware cost than its broadcast counterpart. Furthermore, a good design of an $N \times N$ *f*-*cast* switch covers both the unicast design ($f = 1$) and the broadcast design ($f = N$) as special cases.

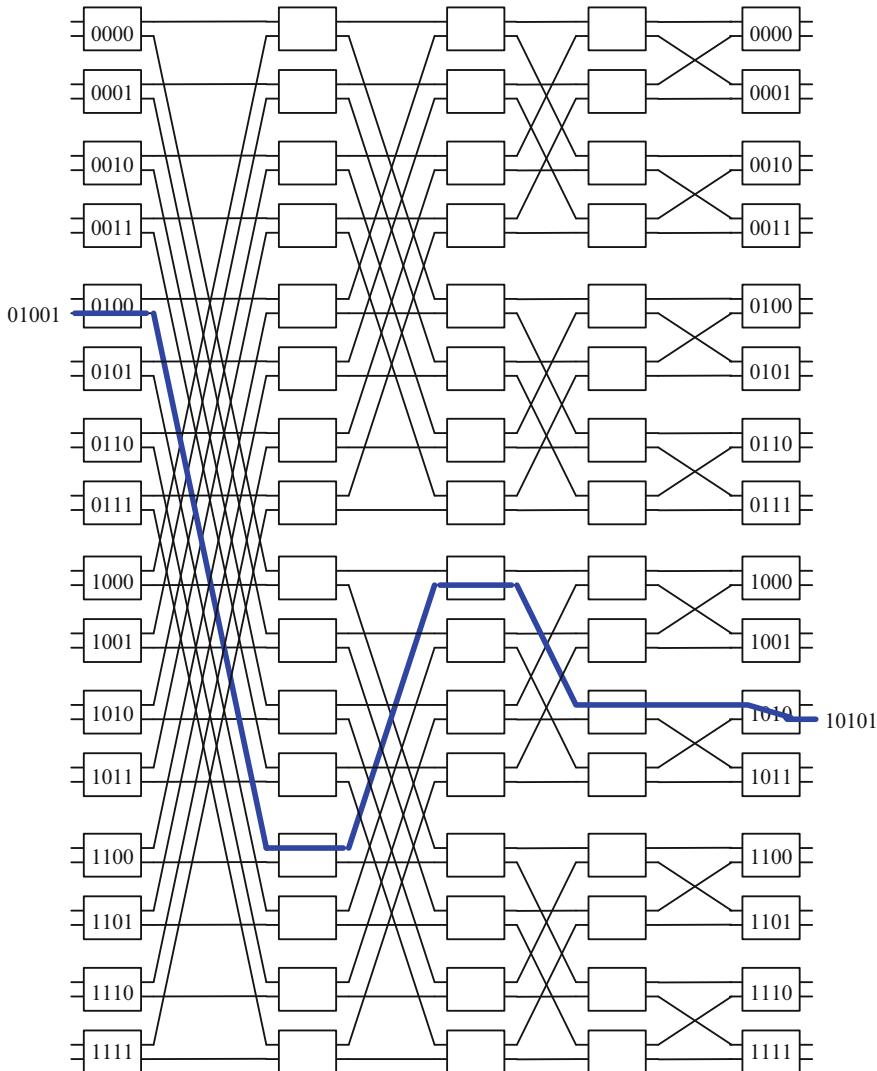

Fig. 1 The inverse Banyan network $\text{BY}^{-1}(5)$

Consequently, studying general f -cast switches is both mathematically pleasing and practically useful, as the results potentially can offer network designers more flexibility in selecting architectures for future multicast-intensive networks.

2.1.2 Switching Environments

Traditionally, each link can only carry one connection at a time. This setting is called the *circuit-switching* or *space-switching* environment, which served as the theoretical foundation for telephone switching [1, 21]. When time-division

multiplexing (TDM) is applicable, multiple connections can time-share a link as long as the total bandwidth of the connections does not exceed the link's capacity. This setting is called the *multirate* environment, which is the theoretical foundation for the development of most Asynchronous Transfer Mode (ATM) switching systems from major ATM equipment manufacturer [8, 50, 51]. With the advances of dense wavelength division multiplexing (DWDM) technology [34, 44, 48], connections can also share (optical) links by being carried on different wavelengths. The number of wavelengths in a wavelength division multiplexed (WDM) network can be up to hundreds or more per fiber, and each wavelength operates at 10 Gbps (OC-192) or higher [30–32].

In circuit switching, a request is a pair (\mathbf{a}, \mathbf{b}) where \mathbf{a} is an unused input and \mathbf{b} is an unused output. A route $R(\mathbf{a}, \mathbf{b})$ realizes the request if it does not share any internal link with existing routes. In an f -cast switching network, each multicast request is of the form (\mathbf{a}, B) where \mathbf{a} is some input and B is a subset of at most f outputs. The number f is called the *fanout restriction*. An $N \times N$ multicast network without fanout restriction is equivalent to an N -cast network.

In the multirate case, each link has a capacity (e.g., bandwidth). All inputs and outputs have the same capacity normalized to 1. An input cannot request more than its capacity, neither can outputs. A request is of the form $(\mathbf{a}, \mathbf{b}, w)$ where \mathbf{a} is an input, \mathbf{b} is an output, and $w \leq 1$ is the requested *rate*. If existing requests have used up to x and y units of \mathbf{a} 's and \mathbf{b} 's capacity, respectively, then the new requested rate w can only be at most $\min\{1 - x, 1 - y\}$. An internal link cannot carry requests with total rate more than 1. In practice, internal links might have higher capacities than 1 because *internal speedup* is needed for throughput guarantees [9]. A simpler picture is presented here for the sake of clarity, even though the analysis technique works in the speedup case just as well.

2.1.3 Nonblockingness

As switching elements and links have limited capacities, one connection can *block* another from being realized. For example, the switching network shown in Fig. 1 is a unique-path network: there is only one path between an input and an output. If each internal link can only carry one connection at a time, then the connection shown in the figure blocks a connection from the other input of switching element 0100 to the other output of switching element 1010. In some switching environment such as photonic switching, it may not even be desirable for two distinct paths to share a switching element. For example, the so-called *crosstalk-free* constraint requires as much. In this case, one route blocks another route if they share a switching element. On the other hand, in a multirate switching environment, routes are allowed to share both links and nodes as long as the total rates of those routes do not exceed the shared element's capacity. Thus, the notion of blockingness intimately depends on the switching environment that the switching architecture is designed for.

One of the main problems in switching network theory is to design and analyze switching network which are nonblocking in a specific sense. There are three levels of nonblockingness of a switching network. A network is *rearrangeably*

nonblocking (RNB) if it can realize any one-to-one mapping between inputs and outputs simultaneously; it is *wide-sense nonblocking* (WSNB) if a new request from a free input to a free output can be realized without disturbing existing connections, as long as all requests are routed according to some algorithm; finally, it is *strictly nonblocking* (SNB) if a new request from a free input to a free output can always be routed no matter how existing connections were arranged. In the multicast case, the three nonblocking concepts are defined similarly.

2.2 The 3-Stage Clos Networks

An $n \times m$ crossbar can be thought of as a switching network with n inputs and m outputs which is strictly nonblocking: a free input can always communicate with a free output without disturbing existing connections between inputs and outputs. This definition of crossbars is sufficient for the purposes of this chapter. How specifically a crossbar is designed is not particularly important.

The *Clos network* $C(n_1, r_1, m, n_2, r_2)$ is a 3-stage interconnection network, where the first stage consists of r_1 crossbars of size $n_1 \times m$, the last stage has r_2 crossbars of dimension $m \times n_2$, and the middle stage has m crossbars of dimension $r_1 \times r_2$ (see Fig. 2). Each input crossbar I_i ($i = 1, \dots, r_1$) is connected to each middle crossbar M_j ($j = 1, \dots, m$). Similarly, the middle stage and the last stage are fully connected. When $n_1 = n_2 = n$ and $r_1 = r_2 = r$, the network is called the *symmetric 3-stage Clos network*, denoted by $C(n, m, r)$. The Clos architecture was proposed by Clos in 1953 [7] for telephone circuit switching. The idea was very influential in the design of modern switching architectures.

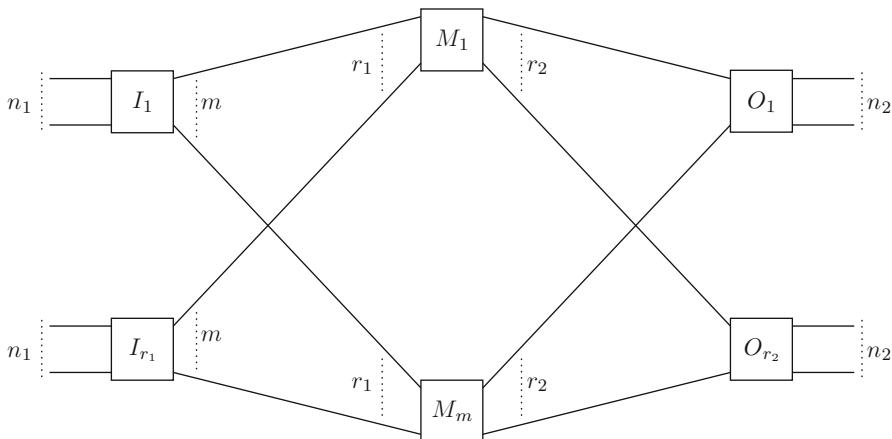

Fig. 2 The 3-stage Clos network $C(n_1, r_1, m, n_2, r_2)$

2.3 The d -Ary Multilog Networks

Let $N = d^n$. The $\log_d(N, 0, m)$ network denotes the stacking of m copies of the d -ary inverse Banyan network $\text{BY}^{-1}(n)$ with N inputs and N outputs. [Figure 3](#) shows a $\log_d(N, 0, 3)$ network. The inputs are connected to a $1 \times m$ demultiplexor (or equivalently a $1 \times m$ crossbar). The output side is the mirror image of the input side, namely, outputs of the network are outputs of multiplexors (or equivalently $m \times 1$ crossbars). [Figure 4](#) illustrates the architecture of a specific multilog network with two planes.

Each of the copies of the inverse Banyan network $\text{BY}^{-1}(n)$ is called a $\text{BY}^{-1}(n)$ -plane or a (inverse) Banyan plane of the multilog network. A d -ary $\text{BY}^{-1}(n)$ -plane is itself a switching network with N inputs and N outputs. [Figures 1](#) and [5](#) illustrate two Banyan planes. Label the inputs and outputs of a $\text{BY}^{-1}(n)$ -plane with d -ary strings of length n . Specifically, each input $\mathbf{x} \in \mathbb{Z}_d^n$ and output $\mathbf{y} \in \mathbb{Z}_d^n$ have the form $\mathbf{x} = x_1 \cdots x_n$, $\mathbf{y} = y_1 \cdots y_n$, where $x_i, y_i \in \mathbb{Z}_d$, $\forall i \in [n]$.

Also, label the $d \times d$ switching elements in each of the n stages of a $\text{BY}^{-1}(n)$ -plane with d -ary strings of length $n - 1$. An input \mathbf{x} (respectively, output \mathbf{y}) is connected to the switching element labeled $\mathbf{x}_{1..n-1}$ in the first stage (respectively, $\mathbf{y}_{1..n-1}$ in the last stage). A switching element labeled $\mathbf{z} = z_1 \cdots z_{n-1}$ in stage $i \leq n - 1$ is connected to d switching elements in stage $i + 1$ numbered $z_1 \cdots z_{i-1} * z_{i+1} \cdots z_{n-1}$, where $*$ is any symbol in \mathbb{Z}_d .

For the sake of clarity, let us first consider a small example. Consider the unicast request $(\mathbf{x}, \mathbf{y}) = (01001, 10101)$ when $d = 2, n = 5$. The input $\mathbf{x} = 01001$ is connected to the switching element labeled 0100 in the first stage, which is connected to two switching elements labeled 0100 and 1100 in the second stage

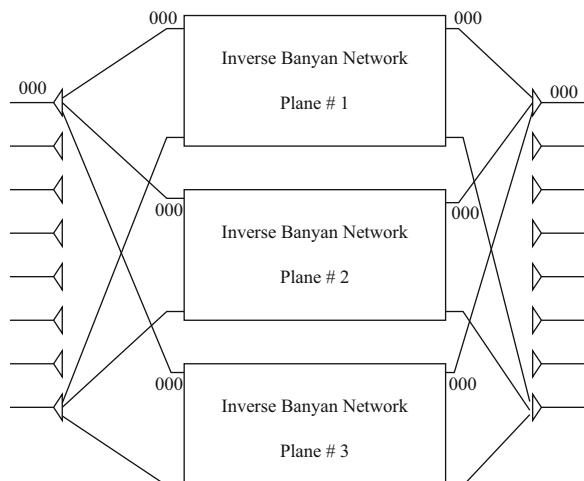

Fig. 3 A multilog network with 3 inverse Banyan planes

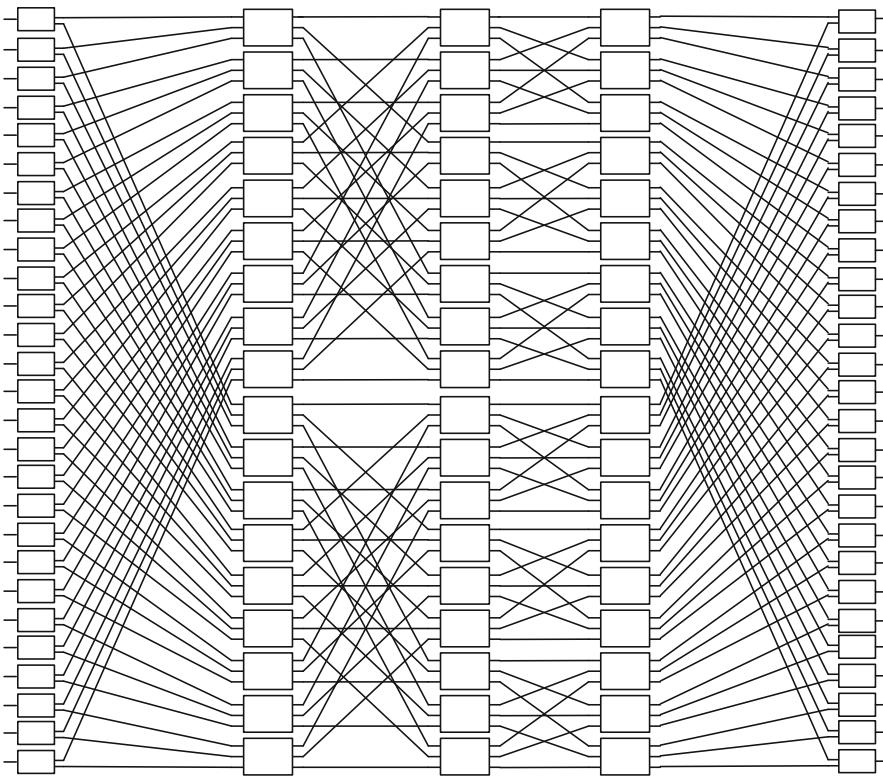

Fig. 4 The $\log_3(27, 0, 2)$ network

and so on. The unique path from \mathbf{x} to \mathbf{y} in the $\text{BY}^{-1}(n)$ -plane can be explicitly written out (see Fig. 1):

input \mathbf{x}	01001
stage-1 switching element	0100
stage-2 switching element	1100
stage-3 switching element	1010
stage-4 switching element	1010
stage-5 switching element	1010
output \mathbf{y}	10101

A pattern emerges from the above example: the prefixes of $\mathbf{y}_{1..n-1}$ are “taking over” the prefixes of $\mathbf{x}_{1..n-1}$ on the path from \mathbf{x} to \mathbf{y} . In general, the unique path $R(\mathbf{x}, \mathbf{y})$ in a $\text{BY}^{-1}(n)$ -plane from an arbitrary input \mathbf{x} to an arbitrary output \mathbf{y} is exactly the following:

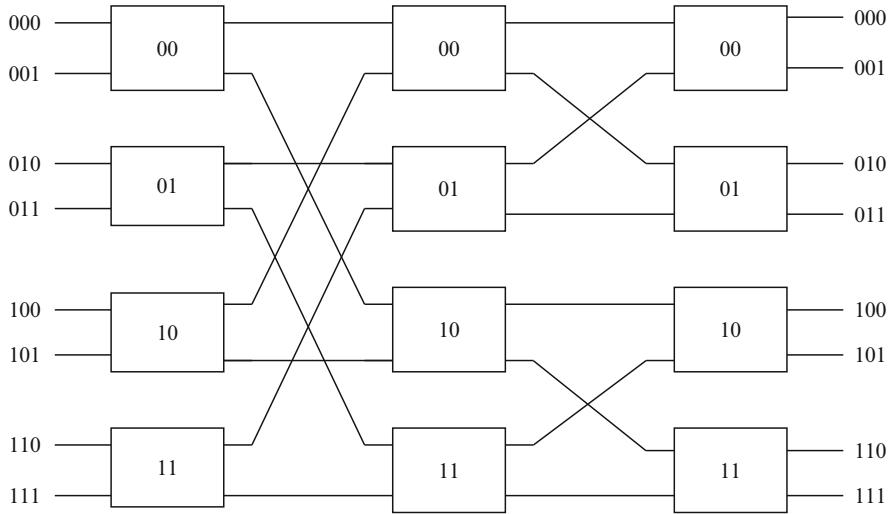

Fig. 5 The inverse Banyan network $\text{BY}^{-1}(3)$

input \mathbf{x}	$x_1 x_2 \dots x_{n-1} x_n$
stage-1 switching element	$x_1 x_2 \dots x_{n-1}$
stage-2 switching element	$y_1 x_2 \dots x_{n-1}$
stage-3 switching element	$y_1 y_2 \dots x_{n-1}$
\vdots	\vdots
stage- n switching element	$y_1 y_2 \dots y_{n-1}$
output \mathbf{y}	$y_1 y_2 \dots y_{n-1} y_n$

Now, consider two unicast requests (\mathbf{a}, \mathbf{b}) and (\mathbf{x}, \mathbf{y}) . From the observation above, on the same $\text{BY}^{-1}(n)$ -plane, the two routes $R(\mathbf{a}, \mathbf{b})$ and $R(\mathbf{x}, \mathbf{y})$ share a switching element (also called a node) if and only if there is some $j \in [n]$ such that $\mathbf{b}_{1..j-1} = \mathbf{y}_{1..j-1}$ and $\mathbf{a}_{j..n-1} = \mathbf{x}_{j..n-1}$. In this case, the two paths intersect at a stage j switching element. It should be noted that two requests' paths may intersect at more than one switching element.

For any two d -ary strings $\mathbf{u}, \mathbf{v} \in \mathbb{Z}_d^l$, let $\text{PRE}(\mathbf{u}, \mathbf{v})$ denote the *longest common prefix*, and $\text{SUF}(\mathbf{u}, \mathbf{v})$ denote the *longest common suffix* of \mathbf{u} and \mathbf{v} , respectively. For example, if $\mathbf{u} = 0100110$ and $\mathbf{v} = 0101010$, then $\text{PRE}(\mathbf{u}, \mathbf{v}) = 010$ and $\text{SUF}(\mathbf{u}, \mathbf{v}) = 10$. The following proposition immediately follows:

Proposition 1 Let (\mathbf{a}, \mathbf{b}) and (\mathbf{x}, \mathbf{y}) be two unicast requests. Then their corresponding routes $R(\mathbf{a}, \mathbf{b})$ and $R(\mathbf{x}, \mathbf{y})$ in a $\text{BY}^{-1}(n)$ -plane share at least a common switching element if and only if

$$|\text{SUF}(\mathbf{a}_{1..n-1}, \mathbf{x}_{1..n-1})| + |\text{PRE}(\mathbf{b}_{1..n-1}, \mathbf{y}_{1..n-1})| \geq n - 1. \quad (1)$$

Moreover, the routes $R(\mathbf{a}, \mathbf{b})$ and $R(\mathbf{x}, \mathbf{y})$ intersect at exactly one switching element if and only if

$$|\text{SUF}(\mathbf{a}_{1..n-1}, \mathbf{x}_{1..n-1})| + |\text{PRE}(\mathbf{b}_{1..n-1}, \mathbf{y}_{1..n-1})| = n - 1, \quad (2)$$

in which case, the common switching element is a switching element at stage $|\text{PRE}(\mathbf{b}_{1..n-1}, \mathbf{y}_{1..n-1})| + 1$ of the $\text{BY}^{-1}(n)$ -plane.

Similarly, on the same Banyan plane, the two routes $R(\mathbf{a}, \mathbf{b})$ and $R(\mathbf{x}, \mathbf{y})$ share a link if and only if there is some $j \in [n - 1]$ such that $\mathbf{b}_{1..j-1} = \mathbf{y}_{1..j-1}$, $\mathbf{a}_{j..n-1} = \mathbf{x}_{j..n-1}$, $\mathbf{b}_{1..j} = \mathbf{y}_{1..j}$, and $\mathbf{a}_{j+1..n-1} = \mathbf{x}_{j+1..n-1}$. In this case, the two routes share the link from a stage j switching element to a stage $j + 1$ switching element. From the analysis, the following proposition follows:

Proposition 2 *Let (\mathbf{a}, \mathbf{b}) and (\mathbf{x}, \mathbf{y}) be two unicast requests. Then their corresponding routes $R(\mathbf{a}, \mathbf{b})$ and $R(\mathbf{x}, \mathbf{y})$ in a $\text{BY}^{-1}(n)$ -plane share at least a common link if and only if*

$$|\text{SUF}(\mathbf{a}_{1..n-1}, \mathbf{x}_{1..n-1})| + |\text{PRE}(\mathbf{b}_{1..n-1}, \mathbf{y}_{1..n-1})| \geq n. \quad (3)$$

3 Clos Network Analysis Examples

3.1 Two Classic Examples in Circuit Switching

The following two simple examples have become classic textbook materials [1, 21].

Example 1 (Strictly nonblocking 3-stage Clos networks) Consider the symmetric Clos network $C(n, m, r)$. Consider a new request from an input of input crossbar I to an output of output crossbar O . Such request is called an I, O -request. A middle-crossbar M cannot carry this request if it already carried some request from I (the link IM is busy) or some request to O (the link MO is busy). Let x and y be the number of middle crossbars which are already carrying some requests from I and to O , respectively. Because the number of existing requests from I or to O is at most $n - 1$, it follows that $x \leq n - 1$ and $y \leq n - 1$. The number of unavailable middle crossbars is thus bounded above by the optimal value of the linear program

$$\begin{aligned} & \max x + y \\ \text{s.t. } & x \leq n - 1 \\ & y \leq n - 1 \\ & x, y \geq 0 \end{aligned}$$

Its optimal objective value $2n - 2$ is an upperbound on the number of unavailable middle crossbars. It follows that $m \geq 2n - 1$ is sufficient for $C(n, m, r)$ to be strictly nonblocking.

The above example is the standard strictly nonblocking analysis of the Clos network, casted in terms of linear programming. Because the example is too simple, it might feel a little forced to employ the heavy linear programming machinery. However, it should give the reader a quick sense of how the constraints and objectives of the linear programs are like in analyzing Clos networks and multilog networks. The next example is less trivial.

Example 2 (Wide-sense nonblocking 3-stage Clos networks) This example is a classic result by Moore, quoted in Beneš [1]. Consider the $C(n, m, 2)$ network. Requests are routed using the so-called *packing algorithm*, which tries to reuse a busy middle crossbar whenever possible. For any $i, j \in \{1, 2\}$, let M_{ij} be the set of middle crossbars carrying an I_i, O_j -request. The sets M_{ij} certainly change over time as requests come and go. However, it can be shown by induction on time that the routing rule ensures $|M_{11} \cup M_{22}| \leq n$ and $|M_{12} \cup M_{21}| \leq n$ at all times. For example, to show that $|M_{11} \cup M_{22}| \leq n$ at time t , without loss of generality, consider a new request from I_1 to O_1 at time t . If $M_{22} \setminus M_{11} \neq \emptyset$, then the new request can be routed using any middle crossbar in M_{22} . In this case, the quantity $|M_{11} \cup M_{22}|$ is unchanged from time $t - 1$ to time t . When $M_{22} \setminus M_{11} = \emptyset$, it follows that $M_{22} \subseteq M_{11}$. And, due to the fact that there are at most $n - 1$ existing requests from I_1 , it follows that $|M_{11} \cup M_{22}| = |M_{11}| \leq n - 1$ at time $t - 1$, which means $|M_{11} \cup M_{22}| \leq n$ at time t after the new I_1, O_1 -request is routed.

Now, consider a new request from I_1 to O_1 . Again, if $M_{22} \setminus M_{11} \neq \emptyset$, then there is a busy crossbar to reuse, and the total number of middle crossbars needed is not changed from time $t - 1$ to time t . Otherwise, the number of unavailable middle crossbars for this new request is precisely

$$|M_{11} \cup M_{12} \cup M_{21}| = |M_{11}| + |M_{12} \cup M_{21}|.$$

Just before the arrival of this new request, the number of existing requests from I_1 or to O_1 is at most $n - 1$, i.e.,

$$|M_{11} \cup M_{12}| = |M_{11}| + |M_{12}| \leq n - 1,$$

and

$$|M_{11} \cup M_{21}| = |M_{11}| + |M_{21}| \leq n - 1.$$

The number of unavailable middle crossbars is thus bounded by the optimal value of the following linear program (think of set cardinalities as variables):

$$\begin{aligned} \max \quad & |M_{11}| + |M_{12} \cup M_{21}| \\ \text{s.t.} \quad & |M_{11}| + |M_{12}| \leq n - 1 \end{aligned}$$

$$\begin{aligned} |M_{11}| + |M_{21}| &\leq n - 1 \\ |M_{12}| + |M_{21}| &\leq n \\ |M_{12} \cup M_{21}| - |M_{12}| - |M_{21}| &\leq 0 \end{aligned}$$

The last inequality is the straightforward union bound. Obviously, all cardinalities are nonnegative, so nonnegativity constraints are added to the above linear program. The dual linear program is

$$\begin{array}{llll} \min & (n-1)(y_1 + y_2) + ny_3 & & \\ \text{s.t.} & y_1 + y_2 & \geq 1 & \\ & y_2 + y_3 - y_4 & \geq 0 & \\ & y_1 + y_3 - y_4 & \geq 0 & \\ & y_4 & \geq 1 & \\ & y_1, y_2, y_3 & \geq 0 & \end{array}$$

The solution $y_1 = y_2 = y_3 = 1/2$ and $y_4 = 1$ is certainly dual feasible with objective value $3n/2 - 1$. Hence, by weak duality, the number of unavailable middle crossbars for the new I_1, O_1 -request is at most $\lfloor 3n/2 \rfloor - 1$, which means $m \geq \lfloor 3n/2 \rfloor$ is sufficient for $C(n, m, 2)$ to be wide-sense nonblocking.

Remark 1 It is known that $m \geq \lfloor 3n/2 \rfloor$ is also necessary [1]. This ($r = 2$) is the only case for which a necessary and sufficient condition is known for the Clos network $C(n, m, r)$ to be wide-sense nonblocking. In [58], Yang and Wang gave an interesting analysis of the so-called *packing algorithm* for $r > 2$, also based on linear programming. Their formulation is different from the one presented here, however.

3.2 Multirate Wide-Sense Nonblocking

The next example is an example from the multirate environment. In this case, each link has unit capacity. Each request has an associated *rate* or *weight* $w \in (0, 1]$. Total rate of requests from an input cannot exceed 1, neither does the total rate of requests to an output. It is known that $C(n, m, r)$ is multirate wide-sense nonblocking when $m \geq 5.75n$ [15]. This section uses the linear programming technique to improve this bound. The result and its linear programming analysis first appeared in [41]. The proof of the following theorem does not need to involve the dual program, partly because the primal program is sufficiently small to be solved directly.

Theorem 1 *The Clos network $C(n, m, r)$ is multirate wide-sense nonblocking if $m \geq 5.6355n + 4$.*

Proof For the sake of presentation clarity, a slightly weaker sufficient condition of $m \geq 5.675n + 1.8$ will be proved. Then, the straightforward way to obtain the better condition $m \geq 5.6355n + 4$ is discussed. The two proofs are basically identical, but the one for the weaker condition is slightly easier to follow.

Requests are classified into one of four types, depending on their weights. A request is of *type 1*, *type 2*, *type 3*, or *type 4*, if its weight belongs to the interval $(\frac{1}{2}, 1]$, $(\frac{2}{5}, \frac{1}{2}]$, $(\frac{1}{3}, \frac{2}{5}]$, or $(0, \frac{1}{3}]$, respectively. The algorithm maintains four *disjoint* sets of middle-stage crossbars, denoted by C_1, C_2, C_3 , and C_4 . Their cardinalities are $|C_i| = \lceil x_i n \rceil$, where x_1, x_2, x_3 , and x_4 are constants to be determined. Thus, the total number of middle-stage crossbars used by the algorithm is

$$\lceil x_1 n \rceil + \lceil x_2 n \rceil + \lceil x_3 n \rceil + \lceil x_4 n \rceil.$$

The routing algorithm is as follows:

- The crossbars in C_1 are used exclusively for requests of type 1.
- For requests of type i , $2 \leq i \leq 4$, the following strategy is applied. When a type- i request arrives, find a crossbar in C_i to route it. If no crossbar in C_i can accommodate this new request, try a crossbar in C_{i+1} , and so on, up to C_4 .

The next step is to show that if the constants x_i are feasible solutions to a certain linear program, then it is always possible to route a new request. Toward this end, define the *IO-load* of a middle-crossbar M to be the total weight of all existing connections (at time $t - 1$) which are either routed through the link IM or the link MO .

Now, suppose a type-1 request from input crossbar I to output crossbar O arrives at time t . If the algorithm cannot find a crossbar in C_1 for the new request, then every crossbar in C_1 must be carrying a type-1 connection either from I or to O at time $t - 1$. The total number of type-1 connections involving either I or O at time $t - 1$ is at most $(n - 1) + (n - 1) = 2n - 2$. (This reasoning is similar to that of [Example 1](#).) Hence, $\lceil x_1 n \rceil = |C_1| \leq 2n - 2$. Consequently, as long as $x_1 \geq 2$, the new type-1 request is not blocked.

Next, consider a request of weight w from input switch I to output switch O of type 2 which arrives at time t , and suppose the algorithm cannot find a crossbar in $C_2 \cup C_3 \cup C_4$ to route it. For a middle-crossbar $M \in C_2$ to be unavailable for the newly arrived (I, O, w) request, M must be carrying either two (existing) type-2 connections from I or two type-2 connections to O . Thus, the total *IO-load* of crossbars in C_2 must be at least $\frac{4}{5}|C_2|$. Similarly, for a middle-stage crossbar $M \in C_3$ to be unavailable, the total load M carries for either I or O must exceed $1/2$. Note that a middle-stage crossbar $M \in C_3$ only carries type-2 or type-3 requests. Hence, either the link IM or the link MO must be carrying either two type-2 connections (with total weight $> \frac{4}{5}$) or one type-2 connection and one type-3 connection (with total weight $> \frac{1}{3} + \frac{2}{5}$) or two type-3 connections (with total weight $> \frac{2}{3}$). The total *IO-load* for M must thus be at least $\frac{2}{3}$. Overall, the total *IO-load* that all crossbars in C_3 carry must be at least $\frac{2}{3}|C_3|$. Finally, if no crossbar in C_4 is

available, then the total *IO*-load that crossbars in C_4 are carrying must be at least $\frac{1}{2}|C_4|$.

Consequently, because the total *IO*-load overall is strictly smaller than $2n$ (at time $t - 1$), the new request is not blocked if

$$\frac{4}{5}|C_2| + \frac{2}{3}|C_3| + \frac{1}{2}|C_4| \geq 2n.$$

The inequality would hold if

$$\frac{4}{5}x_2 + \frac{2}{3}x_3 + \frac{1}{2}x_4 \geq 2.$$

In a similar fashion, it is easy to argue that newly arriving type-3 requests can be routed if

$$\frac{2}{3}x_3 + \frac{3}{5}x_4 \geq 2$$

and a new type-4 request can be routed if

$$\frac{2}{3}x_4 \geq 2.$$

Overall, the routing algorithm works if the variables x_i are feasible for the following linear program:

$$\begin{aligned} & \min x_1 + x_2 + x_3 + x_4 \\ \text{s.t. } & x_1 \geq 2 \\ & \frac{4}{5}x_2 + \frac{2}{3}x_3 + \frac{1}{2}x_4 \geq 2 \\ & \frac{2}{3}x_3 + \frac{3}{5}x_4 \geq 2 \\ & \frac{2}{3}x_4 \geq 2 \\ & x_1, x_2, x_3, x_4 \geq 0. \end{aligned}$$

The solution $x_1 = 2, x_2 = 3/8, x_3 = 3/10, x_4 = 3$ is certainly feasible. The total number of middle crossbars used is

$$\sum_{i=1}^4 \lceil x_i n \rceil \leq (x_1 + x_2 + x_3 + x_4)n + 1.8 = 5.675n + 1.8.$$

To prove the better bound of $5.6355n$, divide the rates into five types belonging to the intervals $(1/2, 1]$, $(2/5, 1/2]$, $(1/3, 2/5]$, $(11/43, 1/3]$, and $(0, 11/43]$. \square

Remark 2 The above strategy can also give a better sufficient condition than the best known in [15] for the case when there is internal speedup in the Clos network.

4 Strictly Nonblocking Unicast Multilog Networks for Photonic Switching Under the General Crosstalk Constraint

When the multilog architecture is employed to design a photonic switch, each 2×2 switching element (SE) needs to be replaced by a functionally equivalent optical component. For instance, when $d = 2$, the so-called *directional couplers* can be used as SEs [34, 48, 56]. However, directional couplers and many other optical switching elements suffer from optical crosstalk between interfering channels, which is one of the major obstacles in designing cost-effective switches [5, 11, 52].

To cope with crosstalk, the *general crosstalk constraint* was introduced by Vaez and Lea [53], which forces each new route to share at most c SEs with other active routes in the switch, where c is a parameter of the design. When $c = 0$, no two routes are allowed to share a common SE, and the switch becomes a *crosstalk-free* switch [5, 11, 25, 27, 33, 53, 54]. On the other hand, when $c = n = \log_d N$, a route can share any number of SEs with other routes (but still, no shared link) because each route in a $\log_d(N, 0, m)$ network contains exactly n SEs. In this case, only link blocking takes effect, and it is commonly referred to as the *link-blocking case*, which is relevant to electronic switches [4, 13, 14, 20, 21, 23, 26, 28, 43, 47]. A switching network which is strictly nonblocking (SNB) under this general crosstalk constraint shall be referred to as a *c-SNB network*.

This section presents the linear programming analysis first derived in [40] for analyzing strictly nonblocking d -ary multilog networks under this general crosstalk constraint. Prior to [40], the only known results are sufficient conditions for the binary $\log_2(N, 0, m)$ network to be c -SNB [53].

One important advantage of the LP-duality approach is the straightforwardness of verifying the sufficiency proofs. All one has to do is to check that a solution is indeed dual feasible, and the dual-objective value automatically gives us a sufficient condition. Earlier works on this problem relied on combinatorial arguments which are quite intricate and somewhat error-prone.

Section 4.1 shows that the number of planes blocking a new request is bounded by the objective value of a general linear program which is dependent on the parameters of the problem (c, d, n) but independent from the request under consideration. By weak duality, in order to bound the number of planes blocking any new request, the objective value of *any* dual-feasible solution can be used.

In Sects. 4.2 and 4.3, families of solutions which are dual feasible are constructed. Then, depending on the relationships between the problem's parameters (c, d, n), the best dual-feasible solution from the constructed families is selected for bounding the number of blocking planes. Although verifying the LP-based proof is straightforward, constructing these families of dual-feasible solutions involves a good deal of experimentation, educated guesses, and even some Maple coding. This “cost” is hidden from the reader; thus, perhaps some insight is lost along the way as to why the bounds hold.

4.1 The Linear Programming Duality Formulation

Let (\mathbf{a}, \mathbf{b}) be an arbitrary request. For each $i \in \{0, \dots, n - 1\}$, let A_i be the set of inputs \mathbf{x} other than \mathbf{a} , where $\mathbf{x}_{1..n-1}$ shares a *suffix* of length exactly i with $\mathbf{a}_{1..n-1}$. Formally, define

$$A_i := \{\mathbf{x} \in \mathbb{Z}_d^n - \{\mathbf{a}\} \mid \text{SUF}(\mathbf{x}_{1..n-1}, \mathbf{a}_{1..n-1}) = i\}.$$

Similarly, for each $j \in \{0, \dots, n - 1\}$, let B_j be the set of outputs \mathbf{y} other than \mathbf{b} which share a *prefix* of length exactly j with \mathbf{b} , namely,

$$B_j := \{\mathbf{y} \in \mathbb{Z}_d^n - \{\mathbf{b}\} \mid \text{PRE}(\mathbf{y}_{1..n-1}, \mathbf{b}_{1..n-1}) = j\}.$$

Note that $|A_i| = |B_i| = d^{n-i} - d^{n-1-i}$ for all $0 \leq i \leq n - 1$. Suppose the network $\log_d(N, 0, m)$ already had some routes established. Consider a $\text{BY}^{-1}(n)$ -plane which blocks the new request (\mathbf{a}, \mathbf{b}) (i.e., (\mathbf{a}, \mathbf{b}) cannot be routed through the plane). There can only be three cases for which this happens:

Case 1: There is a request (\mathbf{x}, \mathbf{y}) routed in the plane for which $R(\mathbf{x}, \mathbf{y})$ and $R(\mathbf{a}, \mathbf{b})$ share a link. By [Proposition 2](#), it must be the case that $(\mathbf{x}, \mathbf{y}) \in A_i \times B_j$ for some $i + j \geq n$. Such a request (\mathbf{x}, \mathbf{y}) shall be called a *link-blocking request* with respect to (\mathbf{a}, \mathbf{b}) . The qualifier “with respect to” will be dropped when it is unambiguous from the current context which request is being blocked.

Case 2: There is a request (\mathbf{x}, \mathbf{y}) whose route $R(\mathbf{x}, \mathbf{y})$ already intersects c other routes at c distinct SEs on the same plane, and adding (\mathbf{a}, \mathbf{b}) would introduce an additional intersecting SE to the route $R(\mathbf{x}, \mathbf{y})$. These c other requests shall be called *secondary requests* accompanying (\mathbf{x}, \mathbf{y}) , and the request (\mathbf{x}, \mathbf{y}) shall be called a *node-blocking request of type 1*.

In particular, by [Proposition 1](#), it must be the case that $(\mathbf{x}, \mathbf{y}) \in A_i \times B_j$ for some $i + j = n - 1$. Note that the common SE between $R(\mathbf{a}, \mathbf{b})$ and $R(\mathbf{x}, \mathbf{y})$ is at stage $j + 1$. The routes for secondary requests must thus intersect $R(\mathbf{x}, \mathbf{y})$ at stages strictly less than $j + 1$ or strictly greater than $j + 1$.

If the route $R(\mathbf{u}, \mathbf{v})$ for the secondary request (\mathbf{u}, \mathbf{v}) intersects $R(\mathbf{x}, \mathbf{y})$ at stage s with $1 \leq s < j + 1$, then it follows that $\text{PRE}(\mathbf{y}, \mathbf{v}) = s - 1 < j$ and $\text{SUF}(\mathbf{x}, \mathbf{u}) = n - 1 - (s - 1) = n - s > n - 1 - j = i$. Hence, $(\mathbf{u}, \mathbf{v}) \in A_i \times B_{s-1}$. Such a request (\mathbf{u}, \mathbf{v}) shall be called a *left secondary request*.

If the route $R(\mathbf{u}, \mathbf{v})$ of secondary request (\mathbf{u}, \mathbf{v}) intersects $R(\mathbf{x}, \mathbf{y})$ at stage s where $j + 1 < s \leq n$, then it follows that $\text{PRE}(\mathbf{y}, \mathbf{v}) = s - 1 > j$ and $\text{SUF}(\mathbf{x}, \mathbf{u}) = n - 1 - (s - 1) = n - s < n - 1 - j = i$. Hence, $(\mathbf{u}, \mathbf{v}) \in A_{n-s} \times B_j$. Such a request (\mathbf{u}, \mathbf{v}) shall be called a *right secondary request*.

The Primal LP

Maximize

$$\sum_{i+j \geq n} x_{ij} + \sum_{i+j=n-1} y_{ij} + \frac{1}{c+1} \sum_{i+j=n-1} z_{ij} \quad (4)$$

Subject to

$$\sum_{j: i+j \geq n} x_{ij} + \sum_{j: i+j=n-1} (y_{ij} + z_{ij}) + \sum_{j: i+j < n-1} (l_{ij} + r_{ij}) \leq d^{n-i} - d^{n-1-i} \forall i \quad (5)$$

$$\sum_{i: i+j \geq n} x_{ij} + \sum_{i: i+j=n-1} (y_{ij} + z_{ij}) + \sum_{i: i+j < n-1} (l_{ij} + r_{ij}) \leq d^{n-j} - d^{n-1-j} \forall j \quad (6)$$

$$cy_{ij} - \left(\sum_{i' < i} r_{i'j} + \sum_{j' < j} l_{ij'} \right) = 0 \quad i+j = n-1 \quad (7)$$

$$l_{ij'} - y_{ij} \leq 0 \quad i+j = n-1, j' < j \quad (8)$$

$$r_{i'j} - y_{ij} \leq 0 \quad i+j = n-1, i' < i \quad (9)$$

$$x_{ij}, y_{ij}, z_{ij}, l_{ij}, r_{ij} \geq 0 \quad \forall i, j \quad (10)$$

Fig. 6 The primal LP for analyzing unicast c -SNB multilog networks

To summarize, there are two types of secondary requests accompanying (\mathbf{x}, \mathbf{y}) : the *left secondary requests* are the requests $(\mathbf{u}, \mathbf{v}) \in A_i \times B_{j'}$ for some $j' < j$, and the *right secondary requests* are the requests $(\mathbf{u}, \mathbf{v}) \in A_{i'} \times B_j$ for some $i' < i$. For each $i' < i$, there is at most one right secondary request in $A_{i'} \times B_j$. Similarly, for each $j' < j$, there is at most one left secondary request in $A_i \times B_{j'}$.

Case 3: There are $c+1$ requests in the plane each of whose routes intersects (\mathbf{a}, \mathbf{b}) at exactly one SE. These will be called *node-blocking requests of type 2*. If (\mathbf{x}, \mathbf{y}) is such a request, then $(\mathbf{x}, \mathbf{y}) \in A_i \times B_j$ for some $i+j = n-1$.

Theorem 2 *The number of blocking planes is the objective value of a feasible solution to the primal linear program as shown in Fig. 6.*

Proof Define the following variables. For each pair i, j such that $i+j \geq n$, let x_{ij} be the number of link-blocking requests in $A_i \times B_j$. For each pair i, j such that $i+j = n-1$, let y_{ij} be the number of node-blocking requests of type 1 and z_{ij} be the number of node-blocking requests of type 2 in $A_i \times B_j$. For each pair i, j such that $i+j < n-1$, let l_{ij} and r_{ij} be the number of left and right secondary requests in $A_i \times B_j$. The number of blocking planes is thus expressed in the objective function (4).

The next step is to verify that the variables satisfy all the constraints. Recall that $|A_i| = d^{n-i} - d^{n-1-i}$, $\forall i$. Thus, the number of requests out of A_i is at most $d^{n-i} - d^{n-1-i}$, justifying constraint (5). Similarly, bounding the number of requests

The Dual LP

Minimize

$$\sum_{i=0}^{n-1} (d^{n-i} - d^{n-1-i}) u_i + \sum_{j=0}^{n-1} (d^{n-j} - d^{n-1-j}) v_j \quad (11)$$

Subject to

$$u_i + v_j \geq 1, \quad i + j \geq n \quad (12)$$

$$u_i + v_j + cw_{ij} - \sum_{i' < i} s_{i'j} - \sum_{j' < j} t_{ij'} \geq 1, \quad i + j = n - 1 \quad (13)$$

$$u_i + v_j \geq \frac{1}{c+1}, \quad i + j = n - 1 \quad (14)$$

$$u_i + v_j - w_{i,n-1-i} + t_{ij} \geq 0, \quad i + j < n - 1 \quad (15)$$

$$u_i + v_j - w_{n-1-j,j} + s_{ij} \geq 0, \quad i + j < n - 1 \quad (16)$$

$$u_i, v_j, s_{ij}, t_{ij} \geq 0, \quad \forall i, j \quad (17)$$

Fig. 7 The dual linear program for analyzing unicast c -SNB multilog networks

to B_j explains constraint (6). Constraint (7) expresses the fact that, for every node-blocking request of type 1 in $A_i \times B_j$ ($i + j = n - 1$), there must be c accompanying secondary requests (left or right). Lastly, for each node-blocking request of type 1 in $A_i \times B_j$, ($i + j = n - 1$) constraint (8) says that for each $j' < j$, there is at most one left secondary request in $A_i \times B_{j'}$, and constraint (9) says that for each $i' < i$, there is at most one right secondary request in $A_{i'} \times B_j$. \square

Remark 3 It should be noted that while the number of blocking planes is the objective value of some feasible solution to the primal LP, the converse may not hold; namely, a feasible solution to the primal LP (even if integral) may not give rise to a blocking configuration with the number of blocking planes equal to the objective value.

The dual linear program is given in Fig. 7. The key idea is the following: due to weak duality, every dual-feasible solution induces an objective value which is at least the number of blocking planes.

As an illustration of the power of the LP-based method, let us first reproduce a few known results. The examples should give the reader the correct insight without delving into too much technicality.

Example 3 ($c = 0$, the node-blocking case) When $c = 0$, the problem becomes the strictly nonblocking problem in the node-blocking sense. It has been shown in [54] (which addressed the node-blocking problem in f -cast switches) that $m \geq d^{\lceil(n-1)/2\rceil} + d^{n-\lceil(n-1)/2\rceil} - 1$ is necessary and sufficient for $\log_d(N, 0, m)$ to be strictly nonblocking.

Let $i_0 = n - \lceil(n-1)/2\rceil$ and $j_0 = \lceil(n-1)/2\rceil$. Assign $u_i = 1$ for all i such that $i_0 \leq i \leq n-1$ and $v_j = 1$ for all j such that $j_0 \leq j \leq n-1$. All other variables are zeros. It is easy to check that this is a dual-feasible solution with objective value precisely $d^{\lceil(n-1)/2\rceil} + d^{n-\lceil(n-1)/2\rceil} - 2$. Thus, at most 1 more BY⁻¹(n) is needed for a total of $d^{\lceil(n-1)/2\rceil} + d^{n-\lceil(n-1)/2\rceil} - 1$ planes in the worst case, matching the known necessary and sufficient condition.

Example 4 ($c = n$, the link-blocking case) When $c = n$, the problem becomes the strictly nonblocking problem in the link-blocking sense. It has been shown in [14, 54] that $m \geq d^{\lceil n/2 \rceil - 1} + d^{\lfloor n/2 \rfloor} - 1$ is necessary and sufficient for $\log_d(N, 0, m)$ to be strictly nonblocking.

Since there can be no path with $n+1$ distinct SEs, the variables y_{ij} and z_{ij} are all zeros, so are the l_{ij} and r_{ij} . The primal LP becomes much simpler:

$$\begin{aligned} \max \quad & \sum_{i+j \geq n} x_{ij} \\ \text{s.t. } & \sum_{j: i+j \geq n} x_{ij} \leq d^{n-i} - d^{n-1-i} \quad \forall i \\ & \sum_{i: i+j \geq n} x_{ij} \leq d^{n-j} - d^{n-1-j} \quad \forall j \\ & x_{ij} \geq 0 \quad \forall i, j \end{aligned}$$

The dual LP is

$$\begin{aligned} \min \quad & \sum_i (d^{n-i} - d^{n-1-i}) u_i + \sum_j (d^{n-j} - d^{n-1-j}) v_j \\ \text{s.t.} \quad & u_i + v_j \geq 1 \quad i + j \geq n \\ & u_i, v_j \geq 0 \quad \forall i, j \end{aligned}$$

Let $i_0 = \lfloor n/2 \rfloor + 1$ and $j_0 = \lceil n/2 \rceil$. Assign $u_i = 1$ for all i such that $i_0 \leq i \leq n-1$ and, $v_j = 1$ for all j such that $j_0 \leq j \leq n-1$. All other variables are zeros. This solution is dual feasible with objective value $d^{\lceil n/2 \rceil - 1} + d^{\lfloor n/2 \rfloor} - 2$. Hence, $m \geq d^{\lceil n/2 \rceil - 1} + d^{\lfloor n/2 \rfloor} - 1$ is sufficient for $\log_d(N, 0, m)$ to be strictly nonblocking in this case. Again, the sufficient condition obtained with the LP-based method matches the known necessary and sufficient condition.

In light of the above examples, in the rest of this section, $1 \leq c \leq n-1$ is assumed.

4.2 The Case When n Is Odd

Lemma 1 Suppose $n = 2k + 1$ and $1 \leq c \leq 2k$. For any integer p where $0 \leq p \leq k$, there exists a feasible solution to the dual LP with objective value

$$2d^k - 2 + \frac{2d^k(d-1)}{c+2} \cdot f(c, d, p),$$

where

$$\begin{aligned} f(c, d, p) &= \sum_{i=0}^p \left(\frac{d}{c+1} \right)^i - \frac{1}{d} \sum_{i=0}^{p-1} \frac{1}{[d(c+1)]^i} \\ &= \begin{cases} p+1 - \frac{1-d^{-2p}}{d-\frac{1}{d}} & c+1 = d \\ \frac{1-\left(\frac{d}{c+1}\right)^{p+1}}{1-\frac{d}{c+1}} - \frac{1-\left(\frac{1}{d(c+1)}\right)^p}{d-\frac{1}{c+1}} & c+1 \neq d. \end{cases} \end{aligned} \quad (18)$$

Proof Consider the following assignment to the dual variables:

$$u_i = v_i = \begin{cases} 1 & k+p+1 \leq i \leq n-1 \\ 1 - \frac{1}{(c+2)(c+1)^{i-k-1}} & k+1 \leq i \leq k+p \\ \frac{1}{(c+2)(c+1)^{k-i}} & k-p \leq i \leq k \\ 0 & 0 \leq i < k-p \end{cases}$$

$$w_{ij} = \min\{u_i, u_j\}, \text{ for all } i+j = n-1$$

$$s_{ij} = t_{ij} = 0, \text{ for all } i+j < n-1.$$

First, it needs to be verified that this assignment is indeed a dual-feasible solution. Note that for $i \leq j$, it holds that $u_i = v_i \leq u_j = v_j$.

Consider the dual constraint (12). When $i+j \geq n = 2k+1$, either $i \geq k+1$ or $j \geq k+1$. Due to symmetry, only $i \geq k+1$ needs to be considered. Note that $v_j \geq v_{n-i}$ because $j \geq n-i$. If $i \geq k+1+p$, then $u_i \geq 1$ and thus $u_i + v_j \geq 1$. If $k+1 \leq i \leq k+p$, then $k-p \leq n-i \leq k$. Thus,

$$u_i + v_j \geq u_i + v_{n-i} = \left(1 - \frac{1}{(c+2)(c+1)^{i-k-1}} \right) + \frac{1}{(c+2)(c+1)^{k-(n-i)}} = 1.$$

Consider the dual constraint (13). When $i+j = n-1 = 2k$, either $i \geq k$ or $j \geq k$. Due to symmetry, only $i \geq k$ needs to be considered. If $i \geq k+p+1$, then $j = 2k-i \leq k-p-1$. Hence, $u_i = 1, v_j = 0, w_{ij} = 0$, and thus the constraint is satisfied. When $k+1 \leq i \leq k+p$, it follows that $k-p \leq j \leq k-1$. Thus,

$$u_i + v_j + cw_{ij} = \left(1 - \frac{1}{(c+2)(c+1)^{i-k-1}} \right) + (c+1) \frac{1}{(c+2)(c+1)^{k-j}} = 1.$$

When $i = j = k$, it follows that $u_i = v_j = w_{ij} = 1/(c+2)$. The constraint is straightforwardly verified.

Constraint (14) is verified similarly. Constraint (15) follows from the fact that $u_i \geq w_{i,n-1-i}$ (and all other variables are nonnegative). Similarly, constraint (16) follows from the fact that $v_j \geq w_{n-1-j,j}$.

Second, it is routine to verify that the objective value of the dual-feasible solution above is precisely $2d^k - 2 + \frac{2d^k(d-1)}{c+2} \cdot f(c, d, p)$. \square

Lemma 2 Suppose $n = 2k + 1$, $k \geq 2$, and $c = k$. There exists a feasible solution to the dual LP with objective value

$$2d^k - 2 + \frac{2(d-1)d^{k-2}}{c+2} \left(d^2 - d + \frac{d^3 - 1}{c+2} \right)$$

Proof The following solution is dual feasible with the desired objective value:

$$\begin{aligned} u_i &= v_i = 1 & k+3 \leq i \leq n-1 \\ u_{k+2} &= v_{k+2} = 1 - \frac{1}{(c+2)^2} \\ u_{k+1} &= v_{k+1} = 1 - \frac{1}{(c+2)} \\ u_k &= v_k = \frac{1}{(c+2)} \\ u_{k-1} &= v_{k-1} = \frac{1}{(c+2)^2} \\ u_i &= v_i = 0 & 0 \leq i \leq k-2 \\ w_{kk} &= \frac{1}{c+2} \\ w_{k+1,k-1} &= w_{k-1,k+1} = \frac{2}{(c+2)^2} \\ w_{k+2,k-2} &= w_{k-2,k+2} = \frac{1}{(c+2)^2} \\ w_{ij} &= 0 & \text{all other } i, j \\ s_{i,k-2} &= t_{k-2,i} = \frac{1}{(c+2)^2} & 0 \leq i \leq k-2 \\ s_{i,k-1} &= t_{k-1,i} = \frac{1}{(c+2)^2} & 0 \leq i \leq k-2 \\ s_{ij} &= t_{ij} = 0 & \text{all other } i, j \end{aligned}$$

Lemma 3 Suppose $n = 2k + 1$ and $k + 1 \leq c \leq 2k$. There exists a feasible solution to the dual LP with objective value

$$2d^k - 2 + \frac{2(d-1)^2 d^{k-1}}{c+2}.$$

Proof The following solution is dual feasible with the desired objective value:

$$u_i = v_i = 1 \quad k+2 \leq i \leq n-1$$

$$\begin{aligned}
u_{k+1} = v_{k+1} &= 1 - \frac{1}{(c+2)} \\
u_k = v_k &= \frac{1}{(c+2)} \\
u_i = v_i &= 0 \quad 0 \leq i \leq k-1 \\
w_{kk} &= \frac{1}{c+2} \\
w_{k+1,k-1} = w_{k-1,k+1} &= \frac{1}{(c+2)} \\
w_{ij} &= 0 \quad \text{all other } i, j \\
s_{i,k-1} = t_{k-1,i} &= \frac{1}{(c+2)} \quad 0 \leq i \leq k-1 \\
s_{ij} = t_{ij} &= 0 \quad \text{all other } i, j
\end{aligned}$$

□

The sufficiency conditions for the odd- n case is now ready to be shown.

Theorem 3 Consider the case when $n = 2k + 1$. Recall that $f(c, d, p)$ is defined in (18).

(a) If $1 \leq c \leq k-1$, then

$$m \geq 2d^k - 1 + \left\lfloor \frac{2d^k(d-1)}{c+2} \cdot f(c, d, \lfloor \log_d(c+1)/2 \rfloor) \right\rfloor$$

is sufficient for $\log_d(N, 0, m)$ to be c -SNB. In particular, when $c \leq \min\{k-1, d^2-1\}$,

$$m \geq 2d^k - 1 + \left\lfloor \frac{2d^k(d-1)}{c+2} \right\rfloor$$

is sufficient.

(b) If $c = k$, then

$$m \geq 2d^k - 1 + \left\lfloor \frac{2(d-1)d^{k-2}}{c+2} \left(d^2 - d + \frac{d^3 - 1}{c+2} \right) \right\rfloor$$

is sufficient for $\log_d(N, 0, m)$ to be c -SNB.

(c) If $k+1 \leq c \leq 2k$, then

$$m \geq 2d^k - 1 + \left\lfloor \frac{2(d-1)^2 d^{k-1}}{c+2} \right\rfloor$$

is sufficient for $\log_d(N, 0, m)$ to be c -SNB.

Proof By Theorem 2, the objective value of any dual-feasible solution is an upperbound on the number of $\text{BY}^{-1}(n)$ -planes blocking a new request. Hence, one plane more than the objective value is sufficient for the network to be c -SNB.

To see (a), [Lemma 1](#) is applied. The best dual-feasible solution is the one whose objective value is minimized. In this case, $f(d - 1, d, p)$ is minimized at $p_0 = \lfloor \log_d(c + 1)/2 \rfloor$. (To see this, notice that $f(c, d, p) \geq f(c, d, p + 1)$ if and only if $p \leq \frac{1}{2} \log_d(c + 1) - 1$.) Thus, one can make use of the dual-feasible solution in [Lemma 1](#) corresponding to $p = p_0$. In particular, when $c \leq d^2 - 1$, the function's minimum value is $f(c, d, \lfloor \log_d(c + 1)/2 \rfloor) = 1$.

Similarly, (b) follows from [Lemma 2](#), and (c) from [Lemma 3](#). □

Remark 4 Compared to the results of [53] (which was only for the binary network case, i.e., $d = 2$), the above sufficient conditions are better when $3 \leq c \leq k - 1$ and are at least as good for other ranges of c .

4.3 The Case When n Is Even

Lemma 4 Suppose $n = 2k$ and $1 \leq c \leq d - 1$. There exists a feasible solution to the dual LP with objective value $2d^k - 2$.

Proof The following solution is dual feasible with the desired objective value: $u_i = v_i = 1$ for all $i \geq k$, all other variables are set to 0. □

Lemma 5 Suppose $n = 2k$ and $d \leq c \leq n - 1$. For any integer p , $1 \leq p \leq k$, there exists a feasible solution to the dual LP with objective value

$$d^k + d^{k-1} - 2 + \frac{(d - 1)d^{k-1}}{c + 2} \cdot (d + g(c, d, p)),$$

where

$$\begin{aligned} g(c, d, p) &= \sum_{i=0}^p \left(\frac{d}{c+1} \right)^i - \sum_{i=0}^{p-1} \frac{1}{[d(c+1)]^i} \\ &= \begin{cases} p + 1 - \frac{1-d^{-2p}}{1-d^{-2}} & c+1=d \\ \frac{1-\left(\frac{d}{c+1}\right)^{p+1}}{1-\frac{d}{c+1}} - \frac{1-\left(\frac{1}{d(c+1)}\right)^p}{1-\frac{1}{d(c+1)}} & c+1 \neq d. \end{cases} \end{aligned} \quad (19)$$

Proof The following solution is dual feasible with the desired objective value:

$$u_i = 1, \text{ for } k + 1 \leq i \leq n - 1,$$

$$u_i = \frac{1}{(c+2)(c+1)^{k-i}}, \text{ for } k - p \leq i \leq k,$$

$$u_i = 0, \text{ for all other } i,$$

$$v_j = 1, \text{ for } k + p \leq j \leq n - 1,$$

$$v_j = 1 - u_{n-j} = 1 - u_{2k-j}, \text{ for } k \leq j \leq k + p - 1,$$

$$v_{k-1} = \frac{1}{c+2},$$

$$v_j = 0, \text{ for all other } j,$$

$$w_{ij} = \min\{u_i, u_j\}, \text{ when } i + j = n - 1.$$

$$s_{ij} = t_{ij} = 0, \text{ for all } i + j < n - 1.$$

□

Remark 5 The previous two Lemmas hold for any c between 1; and $n - 1$ however they were stated for the range of c where they are meant to be applied.

Lemma 6 Suppose $n = 2k$ and $k < c$. There exists a feasible solution to the dual LP with objective value $d^k + d^{k-1} - 2$.

Proof The following solution is dual feasible with the desired objective value:

$$u_i = v_i = 1 \quad k + 1 \leq i \leq n - 1$$

$$u_k = v_k = \frac{1}{2}$$

$$u_i = v_i = 0 \quad 0 \leq i \leq k - 1$$

$$w_{k,k-1} = w_{k-1,k} = 1/2$$

$$w_{ij} = 0 \quad \text{all other } i, j$$

$$s_{i,k-1} = t_{k-1,i} = 1/2 \quad 0 \leq i \leq k - 1$$

$$s_{ij} = t_{ij} = 0 \quad \text{all other } i, j$$

□

With the help of [Lemmas 4–6](#), the following theorem straightforwardly follows:

Theorem 4 Consider the case when $n = 2k$. Recall that $g(c, d, p)$ is defined in [\(19\)](#).

- (a) If $1 \leq c \leq d - 1$, then $m \geq 2d^k - 1$ is sufficient for $\log_d(N, 0, m)$ to be c -SNB.
- (b) If $d \leq c \leq k$, then

$$m \geq d^k + d^{k-1} - 1 + \left\lfloor \frac{(d-1)d^{k-1}}{c+2} \cdot \left(d + g \left(c, d, \left\lfloor \frac{\log_d(c+1)+1}{2} \right\rfloor \right) \right) \right\rfloor$$

is sufficient for $\log_d(N, 0, m)$ to be c -SNB. In particular, when $d \leq c \leq \min\{k, d^3 - 2\}$

$$m \geq d^k + d^{k-1} - 1 + \left\lfloor \frac{(d-1)d^k}{c+1} \right\rfloor$$

is sufficient.

- (c) If $k < c \leq 2k$, then $m \geq d^k + d^{k-1} - 1$ is sufficient for $\log_d(N, 0, m)$ to be c -SNB.

Remark 6 Compared to the results of [53] (which was only for the binary network case, i.e., $d = 2$), the above sufficient conditions are better when $7 \leq c \leq k$ and are at least as good for other ranges of c .

5 Strictly Nonblocking f -Casting Multilog Networks Under the General Crosstalk Constraint

This section derives conditions under which a $\log_d(N, 0, m)$ network is f -cast c -SNB. These results are from [42]. The problem setting is very general and thus challenging in many ways: (1) f -cast covers both unicast ($f = 1$) and multicast/broadcast ($f = N$), (2) d -ary networks are much more general than the commonly considered binary multilog networks, and (3) the crosstalk constraint covers both the usual link-blocking case ($c = n$) and the crosstalk-free case ($c = 0$). Prior to [42], sufficient conditions for the multilog networks to be unicast c -SNB were derived in [40, 53]. In the f -cast strictly nonblocking case, necessary and sufficient conditions are known for both link-blocking and crosstalk-free constraints [14, 54]. As shall be seen, most of these known results are corollaries of the results in this section. The same LP-duality analysis presented in Sect. 4 is deployed. The f -cast case is considerably more complex, however.

The main idea is similar to that in the previous section. Consider a multicast request (\mathbf{a}, B) , where \mathbf{a} is an input and B is a subset of outputs. For each output $\mathbf{b} \in B$, the branch (\mathbf{a}, \mathbf{b}) can be routed independently from all other branches of the request. The number α of $\text{BY}^{-1}(n)$ -planes through which (\mathbf{a}, \mathbf{b}) cannot be routed through (those are called “blocking planes”) can be expressed as the objective value of a feasible solution to a linear program. Thus, by weak duality, α is upperbounded by the objective value β of *any* feasible solution to the dual LP. Then, $m \geq \beta + 1$ planes will be sufficient to route (\mathbf{a}, \mathbf{b}) . Again, this approach makes sufficiency proofs very easy to verify since they only involve checking if a solution is indeed dual feasible. Of course, there is considerable effort “behind the scene” to discover good dual-feasible solutions because the linear programs are very general with many parameters (n, c, f , and d) and variables.

Let (\mathbf{a}, \mathbf{b}) be an arbitrary branch of a multicast request. For each $i \in \{0, \dots, n-1\}$, let A_i be the set of inputs \mathbf{x} other than \mathbf{a} , where $\mathbf{a}_{1..n-1}$ shares a *suffix* of length exactly i with $\mathbf{x}_{1..n-1}$. Formally, define

$$A_i := \{\mathbf{x} \in \mathbb{Z}_d^n - \{\mathbf{a}\} \mid \text{SUF}(\mathbf{x}_{1..n-1}, \mathbf{a}_{1..n-1}) = i\}.$$

Similarly, for each $j \in \{0, \dots, n - 1\}$, let B_j be the set of outputs other than \mathbf{b} which share a prefix of length exactly j with \mathbf{b} , namely,

$$B_j := \{\mathbf{y} \in \mathbb{Z}_d^n - \{\mathbf{b}\} \mid \text{PRE}(\mathbf{y}_{1..n-1}, \mathbf{b}_{1..n-1}) = j\}.$$

Note that $|A_i| = |B_i| = d^{n-i} - d^{n-1-i}$, for all $0 \leq i \leq n - 1$. Suppose the network $\log_d(N, 0, m)$ already had some (f -cast) routes established. Consider a $\text{BY}^{-1}(n)$ plane which blocks (\mathbf{a}, \mathbf{b}) . There can only be three cases for which this happens:

Case 1: There is a branch (\mathbf{x}, \mathbf{y}) of some f -cast request routed in the plane for which $R(\mathbf{x}, \mathbf{y})$ and $R(\mathbf{a}, \mathbf{b})$ share a link. By [Proposition 2](#), $(\mathbf{x}, \mathbf{y}) \in A_i \times B_j$ for some $i + j \geq n$. Such a branch (\mathbf{x}, \mathbf{y}) shall be referred to as a *link-blocking branch*.

Case 2: There is a branch (\mathbf{x}, \mathbf{y}) of some f -cast request whose route $R(\mathbf{x}, \mathbf{y})$ already intersects c other routes at c distinct SEs on the same plane, and adding (\mathbf{a}, \mathbf{b}) would introduce an additional intersecting SE to the route $R(\mathbf{x}, \mathbf{y})$. These c other branches are called *secondary branches* accompanying (\mathbf{x}, \mathbf{y}) , and the branch (\mathbf{x}, \mathbf{y}) is called a *node-blocking branch of type 1*.

By [Proposition 1](#), $(\mathbf{x}, \mathbf{y}) \in A_i \times B_j$ for some $i + j = n - 1$. Moreover, the common SE between $R(\mathbf{a}, \mathbf{b})$ and $R(\mathbf{x}, \mathbf{y})$ is at stage $j + 1$. The routes for secondary branches must thus intersect $R(\mathbf{x}, \mathbf{y})$ at stages strictly less than $j + 1$ or strictly greater than $j + 1$.

If a secondary branch (\mathbf{u}, \mathbf{v}) has its route intersects $R(\mathbf{x}, \mathbf{y})$ at stage $1 \leq s < j + 1$, it follows that $\text{PRE}(\mathbf{y}, \mathbf{v}) = s - 1 < j$ and $\text{SUF}(\mathbf{x}, \mathbf{u}) = n - 1 - (s - 1) = n - s > n - 1 - j = i$. Hence, $(\mathbf{u}, \mathbf{v}) \in A_i \times B_{s-1}$. Such branch (\mathbf{u}, \mathbf{v}) is called a *left secondary branch*.

If a secondary branch (\mathbf{u}, \mathbf{v}) has its route intersects $R(\mathbf{x}, \mathbf{y})$ at stage $j + 1 < s \leq n$, it follows that $\text{PRE}(\mathbf{y}, \mathbf{v}) = s - 1 > j$ and $\text{SUF}(\mathbf{x}, \mathbf{u}) = n - 1 - (s - 1) = n - s < n - 1 - j = i$. Hence, $(\mathbf{u}, \mathbf{v}) \in A_{n-s} \times B_j$. Such branch (\mathbf{u}, \mathbf{v}) is called a *right secondary branch*.

To summarize, there are two types of secondary branches accompanying (\mathbf{x}, \mathbf{y}) : the *left secondary branches* are the branches $(\mathbf{u}, \mathbf{v}) \in A_i \times B_{j'}$ for some $j' < j$, and the *right secondary branches* are the branches $(\mathbf{u}, \mathbf{v}) \in A_{i'} \times B_j$ for some $i' < i$. For each $i' < i$, there is at most one right secondary branch in $A_{i'} \times B_j$. Similarly, for each $j' < j$, there is at most one left secondary branch in $A_i \times B_{j'}$.

Case 3: There are $c + 1$ branches (of some f -cast requests) in the plane each of whose routes intersects (\mathbf{a}, \mathbf{b}) at exactly one SE at a distinct stage. These will be called *node-blocking requests of type 2*. If (\mathbf{x}, \mathbf{y}) is such a request, then $(\mathbf{x}, \mathbf{y}) \in A_i \times B_j$ for some $i + j = n - 1$. Moreover, two node-blocking branches of type 2 belonging to the same $A_i \times B_j$ must belong to different blocking planes.

Theorem 5 *The number of blocking planes for (\mathbf{a}, \mathbf{b}) is the objective value of a feasible solution to the primal linear program as shown in [Fig. 8](#).*

The Primal LP

Maximize

$$\sum_{i+j \geq n} x_{ij} + \sum_{i+j=n-1} y_{ij} + \frac{1}{c+1} \sum_{i+j=n-1} z_{ij} \quad (20)$$

Subject to

$$\sum_{j: i+j \geq n} x_{ij} + \sum_{j: i+j=n-1} (y_{ij} + z_{ij}) + \sum_{j: i+j < n-1} (l_{ij} + r_{ij}) \leq f(d^{n-i} - d^{n-1-i}) \quad \forall i \quad (21)$$

$$\sum_{i: i+j \geq n} x_{ij} + \sum_{i: i+j=n-1} (y_{ij} + z_{ij}) + \sum_{i: i+j < n-1} (l_{ij} + r_{ij}) \leq d^{n-j} - d^{n-1-j} \quad \forall j \quad (22)$$

$$z_{ij} \leq \frac{1}{c+1} \sum_{i'+j'=n-1} z_{i'j'} \quad i+j = n-1 \quad (23)$$

$$cy_{ij} = \left(\sum_{i' < i} r_{i'j} + \sum_{j' < j} l_{ij'} \right) \quad i+j = n-1 \quad (24)$$

$$l_{ij'} \leq y_{ij} \quad i+j = n-1, j' < j \quad (25)$$

$$r_{i'j} \leq y_{ij} \quad i+j = n-1, i' < i \quad (26)$$

$$x_{ij}, y_{ij}, z_{ij}, l_{ij}, r_{ij}, p_i \geq 0 \quad \forall i, j \quad (27)$$

Fig. 8 The dual linear programs for f -cast c -SNB

Proof For each pair $i + j \geq n$, let x_{ij} be the number of link-blocking branches in $A_i \times B_j$. For each $i + j = n - 1$, let y_{ij} be the number of node-blocking branches of type 1 and z_{ij} be the number of node-blocking branches of type 2 in $A_i \times B_j$. For each pair $i + j < n - 1$, let l_{ij} and r_{ij} be the number of left and right secondary branches in $A_i \times B_j$. The number of blocking planes is thus expressed in the objective function (20).

The next step is to verify that the variables satisfy all the constraints. Recall that $|A_i| = d^{n-i} - d^{n-1-i}$, $\forall i$. Thus, the number of branches of f -cast requests out of A_i is at most $f(d^{n-i} - d^{n-1-i})$, justifying constraint (21). Similarly, bounding the number of branches of requests into B_j explains constraint (22). Since all node-blocking branches of type 2 belonging to the same $A_i \times B_j$ must belong to different blocking planes, z_{ij} is at most the number of blocking planes involving these type-2 branches. This is constraint (23). Constraint (24) expresses the fact that, for every node-blocking request of type 1 in $A_i \times B_j$ ($i + j = n - 1$), there must be c accompanying secondary requests (left or right). Lastly, for each node-blocking request of type 1 in $A_i \times B_j$ ($i + j = n - 1$), constraint (24) says that for each $j' < j$, there is at most one left secondary request in $A_i \times B_{j'}$, and constraint (26) says that for each $i' < i$, there is at most one right secondary request in $A_{i'} \times B_j$. \square

The dual of the primal LP is shown in Fig. 9. To get a sense of how to select a good dual-feasible solution, let us reproduce a few known results. The following

The Dual LP

Minimize

$$\sum_{i=0}^{n-1} f(d^{n-i} - d^{n-1-i})u_i + \sum_{j=0}^{n-1} (d^{n-j} - d^{n-1-j})v_j \quad (28)$$

Subject to

$$u_i + v_j \geq 1, \quad i + j \geq n \quad (29)$$

$$u_i + v_j + cw_{ij} - \sum_{i' < i} s_{i'j} - \sum_{j' < j} t_{ij'} \geq 1, \quad i + j = n - 1 \quad (30)$$

$$u_i + v_j + \frac{c}{c+1} p_i - \frac{1}{c+1} \sum_{i' \neq i} p_{i'} \geq \frac{1}{c+1}, \quad i + j = n - 1 \quad (31)$$

$$u_i + v_j - w_{i,n-1-i} + t_{ij} \geq 0, \quad i + j < n - 1 \quad (32)$$

$$u_i + v_j - w_{n-1-j,j} + s_{ij} \geq 0, \quad i + j < n - 1 \quad (33)$$

$$u_i, v_j, s_{ij}, t_{ij} \geq 0, \quad \forall i, j \quad (34)$$

Fig. 9 The dual linear programs for f -cast c -SNB

corollaries should give the reader the correct insight without delving into too much technicality.

The following condition has been shown in [54] to be necessary and sufficient, with a fairly involved combinatorial argument.

Corollary 1 (The crosstalk-free case) *For $\log_d(N, 0, m)$ to be f -cast crosstalk-free strictly nonblocking, it is sufficient that*

$$m \geq f(d^{\lceil \frac{n-r-1}{2} \rceil} - 1) + d^{n-\lceil \frac{n-r-1}{2} \rceil}$$

where $r = \lfloor \log_d f \rfloor$.

Proof Being crosstalk-free, strictly nonblocking is the same as being 0-SNB (i.e., $c = 0$). Let $b = \lceil \frac{n-r-1}{2} \rceil$ and $a = n - b$. Consider the following assignment to the dual variables: $u_i = 1, \forall i \geq a, v_j = 1, \forall j \geq b$, and all other variables are 0. This solution is dual feasible with objective value

$$f(d^{\lceil \frac{n-r-1}{2} \rceil} - 1) + d^{n-\lceil \frac{n-r-1}{2} \rceil} - 1,$$

which is an upperbound on the number of blocking planes. One more plane is needed for the network to be strictly nonblocking, which completes the proof. \square

The following condition has been shown in [14, 54] to be necessary and sufficient for the link-blocking case using a complex combinatorial argument. The proof presented here is much simpler to verify.

Corollary 2 (The link-blocking case) *Define*

$$m_{lb}(n, f, d) := f(d^{\lceil \frac{n-r-2}{2} \rceil} - 1) + d^{n-\lceil \frac{n-r}{2} \rceil}.$$

For $\log_d(N, 0, m)$ to be f -cast strictly nonblocking in the link-blocking sense, it is sufficient that

$$m \geq \begin{cases} m_{lb}(n, f, d) & f < d^{n-2} \\ m_{lb}(n, d^{n-2}, d) & f \geq d^{n-2} \end{cases}$$

Proof First, suppose $f < d^{n-2}$. Let $b = \lceil \frac{n-r}{2} \rceil$ and $a = n + 1 - b$. Consider the following assignment to the dual variables: $u_i = 1, \forall i \geq a, v_j = 1, \forall j \geq b, w_{a-1,n-a} = 1, p_{a-1} = 1/c, s_{i,b-1} = t_{a-1,j} = 1$ when $i < a-1, j < b-1$, and all other variables are 0. This solution is dual feasible with objective value precisely $m_{lb}(n, f, d) - 1$. Second, when $f \geq d^{n-2}$, assign all $v_j = 1, j > 0, w_{n-1,0} = 1, p_{n-1} = 1/c, s_{i,0} = 1, \forall i < n-1$, and all other variables to be 0. \square

Henceforth, consider the case when $1 \leq c \leq n-1$. In the next three lemmas, several general dual-feasible solutions are derived. Then, depending on the relative relationships between f, n, c , and d , one of the lemmas is applied to get the best sufficient condition.

Lemma 7 *Suppose $1 \leq c \leq n-1$. Let a, b, p, q be any integers satisfying $0 \leq a \leq n-1, b = n-1-a, 0 \leq p \leq b, 0 \leq q \leq a$. Define $\delta = \frac{1}{d(c+1)}$ and $\lambda = \frac{d}{c+1}$. Then, there exists a dual-feasible solution with objective value*

$$f(d^b - 1) + (d^a - 1) - \frac{(d-1)[fd^b(1-\delta^p) + d^a(1-\delta^q)]}{d(c+2)(1-\delta)} + \frac{(d-1)}{c+2} \left[fd^b \frac{1-\lambda^{q+1}}{1-\lambda} + d^a \frac{1-\lambda^{p+1}}{1-\lambda} \right].$$

The following convention is made: for any integer k , $\frac{(1-\lambda^k)}{(1-\lambda)} = k$ when $\lambda = 1$.

Proof Consider the following assignment to the dual variables:

$$u_i = \begin{cases} 0 & 0 \leq i \leq a-q-1 \\ \frac{1}{(c+2)(c+1)^{a-i}} & a-q \leq i \leq a \\ 1 - \frac{1}{(c+2)(c+1)^{i-(a+1)}} & a+1 \leq i \leq a+p \\ 1 & a+p+1 \leq i \leq n-1 \end{cases}$$

$$v_j = \begin{cases} 0 & 0 \leq i \leq b-p-1 \\ \frac{1}{(c+2)(c+1)^{b-j}} & b-p \leq j \leq b \\ 1 - \frac{1}{(c+2)(c+1)^{j-(b+1)}} & b+1 \leq j \leq b+q \\ 1 & b+q+1 \leq j \leq n-1 \end{cases}$$

$$w_{ij} = \begin{cases} \min\{u_i, u_j\} & i+j = n-1 \\ 0 & \text{otherwise} \end{cases}$$

All other variables are 0.

The next step is to verify that this solution is indeed dual feasible. Constraints (29) and (31) can be verified straightforwardly. Constraints (32) and (33) follow from the fact that $u_i \geq w_{i,n-1-i}$, and $v_j \geq w_{n-1-j,j}$.

Next, consider the dual constraint (30). When $i \leq a-q-1$ or $i \geq a+p+1$, it holds that $v_j = 1$ or $u_i = 1$ (recall $i+j = n-1$). The constraint is satisfied because in these cases $w_{ij} = 0$. When $i = a$, $u_i + v_j + cw_{ij} = 1$. When $a+1 \leq i = a+k \leq a+p$, it follows that

$$\begin{aligned} u_i + v_j + cw_{ij} &= 1 - \frac{1}{(c+2)(c+1)^{k-1}} + \frac{1}{(c+2)(c+1)^k} + \frac{c}{(c+2)(c+1)^k} \\ &= 1 \end{aligned}$$

When $a-q \leq i = a-k \leq a-1$, the constraint is verified similarly. \square

Proposition 3 Given $a, b = n-1-a, q$, and a feasible solution as assigned as in Lemma 7, the dual objective value is minimized at

$$p_0 = \max \left\{ 0, \min \left\{ \left\lfloor \frac{1}{2} \log_d(f(c+1)) + \frac{n-1}{2} - a \right\rfloor, b \right\} \right\}$$

Proof To see this, it will be shown that $g(a, b, p, q) \geq g(a, b, p+1, q)$ iff $p \leq \frac{1}{2} \log_d(f(c+1)) + \frac{n-3}{2} - a$ where $g(a, b, q, p)$ is the dual-objective value of feasible solution as assigned as in Lemma 7. First,

$$\begin{aligned} g(a, b, p, q) &= \sum_{i=a-q}^a f(d^{n-i} - d^{n-1-i}) \frac{1}{(c+2)(c+1)^{a-i}} \\ &\quad + \sum_{i=a+1}^{a+p} f(d^{n-i} - d^{n-1-i}) \left(1 - \frac{1}{(c+2)(c+1)^{i-(a+1)}} \right) \\ &\quad + \sum_{j=b-p}^b (d^{n-j} - d^{n-1-j}) \frac{1}{(c+2)(c+1)^{b-j}} \end{aligned}$$

$$\begin{aligned}
& + \sum_{j=b+1}^{b+q} (d^{n-j} - d^{n-1-j})(1 - \frac{1}{(c+2)(c+1)^{j-(b+1)}}) \\
& + \sum_{i=a+p+1}^{n-1} f(d^{n-i} - d^{n-1-i}) + \sum_{j=b+q+1}^{n-1} (d^{n-j} - d^{n-1-j}) \\
g(a, b, p+1, q) = & \sum_{i=a-q}^a f(d^{n-i} - d^{n-1-i}) \frac{1}{(c+2)(c+1)^{a-i}} \\
& + \sum_{i=a+1}^{a+p+1} f(d^{n-i} - d^{n-1-i})(1 - \frac{1}{(c+2)(c+1)^{i-(a+1)}}) \\
& + \sum_{j=b-p-1}^b (d^{n-j} - d^{n-1-j}) \frac{1}{(c+2)(c+1)^{b-j}} \\
& + \sum_{j=b+1}^{b+q} (d^{n-j} - d^{n-1-j})(1 - \frac{1}{(c+2)(c+1)^{j-(b+1)}}) \\
& + \sum_{i=a+p+2}^{n-1} f(d^{n-i} - d^{n-1-i}) + \sum_{j=b+q+1}^{n-1} (d^{n-j} - d^{n-1-j})
\end{aligned}$$

Second,

$$\begin{aligned}
g(a, b, p+1, q) - g(a, b, p, q) = & f(d^{n-(a+p+1)} - d^{n-1-(a+p+1)}) \\
& \times (1 - \frac{1}{(c+2)(c+1)^p}) - f(d^{n-(a+p+1)} \\
& - d^{n-1-(a+p+1)}) \\
& + (d^{n-(b-p-1)} - d^{n-1-(b-p-1)}) \frac{1}{(c+2)(c+1)^{p+1}}
\end{aligned}$$

It is easy to see that $g(a, b, p, q) \geq g(a, b+1, p, q)$ if and only if

$$\begin{aligned}
& (d^{n-(b-p-1)} - d^{n-1-(b-p-1)}) \frac{1}{(c+2)(c+1)^{p+1}} \leq f(d^{n-(a+p+1)} \\
& - d^{n-1-(a+p+1)}) \frac{1}{(c+2)(c+1)^p}
\end{aligned}$$

By dividing both sides by $(d-1)$ and some simple cancelations, the following inequality is obtained:

$$d^{n-1-(b-p-1)} \leq f(c+1)d^{n-1-(a+p+1)}.$$

Now, taking logarithms of both sides, it is easy to obtain

$$p \leq \frac{1}{2} \log_d(f(c+1)) + \frac{n-1}{2} - a - 1.$$

As p is an integer and p must satisfy $0 \leq p \leq b$, the function $g(a, b, p, q)$ is minimized at

$$p_0 = \max \left\{ 0, \min \left\{ \left\lfloor \frac{1}{2} \log_d(f(c+1)) + \frac{n-1}{2} - a \right\rfloor, b \right\} \right\}.$$

□

Proposition 4 Given $a, b = n - 1 - a$, p , and a feasible solution as assigned as in [Lemma 7](#), the dual-objective value is minimized at

$$q_0 = \max \left\{ 0, \min \left\{ \left\lfloor \frac{1}{2} \log_d \frac{c+1}{f} + \bar{a} - \frac{n-1}{2} \right\rfloor, a \right\} \right\}$$

Proof Similar to the proof for [Proposition 3](#), one can prove that $g(a, b, p, q) \geq g(a, b, p, q+1)$ if and only if

$$q \leq \frac{1}{2} \log_d \frac{c+1}{f} + \bar{a} - \frac{n-1}{2} - 1.$$

□

Lemma 8 Suppose $c \geq \frac{n}{2} + 1$. Let a be any integer where $n - c + 1 \leq a \leq c - 1$ and x be any real number in the interval $\left[\frac{1}{c-a+1}, \frac{c+a-n}{c+a-n+1} \right]$. Then, there exists a feasible solution to the dual LP with objective value

$$f(d^{n-a-2} - 1) + (d^{a-1} - 1) + (d - 1)d^{n-a+1}x(f - d^{2a-n}).$$

Proof Consider the following assignment to the dual variables:

$$u_a = x,$$

$$v_{n-a} = 1 - x,$$

$$u_i = v_j = 1, \text{ when } i > a + 1 \text{ and } j > n - a + 1,$$

$$w_{a,n-1-a} = s_{i,n-1-a} = \frac{1}{c-a+1}, \text{ when } 0 \leq i \leq a-1,$$

$$w_{a-1,n-1} = t_{a-1,j} = \frac{1}{c+a-n+1}, \text{ when } 0 \leq j \leq n-a-1.$$

All other variables are 0. \square

Lemma 9 Suppose $c \geq \frac{n}{2} + 1$. Let a be any integer where $a > c - 1$. There exists a dual-feasible solution with objective value

$$f(d^{n-a-1} - 1) + (d^a - 1) + \frac{1}{c+2} d^{a-1} (d-1)^2 (fd^{n-2a-1} + 1).$$

Proof Consider the following assignment to the dual variables:

$$\begin{aligned} u_a &= v_{n-1-a} = \frac{1}{c+2}, \\ u_{a+1} &= v_{n-a} = \frac{c+1}{c+2}, \\ u_i &= v_j = 1, \text{ when } i > a, j > n-a, \\ w_{a-1,n-a} = t_{a_1,j} &= \frac{1}{(c+2)(c+a+1-n)} \text{ where } j \leq n-a-2, \\ w_a &= \frac{1}{c+2}, \\ w_{a+1} = s_{i,n-a-2} &= \frac{1}{(c+2)(c-a)}, \text{ when } i \leq a-1. \end{aligned}$$

All other variables are 0. \square

Theorem 6 Consider the case when $c \leq \frac{n}{2}$. Let $\bar{a} = \lfloor \frac{n+r}{2} \rfloor$, $\bar{b} = n-1-\bar{a}$, $\bar{p} = p_0$, $\bar{q} = q_0$, $\delta = \frac{1}{d(c+1)}$, and $\lambda = \frac{d}{c+1}$. Then,

$$\begin{aligned} m \geq f(d^{\bar{b}} - 1) + d^{\bar{a}} - &\frac{(d-1) \left[fd^{\bar{b}}(1-\delta^{\bar{p}}) + d^{\bar{a}}(1-\delta^{\bar{q}}) \right]}{d(c+2)(1-\delta)} \\ &+ \frac{(d-1)}{c+2} \left[fd^{\bar{b}} \frac{1-\lambda^{\bar{q}+1}}{1-\lambda} + d^{\bar{a}} \frac{1-\lambda^{\bar{p}+1}}{1-\lambda} \right] \end{aligned}$$

is sufficient for $\log_d(N, 0, m)$ to be f -cast c -SNB. (Again, set $\frac{(1-\lambda^k)}{(1-\lambda)} = k$ when $\lambda = 1$.)

Remark 7 The results for $c \leq n/2$ in [40, 53] are direct consequences of this theorem for $f = 1$.

Applying [Lemmas 8](#) and [9](#) appropriately, the following theorem is obtained. Again, the results for $c > n/2$ in [\[40, 53\]](#) are consequences of this theorem for $f = 1$.

Theorem 7 Consider the case when $c \geq \frac{n}{2} + 1$. Set $\bar{a} = \lceil (n+r)/2 \rceil$. Note that in this case, $n - c + 1 \leq \bar{a}$.

(i) If $\bar{a} \leq c - 1$ and $n + r$ is even, then

$$m \geq f(d^{n-\bar{a}-1} - 1) + d^{\bar{a}} + \frac{(d-1)d^{n-\bar{a}+1}(f - d^{2\bar{a}-n})}{c - \bar{a} + 1}$$

is sufficient for the network to be f -cast c -SNB.

(ii) If $\bar{a} \leq c - 1$ and $n + r$ is odd, then

$$m \geq f(d^{n-\bar{a}-1} - 1) + d^{\bar{a}} + \frac{(d-1)d^{n-\bar{a}+1}(f - d^{2\bar{a}-n})(c + \bar{a} - n)}{c + \bar{a} - n + 1}$$

is sufficient for the network to be f -cast c -SNB.

(iii) If $\bar{a} > c - 1$, then

$$m \geq f(d^{n-\bar{a}} - 1) + d^{\bar{a}-1} + \frac{d^{\bar{a}-2}(d-1)^2(fd^{n-2\bar{a}+1} + 1)}{c + 2}$$

is sufficient for the network to be f -cast c -SNB.

Proof (i) Apply [Lemma 8](#) with $x = \frac{1}{c-\bar{a}+1}$.

(ii) Apply [Lemma 8](#) with $x = \frac{c+\bar{a}-n}{c+\bar{a}-n+1}$.

(ii) Apply [Lemma 9](#) with $a = \bar{a}$.

□

6 Analyzing f -Cast Wide-Sense Nonblocking Multilog Networks

Let f, t be given integers with $0 \leq t \leq n$ and $1 \leq f \leq N = d^n$. This section analyzes f -cast wide-sense nonblocking $\log_d(N, 0, m)$ networks under the *window algorithm* with window size d^t . The algorithm was proposed and analyzed for one window size $d^{\lfloor n/2 \rfloor}$ in [\[49\]](#) and later analyzed more carefully for varying window sizes in [\[10\]](#). Both papers considered the multicast case with no fanout restriction. A more general theorem for the f -cast case will be derived in this section:

- *The window algorithm with window size d^t :* Given any integer t , $0 \leq t \leq n$, divide the outputs into “windows” of size d^t each. Each window consists of all outputs sharing a prefix of length $n - t$ for a total of d^{n-t} windows. Denote the windows by W_w , $0 \leq w \leq d^{n-t} - 1$. Given a new multicast request (\mathbf{a}, B) , where \mathbf{a} is an input and B is a subset of outputs, the routing rule is, for every $0 \leq w \leq d^{n-t} - 1$, the subrequest $(\mathbf{a}, B \cap W_w)$ is routed entirely on one

single $\text{BY}^{-1}(n)$ -plane. (Different subrequests can be routed through the same or different $\text{BY}^{-1}(n)$ -planes.)

Remark 8 There is a subtle point about the window algorithm due to which the original authors in [49] thought their multilog network was strictly nonblocking instead of wide-sense nonblocking. Basically, for some specific values of the parameters, the algorithm is *no* algorithm at all. In those cases, any sufficient condition for the network to be nonblocking under the window algorithm is in fact a strictly nonblocking condition, not a wide-sense nonblocking condition.

For example, in the unicast case, it holds that $f = 1$, which means the window algorithm does not specify any routing strategy; consequently, any nonblocking condition is actually a strictly nonblocking condition. Another example is when $t = 0$. In this case, the routing rule says that each branch of a (multicast) request should be routed on some plane, independent of other branches. Because there is no restriction on how to route the branches, any nonblocking condition is a strictly nonblocking one.

Yet another example is when $t = n$. Here, the routing rule is for each request to be routed entirely on some plane. If the $1 \times m$ -SE stage of the multilog network has fanout capability, then the rule *does* restrict how requests are routed, and thus the setting is indeed a wide-sense nonblocking setting. However, if the $1 \times m$ -SE stage is implemented with $1 \times m$ -unicast crossbars or $1 \times m$ -demultiplexers, then an algorithm following the rule *has to* route each request entirely on some plane. Thus, any sufficient condition is a strictly nonblocking condition.

6.1 Setting Up the Linear Program and Its Dual

Let (\mathbf{a}, B) be an arbitrary f -cast request to be routed using the window algorithm with window size d^t . Following the window algorithm, due to symmetry without loss of generality, it can be assumed that $B = \{\mathbf{b}^{(1)}, \dots, \mathbf{b}^{(k)}\}$ where all the outputs $\mathbf{b}^{(l)}$ ($l \in [k]$) belong to the same window W_0 and $k \leq \min\{f, d^t\}$. The $\mathbf{b}^{(l)}$ thus share a common prefix of length $n - t$. (This is because subrequests to the same window are routed through the same plane and different subrequests of the same request are routed independently from each other and they do not block one another.)

For each $i \in \{0, \dots, n - 1\}$, let A_i be the set of inputs \mathbf{u} other than \mathbf{a} , where $\mathbf{u}_{1..n-1}$ shares a *suffix* of length exactly i with $\mathbf{a}_{1..n-1}$. Formally, define

$$A_i := \{\mathbf{u} \in \mathbb{Z}_d^n - \{\mathbf{a}\} \mid \text{SUF}(\mathbf{u}_{1..n-1}, \mathbf{a}_{1..n-1}) = i\}.$$

For each $j \in \{0, \dots, n - 1\}$, let B_j be the set of outputs other than those in B which share a *prefix* of length exactly j with *some* member of B , namely,

$$B_j := \left\{ \mathbf{v} \in \mathbb{Z}_d^n - B \mid \exists l \in [k], \text{PRE}(\mathbf{v}_{1..n-1}, \mathbf{b}_{1..n-1}^{(l)}) = j \right\}.$$

Note that

$$\begin{aligned}|A_i| &= d^{n-i} - d^{n-1-i}, 0 \leq i \leq n-1, \\ |B_j| &= d^{n-j} - d^{n-1-j}, 0 \leq j \leq n-t-1.\end{aligned}$$

Define $\mathcal{A} = \bigcup_{i=0}^{n-1} A_i$. It is easy to see that

$$\begin{aligned}\bigcup_{j=0}^{n-t-1} B_j &= \bigcup_{w=1}^{d^{n-t}-1} W_w \\ \bigcup_{j=n-t}^{n-1} B_j &= W_0 - B.\end{aligned}$$

Furthermore, for each $j \leq n-t-1$, B_j is the disjoint union of precisely $d^{n-j-t} - d^{n-1-j-t}$ windows each of size d^t .

Note that the sets B_j for $0 \leq j \leq n-t-1$ are mutually disjoint. On the other hand, the sets B_j for $n-t \leq j \leq n-1$ are not necessarily disjoint, because for the same output $\mathbf{v} \in W_0 - B$, it might be the case that $\text{PRE}(\mathbf{v}_{1..n-1}, \mathbf{b}_{1..n-1}^{(l)}) = j$ and $\text{PRE}(\mathbf{v}_{1..n-1}, \mathbf{b}_{1..n-1}^{(l')}) = j'$ for $j \neq j'$, $l \neq l'$. The following simple observation turns out to be an important analytical detail in many of the proofs.

Proposition 5 *Let q be an integer such that $n-t \leq q \leq n-1$. Then,*

$$\left| \bigcup_{j=q}^{n-1} B_j \right| \leq \min\{d^t - k, k(d^{n-q} - 1)\}$$

and

$$\left| \bigcup_{j=n-t}^{n-1} B_j \right| = d^t - k.$$

Proof To see the inequality, note that $\left| \bigcup_{j=q}^{n-1} B_j \right|$ counts the number of strings \mathbf{v} in $W_0 - B$ for which $\text{PRE}(\mathbf{v}_{1..n-1}, \mathbf{b}_{1..n-1}^{(l)}) \geq q$ for some $\mathbf{b}^{(l)}$, $l \in [k]$. As $|W_0| = d^t$, the upperbound $d^t - k$ for the number of such strings is trivial. On the other hand, the number of strings \mathbf{v} where $\text{PRE}(\mathbf{v}_{1..n-1}, \mathbf{b}_{1..n-1}^{(l)}) \geq q$ for a fixed string $\mathbf{b}^{(l)}$ is at most $d^{n-q} - 1$ (discounting $\mathbf{b}^{(l)}$ itself). Hence, the upperbound $k(d^{n-q} - 1)$ is obtained via a simple application of the union bound. The equality trivially holds because $\bigcup_{j=n-t}^{n-1} B_j = W_0 - B$. \square

For every input $\mathbf{u} \in \mathcal{A}$, let $i(\mathbf{u})$ denote the index i such that $\mathbf{u} \in A_i$. For every $w \in [d^{n-t} - 1] = \{1, \dots, d^{n-t} - 1\}$, let $j(w)$ be the index j such that $W_w \subseteq B_j$. For every $\mathbf{v} \in W_0 - B$, let $j(\mathbf{v})$ denote the largest j for which $\mathbf{v} \in B_j$. Note that $j(\mathbf{v}) \geq n - t$ for such output \mathbf{v} because $W_0 - B = \bigcup_{j=n-t}^{n-1} B_j$.

Lemma 10 *For each input $\mathbf{u} \in \mathcal{A}$ and each $w \in [d^{n-t} - 1]$ such that $i(\mathbf{u}) + j(w) \geq n$, define a variable $x_{\mathbf{u},w}$. Also, for each input $\mathbf{u} \in \mathcal{A}$ and each output $\mathbf{v} \in W_0 - B$ such that $i(\mathbf{u}) + j(\mathbf{v}) \geq n$, define a variable $x_{\mathbf{u},\mathbf{v}}$. Then, the number of Banyan planes blocking the new multicast request (\mathbf{a}, B) is upperbounded by the optimal value of the following linear program:*

$$\begin{aligned} \max \quad & \sum_{\mathbf{u}, w} x_{\mathbf{u}, w} + \sum_{\mathbf{u}, \mathbf{v}} x_{\mathbf{u}, \mathbf{v}} \\ \text{s.t.} \quad & \sum_{\mathbf{u}} x_{\mathbf{u}, w} \leq d^t \quad w \in [d^{n-t} - 1] \\ & x_{\mathbf{u}, w} \leq 1 \quad \forall \mathbf{u}, w \\ & \sum_{\mathbf{v}} x_{\mathbf{u}, \mathbf{v}} \leq 1 \quad \forall \mathbf{u} \in \mathcal{A} \\ & \sum_{\mathbf{u}} x_{\mathbf{u}, \mathbf{v}} \leq 1 \quad \forall \mathbf{v} \in W_0 - B \\ & \sum_w x_{\mathbf{u}, w} + \sum_{\mathbf{v}} x_{\mathbf{u}, \mathbf{v}} \leq f \quad \forall \mathbf{u} \in \mathcal{A} \\ & x_{\mathbf{u}, w}, x_{\mathbf{u}, \mathbf{v}} \geq \mathbf{0} \quad \forall \mathbf{u}, w, \mathbf{v} \end{aligned} \tag{35}$$

Obviously, the sums and the constraints only range over values for which the variables are defined.

Proof Suppose the network $\log_d(N, 0, m)$ already had some routes established. Consider a $\text{BY}^{-1}(n)$ -plane which blocks the new request (\mathbf{a}, B) . There must be one route $R(\mathbf{u}, \mathbf{v})$ on this plane for which $R(\mathbf{u}, \mathbf{v})$ and $R(\mathbf{a}, \mathbf{b}^{(l)})$ share a link for some $l \in [k]$. Note that the branch $R(\mathbf{u}, \mathbf{v})$ could be part of a multicast tree from input \mathbf{u} , but only an arbitrary blocking branch (\mathbf{u}, \mathbf{v}) of this tree is needed. Note also that $\mathbf{u} \neq \mathbf{a}$ because subrequests from the same input are parts of the same request and thus their routes do not block one another. Let S be the set constructed by arbitrarily taking exactly one blocking branch (\mathbf{u}, \mathbf{v}) per blocking plane. Then, the number of blocking planes is $|S|$.

Fact 1 If (\mathbf{u}, \mathbf{v}) and $(\mathbf{u}, \mathbf{v}')$ are both in S , then \mathbf{v} and \mathbf{v}' must belong to different windows because, if they belong to the same window, the window algorithm would have routed them through the same plane and S only contains one branch per blocking plane.

Fact 2 Each output \mathbf{v} can only appear once in S because each output can only be part of at most one existing request.

Fact 3 If $(\mathbf{u}, \mathbf{v}) \in S$, then $(\mathbf{u}, \mathbf{v}) \in A_i \times B_j$ for some $i + j \geq n$, thanks to Proposition 2.

Straightforwardly, it will be shown that S defines a feasible solution to the linear program with objective value precisely $|S|$. Set $x_{\mathbf{u},w} = 1$ if there is some $(\mathbf{u}, w) \in S$ such that $w \in W_w$ and $x_{\mathbf{u},v} = 1$ if there is some $(\mathbf{u}, v) \in S$ such that $v \in W_0 - B$. All other variables are set to 0. Due to Fact 3, the procedure does not set value for an undefined variable. Certainly $|S|$ is equal to the objective value of this solution.

The next step is to verify that the solution satisfies all the constraints. The first constraint expresses the fact that each output in a window W_w of size d^t only appears at most once in S (Fact 2). The second and third constraints are a restatement of Fact 1. Note that the sum in the third constraint is only over $v \in W_0 - B$. The fourth constraint says that each output $v \in W_0 - B$ appears at most once in S (Fact 2 again). The fifth constraint says that each input can only be part of at most f members of S due to the f -cast nature of the network. \square

The dual linear program can be written as follows:

$$\begin{aligned} \min & \sum_w d^t \alpha_w + \sum_{\mathbf{u},w} \beta_{\mathbf{u},w} + \sum_{\mathbf{u}} \gamma_{\mathbf{u}} + \sum_v \delta_v + \sum_{\mathbf{u}} f \epsilon_{\mathbf{u}} \\ \text{s.t. } & \alpha_w + \beta_{\mathbf{u},w} + \epsilon_{\mathbf{u}} \geq 1, \quad x_{\mathbf{u},w} \text{ defined (DC-1)} \\ & \gamma_{\mathbf{u}} + \delta_v + \epsilon_{\mathbf{u}} \geq 1, \quad x_{\mathbf{u},v} \text{ defined (DC-2)} \\ & \alpha_w, \beta_{\mathbf{u},w}, \gamma_{\mathbf{u}}, \delta_v, \epsilon_{\mathbf{u}} \geq 0 \quad \forall \mathbf{u}, \mathbf{v}, w \end{aligned} \quad (36)$$

Note that the dual constraints only exist over all $\mathbf{u}, \mathbf{v}, w$ for which $x_{\mathbf{u},w}$ and $x_{\mathbf{u},v}$ are defined; in particular, they exist for pairs (\mathbf{u}, w) such that $i(\mathbf{u}) + j(w) \geq n$ and pairs (\mathbf{u}, \mathbf{v}) such that $i(\mathbf{u}) + j(\mathbf{v}) \geq n$.

6.2 Specifying a Family of Dual-Feasible Solutions

To illustrate the technique, let us first derive a couple of known results “for free.” The first is Theorem III.2 in [54].

Corollary 3 (Theorem III.2 in [54]) *Let $r = \lfloor \log_d f \rfloor$. Suppose the $1 \times m$ -SE stage of the $\log_d(N, 0, m)$ network does not have fanout capability, then when $f \leq d^{n-2}$, the network is f -cast strictly nonblocking if*

$$m \geq d^{\lfloor \frac{n+r}{2} \rfloor} + f \left(d^{\lceil \frac{n-r-2}{2} \rceil} - 1 \right).$$

When $f > d^{n-2}$, the network is f -cast strictly nonblocking if $m \geq d^{n-1}$.

Proof Recall Remark 8: routing using the window algorithm with window size $t = n$ is the same as routing arbitrarily in the network when the $1 \times m$ -SE stage cannot fanout. Thus, any sufficient condition for the window algorithm to work is a strictly nonblocking condition. Note that when $t = n$, the dual constraints (DC-1) do not exist! A feasible solution to the dual linear program is constructed as follows:

When $f > d^{n-2}$, set $\gamma_{\mathbf{u}} = 1$ for all $\mathbf{u} \in \bigcup_{i=1}^{n-1} A_i$ and all other variables to be 0. The dual-objective value in this case is

$$\sum_{\mathbf{u} \in \bigcup_{i=1}^{n-1} A_i} \gamma_{\mathbf{u}} = \sum_{i=1}^{n-1} |A_i| = \sum_{i=1}^{n-1} (d^{n-i} - d^{n-i-1}) = d^{n-1} - 1,$$

and hence one more plane (i.e., $m \geq d^{n-1}$) is sufficient. Note that this solution is dual feasible, because for $\mathbf{u} \in \mathbf{A}_0$, there is no \mathbf{v} for which $i(\mathbf{u}) + j(\mathbf{v}) \geq n$. In other words, there is no dual constraint for which $\mathbf{u} \in A_0$.

Next, suppose $f \leq d^{n-2}$. Define $q = \lfloor \frac{n+r}{2} \rfloor + 1$. Note that $r + 1 \leq q \leq n - 1$ in this case; in particular,

$$kd^{n-q} < d^{r+1}d^{n-q} \leq d^n,$$

which implies

$$\min\{d^n - k, k(d^{n-q} - 1)\} = kd^{n-q}.$$

Set

$$\gamma_{\mathbf{u}} = \begin{cases} 1 & \text{if } i(\mathbf{u}) \geq n - q + 1 \\ 0 & \text{otherwise} \end{cases} \quad (37)$$

and

$$\delta_{\mathbf{v}} = \begin{cases} 1 & \text{if } \mathbf{v} \in \bigcup_{j=q}^{n-1} B_j \\ 0 & \text{otherwise.} \end{cases} \quad (38)$$

All other dual variables are 0. The solution is dual feasible because, for any pair (\mathbf{u}, \mathbf{v}) for which $i(\mathbf{u}) + j(\mathbf{v}) \geq n$, it must either be the case that $i(\mathbf{u}) \geq n - q + 1$ or that $j(\mathbf{v}) \geq q$ (which is the same as saying $\mathbf{v} \in \bigcup_{j=q}^{n-1} B_j$). Recalling [Proposition 5](#), the dual-objective value is

$$\begin{aligned} \sum_{\mathbf{u} : i(\mathbf{u}) \geq n - q + 1} \gamma_{\mathbf{u}} + \sum_{\mathbf{v} \in \bigcup_{j=q}^{n-1} B_j} \delta_{\mathbf{v}} &= \sum_{i=n-q+1}^{n-1} |A_i| + \left| \bigcup_{j=q}^{n-1} B_j \right| \\ &\leq d^{q-1} - 1 + \min\{d^n - k, k(d^{n-q} - 1)\} \\ &= d^{q-1} - 1 + k(d^{n-q} - 1) \\ &\leq d^{q-1} + f(d^{n-q} - 1) - 1. \end{aligned}$$

This is an upperbound on the number of blocking planes. Hence, one more plane is sufficient to route the new (arbitrary) request. \square

Because unicast is 1-cast, by setting $r = 0$ in the previous corollary, the following corollary is obtained, whose proof was about 5 pages long in [20]. Recall

Remark 8 which ensures that our result is a strictly nonblocking condition rather than a wide-sense nonblocking one.

Corollary 4 (Theorem 1 in [20]) *For $\log_d(N, 0, m)$ to be unicast strictly non-blocking, it is sufficient that $m \geq d^{\lceil n/2 \rceil - 1} + d^{\lfloor n/2 \rfloor} - 1$.*

Corollary 3 solves the $t = n$ case. Henceforth, $0 \leq t < n$ can be assumed. The next step is to specify a family of dual-feasible solutions to the dual LP (36). The main remaining task will be simple calculus as the best dual-feasible solution is selected, depending on the parameters f, n, d, t of the problem.

The family of dual-feasible solution is specified with two integral parameters where $0 \leq p \leq n - t - 1$ and $n - t \leq q \leq n$. The parameter p is used to set the variables $\epsilon_{\mathbf{u}}$, α_w and $\beta_{\mathbf{u},w}$, and the parameter q is used to set the variables $\gamma_{\mathbf{u}}$ and $\delta_{\mathbf{v}}$. As the variables are set, the feasibility of the constraints (DC-1) and (DC-2) are also verified, and the contributions of those variables to the final objective value are computed:

- *Specifying the $\epsilon_{\mathbf{u}}$ variables.* The $\epsilon_{\mathbf{u}}$ are defined as follows:

$$\epsilon_{\mathbf{u}} = \begin{cases} 1 & i(\mathbf{u}) \geq n - p \\ 0 & \text{otherwise} \end{cases} \quad (39)$$

The contribution of the $\epsilon_{\mathbf{u}}$ to the objective is

$$\sum_{\mathbf{u}} f \epsilon_{\mathbf{u}} = \sum_{i=n-p}^{n-1} f \sum_{\mathbf{u}:i(\mathbf{u})=i} 1 = \sum_{i=n-p}^{n-1} f |A_i| = f(d^p - 1).$$

- *Specifying the α_w and $\beta_{\mathbf{u},w}$ variables.* Next, define the α_w and $\beta_{\mathbf{u},w}$ as follows. The constraints (DC-1) with $i(\mathbf{u}) \geq n - p$ are already satisfied by the $\epsilon_{\mathbf{u}}$; hence, the α_w and $\beta_{\mathbf{u},w}$ only need to be set to satisfy (DC-1) when $j(w) \geq p + 1$. (If $j(w) \leq p$, then for the constraint to exist, it must hold that $i(\mathbf{u}) \geq n - j(w) \geq n - p$.) The variables α_w and $\beta_{\mathbf{u},w}$ are set differently based on three cases as follows:

Case 1. If $t \geq \lfloor \frac{n}{2} \rfloor$, then set

$$\beta_{\mathbf{u},w} = \begin{cases} 1 & p + 1 \leq j(w) \leq n - t - 1, \text{ and } n - j(w) \leq i(\mathbf{u}) \leq n - p - 1, \\ 0 & \text{otherwise} \end{cases} \quad (40)$$

and set all the α_w to 0. It can be verified straightforwardly that all constraints (DC-1) are satisfied. Recall that the number of windows W_w for which $j(w) = j$ is precisely $d^{n-j-t} - d^{n-j-t-1}$. Thus, the contributions of the α_w and $\beta_{\mathbf{u},w}$ to the dual-objective value are

$$\begin{aligned}
\sum_{\substack{\mathbf{u}, w \\ p+1 \leq j(w) \leq n-t-1 \\ n-j(w) \leq i(\mathbf{u}) \leq n-p-1}} \beta_{\mathbf{u}, w} &= \sum_{j=p+1}^{n-t-1} |\{w : j(w) = j\}| \sum_{i=n-j}^{n-p-1} |\{\mathbf{u} \in \mathcal{A} : i(\mathbf{u}) = i\}| \\
&= \sum_{j=p+1}^{n-t-1} (d^{n-j-t} - d^{n-j-t-1}) \sum_{i=n-j}^{n-p-1} |A_i| \\
&= \sum_{j=p+1}^{n-t-1} (d^{n-j-t} - d^{n-j-t-1})(d^j - d^p) \\
&= (n-t-1-p)(d^{n-t} - d^{n-t-1}) - d^{n-t-1} + d^p.
\end{aligned}$$

Case 2. When $p+1 \leq t \leq \lfloor \frac{n}{2} \rfloor - 1$, set

$$\beta_{\mathbf{u}, w} = \begin{cases} 1 & p < j(w) \leq t \text{ and } n - j(w) \leq i < n - p \\ 0 & \text{otherwise} \end{cases}$$

and

$$\alpha_w = \begin{cases} 1 & t < j < n-t \\ 0 & \text{otherwise} \end{cases}$$

All constraints (DC-1) are thus satisfied. The α_w 's and $\beta_{\mathbf{u}, w}$'s contributions to the objective is

$$\begin{aligned}
&\sum_{\substack{w \\ t < j(w) < n-t}} d^t \alpha_w + \sum_{\substack{\mathbf{u}, w \\ p+1 \leq j(w) \leq t \\ n-j(w) \leq i(\mathbf{u}) \leq n-p-1}} \beta_{\mathbf{u}, w} \\
&= \sum_{j=t+1}^{n-t-1} d^t \cdot |\{w : j(w) = j\}| + \sum_{j=p+1}^t |\{w : j(w) = j\}| \\
&\quad \sum_{i=n-j}^{n-p-1} |\{\mathbf{u} \in \mathcal{A} : i(\mathbf{u}) = i\}| \\
&= \sum_{j=t+1}^{n-t-1} d^t (d^{n-j-t} - d^{n-j-t-1}) + \sum_{j=p+1}^t (d^j - d^p)(d^{n-j-t} - d^{n-j-t-1}) \\
&= (t-p)(d^{n-t} - d^{n-t-1}) + d^{n+p-2t-1} - d^t.
\end{aligned}$$

Case 3. When $t \leq p$ (which is $\leq n - t - 1$), set

$$\alpha_w = \begin{cases} 1 & p + 1 \leq j(w) \leq n - t - 1 \\ 0 & \text{otherwise} \end{cases} \quad (41)$$

and all the $\beta_{\mathbf{u}, w}$ to be zero. Again, the feasibility of the constraints (DC-1) is easy to verify. The contribution to the objective value is

$$\begin{aligned} \sum_{\substack{w \\ p < j(w) < n-t}} d^t \alpha_w &= \sum_{j=p+1}^{n-t-1} d^t \cdot |\{w : j(w) = j\}| \\ &= \sum_{j=p+1}^{n-t-1} d^t (d^{n-j-t} - d^{n-j-t-1}) \\ &= d^{n-p-1} - d^t. \end{aligned}$$

- *Specifying the $\gamma_{\mathbf{u}}$ and $\delta_{\mathbf{v}}$ variables.* Here, there are two cases.

When $q = n - t$, set $\delta_{\mathbf{v}} = 1$ for all $\mathbf{v} \in \bigcup_{j=n-t}^{n-1} B_j$ and all $\gamma_{\mathbf{u}} = 0$. The dual-objective contribution in this case is

$$\sum_{\mathbf{v} \in \bigcup_{j=n-t}^{n-1} B_j} \delta_{\mathbf{v}} = \left| \bigcup_{j=n-t}^{n-1} B_j \right| = d^t - k.$$

When $n - t + 1 \leq q \leq n$, define

$$\delta_{\mathbf{v}} = \begin{cases} 1 & \mathbf{v} \in \bigcup_{j=q}^{n-1} B_j \\ 0 & \text{otherwise} \end{cases} \quad (42)$$

and

$$\gamma_{\mathbf{u}} = \begin{cases} 1 & n - q + 1 \leq i(\mathbf{u}) \leq n - p - 1 \\ 0 & \text{otherwise} \end{cases} \quad (43)$$

From [Proposition 5](#), the total contribution of the $\gamma_{\mathbf{u}}$ and $\delta_{\mathbf{v}}$ to the dual objective is at most

$$\begin{aligned} \sum_{\substack{\mathbf{u} \\ n-q+1 \leq i(\mathbf{u}) \leq n-p-1}} \gamma_{\mathbf{u}} + \sum_{\mathbf{v} \in \bigcup_{j=q}^{n-1} B_j} \delta_{\mathbf{v}} &= \sum_{i=n-q+1}^{n-p-1} |\{\mathbf{u} : i(\mathbf{u}) = i\}| + \left| \bigcup_{j=q}^{n-1} B_j \right| \\ &\leq \sum_{i=n-q+1}^{n-p-1} |A_i| + \min\{d^t - k, k(d^{n-q} - 1)\} \\ &= d^{q-1} - d^p + \min\{d^t - k, k(d^{n-q} - 1)\}. \end{aligned}$$

The objective value $c(k, p, q)$
--

For $t \geq \lfloor \frac{n}{2} \rfloor$ and $q = n - t$,

$$c(k, p, q) = f(d^p - 1) + (n - t - 1 - p)(d^{n-t} - d^{n-t-1}) - d^{n-t-1} + d^p + d^t - k.$$

For $t \geq \lfloor \frac{n}{2} \rfloor$ and $q > n - t$,

$$\begin{aligned} c(k, p, q) = & f(d^p - 1) + (n - t - 1 - p)(d^{n-t} - d^{n-t-1}) - d^{n-t-1} + d^{q-1} \\ & + \min\{d^t - k, k(d^{n-q} - 1)\}. \end{aligned}$$

For $p + 1 \leq t \leq \lfloor \frac{n}{2} \rfloor - 1$ and $q = n - t$

$$c(k, p, q) = f(d^p - 1) + (t - p)(d^{n-t} - d^{n-t-1}) + d^{n+p-2t-1} - k.$$

For $p + 1 \leq t \leq \lfloor \frac{n}{2} \rfloor - 1$ and $q > n - t$

$$\begin{aligned} c(k, p, q) = & f(d^p - 1) + (t - p)(d^{n-t} - d^{n-t-1}) + d^{n+p-2t-1} - d^t + d^{q-1} - d^p \\ & + \min\{d^t - k, k(d^{n-q} - 1)\}. \end{aligned}$$

For $t \leq p$ and $q = n - t$,

$$c(k, p, q) = f(d^p - 1) + d^{n-p-1} - k.$$

For $t \leq p$ and $q > n - t$,

$$c(k, p, q) = f(d^p - 1) + d^{n-p-1} - d^t + d^{q-1} - d^p + \min\{d^t - k, k(d^{n-q} - 1)\}.$$

Fig. 10 The dual-objective value of the family of dual-feasible solutions

The feasibility of all the constraints (DC-2) is easy to verify.

Define the “cost” $c(k, p, q)$ to be the total contribution of all variables to the dual-objective value. The values of $c(k, p, q)$ are summarized in Fig. 10. The following has just been proved:

Theorem 8 *The above family of solutions is feasible for the dual linear program (36) with objective value equal to $c(k, p, q)$. Consequently, for the network $\log_d(N, 0, m)$ to be wide-sense nonblocking under the window algorithm with window size d^t , it is sufficient that*

$$m \geq 1 + \max_{1 \leq k \leq \min(f, d^t)} \min_{p,q} c(k, p, q). \quad (44)$$

6.3 Selecting the Best Dual-Feasible Solution

It is a very straightforward though somewhat analytically tedious task to derive the best possible sufficient condition using Theorem 8. The idea is as follows. For a given $k \leq \min(f, d^t)$, p and q are set to be $p = p_k, q = q_k$ so that $c(k, p_k, q_k)$ is

as small as possible. Then, an upperbound $C(t, f) \geq \max_k c(k, p_k, q_k)$ is derived. Finally, the sufficient condition is $m \geq C(t, f) + 1$.

A technical lemma is in order.

Lemma 11 *Let d, n, k be positive integers and $x = \lfloor \log_d k \rfloor$. Then, the following function*

$$h(k) = d^{\lfloor \frac{n+x}{2} \rfloor} + k \left(d^{n-\lfloor \frac{n+x}{2} \rfloor-1} - 1 \right) \quad (45)$$

is nondecreasing in k .

Proof The lemma is proved by induction on k . The inequality trivially holds when $k = 1$. Consider $k > 2$. First, suppose k is not an exact power of d , i.e., $k > d^x$. In this case, it follows that

$$\begin{aligned} h(k-1) &= d^{\lfloor \frac{n+x}{2} \rfloor} + (k-1) \left(d^{n-\lfloor \frac{n+x}{2} \rfloor-1} - 1 \right) \leq d^{\lfloor \frac{n+x}{2} \rfloor} \\ &\quad + k \left(d^{n-\lfloor \frac{n+x}{2} \rfloor-1} - 1 \right) = h(k). \end{aligned}$$

Second, consider the case when $k = d^x$. It can be verified that, no matter what the parities of n and x are, the multiset $\{\lfloor \frac{n+x-1}{2} \rfloor, \lceil \frac{n+x-1}{2} \rceil\}$ is exactly equal to the multiset $\{\lfloor \frac{n+x}{2} \rfloor, \lceil \frac{n+x}{2} \rceil - 1\}$. Thus, noting that $\lfloor \log_d (k-1) \rfloor = x-1$, it follows that

$$\begin{aligned} h(k-1) &= d^{\lfloor \frac{n+x-1}{2} \rfloor} + (k-1) \left(d^{n-\lfloor \frac{n+x-1}{2} \rfloor-1} - 1 \right) \\ &= d^{\lfloor \frac{n+x-1}{2} \rfloor} + (d^x - 1) \left(d^{\lceil \frac{n-x-1}{2} \rceil} - 1 \right) \\ &= d^{\lfloor \frac{n+x-1}{2} \rfloor} + d^{\lceil \frac{n+x-1}{2} \rceil} - d^{\lceil \frac{n-x-1}{2} \rceil} - d^x + 1 \\ &= d^{\lfloor \frac{n+x}{2} \rfloor} + d^{\lceil \frac{n+x}{2} \rceil-1} - d^{\lceil \frac{n-x-1}{2} \rceil} - d^x + 1 \\ &\leq d^{\lfloor \frac{n+x}{2} \rfloor} + d^{\lceil \frac{n+x}{2} \rceil-1} - d^x \\ &= d^{\lfloor \frac{n+x}{2} \rfloor} + d^x \left(d^{n-\lfloor \frac{n+x}{2} \rfloor-1} - 1 \right) \\ &= h(k). \end{aligned}$$

□

Theorem 9 *The $\log_d(N, 0, m)$ network is nonblocking under the window algorithm with window size d^t if $m \geq 1 + C(t, f)$ where $C(t, f)$ is defined in Fig. 11.*

Proof Consider 5 cases in the definition of $C(t, f)$. For each k , the values p_k and q_k will be specified, and then, $c(k, p_k, q_k) \leq C(t, f)$ is verified.

- *Case 1:* $t < \lfloor \frac{n}{2} \rfloor, r \leq n - 2t - 1$. For any k , choose $p_k = \lceil \frac{n-r}{2} - 1 \rceil$ and $q_k = n - t$. Noting that $p_k \geq t$ and $k \geq 1$, the following holds

The upperbound $C(t, f)$

To shorten the notations, let $r = \lfloor \log_d f \rfloor$.

$$C(t, f) = \begin{cases} f \left(d^{\lceil \frac{n-r}{2} \rceil - 1} - 1 \right) + d^{n-\lceil \frac{n-r}{2} \rceil} - 1 & t < \lfloor \frac{n}{2} \rfloor, r \leq n - 2t - 1 \\ t(d-1)d^{n-t-1} + d^{n-2t-1} - 1 & t < \lfloor \frac{n}{2} \rfloor, r \geq n - 2t \\ [(n-t-1)(d-1)-1]d^{n-t-1} + d^t \\ -(d-1)d^{2t-n-1} & t \geq \lfloor \frac{n}{2} \rfloor, r \geq n - t \\ f(d^{n-t-r-1}-1) + [r(d-1)-1]d^{n-t-1} \\ + d^{n-t-r-1} + d^t - (d-1)d^{2t-n-1} & t \geq \lfloor \frac{n}{2} \rfloor, \text{ and} \\ 2t-n-2 < r \leq n-t-1 \\ f(d^{n-t-r-1}-1) + [r(d-1)-1]d^{n-t-1} \\ + d^{\lfloor \frac{n+r}{2} \rfloor} + f\left(d^{n-\lfloor \frac{n+r}{2} \rfloor-1}-1\right) & t \geq \lfloor \frac{n}{2} \rfloor, \text{ and} \\ r \leq \min(2t-n-2, n-t-1) \end{cases}$$

Fig. 11 Theorem 9 shows that $C(t, f) \geq \max_k \min_{p,q} c(k, p, q)$

$$c(k, p_k, q_k) = f \left(d^{\lceil \frac{n-r}{2} \rceil - 1} - 1 \right) + d^{n-\lceil \frac{n-r}{2} \rceil} - k \leq C(t, f).$$

- Case 2: $t < \lfloor \frac{n}{2} \rfloor, r \geq n - 2t$. For any k , set $p_k = 0$ and $q_k = n - t$. Then,

$$\begin{aligned} c(k, p_k, q_k) &= t(d^{n-t} - d^{n-t-1}) + d^{n-2t-1} - k \leq t(d^{n-t} - d^{n-t-1}) \\ &\quad + d^{n-2t-1} - 1 = C(t, f). \end{aligned}$$

- Case 3: $t \geq \lfloor \frac{n}{2} \rfloor, r \geq n - t$. This case is a little trickier analytically. Define $x = \lfloor \log_d k \rfloor$. The values p_k and q_k are set differently depending on how large x is so that the inequality $c(k, p_k, q_k) \leq C(t, f)$ always holds.

If $0 \leq x \leq 2t - n - 2$, which can only hold when $t \geq \frac{n+1}{2}$, then set $q_k = \lfloor \frac{n+x}{2} \rfloor + 1$ and $p_k = 0$. Note that $q_k > n - t$ and $x + 1 + n - q_k < t$. Thus, $kd^{n-q_k} < d^t$. Recall from Lemma 11 that function $h(k)$ defined in (45) is nonincreasing, and the fact that in this case $k \leq d^{x+1} - 1 \leq d^{2t-n-1} - 1$, it follows that

$$\begin{aligned} c(k, p_k, q_k) &= [(n-t-1)(d-1)-1]d^{n-t-1} + d^{q_k-1} \\ &\quad + \min\{d^t - k, k(d^{n-q_k} - 1)\} \\ &= [(n-t-1)(d-1)-1]d^{n-t-1} + d^{q_k-1} + k(d^{n-q_k} - 1) \\ &= [(n-t-1)(d-1)-1]d^{n-t-1} + h(k) \\ &\leq [(n-t-1)(d-1)-1]d^{n-t-1} + h(d^{2t-n-1} - 1) \end{aligned}$$

$$\begin{aligned}
&= [(n-t-1)(d-1)-1]d^{n-t-1} + d^{t-1} \\
&\quad + (d^{2t-n-1}-1)(d^{n-t}-1) \\
&< [(n-t-1)(d-1)-1]d^{n-t-1} + d^{t-1} \\
&\quad + d^{2t-n-1}(d-1)(d^{n-t}-1) \\
&= [(n-t-1)(d-1)-1]d^{n-t-1} + d^t - (d-1)d^{2t-n-1} \\
&= C(t, f).
\end{aligned}$$

If $x = 2t - n - 1$ and $k \leq d^{x+1} - d^x$, then set $q_k = \lfloor \frac{n+x}{2} \rfloor + 1 = t$ and $p_k = 0$. Note that $q_k = t > n - t$ because $x \geq 0$. In this case,

$$\begin{aligned}
c(k, p_k, q_k) &= [(n-t-1)(d-1)-1]d^{n-t-1} + h(k) \\
&\leq [(n-t-1)(d-1)-1]d^{n-t-1} + h(d^{2t-n} - d^{2t-n-1}) \\
&= [(n-t-1)(d-1)-1]d^{n-t-1} + d^{t-1} \\
&\quad + (d^{2t-n} - d^{2t-n-1})(d^{n-t}-1) \\
&= [(n-t-1)(d-1)-1]d^{n-t-1} + d^t - (d-1)d^{2t-n-1} \\
&= C(t, f).
\end{aligned}$$

If $x = 2t - n - 1$ and $k \geq d^{x+1} - d^x + 1$, then set $q_k = n - t$ and $p_k = 0$. Then,

$$\begin{aligned}
c(k, p_k, q_k) &= [(n-t-1)(d-1)-1]d^{n-t-1} + 1 + d^t - k \\
&\leq [(n-t-1)(d-1)-1]d^{n-t-1} + 1 + d^t - d^{x+1} + d^x - 1 \\
&= [(n-t-1)(d-1)-1]d^{n-t-1} + d^t - (d-1)d^{2t-n-1} \\
&= C(t, f).
\end{aligned}$$

Finally, when $x \geq 2t - n$, again set $q_k = n - t$ and $p_k = 0$. Note that $k \geq d^x \geq d^{2t-n} > (d-1)d^{2t-n-1}$. Thus, $d^t - k < d^t - (d-1)d^{2t-n-1} - 1$ and $c(k, p_k, q_k) \leq C(t, f)$ follow straightforwardly.

- *Case 4:* $t \geq \lfloor \frac{n}{2} \rfloor$, $2t - n - 2 < r \leq n - t - 1$. Note that this case can only happen when $t \leq 2n/3$. In particular, if $t > 2n/3$ and $r \leq n - t - 1$, then case 5 applies. Set $p_k = n - t - r - 1$ and $q_k = \lfloor \frac{n+x}{2} \rfloor + 1$. Proving $c(k, p_k, q_k) \leq C(t, f)$ is almost identical to Case 3 where one considers different ranges of $x = \lfloor \log_d k \rfloor$.
- *Case 5:* $t \geq \lfloor \frac{n}{2} \rfloor$, $r \leq \min(2t - n - 2, n - t - 1)$. Set $p_k = n - t - r - 1$ and $q_k = \lfloor \frac{n+x}{2} \rfloor + 1$. Showing $c(k, p_k, q_k) \leq C(t, f)$ is similar to Case 3. The only slight variation is, instead of bounding $k \leq d^{x+1} - 1$, the relation $k \leq f$ is applied directly. The function $h(k)$ is then bounded by $h(f)$. Furthermore, it is not necessary to consider the cases when $x \geq 2t - n - 1$ because $x \leq r \leq 2t - n - 2$. \square

6.4 Some Quick Consequences of Theorem 9

By plugging in the parameters t and f and computing $1 + C(t, f)$, the following results follow straightforwardly.

Corollary 5 (Theorem 4 in [14]) *Let $r = \lfloor \log_d f \rfloor$. The network $\log_d(N, 0, m)$ is f -cast strictly non-blocking if*

$$m \geq f \left(d^{\lceil \frac{n-r}{2} \rceil - 1} - 1 \right) + d^{n - \lceil \frac{n-r}{2} \rceil}.$$

Proof This corresponds to the $t = 0$ case of the window algorithm, which becomes a strictly nonblocking condition as noted earlier:

$$C(0, f) = f \left(d^{\lceil \frac{n-r}{2} \rceil - 1} - 1 \right) + d^{n - \lceil \frac{n-r}{2} \rceil} - 1. \quad \square$$

The following result took about 6 pages in [10] to be proved (in two theorems) with combinatorial reasoning. The result is on the general multicast case, without the fanout restriction f . In the current setting, one can simply set $f = N = d^n$. In fact, even though the corollary states exactly the same results as in [10], the statement is simpler.

Corollary 6 (Theorems 1 and 2 in [10]) *The d -ary multilog network $\log_d(N, 0, m)$ is wide-sense nonblocking with respect to the window algorithm with window size d^t if*

$$m \geq \begin{cases} d^{n-2t-1} + t d^{n-t-1}(d-1) & \text{when } t \leq \lfloor \frac{n}{2} \rfloor - 1, \\ d^{n-t-1}[(d-1)(n-t-1)-1] + d^t - d^{2t-n-1} & \\ (d-1) + 1 & \text{when } t \geq \lfloor \frac{n}{2} \rfloor. \end{cases}$$

Proof Note that $r = n$. It follows that

$$C(t, d^n) = d^{n-2t-1} + t d^{n-t-1}(d-1) - 1, \text{ when } t \leq \lfloor \frac{n}{2} \rfloor - 1$$

and

$$C(t, d^n) = d^{n-t-1}[(d-1)(n-t-1)-1] + d^t - d^{2t-n-1}(d-1), \text{ otherwise.}$$

\square

7 Analyzing Crosstalk-Free f -Cast Wide-Sense Nonblocking Multilog Networks

Thanks to [Proposition 1](#), to analyze crosstalk-free f -cast wide-sense nonblocking multilog networks under the window algorithm, basically all one has to do is to replace the constraint $i + j \geq n$ by the constraint $i + j \geq n - 1$. That was essentially the only difference between [Properties 1](#) and [2](#). Replacing n by $n - 1$ leads to changes in the final formula for the required number of Banyan planes. Deriving the formulas is relatively straightforward but also takes some calculus effort, and thus for completeness, they are done here. The overall outline of the analysis, however, is identical, and much of the analysis for the noncrosstalk-free case can be reused.

7.1 Setting Up the Linear Program and Its Dual

Identical notations as in the previous section are used. The following lemma is the crosstalk-free analog of [Lemma 10](#).

Lemma 12 *For each input $\mathbf{u} \in \mathcal{A}$ and each $w \in [d^{n-t} - 1]$ such that $i(\mathbf{u}) + j(w) \geq n - 1$, define a variable $x_{\mathbf{u},w}$. Also, for each input $\mathbf{u} \in \mathcal{A}$ and each output $\mathbf{v} \in W_0 - B$ such that $i(\mathbf{u}) + j(\mathbf{v}) \geq n - 1$, define a variable $x_{\mathbf{u},\mathbf{v}}$. Then, the number of Banyan planes blocking (\mathbf{a}, B) is upperbounded by the optimal value of the linear program (35), whose dual is (36).*

Some quick consequences of the formulation are derived next.

Corollary 7 (Theorem III.1 in [54]) *Let $r = \lfloor \log_d f \rfloor$. Suppose the $1 \times m$ -SE stage of the $\log_d(N, 0, m)$ network does not have fanout capability, then when $f \leq d^{n-2}(d - 1)$, the network is crosstalk-free f -cast strictly nonblocking if*

$$m \geq d^{\lfloor \frac{n+r+1}{2} \rfloor} + f \left(d^{\lceil \frac{n-r-1}{2} \rceil} - 1 \right).$$

When $f > d^{n-2}(d - 1)$, the network is f -cast strictly nonblocking if $m \geq d^n - d^{n-2}(d - 1)$.

Proof Routing using the window algorithm with window size, $t = n$ is the same as routing arbitrarily in the network when the $1 \times m$ -SE stage cannot fanout. Thus, any sufficient condition for the window algorithm to work is a strictly nonblocking condition. Note that when $t = n$, the dual constraints (DC-1) do not exist. Consider a solution to the dual LP as follows:

When $f > d^{n-2}(d - 1)$, consider two cases. If $k > d^{n-2}(d - 1)$, set $\delta_v = 1$ for all $\mathbf{v} \in \bigcup_{j=0}^{n-1} B_j$ and all other variables to be 0. Then, the dual-objective value is

$$\sum_{\mathbf{v} \in \bigcup_{j=0}^{n-1} B_j} \delta_{\mathbf{v}} = \left| \bigcup_{j=0}^{n-1} B_j \right| = d^n - k \leq d^n - d^{n-2}(d-1) - 1.$$

Thus, in this case $d^n - d^{n-2}(d-1)$, Banyan planes are sufficient. Next, suppose $k \leq d^{n-2}(d-1)$, in which case $kd < d^n$. Set $\gamma_{\mathbf{u}} = 1$ for all \mathbf{u} with $i(\mathbf{u}) \geq 1$, $\delta_{\mathbf{v}} = 1$ for all $\mathbf{v} \in B_{n-1}$, and all other variables to be 0. The solution is dual feasible with dual-objective value

$$\begin{aligned} \sum_{\mathbf{u}: i(\mathbf{u}) \geq 1} \gamma_{\mathbf{u}} + \sum_{\mathbf{v} \in B_{n-1}} \delta_{\mathbf{v}} &= \sum_{i=1}^{n-1} |A_i| + |B_{n-1}| \\ &\leq \sum_{i=1}^{n-1} (d^{n-i} - d^{n-i-1}) + \min\{d^n - k, k(d-1)\} \\ &= d^{n-1} - 1 + k(d-1) \\ &\leq d^{n-1} + d^{n-2}(d-1)^2 - 1 \\ &= d^n - d^{n-2}(d-1) - 1 \end{aligned}$$

and thus again $d^n - d^{n-2}(d-1)$, Banyan planes are sufficient.

Next, consider the case when $f \leq d^{n-2}(d-1)$. In this case, $r \leq n-2$. Let $p = \lceil \frac{n-r-1}{2} \rceil$. Then, $1 \leq p \leq \lceil \frac{n-1}{2} \rceil$. Furthermore,

$$kd^p \leq fd^p < d^{r+1}d^{\lceil \frac{n-r-1}{2} \rceil} = d^{\lceil \frac{n+r+1}{2} \rceil} \leq d^n.$$

Set $\gamma_{\mathbf{u}} = 1$ for all \mathbf{u} with $i(\mathbf{u}) \geq p$, $\delta_{\mathbf{v}} = 1$ for all $\mathbf{v} \in \bigcup_{j=n-p}^{n-1} B_j$, and all other variables to be 0. The solution is dual feasible because, for any pair (\mathbf{u}, \mathbf{v}) for which $i(\mathbf{u}) + j(\mathbf{v}) \geq n-1$, it must either be the case that $i(\mathbf{u}) \geq p$ or that $j(\mathbf{v}) \geq n-p$ (which is the same as saying $\mathbf{v} \in \bigcup_{j=n-p}^{n-1} B_j$). Recalling [Proposition 5](#) and the fact that $kd^p < d^n$ shown above, the dual-objective value is

$$\begin{aligned} \sum_{\mathbf{u}: i(\mathbf{u}) \geq p} \gamma_{\mathbf{u}} + \sum_{\mathbf{v} \in \bigcup_{j=n-p}^{n-1} B_j} \delta_{\mathbf{v}} &= \sum_{i=p}^{n-1} |A_i| + \left| \bigcup_{j=n-p}^{n-1} B_j \right| \\ &\leq \sum_{i=p}^{n-1} (d^{n-i} - d^{n-i-1}) + \min\{d^n - k, k(d^p - 1)\} \\ &= d^{n-p} - 1 + k(d^p - 1) \\ &\leq d^{n-p} + f(d^p - 1) - 1. \end{aligned}$$

Hence, in this case, $d^{n-p} + f(d^p - 1)$ is a sufficient number of Banyan planes. \square

7.2 Specifying a Family of Dual-Feasible Solutions

The family of dual-feasible solution is specified with two integral parameters where $0 \leq p \leq n - t - 1$ and $n - t \leq q \leq n$. The parameter p is used to set the variables ϵ_u , α_w , and $\beta_{u,w}$, and the parameter q is used to set the variables γ_u and δ_v . As the variables are set, the feasibility of the constraints (DC-1) and (DC-2) is also verified, and the contributions of those variables to the final objective value are computed:

- *Specifying the ϵ_u variables.* The ϵ_u are defined as follows:

$$\epsilon_u = \begin{cases} 1 & i(\mathbf{u}) \geq n - p \\ 0 & \text{otherwise} \end{cases} \quad (46)$$

The contribution of the ϵ_u to the objective is

$$\sum_{\mathbf{u}} f \epsilon_u = \sum_{i=n-p}^{n-1} f \sum_{\mathbf{u}:i(\mathbf{u})=i} 1 = \sum_{i=n-p}^{n-1} f |A_i| = f(d^p - 1).$$

- *Specifying the α_w and $\beta_{u,w}$ variables.* Next, the α_w and $\beta_{u,w}$ are defined. The constraints (DC-1) with $i(\mathbf{u}) \geq n - p$ are already satisfied by the ϵ_u ; hence, the α_w and $\beta_{u,w}$ only need to be set to satisfy (DC-1) when $j(w) \geq p$. (If $j(w) \leq p - 1$, then for the constraint to exist, it must hold that $i(\mathbf{u}) \geq n - 1 - j(w) \geq n - p$.) The variables α_w and $\beta_{u,w}$ are set differently based on three cases as follows:

Case 1. If $t \geq \lceil \frac{n}{2} \rceil$, then set

$$\beta_{u,w} = \begin{cases} 1 & p \leq j(w) \leq n - t - 1, \text{ and } n - 1 - j(w) \leq i(\mathbf{u}) \leq n - p - 1, \\ 0 & \text{otherwise} \end{cases} \quad (47)$$

and set all the α_w to 0. It can be verified straightforwardly that all constraints (DC-1) are satisfied. Thus, the contributions of the α_w and $\beta_{u,w}$ to the dual-objective value are

$$\begin{aligned} \sum_{\substack{\mathbf{u}, w \\ p \leq j(w) \leq n - t - 1 \\ n - 1 - j(w) \leq i(\mathbf{u}) \leq n - p - 1}} \beta_{u,w} &= \sum_{j=p}^{n-t-1} |\{w : j(w) = j\}| \\ &= \sum_{i=n-1-j}^{n-p-1} |\{\mathbf{u} \in \mathcal{A} : i(\mathbf{u}) = i\}| \\ &= \sum_{j=p}^{n-t-1} (d^{n-j-t} - d^{n-j-t-1}) \sum_{i=n-1-j}^{n-p-1} |A_i| \end{aligned}$$

$$\begin{aligned}
&= \sum_{j=p}^{n-t-1} (d^{n-j-t} - d^{n-j-t-1})(d^{j+1} - d^p) \\
&= (n-t-p)(d^{n-t+1} - d^{n-t}) - d^{n-t} + d^p.
\end{aligned}$$

The second equality follows from the fact that the number of windows W_w for which $j(w) = j$ is precisely $d^{n-j-t} - d^{n-j-t-1}$.

Case 2. When $p+1 \leq t \leq \lceil \frac{n}{2} \rceil - 1$, set

$$\beta_{\mathbf{u},w} = \begin{cases} 1 & p \leq j(w) \leq t-1 \text{ and } n-1-j(w) \leq i < n-p \\ 0 & \text{otherwise} \end{cases}$$

and

$$\alpha_w = \begin{cases} 1 & t \leq j < n-t \\ 0 & \text{otherwise} \end{cases}$$

All constraints (DC-1) are thus satisfied. The α_w 's and $\beta_{\mathbf{u},w}$'s contributions to the objective are

$$\begin{aligned}
&\sum_{\substack{w \\ t \leq j(w) < n-t}} d^t \alpha_w + \sum_{\substack{\mathbf{u},w \\ p \leq j(w) \leq t-1 \\ n-1-j(w) \leq i(\mathbf{u}) \leq n-p-1}} \beta_{\mathbf{u},w} \\
&= \sum_{j=t}^{n-t-1} d^t \cdot |\{w : j(w) = j\}| + \sum_{j=p}^{t-1} |\{w : j(w) = j\}| \\
&= \sum_{i=n-1-j}^{n-p-1} |\{\mathbf{u} \in \mathcal{A} : i(\mathbf{u}) = i\}| \\
&= \sum_{j=t}^{n-t-1} d^t (d^{n-j-t} - d^{n-j-t-1}) + \sum_{j=p}^{t-1} (d^{n-j-t} - d^{n-j-t-1})(d^{j+1} - d^p) \\
&= (t-p)(d^{n-t+1} - d^{n-t}) + d^{n-2t+p} - d^t.
\end{aligned}$$

Case 3. When $t \leq p$ (which is $\leq n-t-1$), set

$$\alpha_w = \begin{cases} 1 & p \leq j(w) \leq n-t-1 \\ 0 & \text{otherwise} \end{cases} \quad (48)$$

and all the $\beta_{\mathbf{u},w}$ to be zero. Again, the feasibility of the constraints (DC-1) is easy to verify. The contribution to the objective value is

$$\begin{aligned}
\sum_{\substack{w \\ p \leq j(w) < n-t}} d^t \alpha_w &= \sum_{j=p}^{n-t-1} d^t \cdot |\{w : j(w) = j\}| \\
&= \sum_{j=p}^{n-t-1} d^t (d^{n-j-t} - d^{n-j-t-1}) \\
&= d^{n-p} - d^t.
\end{aligned}$$

Specifying the γ_u and δ_v variables. When $q = n - t$, set $\delta_v = 1$ for all $v \in \bigcup_{j=n-t}^{n-1} B_j$ and all $\gamma_u = 0$. The dual-objective contribution in this case is

$$\sum_{v \in \bigcup_{j=n-t}^{n-1} B_j} \delta_v = \left| \bigcup_{j=n-t}^{n-1} B_j \right| = d^t - k.$$

When $n - t + 1 \leq q \leq n$, define

$$\delta_v = \begin{cases} 1 & v \in \bigcup_{j=q}^{n-1} B_j \\ 0 & \text{otherwise} \end{cases} \quad (49)$$

and

$$\gamma_u = \begin{cases} 1 & n - q \leq i(u) \leq n - p - 1 \\ 0 & \text{otherwise} \end{cases} \quad (50)$$

From [Proposition 5](#), the total contribution of the γ_u and δ_v to the dual objective is

$$\begin{aligned}
\sum_{\substack{u \\ n-q \leq i(u) \leq n-p-1}} \gamma_u + \sum_{v \in \bigcup_{j=q}^{n-1} B_j} \delta_v &= \sum_{i=n-q}^{n-p-1} |\{u : i(u) = i\}| + \left| \bigcup_{j=q}^{n-1} B_j \right| \\
&\leq \sum_{i=n-q}^{n-p-1} |A_i| + \min\{d^t - k, k(d^{n-q} - 1)\} \\
&= d^q - d^p + \min\{d^t - k, k(d^{n-q} - 1)\}.
\end{aligned}$$

The feasibility of all the constraints (DC-2) is easy to verify.

Define the “cost” $g(k, p, q)$ to be the total contribution of all variables to the dual-objective value. The values of $g(k, p, q)$ are summarized in [Fig. 12](#). The following has just been proved:

Theorem 10 *The above family of solutions is feasible for the dual LP (36) with objective value equal to $g(k, p, q)$. (Recall that, in this problem, the dual constraints*

The objective value $g(k, p, q)$
--

For $t \geq \lceil \frac{n}{2} \rceil$ and $q = n - t$,

$$g(k, p, q) = f(d^p - 1) + (n - t - p)(d^{n-t+1} - d^{n-t}) - d^{n-t} + d^p + d^t - k.$$

For $t \geq \lceil \frac{n}{2} \rceil$ and $q > n - t$,

$$g(k, p, q) = f(d^p - 1) + (n - t - p)(d^{n-t+1} - d^{n-t}) - d^{n-t} + d^q + \min\{d^t - k, k(d^{n-q} - 1)\}.$$

For $p + 1 \leq t \leq \lceil \frac{n}{2} \rceil - 1$ and $q = n - t$

$$g(k, p, q) = f(d^p - 1) + (t - p)(d^{n-t+1} - d^{n-t}) + d^{n+p-2t} - k.$$

For $p + 1 \leq t \leq \lceil \frac{n}{2} \rceil - 1$ and $q > n - t$

$$\begin{aligned} g(k, p, q) = & f(d^p - 1) + (t - p)(d^{n-t+1} - d^{n-t}) + d^{n+p-2t} - d^t + d^q - d^p \\ & + \min\{d^t - k, k(d^{n-q} - 1)\}. \end{aligned}$$

For $t \leq p$ and $q = n - t$,

$$g(k, p, q) = f(d^p - 1) + d^{n-p} - k.$$

For $t \leq p$ and $q > n - t$,

$$g(k, p, q) = f(d^p - 1) + d^{n-p} - d^t + d^q - d^p + \min\{d^t - k, k(d^{n-q} - 1)\}.$$

Fig. 12 The dual-objective value of the family of dual-feasible solutions

for which $i(\mathbf{u}) + j(\mathbf{v}) \geq n - 1$ and $i(\mathbf{u}) + j(\mathbf{w}) \geq n - 1$ are being considered.) Consequently, for the network $\log_d(N, 0, m)$ to be crosstalk-free f -cast wide-sense nonblocking under the window algorithm with window size d^t , it is sufficient that

$$m \geq 1 + \max_{1 \leq k \leq \min(f, d^t)} \min_{p,q} g(k, p, q). \quad (51)$$

7.3 Selecting the Best Dual-Feasible Solution

The proof of the following technical lemma is similar to that of [Lemma 11](#), and thus the proof is omitted.

Lemma 13 Let d, n, k be positive integers and $x = \lfloor \log_d k \rfloor$. Then, the following function

$$\bar{h}(k) = d^{\lfloor \frac{x+n+1}{2} \rfloor} + k \left(d^{n-\lfloor \frac{x+n+1}{2} \rfloor} - 1 \right) \quad (52)$$

is nondecreasing in k .

The upperbound $G(t, f)$

To shorten the notations, let $r = \lfloor \log_d f \rfloor$.

$$G(t, f) = \begin{cases} d^{n-t}[(n-t)(d-1)-1] \\ + d^t - d^{2t-n+1}(d-1) & t > n/2, r \geq \max\{2t-n-2, \\ & n-t+1\} \\ f(d^{n-t-r}-1) + rd^{n-t}(d-1) - d^{n-t} \\ + d^{\lfloor \frac{r+n+1}{2} \rfloor} + f(d^{n-\lfloor \frac{r+n+1}{2} \rfloor}-1) & t > n/2, r \leq \min\{2t-n-3, \\ & n-t\} \\ d^{n-t}[(n-t)(d-1)-1] + d^{\lfloor \frac{r+n+1}{2} \rfloor} \\ + f(d^{n-\lfloor \frac{r+n+1}{2} \rfloor}-1) & t > n/2, n-t+1 \leq r \leq 2t \\ & -n-3 \\ f(d^{n-t-r}-1) + d^{n-t}[r(d-1)-1] & t > n/2, 2t-n-2 \leq r \leq \\ + d^t - d^{2t-n-2}(d-1) & n-t \\ d^{n-t}[(n-t)(t-1)-1] + d^t \\ f(d^{\lceil \frac{n-r-1}{2} \rceil}-1) + d^{n-\lceil \frac{n-r-1}{2} \rceil}-1 & t = n/2 \\ f(d^{t-1}-1) + d^{n-t-1}(d^2-d+1)-1 & t < n/2, r \leq n-2t \text{ and } f \leq \\ & d^{n-2t}(d-1) \\ f(d^{n-t-r}-1) + (2t-n-r) & t < n/2, r \leq n-2t, f > \\ (d-1)d^{n-t} + d^{2n-3t-r}-1 & d^{n-2t}(d-1) \\ t(d-1)d^{n-t} + d^{n-2t}-1 & t < n/2, n-t < r \end{cases}$$

Fig. 13 Theorem 11 shows that $G(t, f) \geq \max_k \min_{p,q} g(k, p, q)$

Theorem 11 *The $\log_d(N, 0, m)$ network is crosstalk-free nonblocking under the window algorithm with window size d^t if $m \geq 1 + G(t, f)$ where $G(t, f)$ is defined in Fig. 13.*

Proof Suppose $t > n/2$, i.e., $2t \geq n+1$. Four cases are considered as follows. In all cases, define an integral variable $x = \lfloor \log_d k \rfloor$:

- *Case 1.* $r \geq \max\{2t-n-2, n-t+1\}$.

If $k \geq d^{2t-n-2}(d-1)+1$, then pick $p_k=0$ and $q_k=n-t$. Then,

$$\begin{aligned} g(k, p_k, q_k) &= (n-t)(d^{n-t+1}-d^{n-t}) - d^{n-t} + 1 + d^t - k \\ &\leq (n-t)(d^{n-t+1}-d^{n-t}) - d^{n-t} + 1 + d^t - d^{2t-n+1}(d-1)-1 \\ &= d^{n-t}[(n-t)(d-1)-1] + d^t - d^{2t-n+1}(d-1). \end{aligned}$$

On the other hand, if $k \leq d^{2t-n-2}(d-1)$, then set $p_k = 0$ and $q_k = \lfloor \frac{x+n+1}{2} \rfloor > n-t$. Note that $k d^{n-q_k} \leq d^t$. Thus, recall from Lemma 13 that the function $\bar{h}(k)$ defined in (52) is nondecreasing in k , it follows that

$$\begin{aligned} g(k, p_k, q_k) &= (n-t)(d^{n-t+1} - d^{n-t}) - d^{n-t} + d^{\lfloor \frac{x+n+1}{2} \rfloor} \\ &\quad + \min \left\{ d^t - k, k \left(d^{n-\lfloor \frac{x+n+1}{2} \rfloor} - 1 \right) \right\} \\ &= (n-t)(d^{n-t+1} - d^{n-t}) - d^{n-t} + d^{\lfloor \frac{x+n+1}{2} \rfloor} + k \left(d^{n-\lfloor \frac{x+n+1}{2} \rfloor} \right) \\ &= (n-t)(d^{n-t+1} - d^{n-t}) - d^{n-t} + \bar{h}(k) \\ &\leq (n-t)(d^{n-t+1} - d^{n-t}) - d^{n-t} + \bar{h}(d^{2t-n-2}(d-1)) \\ &= d^{n-t}[(n-t)(d-1)-1] + d^t - d^{2t-n+1}(d-1). \end{aligned}$$

- Case 2. $r \leq \min\{2t-n-3, n-t\}$.

In this case, set $p_k = n-t-r \leq t-1$ and $q_k = \lfloor \frac{x+n+1}{2} \rfloor > n-t$. Similar to the above analysis, the following is obtained:

$$\begin{aligned} g(k, p_k, q_k) &= f(d^{n-t-r}-1) + r d^{n-t}(d-1) - d^{n-t} + d^{\lfloor \frac{x+n+1}{2} \rfloor} \\ &\quad + k(d^{n-\lfloor \frac{x+n+1}{2} \rfloor} - 1) \\ &= f(d^{n-t-r}-1) + r d^{n-t}(d-1) - d^{n-t} + \bar{h}(k) \\ &\leq f(d^{n-t-r}-1) + r d^{n-t}(d-1) - d^{n-t} + \bar{h}(f) \\ &= f(d^{n-t-r}-1) + r d^{n-t}(d-1) - d^{n-t} + d^{\lfloor \frac{r+n+1}{2} \rfloor} \\ &\quad + f(d^{n-\lfloor \frac{r+n+1}{2} \rfloor} - 1). \end{aligned}$$

For the inequality, note that the function $\bar{h}(k)$ is nondecreasing in k and $k \leq f$.

- Case 3. $n-t+1 \leq r \leq 2t-n-3$. In this case, set $p_k = 0$ and $q_k = \lfloor \frac{x+n+1}{2} \rfloor > n-t$. Then,

$$g(k, p_k, q_k) \leq d^{n-t}[(n-t)(d-1)-1] + d^{\lfloor \frac{r+n+1}{2} \rfloor} + f(d^{n-\lfloor \frac{r+n+1}{2} \rfloor} - 1).$$

- Case 4. $2t-n-2 \leq r \leq n-t$. In this case, set $p_k = n-t-r$ and consider two sub-cases as in case 1: $k \geq d^{2t-n-2}(d-1)+1$ or $k \leq d^{2t-n-2}(d-1)$. The eventual bound is

$$g(k, p_k, q_k) \leq f(d^{n-t-r}-1) + d^{n-t}[r(d-1)-1] + d^t - d^{2t-n-2}(d-1).$$

When $t = n/2$, simply set $q_k = n-t$ and $p_k = 0$. Then,

$$g(k, p_k, q_k) = d^{n-t}[(n-t)(d-1)-1] + d^t.$$

Finally, suppose $t < n/2$. The value $p_k = q - t$ will always be set in this situation. Also consider four cases:

Case 1. $r \leq n - 2t$ and $f \leq d^{n-2t}(d - 1)$, then set $p_k = \lceil \frac{n-r-1}{2} \rceil \geq t$. In this case,

$$g(k, p_k, q_k) = f(d^{\lceil \frac{n-r-1}{2} \rceil} - 1) + d^{n-\lceil \frac{n-r-1}{2} \rceil} - 1.$$

Case 2. $r \leq n - 2t$ and $f > d^{n-2t}(d - 1)$, then set $p_k = t - 1$. In this case,

$$g(k, p_k, q_k) = f(d^{t-1} - 1) + d^{n-t-1}(d^2 - d + 1) - 1.$$

Case 3. $n - 2t + 1 \leq r \leq n - t$, then set $p_k = n - t - r$. In this case,

$$g(k, p_k, q_k) = f(d^{n-t-r} - 1) + (2t - n - r)(d - 1)d^{n-t} + d^{2n-3t-r} - 1.$$

Case 4. $n - t < r$, then set $p_k = 0$. In this case,

$$g(k, p_k, q_k) = t(d - 1)d^{n-t} + d^{n-2t} - 1. \quad \square$$

Corollary 8 (Theorems 1 in [39]) *The d -ary multilog network $\log_d(N, 0, m)$ is crosstalk-free wide-sense nonblocking with respect to the window algorithm with window size d^t if*

$$m \geq \begin{cases} d^{n-2t} + td^{n-t}(d - 1) & t < n/2 \\ d^{n-t}[(n - t)(d - 1) - 1] + d^t + 1 & t = n/2 \\ d^{n-t}[(n - t)(d - 1) - 1] + d^t - d^{2t-n-2}(d - 1) + 1 & t > n/2. \end{cases}$$

8 Conclusion

As illustrated with many examples in this chapter, the linear programming technique seems to be effective in deriving sufficient conditions for a switching network to be nonblocking. In many of the examples discussed above, the sufficient conditions turn out to be necessary also (Examples 1, 2, and many special cases of later theorems on the multilog networks). However, it is not clear how one can “quickly” prove corresponding necessary conditions. The main reason is that a dual-feasible solution may not naturally lead to an integral primal feasible solution, which is needed to combinatorially design a network configuration showing the necessary condition.

Another line of open research questions is on multilog networks with extra stages [22]. For example, adding $\log_d N$ extra stages to a Banyan plane, one obtains the

Beneš network [1], a very important building block for many useful switching network architectures such as the Cantor network [2].

Abstract

This chapter considers the following problem of computing a map of geometric minimal cuts (called the MGMC problem): Given a graph $G = (V, E)$ and a planar embedding of a subgraph $H = (V_H, E_H)$ of G , compute the map of geometric minimal cuts induced by axis-aligned rectangles in the embedding plane. The MGMC problem is motivated by the *critical area* extraction problem in VLSI designs and finds applications in several other fields. This chapter surveys two different approaches for the MGMC problem based on a mix of geometric and graph algorithm techniques that can be regarded complementary. It is first shown that unlike the classic min-cut problem on graphs, the number of all rectilinear geometric minimal cuts is bounded by a low polynomial, $O(n^3)$. Based on this observation, the first approach enumerates all rectilinear geometric minimal cuts and computes their L_∞ Hausdorff Voronoi diagram, which is equivalent to the L_∞ Hausdorff Voronoi diagram of axis-aligned rectangles. The second approach is based on higher-order Voronoi diagrams and identifies necessary geometric minimal cuts and their Hausdorff Voronoi diagram in an iterative manner. The embedding in the latter approach includes arbitrary polygons. This chapter also presents the structural properties of the L_∞ Hausdorff Voronoi diagram of rectangles that provides the map of the MGMC problem and plane sweep algorithms for its construction.

1 Introduction

This chapter considers the following problem called *map of geometric minimal cuts (MGMC)*: Given a graph $G = (V, E)$ and a planar embedding of a subgraph $H = (V_H, E_H)$ of G , compute a map¹ \mathcal{M} of the embedding plane P of H so that for every point $p \in P$, the cell in \mathcal{M} containing p is associated with the “closest” *geometric cut* (in G) to p , where distance between a point p and a cut C is defined as the maximum distance between p and any individual element of C . A geometric cut C of G induced by a given geometric shape S is a set of edges and vertices in H that overlaps S in P and whose removal from G disconnects G . This chapter considers the case where geometric cuts are induced by axis-aligned rectangles and distances are measured in the L_∞ metric. The main objective of the MGMC problem is to compute the map \mathcal{M} of all geometric minimal (or canonical) cuts (the exact definition of geometric minimal cuts will be given in the next section) of the planar embedding of H .

¹A map means a partition of the embedding plane (as in a trapezoidal map) into cells so that all points in the same cell share the same “closest” geometric minimal cut.

The MGMC problem was formulated in [47]. It was introduced, as the *geometric min-cut problem*, in [34], in order to model the *critical area* computation problem for *open faults* in a VLSI design. Critical area is a measure reflecting the sensitivity of a VLSI design to random defects occurring during the manufacturing process. For a survey on VLSI yield analysis and optimization, see, for example, [16]. The critical area computation problem in a VLSI design for various types of fault mechanisms has been reduced to variants of generalized Voronoi diagrams; see, for example, [5, 32, 34–36, 46]. The Voronoi framework for critical area extraction asks for a subdivision of a layer A into regions that reveal, for every point p , the size of the smallest defect centered at p causing a circuit failure. For *open faults*, this results in the MGMC problem. In more detail, a VLSI net N can be modeled as a graph $G = (V, E)$ having a subgraph $H = (V_H, E_H)$ embedded on any conducting layer A ; see, for example, [34]. The embedded subgraph $H = (V_H, E_H)$ is vulnerable to random manufacturing defects that are associated with the layer of the embedding and may create open faults. The MGMC problem computes, for every point p on layer A , the disk of minimum radius, which is centered at p and induces a cut on graph G resulting in an open fault. The subdivision of layer A that solves the MGMC problem corresponds to the *Hausdorff Voronoi diagram* of the geometric minimal cuts (see, e.g., [34, 47]). The MGMC problem finds applications in other networks, such as transportation networks, where critical area may need to be extracted for the purpose of flow control and disaster avoidance.

This chapter surveys the literature on the MGMC problem and presents two complimentary approaches. These approaches are based on a mix of geometric and graph algorithm techniques, and they produce, by different means, the L_∞ Hausdorff Voronoi diagram of geometric minimal cuts on the embedding plane. In addition, this chapter presents structural properties and algorithms for the L_∞ Hausdorff Voronoi diagram, which provides a solution to the MGMC problem, and it is a geometric structure of independent interest.

The first approach to the MGMC problem presented in this chapter is based on the results of [47] for a rectilinear embedding of the embedded subgraph H . This approach first classifies geometric cuts into two classes – 1-D cuts and 2-D cuts – and shows that the number of all possible geometric 1-D and 2-D minimal cuts, given a rectilinear embedding of H , is $O(n^2)$ and $O(n^3)$, respectively, where n is the size of H . The $O(n^3)$ bound on the number of geometric minimal cuts makes the enumeration of geometric cuts feasible. In contrast, the corresponding bound of the classic min-cut problem in graphs is exponential. Based on interesting observations and dynamic connectivity data structures, the approach in [47] directly computes all geometric minimal cuts in $O(n^3 \log n (\log \log n)^3)$ time. A special case in which the inducing rectangle of a cut has a constantly bounded edge length is also considered, in which case the time complexity of the algorithm can be significantly improved to $O(n \log n (\log \log n)^3)$. Once all geometric minimal cuts are identified, the solution to the MGMC problem is reduced to computing their Hausdorff Voronoi diagram. The method in [47] revisits the plane sweep construction of the L_∞ Hausdorff Voronoi diagram of rectangles and presents the first output-sensitive algorithm for

its construction, which runs in $O((N + K) \log^2 N \log \log N)$ time and $O(N \log^2 N)$ space, where N is the number of rectangles and K is the complexity (or size) of the Hausdorff Voronoi diagram. The algorithm is based on a plane sweep construction in 3-D and uses several interesting data structures that can achieve an output-sensitive result.

The second approach is based on results in [34], and it is based on higher-order Voronoi diagrams. The embedded subgraph needs not be rectilinear, it can be arbitrary; moreover, it corresponds to polygonal shapes. Given a geometric graph with a subgraph embedded in the plane, the method in [34] iteratively identifies geometric minimal cuts and their *generators*,² based on an iterative construction of order- k Voronoi diagrams in increasing order of k . In the worst case, the method requires time $O(n^3 \log n)$ to compute higher-order Voronoi diagrams, plus time $O(n^3 \log n (\log \log n)^3)$ to answer connectivity queries on the graph G , assuming that the dynamic connectivity data structures of [20, 45] are used for this purpose. The resulting map provides a solution to the MGMC problem and reveals the Hausdorff Voronoi diagram of all geometric minimal cuts. In practice, typically, it is not necessary to guarantee the identification of all possible geometric cuts, in which case the iterative construction of [34] can be considerably sped up. Once a sufficient set of cut generators are identified, their weighted Voronoi diagram can be computed in a simple manner, providing a map that reliably approximates the solution to the MGMC problem. In the case of rectilinear embeddings, generators are simple axis-parallel line segments of constant weights. For arbitrary embeddings, generators correspond to portions of farthest Voronoi diagrams of cuts in the final map, and their weights correspond to farthest distance functions. Assuming that the number of iterations is kept to a small constant, as experimental results in [34] suggest, this results in an $O(n \log n (\log \log n)^3)$ algorithm for an approximate map solving the MGMC problem.

The Hausdorff Voronoi diagram of a set S of point clusters in the plane is a subdivision of the plane into regions, such that the Hausdorff Voronoi region of a cluster P is the locus of points *closer* to P than to any other cluster in S , where distance between a point t and a cluster P is measured as the *farthest* distance between t and any point in P . The Hausdorff Voronoi diagram first appeared in [11] as the *cluster Voronoi diagram*, where several combinatorial bounds were derived by means of a powerful geometric transformation in three dimensions and an $O(n^2)$ -time algorithm for its construction. A tight combinatorial bound on its structural complexity in the Euclidean plane, as well as a plane sweep construction were given in [33]. The L_∞ version of the problem was introduced in [32] for the VLSI *critical area extraction* problem for a defect mechanism called a *via-block*. In [32], the problem was reduced to an L_∞ Voronoi diagram of additively weighted line segments, and it was computed by a plane sweep procedure. The plane sweep construction was revisited in [47] and [39]. Additional work on Hausdorff Voronoi

²The generator of a cut is a portion of the farthest Voronoi diagram of the elements constituting the cut.

diagrams is included in [1, 9, 38]. In this chapter, we first present an output-sensitive version of the plane sweep in three dimensions for the L_∞ Hausdorff Voronoi diagram of rectangles as given in [47]. We also present the structural properties of this diagram and a simple two-dimensional plane sweep as given in [32, 39], which is not output sensitive; nevertheless, it achieves optimal $O(n \log n)$ -time and $O(n)$ -space in the case of non-crossing rectangles. In case of a large number of crossings, the size of the Hausdorff Voronoi diagram may be $\Omega(n^2)$ [11], and the $O(n^2)$ algorithm of [11] may result in a better approach.

This chapter is organized as follows. [Section 2](#) refers to [47], [Section 3](#) refers to [34], and [Section 4](#) to [39]. The sections are presented independently and they can be read in any order. In more detail, [Sect. 2.1](#) introduces the concepts of 1-D and 2-D geometric minimal cuts; [Sect. 2.2](#) presents the algorithms of [47] for computing the geometric minimal cuts; and [Sect. 2.3](#) presents the output-sensitive plane sweep algorithm in 3-dimensions of [47]. [Section 3](#) presents an iterative approach to the MGMC problem via higher-order Voronoi diagrams based on [34]. [Section 4](#) analyzes the structural complexity of the L_∞ Hausdorff Voronoi diagram and summarizes the simple two-dimensional plane sweep algorithm for its construction presented in [32, 39]. In [Section 5](#) we provide concluding remarks.

2 On Geometric Minimal Cuts and Their Map

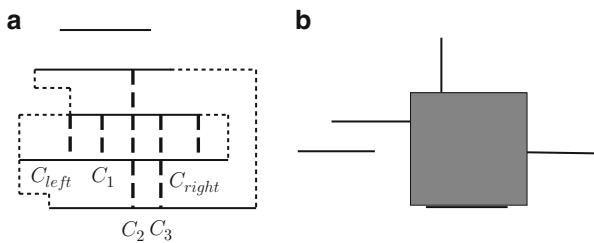

2.1 Geometric Cuts

Let $G = (V, E)$ be the undirected graph in an MGMC problem and $H = (V_H, E_H)$ be its planar subgraph embedded in the plane P with $|V| = N$, $|E| = M$, $|V_H| = n$, and $|E_H| = m$. Due to the planarity of H , $m = O(n)$. In this chapter, unless explicitly mentioned otherwise, all edges in H are either horizontal or vertical straight-line segments. A pair of vertices u and v in a graph are connected if there is a path in this graph from u to v . Otherwise, they are disconnected. A graph is connected if every pair of its distinct vertices is connected. Without loss of generality, G is assumed to be connected in this chapter. A cut C of G is a subset of edges in G whose removal disconnects G . A cut C is minimal if removing any edge from C no longer forms a cut.

Definition 1 Let R be a connected region in P , and $C = R \cap H$ be the set of edges in H intersected by R . The cut C is called a geometric cut induced by R if the removal of C from G disconnects G .

When there is no ambiguity of the region R , the cut induced by R is called a “geometric cut” for simplicity. For a given cut C , its *minimum inducing region* $R(C)$ is the minimum axis-aligned rectangle which intersects every edge of C (i.e., if we shrink the width or length of $R(C)$ by any arbitrarily small value ϵ , some edge in C will no longer be intersected by $R(C)$). For some geometric cut C , its minimum inducing region $R(C)$ could be degenerated into a horizontal or vertical

Fig. 1 (a) 1-D cuts C_1 , C_2 , and C_3 with C_3 being the minimal cut. (b) A 2-D cut bounded by 4 edges

line segment, or even a single point. It is easy to see that if $R(C)$ is not degenerate, it is unique.

Definition 2 A geometric cut C is called a 1-D geometric cut (or a 1-D cut) if $R(C)$ is a line segment. If $R(C)$ is an axis-aligned rectangle, then C is called a 2-D geometric cut (or a 2-D cut).

Definition 3 A geometric cut C is a geometric minimal cut if the set of edges intersected by any region obtained by shrinking $R(C)$ no longer forms a geometric cut.

The following lemma easily follows from the above definitions and the problem setting.

Lemma 1 Let C be any geometric minimal cut. If C is a 1-D cut, then each endpoint u of $R(C)$ is incident to either an endpoint of an edge e in H with the same orientation as $R(C)$ and $e \cap R(C) = u$ or an edge in H with different orientation as $R(C)$ (see Fig. 1a). If C is a 2-D cut, each bounding edge s of $R(C)$ is incident to either an endpoint v of an edge e in H of different orientation with s and $R(C) \cap e = v$, or an edge in H with the same orientation as s (see Fig. 1b; note that s could be incident to multiple edges).

From the above lemma, it is clear that each 1-D geometric minimal cut is bounded by up to two edges in H and each 2-D geometric minimal cut is bounded by up to 4 edges in H . For a cut C , let $B(C)$ denote the set of edges bounding C . Due to the minimality nature of C , removing any edge in $B(C)$ will lead to a non-cut. This means that any edge in $B(C)$ is necessary for forming the cut. However, this is not necessarily true for edges in $C \setminus B(C)$. Thus, a geometric minimal cut may not be a minimal cut. Note that for a given graph, the number of minimal cuts could be exponential. However, as shown later, the number of geometric minimal cuts is much less (i.e., bounded by a low degree polynomial).

For a 1-D geometric minimal cut C , it is possible that all edges in C have different orientation with $R(C)$. In this case, there may exist an infinite number of 1-D geometric minimal cuts, all cutting the same set of edges C (in other words, the minimum inducing region for such a 1-D geometric C is not unique). For example, sliding $R(C)$ along $B(C)$ will obtain an infinite number of 1-D minimal cuts.

Among these cuts, there are two extreme cuts, C_{left} and C_{right} (or C_{top} and C_{bottom} if $R(C)$ is horizontal), incident with the left and right (or up and bottom) endpoints of some edges in C , respectively. Since all these geometric cuts cut the same set of edges, they are counted as one cut.

2.2 Identifying Geometric Minimal Cuts

To solve the MGMC problem, the main idea in [47] is to first identify all possible geometric minimal cuts and then construct a Hausdorff Voronoi diagram of these cuts as the map \mathcal{M} . Thus, three major problems need to be solved:

1. Finding all 1-D minimal cuts;
2. Finding all 2-D minimal cuts; and
3. Efficiently constructing the Hausdorff Voronoi diagram for the geometric cuts.

This section discusses the main ideas for problems 1 and 2. The approach for problem 3 will be discussed in the next section.

2.2.1 Computing 1-D Geometric Minimal Cuts

As discussed in the previous section, a 1-D geometric minimal cut can be induced by either horizontal or vertical segments. The following lemma bounds from above the total number of 1-D geometric minimal cuts.

Lemma 2 *There are $O(n^2)$ 1-D geometric minimal cuts in H .*

Proof Only the 1-D cuts induced by vertical segments are considered. Cuts induced by horizontal segments can be proved similarly. If we place a vertical line through each vertex (or endpoint), then the plane P is partitioned into $O(n)$ vertical slabs, with each slab containing no endpoint in its interior. For a particular slab S containing k edges, say e_1, e_2, \dots, e_k , it could be shown that there are at most $O(k)$ 1-D geometric minimal cuts. To see this, all 1-D minimal cuts formed by the k edges are considered. A cut C is owned by an edge e_i if $e_i \in B(C)$. Clearly, each 1-D minimal cut has at least one owner. Now consider each edge e_i , it can only be the owner of up to two 1-D minimal cuts, one bounded by e_i from the bottom and one bounded by e_i from the top. Note that due to the fact that the cuts are all minimal, it is impossible to have two cuts bounded by e_i from the top (or bottom) simultaneously. Thus, each edge in S owns at most two 1-D geometric minimal cuts. Hence, the total number of 1-D geometric minimal cuts in S is $O(k)$. Summing over all slabs, the total number of 1-D geometric minimal cuts is $O(n^2)$. Thus, the lemma follows. \square

To compute the $O(n^2)$ 1-D geometric minimal cuts, since each cut is a set of edges $C \in H$ which appear consecutively in some slab and whose removal disconnects G , it is necessary to first (a) Identify all possible cuts in H , and then (b) For each possible cut, determine whether it is indeed a cut (such a test is called a *cut query*). To overcome the two difficulties, a straightforward way is to enumerate

all possible cuts, and for each possible cut C , use graph search algorithms (such as depth first search (DFS) or breadth first search (BFS)) to check the connectivity of $G \setminus C$. As shown in the proof of Lemma 2, the embedding plane P can be partitioned into $O(n)$ slabs, and for each slab with k edges, there are $O(k^2)$ subsets of consecutive edges. Thus, a total of $O(n^3)$ possible subsets need to be checked, and the connectivity checking for each subset takes $O(N + M)$ time. Therefore, this will lead to a total of $O(n^3(N + M))$ time.

To speed up the computation, the idea is to first simplify the graph G . Since the cuts involve only the edges in H , the connectivity in $G \setminus E_H$ will not be affected no matter which subset of edges in H is removed. To make use of this invariant, the connected components of $G \setminus E_H$ are firstly computed. For each connected component CC , it is contracted into a supernode v_{CC} . For each vertex $u \in H \cap CC$, an edge (u, v_{CC}) is added. Let the resulting graph be $G' = (V', E')$ (called contracted graph). The following lemma gives some properties of this graph.

Lemma 3 *The number of vertices in G' is $|V'| = O(n)$ and the number of edges in G' is $|E'| = O(n)$. Furthermore, a subset of edges in H is a cut of G if and only if it is a cut of G' .*

Proof Follows from the construction of G' . □

The above lemma shows that the size of G' could be much smaller than G . Thus, the time needed for answering a cut query is significantly reduced from $O(N + M)$ to $O(n)$.

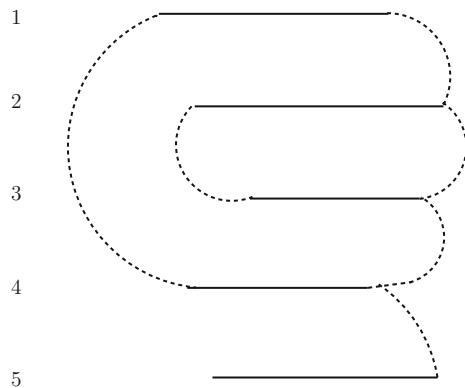

Converting Cut Queries to Connectivity Queries As discussed previously, to compute all 1-D geometric minimal cuts, it is necessary to check $O(n^3)$ possible subsets of edges in H . Many of them are quite similar (i.e., differ only by one or a small number of edges). Thus, it would be highly inefficient to handle them independently and answer each cut query by searching the graph G' . To yield a better solution, it is better to consider all these cut queries simultaneously and share the connectivity information among similar cut queries.

To share information among slightly different cut queries, one possible way is to use persistent data structure [10]. However, due to the fact that inserting (or removing) an edge could cause a linear, instead of a constant, number of 1-D geometric minimal cuts to be destroyed or generated, persistent data structures require substantial amount of updating after each insertion or deletion, thus they do not lead to a highly efficient solution.

To overcome this difficulty, the main idea is to further decompose each cut query into a set of connectivity queries with each connectivity query involving only one edge. The reduced granularity in query enables us to better share information among related cut queries.

Connectivity Query Before continuing the discussion on connectivity queries, some existing algorithms and data structures for the dynamic connectivity problem

Fig. 2 An example for 1DSlab, where the dotted lines are the edges in $G' \setminus H$. $\{2, 3\}$ and $\{5\}$ are the 1-D geometric minimal cuts

are briefly reviewed. In the fully dynamic connectivity problem, the input is a graph G whose vertex set is fixed and whose edges can be inserted and deleted. The objective is to construct a data structure for G so that the connectivity of any pair of vertices can be efficiently determined. Most fully dynamic connectivity data structures support the following three operations: (1) $Insert(e)$, (2) $Delete(e)$, and (3) $Connectivity(u, v)$, where the $Insert(e)$ operation inserts edge e into G , the $Delete(e)$ operation removes edge e from G , and the $Connectivity(u, v)$ operation determines whether u and v are connected in the current graph G . Extensive research has been done on this problem, and a number of results were obtained [12, 13, 17, 18, 20, 45]. In [20], Thorup et al. gave a simple and interesting solution for this problem which answers each connectivity query in $O(\log n)$ time and takes $O(\log^2 n)$ time for each update. Later Thorup gave a near-optimal solution for this problem [45] which answers each connectivity query in $O(\log n / \log \log \log n)$ time and completes each insertion or deletion operation in $O(\log n (\log \log n)^3)$ expected amortized time.

The approach described in this chapter uses the data structure in [45] for the MGMC problem. In practice (e.g., critical area computation), the simpler algorithm in [20] may be more practical. When the choice of the connectivity data structure is unclear, $MaxQU$ is used to represent the maximum of the connectivity query time and the update operation time.

Enumerating 1-D Geometric Minimal Cuts in a Slab The problem of identifying 1-D geometric minimal cuts in a vertical slab S with k edges (see Fig. 2) is to make use of the connectivity data structure. Clearly, there are $O(k^2)$ possible 1-D geometric cuts and $O(k)$ 1-D geometric minimal cuts. To find out the $O(k)$ minimal cuts from $O(k^2)$ possible locations, edges are sorted based on the y coordinates, and let $e_1 = (u_1, v_1), e_2 = (u_2, v_2), \dots, e_k = (u_k, v_k)$ be the k edges. A fully dynamic connectivity data structure $FDC(G')$ for the contracted graph G' is built, and then the algorithm for a slab (called 1DSlab) is run on it. The main steps of 1DSlab are the follows.

1. Initialize a variable $r = 1$ to represent the index of the next to-be-deleted edge.
2. Starting from e_r , repeatedly delete edges of S from G' according to their sorted order and store them in a queue Q . For each deleted edge e_i , query $FDC(G')$ about the connectivity of u_i and v_i . Stop the deletion until encountering the first edge e_j whose two endpoints u_j and v_j are disconnected or the last edge. In the latter case, insert all deleted edges back and stop.
3. Insert the deleted edges in Q back in the same order as they are deleted and updating $FDC(G')$. After inserting each edge e_i , query the connectivity of the two endpoints of e_j, u_j , and v_j .
4. If u_j and v_j are disconnected, add a forward pointer from e_i to e_j and insert edges in Q back to G' .
5. If u_j and v_j are connected, add a forward pointer from e_i to e_j , set $r = j + 1$, and repeat Steps 2–5 until encountering the last edge e_k . In this case, insert all remaining edges in Q back to G' and $FDC(G')$.
6. Reverse the order of the k edges and repeat the above procedure. In this step the added pointers are backward pointers.
7. For each edge e_j , find the nearest edge e_i which has a forward pointer to e_j and the nearest edge e'_i with a backward pointer to e_j . Output the set of edges between e_i and e_j (including e_i and e_j) as a 1-D geometric minimal cut and edges between e_j and e'_i (including e_j and e'_i) as another 1-D geometric minimal cut.

The correctness of the above algorithm is shown below.

Lemma 4 *Assume G' is originally a connected graph. In Step 2 of the 1DSlab algorithm, if u_i and v_i (the endpoints of the last deleted edge e_i) are connected, the set of deleted edges (i.e., e_r to e_i) does not form a cut in G' . On the other hand, if u_i and v_i are disconnected, then the set of deleted edges does form a cut in G .*

Proof Firstly, if u_i and v_i are disconnected, obviously the set of deleted edges forms a cut. Thus, only the case that u_i and v_i are connected is considered. In this case, the set of deleted edges does not form a cut.

This could be proved by induction on the number i of deleted edges. The base case is $i = 1$. In this case, since G' is originally a connected graph and u_i and v_i are still connected in $G' \setminus \{e_i\}$, obviously there exists no cut. Assume that after deleting $i - 1$ edges, the set of edges $S_{i-1} = \{e_1, e_2, \dots, e_{i-1}\}$ does not form a cut. Then since $G' \setminus S_{i-1}$ is a connected graph, after deleting edge e_i , the case becomes the same as the base case. Thus, the lemma follows. \square

Lemma 5 *In the 1DSlab algorithm, the disconnectivity of u_j and v_j in Step 4 or the connectivity of u_j and v_j in Step 5 implies that the set $S_{i,j} = \{e_i, e_{i+1}, \dots, e_j\}$ forms a cut in G' .*

Proof The first case (i.e., u_j and v_j are disconnected in Step 4) is obvious. For the second case (i.e., u_j and v_j are connected in Step 5), since u_j and v_j are disconnected before the insertion of e_i , it follows that $S_{i,j}$ is a cut. \square

The above lemmas indicate that the cut query can be answered by a sequence of connectivity queries.

Theorem 1 *The 1DSlab algorithm generates all 1-D geometric minimal cuts in the slab S in $O(k \text{Max}QU)$ time, where $\text{Max}QU$ is the maximum of the query time and the updating time of the $\text{FDC}(G')$ data structure.*

Proof The reason that the 1DSlab algorithm generates all 1-D geometric minimal cuts is shown below. By Lemmas 4 and 5, it is known that the forward pointers to e_j indicate all cuts whose edge set appears consecutively and ends at edge e_j . Similarly, the backward pointers to e_j indicate all cuts whose edge set appears consecutively and starts from e_j . By finding the nearest edges with forward and/or backward pointers to e_j , the algorithm identifies the (up to) two 1-D geometric minimal cuts starting from and ending at e_j . Since the computation is for every edge in S , it generates all 1-D geometric minimal cuts.

For the running time, it is clear that the sorting takes $O(k \log k)$ time. After sorting, in each of the forward and backward computations, every edge in S is deleted and inserted once. As for the connectivity queries, the endpoints of each edge can be queried multiple times (one in Step 2 and others in Step 3). To bound the total query time, the query on u_j and v_j in Step 3 is charged to edge e_i . Since e_i is inserted only once, it will be charged only once. Thus, each edge in S will be responsible for at most two queries. Therefore, the total number of connectivity queries is $O(k)$. Since the insertion, deletion, and query operations take no more than $O(\text{Max}QU)$ time, the theorem follows. \square

From the above theorem, it is known that even though there are $O(k^2)$ consecutively appeared subsets of edges that could be 1-D geometric minimal cuts, the connectivity data structure can reduce the time to near linear.

Generating 1-D Geometric Minimal Cuts The algorithm 1DSlab is combined with a plane sweep algorithm to generate all possible 1-D geometric minimal cuts in H .

A straightforward way of using 1DSlab is to partition the plane P into $O(n)$ slabs and apply the 1DSlab algorithm in each slab. This will lead to a $O(n^2 \text{Max}QU)$ -time solution. A more output-sensitive solution is to use the following plane sweep algorithm.

In the plane sweep algorithm, a vertical sweeping line L is used to sweep through all edges in H to generate those 1-D geometric minimal cuts induced by vertical segments. Similarly, those 1-D geometric minimal cuts induced by horizontal segments can be generated by sweeping a horizontal line. For the vertical sweeping line algorithm, the event points are the set V_H of endpoints in H . At each event point, the set of edges intersecting the sweeping line L forms a slab. However, instead of applying the 1DSlab algorithm to the whole set of intersecting edges, only a subset of edges are considered.

Let u be the event point. If u is the left endpoint of an edge e , then e is the new edge just encountered by L . Thus, it is only needed to identify all 1-D geometric minimal cuts which contain e . This means that the 1DSlab algorithm needs only to consider the minimal cut C_1 bounded by e from the bottom, the minimal cut C_2 bounded by e from the top, and all minimal cuts between the top edge e_t of C_1 and the bottom edge e_b of C_2 . To deal with this case, the 1DSlab algorithm can be easily modified. Particularly, the modified algorithm can start from e , have a backward computation, and stop at the first edge e_t , whose removal disconnects its two endpoints, to generate C_1 . Similarly, the algorithm can start from e and have a forward computation to generate C_2 . In this way, dealing with possibly many edges beyond e_t and e_b is avoided.

If u is the right endpoint of e , it is necessary to check those cuts containing e to see whether they are still geometric minimal cuts. It is also needed to check whether new cuts can be generated. Clearly, it is only needed to consider the edges between e'_t and e'_b , where e'_t is the top edge of the 1-D geometric minimal cut bounded by e from the bottom and e'_b is the bottom edge of the 1-D geometric minimal cut bounded by e from the top. Thus, such information from the previous step (i.e., the step before encountering u) are first obtained and then the 1DSlab algorithm on the subset of edges between e'_t and e'_b is applied directly.

Theorem 2 All 1-D geometric minimal cuts of H can be found in $O(n \times \text{Max } C \times \text{Max } QU)$ time, where $\text{Max } C$ is the maximum size of a 1-D geometric minimal cut.

Proof Follows from the above discussion. □

2.2.2 Computing 2-D Geometric Minimal Cuts

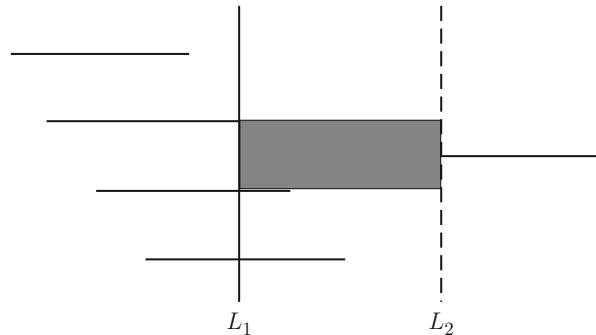

This section extends the algorithm in Sect. 2.2.1 to compute 2-D geometric minimal cuts.

To compute 2-D geometric minimal cuts, it is easy to see that a 1-D geometric minimal cut is a degenerate version of a 2-D geometric minimal cut. The only difference is that the minimum inducing region of a 1-D cut has two opposite sides degenerated to points. Thus, if two opposite sides of the minimum inducing region $R(C)$ of a 2-D cut C are conceptually “contracted” into “points,” the plane sweep algorithm for 1-D cuts can be applied to generate 2-D cuts.

To implement this idea, two parallel sweeping lines L_1 and L_2 (called primary and secondary sweeping lines) are used to bound the “contracted” sides of $R(C)$. By Lemma 1, it is known that each 2-D geometric minimal cut is bounded by the endpoints (or edges) of up to four edges. This suggests that the possible locations of L_1 and L_2 are the endpoints of the input edges. Similarly to the plane sweep algorithm for 1-D cuts, the edges in H are swept twice, one time vertically and the other time horizontally. The discussion below is focused on horizontal sweeping (i.e., using vertical sweeping lines).

The double plane sweep algorithm first sorts all edges in H based on the x coordinates of their left endpoints (for vertical segments, their upper endpoints are viewed as the left endpoints and their lower endpoints as the right endpoints).

Fig. 3 An example for illustrating the double plane sweep algorithm for 2-D cuts

Let $S_1 = \{e_1, e_2, \dots, e_n\}$ be the sorted order. The primary sweeping line L_1 stops at the left endpoint of each edge e in the order of S_1 . If the right endpoint of e is to the left of the left endpoint of the next edge $e' \in S_1$, the sweep line L_1 is moved to the right endpoint of e (see Fig. 3). If e is a cut by itself, L_1 is moved to the next edge in S_1 . If e is not a cut, L_1 is fixed and the secondary sweeping line L_2 is swept from the left endpoint of the next edge e' in S_1 to the last edge in S_1 . When L_2 stops, the plane sweep algorithm for 1-D cuts (in Sect. 2.2) is used to compute all 2-D geometric minimal cuts formed by the set S of edges intersecting the vertical region VR bounded by L_1 and L_2 .

For edges in S , there are two sorted orders S_L and S_U . S_L is sorted based on the y coordinates of the lower endpoints, and S_U is based on the y coordinates of the upper endpoints. (For horizontal edges, their left endpoints are viewed as upper endpoints and right endpoints as the lower endpoints. It is not difficult to see that the two sorted lists can be dynamically maintained in the double plane sweep algorithm.) S_L is used to generate cuts for edges above e and S_U is used to generate cuts for edges below e .

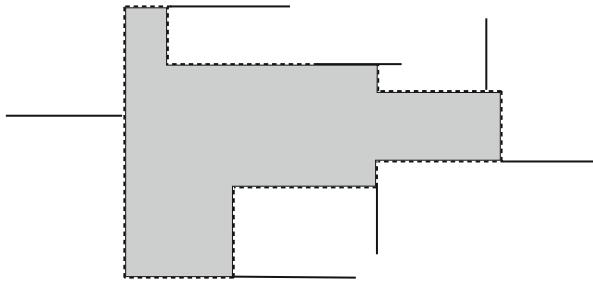

Each 2-D geometric minimal cut C in the vertical region VR is bounded by L_1 from left, L_2 from right, an edge e_u from above, and an edge e_d from below. Since all edges in S are in sorted order and $R(C)$ intersects edges in the same order in either S_L or S_U (depending on their relative locations to e), the 2-D geometric minimal cuts in VR can be viewed as 1-D geometric minimal cuts induced by vertical “segments” with a segment width equal to the horizontal distance of L_1 and L_2 . Thus, they can be generated by using the plane sweep algorithm for 1-D cuts. Furthermore, similar to the plane sweep algorithm for 1-D cuts, in VR it is only needed to consider those 2-D geometric minimal cuts containing edge e (see Fig. 4).

Once all the cuts in VR are identified, L_2 is moved to the next edge in S_1 . After sweeping L_2 , L_1 is moved to the next edge in S_1 and the above procedure is repeated until L_1 sweeps every edge.

The following lemma is used to analyze the double plane sweep algorithm.

Lemma 6 *There are at most $O(n^3)$ 2-D geometric minimal cuts in H .*

Fig. 4 Example of the double plane sweep algorithm for 2-D cuts. The region bounded by the dotted lines is the actual region where the algorithm searches for all 2-D geometric minimal cuts bounded by the leftmost segment from the *left*.

Proof By Lemma 1, it is known that the inducing region of each 2-D geometric minimal cut is bounded by an edge on each side. There are $O(n^2)$ pairs of edges to bound the left and right sides of the inducing region. For each pair, the vertical region is similar to a slab (according to the above discussion). By a similar argument in the proof of Lemma 2, it is easy to see that in each vertical region, there at most $O(n)$ 2-D geometric minimal cuts. Thus, the lemma follows. \square

For the running time of the double plane sweep algorithm, the primary sweeping line L_1 stops at $O(n)$ location. For each fixed location of L_1 , L_2 sweeps all edges not yet encountered by L_1 , whose number can be $O(n)$. For each vertical region bounded by L_1 and L_2 , it takes $O(\text{MaxC} \times \text{MaxQU})$ time (by Theorem 2). Thus, the total time is $O(n^2 \times \text{MaxC} \times \text{MaxQU})$.

Theorem 3 All 2-D geometric minimal cuts in H can be found in $O(n^2 \times \text{MaxC} \times \text{MaxQU})$ time.

Proof Follows from the above discussion. \square

Corollary 1 All geometric minimal cuts in the MGMC problem can be found in $O(n^3 \log n (\log \log n)^3)$ time in the worst case.

Proof Follows from Theorems 2 and 3, and article [45]. \square

Corollary 2 If the maximum size of a cut is bounded by a constant, then all geometric minimal cuts in H can be found in $O(n \log n (\log \log n)^3)$ -time.

Proof If the maximum size of a defect is bounded by some constant, the size of an inducing rectangle is bounded by a constant. Furthermore, since edges in VLSI design are separated by some constant distance, thus the total number of edges in an inducing rectangle is also a constant. In this case, the secondary sweeping line L_2 needs only to sweep a constant number of edges. Thus, the running time of both plane sweep algorithms is $O(n \times \text{MaxQU})$. Also from Theorems 2 and 3, article [45], the lemma follows. \square

2.3 Generating Map of Geometric Minimal Cuts

This section shows that Problem 3 can be solved by using the Hausdorff Voronoi diagram.

2.3.1 From Geometric Minimal Cuts to Hausdorff Voronoi Diagram

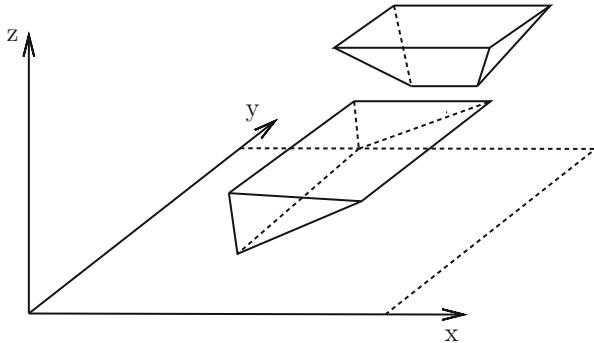

Given two sets A and B , the directed Hausdorff distance from A to B is $h(A, B) = \{\max_{a \in A} \min_{b \in B} d(a, b)\}$, and the undirected Hausdorff distance between A and B is $d_h(A, B) = \max\{h(A, B), h(B, A)\}$, where $d(a, b)$ is the distance between the points a and b . In this chapter, the L_∞ metric is used to measure the distance.

Given a set \mathcal{C} of geometric minimal cuts of H , the Hausdorff Voronoi diagram of \mathcal{C} is a partition of the embedding plane P of H into regions (or cells) so that the Hausdorff Voronoi cell of a cut $C \in \mathcal{C}$ is the union of all points whose Hausdorff distance to C is closer than to any other cut in \mathcal{C} . This means that for any point $p \in P$, if an L_∞ ball is grown from p (i.e., an axis-aligned square centered at p), the ball entirely contains $R(C(p))$ earlier than the minimum inducing region of any other cut, where $C(p)$ is the cut owning the Hausdorff Voronoi cell containing p . Thus, if such a map \mathcal{M} exists for the critical area extraction problem, then for each point p , one can easily determine the minimum size of a defect centered at p and disconnecting the circuit.

In the MGMC problem, two types of objects exist, the minimum inducing regions of 1-D geometric minimal cuts and the minimum inducing regions of 2-D geometric minimal cuts. For every 2-D cut C , the rectangle $R(C)$ is fixed. However, for a 1-D cut C , the location of $R(C)$ is not fixed, since there may be an infinite number of 1-D cuts cutting the same set of edges. In this case, the union of the infinite number of inducing segments $R(C)$ is used to represent the cut, which is a rectangle (denoted by $UR(C)$) bounded by the two extreme 1-D cuts C_{left} and C_{right} (or C_{top} and C_{bottom}) and the two bounding edges $B(C)$ of C . Thus, from thereafter, the objects of the Hausdorff Voronoi diagram are a set of axis-aligned rectangles.

As it is well known, the Hausdorff Voronoi diagram construction can be viewed as propagating a wave from each rectangle with unit speed. The Hausdorff distance from an arbitrary point p to an axis-aligned rectangle $R(C)$, corresponding to the minimum inducing region of a 2-D cut C , is considered to better illustrate the wave propagation. The Hausdorff distance of $d_h(p, R(C))$ is achieved at one of the four corner points, $v_1(C), v_2(C), v_3(C)$, and $v_4(C)$, of $R(C)$. Thus, $d_h(p, R(C)) = \max\{d_\infty(p, v_1(C)), d_\infty(p, v_2(C)), d_\infty(p, v_3(C)), d_\infty(p, v_4(C))\}$. To propagate a wave $W(C)$ from $R(C)$, the initial wavefront $\partial W(C)$ is the set of points whose Hausdorff distance to $R(C)$ is the minimum. Notice that when $R(C)$ has positive size (i.e., $R(C)$ is not a point), the minimum Hausdorff distance is positive (i.e., $\max\{a, b\}/2$, where a, b are the length and width of $R(C)$ respectively) and it is achieved when $d_\infty(p, v_1(C)), d_\infty(p, v_2(C)), d_\infty(p, v_3(C))$ and $d_\infty(p, v_4(C))$ are equal. The wavefront then expands to points having larger Hausdorff distance to $R(C)$. Since the Hausdorff distance to $R(C)$ is determined by the four corner points, an equivalent view is to propagate four distinct waves from the four corner points of $R(C)$ with each being an L_∞ ball. Let $B_1(C), B_2(C), B_3(C)$, and $B_4(C)$ be the

Fig. 5 Wavefronts of geometric minimal cuts

four L_∞ balls. The common intersections of the four balls constitute the wave of $R(C)$ (i.e., $W(C) = \cap_{i=1}^4 B_i(C)$). Initially, $\partial W(C)$ is empty. Once the size of the four balls $B_i(C)$ reaches the minimum Hausdorff distance to $R(C)$, their common intersection forms a segment s_C located at the center of $R(C)$ and parallel to the shorter side of $R(C)$. As $B_i(C)$ grows, $\partial W(C)$ becomes a rectangle.

To visualize the whole growing process, the waves can be lifted to 3-D with time being the third dimension. Thus, the wavefront of $R(C)$ becomes a 4-sided facet cone in the 3-D space and apedex at s_C (i.e., the apex is not in the xy plane due to its positive minimum Hausdorff distance; see Fig. 5). Each facet of $\partial W(C)$ forms a 45° angle with the xy plane.

For a 1-D cut C , its wavefront is slightly different. Let $UR(C)$ be the rectangle of C . Since $UR(C)$ is the union of an infinite number of inducing segments $R(C)$, the Hausdorff distance to an arbitrary point p is calculated differently. For a fixed inducing segment $R(C) \in UR(C)$, let $u_1(R(C))$ and $u_2(R(C))$ be its two endpoints. The Hausdorff distance from $R(C)$ to p is achieved at one of the two endpoints (i.e., $d_h(p, R(C)) = \max\{d(p, u_1(R(C))), d(p, u_2(R(C)))\}$). Thus, the wavefront of $R(C)$ is the common intersection of two L_∞ balls centered at the two endpoints, respectively, which is also a facet cone in 3-D space.

The Hausdorff distance from p to $UR(C)$ is the minimum distance from p to one of the inducing segments in $UR(C)$, that is,

$$d_h(p, UR(C)) = \min_{R(C) \in UR(C)} d_h(p, R(C)).$$

Thus, the wavefront of $UR(C)$ is the union of an infinite number of wavefronts, which is still a facet cone with similar shape to the wavefront of a 2-D cut. The difference between the wavefront of $UR(C)$ and that of a 2-D cut with exactly same-shaped $R(C)$ is that their respective s_C may orient differently and locate at different heights.

Lemma 7 *Let C be a 1-D or 2-D geometric minimal cut. At any moment, the wavefront of C is either empty or an axis-aligned rectangle. Furthermore, the*

wavefront in 3-D is a facet cone apexed at a segment and with each facet forming a 45° angle with the xy plane.

Proof Follows from the above discussion. \square

With the 3-D wavefronts of all cuts, the Hausdorff Voronoi diagram can be constructed by computing the vertical projection of the lower envelope of the set of 3-D wavefronts.

Lemma 8 *The Hausdorff Voronoi diagram can be obtained by projecting the lower envelope of the 3-D facet cones to the xy plane.*

Proof Follows from the definitions of the 3-D wavefronts and the Hausdorff Voronoi diagram. \square

2.3.2 Plane Sweep Approach and Properties of 3-D Cones and Hausdorff Voronoi Diagram

To efficiently construct the Hausdorff Voronoi diagram $HVD(C)$, the approach follows the spirit of Fortune's plane sweep algorithm for points [15] and sweeps along the x axis direction a tilted plane Q in 3-D which is parallel to the y axis and forms a 45° with the xy plane (see Fig. 6a). Q intersects the xy plane at a sweep line L parallel to the y axis.

Since every facet of a 3-D facet cone forms a 45° angle with the xy plane and apexed at either a horizontal or vertical segment, the intersection of Q and a cone $\partial W(C)$ is either a V -shape curve (i.e., consisting of a 45° ray and a 135° ray on Q) or a U -shape curve (i.e., consisting of a 45° ray, a segment parallel to L , and a 135° ray; see Fig. 6b). When the cone is first encountered, it introduces either a V -shape curve or a U -shape curve to Q . When L (or Q) moves, the curve grows and its shape may change from a V -shape to a U -shape. Accordingly, the lower envelope (or beach line) of all those V - or U -shape curves forms a monotone polygonal curve, instead of parabolic arcs as in Fortune's algorithm.

With the beach line, one might think of directly applying Fortune's algorithm to sweep the objects. However, due to the special properties of this problem, quite a few significant differences exist between the MGMC problem and the ordinary Voronoi diagram problem, which fail the Fortune's algorithm. Below is a list of major differences.

1. When a cone is first encountered by Q , its corresponding initial V - or U -shape curve may not necessarily be part of the beach line.
2. The initial V - or U -shape curve may affect a number of curves in the beach line.
3. Once a V shape moves away from the beach line, it may re-appear in the beach line in a later time.

The differences indicate that it is not sufficient to maintain only the beach line in order to extract all possible event points and produce the Voronoi diagram. More information of the arrangement of the V - and U -shape curves is needed. This seemingly suggests that an algorithm with running time of the order of the

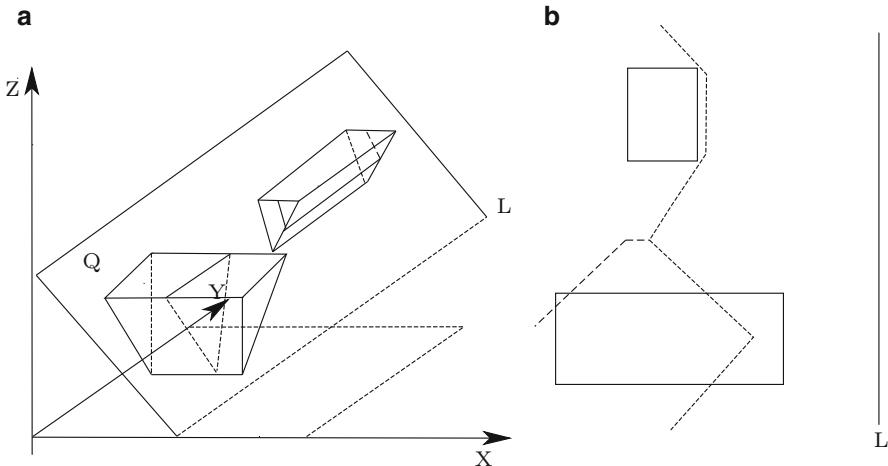

Fig. 6 (a) The intersections of 3-D plane Q and cones. (b) The Voronoi diagram with sweep line and beach line

complexity of the arrangement might be unavoidable. With several interesting observations and ideas, an output-sensitive plane sweep algorithm could be achieved. First, some basic properties of the Hausdorff Voronoi diagram of \mathcal{C} are presented below.

Definition 4 A 3-D facet cone $\partial W(C)$ is a U cone (or V cone) if its apex segment s_C is parallel to the y (or x) axis.

For U cones, let $\partial W(C)$ be any U cone with apex segment s_C , and v_1 and v_2 be the two endpoints of s_C . When the sweep plane Q first encounters $\partial W(C)$, it introduces a U -shape curve C_u to Q . Let r_l , r_r , and s_m be the left and right rays and the middle segment of C_u , respectively. Initially, s_m is the apex segment s_C , and r_l and r_r are the two edges of facet cone. When Q (or L) moves, C_u grows and always maintains its U -shape.

Lemma 9 Let $\partial W(C)$, C_u , r_l , r_r , and s_m be defined as above. When Q moves in the direction of the x axis, C_u is always a U -shape curve. The two supporting lines of r_l and r_r remain the same on Q , and the two endpoints of s_m (also the fixed points of r_l and r_r) move upwards in unit speed along the two supporting lines.

Proof Follows from the shape and orientation of a U cone. \square

For an arbitrary V cone $\partial W(C')$, let $s_{C'}$ be its apex segment and v'_1 and v'_2 be its two endpoints (or left and right endpoints). When Q first touches $\partial W(C')$ at v'_1 ,

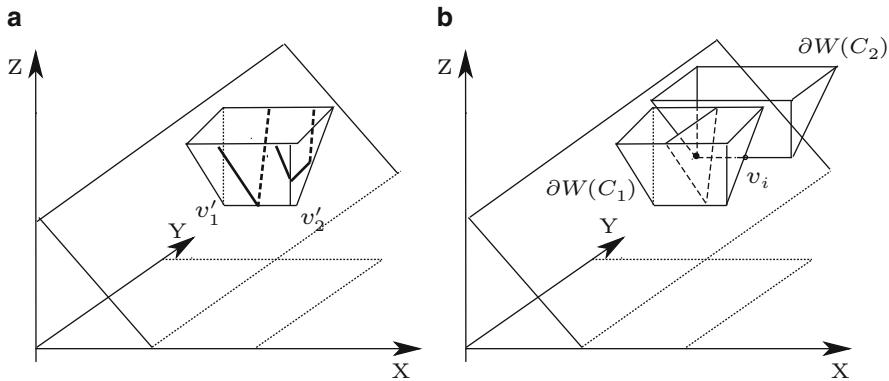

Fig. 7 (a) The V -shape curve changes to U -shape curve. (b) The V cone is hidden by another V cone

it generates a V -shape curve C'_v . C'_v remains a V -shape curve before encountering v'_2 . After that, C'_v becomes a U -shape curve (see Fig. 7a).

Lemma 10 Let r_l and r_r be the two rays of C'_v , and s_m be the middle segment of the U -shape curve C'_v after Q visits v'_2 . During the whole sweeping process, the supporting lines of r_l and r_r are fixed lines on Q . C'_v remains the same V -shape curve on Q before encountering v'_2 . s_m moves upwards in unit speed along the supporting lines of r_l and r_r after Q encounters v'_2 .

Proof Follows from the shape and orientation of a V cone. \square

As mentioned earlier, the apex segment of each 3-D cone is located at different height (i.e., its minimum Hausdorff distance). The heights and shapes of the 3-D cones are the main reasons which cause the three differences in the MGMC problem. For example, due to the existence of height in a 3-D cone, the initial curve created by a newly encountered cone may be above the beach line (i.e., Difference (1)). In addition due to the different size of the initial curve (unlike the ordinary Voronoi diagram in which the initial curve is a vertical ray), it may intersect a number of segments or rays of the beach line (i.e., Difference (2)). More importantly, due to the existence of U - and V -shape curves, a V -shape curve which is not part of the beach line could become part of the beach line in a later time (i.e., Difference (3)). It is shown in the following lemma.

Lemma 11 Let $\partial W(C_1)$ be either a U or V cone and $\partial W(C_2)$ be a V cone with its left endpoint v_1 of s_{C_2} being inside of $\partial W(C_1)$ and its right endpoint v_2 being outside of $\partial W(C_1)$. If $\partial W(C_2)$ is not entirely contained by the union $\cup_{C_i \in \mathcal{C}; C_i \neq C_2} \partial W(C_i)$, the V -shape curve C_2 introduced by $\partial W(C_2)$ will be hidden by the beach line at the

beginning and will become part of the beach line later. This is the only case in which a hidden U- or V-shape curve can appear in the beach line.

Proof To simplify the proof, $\partial W(C_1)$ and $\partial W(C_2)$ are assumed to be the only two cones in \mathcal{C} (see Fig. 7b). The multiple cones case can be proved similarly by induction.

By the definition of the two 3-D cones, it is known that Q first encounters $\partial W(C_1)$ and generates a curve C_1 on Q . C_1 is the only curve in the beach line. When v_1 of $\partial W(C_2)$ is first encountered by Q , it introduces a V-shape curve C_2 on Q . Since v_1 is inside $\partial W(C_1)$ and every facet of the two cones forms a 45° angle with the xy plane, the two rays of C_2 will be inside the region defined by the two rays of C_1 . This means C_2 will not be part of the beach line (or lower envelope). Since $\partial W(C_2)$ is not entirely inside $\partial W(C_1)$, v_2 must be outside of $\partial W(C_1)$. Let v_i be the intersection point of s_{C_2} and the wall of $\partial W(C_1)$. When Q sweeps through v_i , the apex point of the V-shape curve C_2 will intersect the U-shape curve C_1 (note that at this moment C_1 can only be a U-shape curve even if $\partial W(C_1)$ is a V cone), since C_1 is the intersection of Q and $\partial W(C_1)$ and v_i is the intersection of $\partial W(C_1)$ and s_{C_2} . Thus, C_2 becomes part of the beach line.

To show that this is the only case where a hidden curve could appear in the beach line, first it is noted that the apex segment s_{C_2} of $\partial W(C_2)$ cannot be completely outside of $\partial W(C_1)$, otherwise the initial curve of C_2 will be part of the beach line. Second, $\partial W(C_1)$ cannot be a U cone. If this is the case, then s_{C_2} is either partially or entirely inside $\partial W(C_1)$. For the first case, the middle segment s_m of the initial U-shape curve C_2 will intersect one of the two rays of C_1 , which makes C_2 be part of the beach line. For the second case, the initial U-shape curve C_2 will be hidden by C_1 . When Q moves, only the middle segment s_m of C_2 moves upwards in unit speed along the two rays of C_2 (by Lemma 9). If $\partial W(C_1)$ is a U cone, then by Lemma 9, the middle segment of C_1 will also move upwards in unit speed. Thus, it will never catch up s_m . Therefore C_2 will never be part of the beach line. Similarly the same for the case $\partial W(C_1)$ is a V cone can be proved. Thus, $\partial W(C_2)$ has to be a V cone. In this case, if s_{C_2} is completely inside of $\partial W(C_1)$, then by the same argument, it can be shown that C_2 will never be part of the beach line. Thus, the lemma follows. \square

In the above lemma, the point v_i indicates that when Q sweeps it, the beach line is having a topological structure change. Thus, v_i needs to be an event point for the plane sweep algorithm. However, since v_i is the intersection point of an apex segment and a 3-D cone, it has to be computed on the fly. This indicates that in the MGMC problem there is a new type of event points.

The ideas for constructing the Hausdorff Voronoi diagram $HVD(\mathcal{C})$ are discussed below. First, the bisector of two rectangles (or cuts) is considered. Let C_1 and C_2 be two axis-aligned rectangles in \mathcal{C} . The bisector of C_1 and C_2 is a segment with two rays as shown in Fig. 8. Each bisector contributes two vertices to the Hausdorff Voronoi diagram. Hence, the Hausdorff Voronoi diagram consists of two types of vertices: (a) The intersection points of the bisectors; and (b) The vertices of the bisectors.

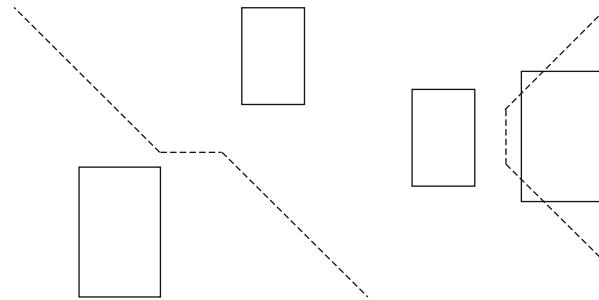

Fig. 8 Bisector is composed by a segment with two half-lines

Lemma 12 Let \mathcal{C} be a set of N rectangles. The edges of $HVD(\mathcal{C})$ are either segments or rays, and the vertices of the $HVD(\mathcal{C})$ are either the vertices of bisectors or the intersections of bisectors.

Proof Follows from the above discussion. \square

To obtain a plane sweep algorithm, it is needed to design data structures to maintain the beach line and the event points. In the MGMC problem, the beach line is the lower envelope of the set of V - and U -shape curves and is a y -monotone polygonal curve. For non-disjoint 3-D cones, the complexity of the beach line may not be linear in the number of the rectangles in \mathcal{C} . Figure 9b shows a newly generated U -shape curve intersecting the beach line a number of times and contributing multiple edges to it. Consequently, the complexity of $HVD(\mathcal{C})$ is not linear. The following lemma is a straightforward adaptation of Theorem 1 in [33] for the L_∞ metric.

Lemma 13 The size of the L_∞ Hausdorff Voronoi diagram of N rectangles is $O(N + M')$, where M' is the number of intersecting pairs of rectangles. In the worst case, the bound is tight.

2.3.3 Events

For event points, it is needed to detect all events that cause the beach line to have topological structure changes. More specifically, it is necessary to identify all the moments when a U - or V -shape curve is inserted or deleted from the beach line. There are two ways by which a curve could appear in the beach line:

- (A) A newly generated U - or V -shape curve becomes part of the beach line.
- (B) A hidden V -shape curve appears in the beach line.

There are also two ways for a curve or a portion of a curve to disappear from the beach line:

- (C) A curve (or part of the curve) becomes hidden by a newly generated curve.
- (D) A U -shape curve (or part of the U -shape curve) moves out of the beach line.

Fig. 9 The beach line L is intersected by a new U cone (dashed line) or V cone (dotted line)

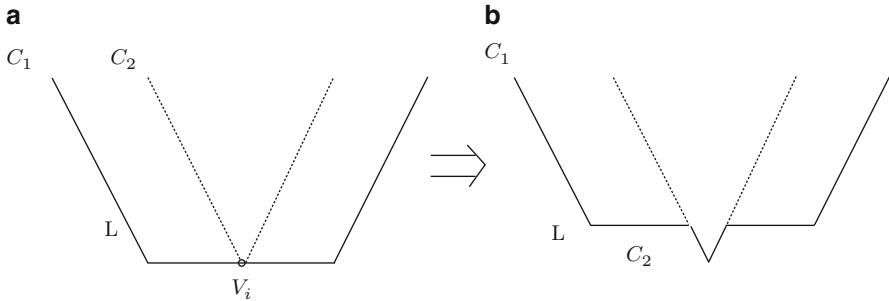

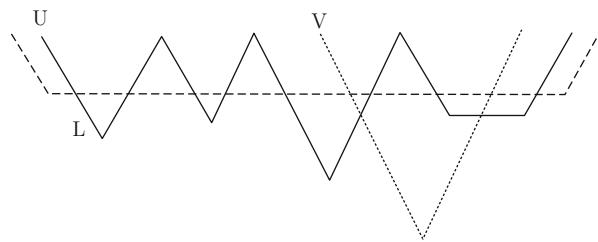

Fig. 10 (a) The *bottom* segment of U -shape curve C_1 reached V_i . (b) The hidden V -shape curve C_2 appeared on the beach line L

For (A), it is known that this is caused by the sweep plane Q encountering a new 3-D cone $\partial W(C)$. Such events can be detected in advance and are called *site events*. A site event, however, does not necessarily lead to a topological structure change to the beach line, since the new curve C can be hidden by the beach line. If $\partial W(C)$ is a U cone, the two endpoints of s_C are encountered by Q at the same time and either of them can be treated as a site event. If the corresponding U -shape curve C is not hidden, it may intersect the beach line multiple times as shown in Fig. 9. In this case, it is necessary to update the beach line for each breakpoint introduced by C . Consequently, the U -shape curve C will be partitioned into multiple pieces. Each piece is either a part of the beach line (called unhidden portion of C) or hidden by other U - or V -shape curves in the beach line (called a hidden portion of C). If $\partial W(C)$ is a V cone, then the left endpoint v_1 of s_C is encountered first and can be viewed as a site event. When Q sweeps the right endpoint v_2 of s_C , the C changes from a V -shape curve to a U -shape curve. To distinguish from the site event, v_2 is called as a U event. For unhidden V -shape curve C , it intersects the beach line at most twice (see Fig. 9).

For (B), it occurs when an unhidden portion of the bottom segment s_m of a U -shape curve C_1 moves upwards and encounters the apex point of a hidden V -shape curve C_2 . This kind of events is called V events (see Figs. 10 and 7b). The V events are not known in advance and need to be computed by using the saved information in the data structures. Note that when s_m moves upwards, its hidden portions may also encounter the apex point of some hidden V -shape curve. In this case, it is not viewed as an event since the beach line has no topological structure

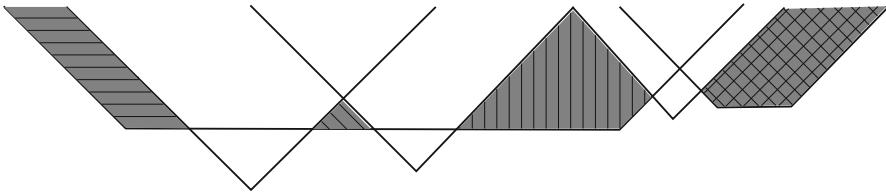

Fig. 11 Dominating regions of unhidden portions of U -shape curves

change, thus generating no new Voronoi vertex or edge. To distinguish the two cases, each unhidden portion of a U -shape curve is associated with a region, called *dominating region* (see Fig. 11), which is the region swept by the unhidden portion when it moves upwards. The dominating regions could have a few different shapes (see the shaded regions in Fig. 11), with each of them bounded by zero, one, or two 45° rays, zero, one, or two 135° rays, and an unhidden portion of the bottom segment s_m of some U -shape curve. Clearly, for a hidden V -shape curve to cause a V event, its apex point has to fall in a dominating region of an unhidden portion of a U -shape curve. Thus, to capture all V events, it is only needed to focus on those hidden V -shape curves whose apex points fall in the dominating regions.

For (C), it is obviously caused by a site event and thus can be detected in advance. For (D), the disappearing U -shape curve C (or its unhidden portion) is caused by the upward movement of the bottom segment of C . It involves three curves, C and its immediate left and right neighbors C' and C'' in the beach line. Since this event is similar to the circle event in the computation of the standard Voronoi diagram, it is also called here a circle event. The circle events cannot be detected in advance and have to be computed on the fly.

Thus, there are in total four types of events, site events, circle events, U events, and V events. The ideas on how to handle these events are discussed in the next section.

2.3.4 Data Structures and Events Handling

To construct $HVD(C)$, doubly connected edge lists are used to store $HVD(C)$. Two data structures for the plane sweep algorithm are also needed: an event queue and a sweep plane status structure representing the beach line.

The status structure for the beach line consists of three balanced binary search trees \mathcal{T} , $\mathcal{T}_{\pi/4}$, and $\mathcal{T}_{3\pi/4}$. \mathcal{T} stores the y -monotone polygonal curve of the beach line. Each part of the curve corresponds to a V -shape curve or an unhidden portion of a U -shape curve. The leaves of \mathcal{T} correspond to the V -shape curves and the unhidden portions of the U -shape curves on the beach line sorted by their y coordinates. Each leaf also stores location information of the corresponding 3-D cone. The internal nodes of \mathcal{T} adjacent to the leaves represent the breakpoints (i.e., the intersection of a pair of U or V curves) on the beach line. A breakpoint is stored at an internal node by an ordered tuple of curves $\langle C_i, C_j \rangle$, where C_i is the left curve of the breakpoint and C_j is the right curve of the breakpoint. $\mathcal{T}_{\pi/4}$ is used to maintain the

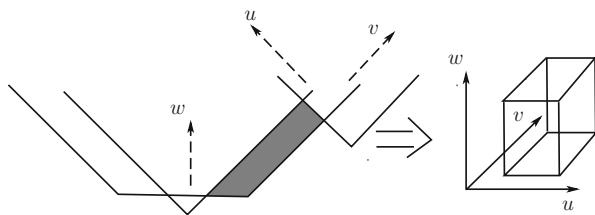

orders (along the norm direction) of the 45° rays of all U - or V -shape curves which appear in the beach line. Similarly, $\mathcal{T}_{3\pi/4}$ maintains the orders of the 135° rays of U - or V -shape curves which appear in the beach line. Each leaf node in $\mathcal{T}_{\pi/4}$ or $\mathcal{T}_{3\pi/4}$ represents a 45° or 135° ray, and each ray corresponds to a U - or V -shape curve (represented by a leaf node in \mathcal{T}) in the beach line. For each leaf node of $\mathcal{T}_{\pi/4}$ and $\mathcal{T}_{3\pi/4}$, a pointer pointing to the corresponding leaf node in \mathcal{T} is maintained. In this case, by doing binary search on $\mathcal{T}_{\pi/4}$ and $\mathcal{T}_{3\pi/4}$ and the pointers between the trees, the positions in the beach line for the apex points of each newly encountered cone at a site event could be located in $O(\log N)$ time, and the beach line is updated in $O(k \log N)$ time, where k is the number of breakpoints destroyed and created after inserting the newly encountered U - or V -shape curve into the beach line.

The event queue \mathcal{Q} is implemented by a priority queue, where the priority of an event is the x coordinate of the corresponding event point. If two points have the same x -coordinate, the one with larger y coordinate has the priority. All the site events and U -events are known in advance and are stored in \mathcal{Q} . The main challenge is to detect the V events.

For a V event, it is known that it occurs when the apex point of a hidden V -shape curve C_2 appears in the beach line. To detect such events, it is necessary to store in the data structure the information of all hidden V -shape curves. This could potentially require us to maintain the whole arrangement of all curves on \mathcal{Q} and therefore results in unnecessarily high computational cost. To efficiently detect all possible V events, the main idea is not to maintain the arrangement, but rather to use the properties of V events to convert the problem into a query problem in 3-D. To achieve this, first it is easy to see that a V event is always caused by the upward movement of an unhidden portion of the bottom segment s_m of some U -shape curve C_1 and occurs when s_m coincides with the apex point v of a hidden V -shape curve C_2 (by Lemma 11). Thus, in order to detect all possible V events, it is needed to solve the following two difficulties: (1) Identify the next V event associated with each unhidden portion of a U -shape curve, and (2) for each newly encountered hidden V -shape curve (in a site event), find the unhidden portion of a U -shape curve which will later cause a V event involving this V -shape curve. There is another one (Difficulty (3)) related to the two difficulties: How to find the exact boundary of the dominating region for a given unhidden portion c of a U -shape curve.

First Difficulty (1) is considered. For this difficulty, it is known that the next V event associated with an unhidden portion c of a U -shape curve C_1 is the hidden V -shape curve C_2 whose apex point v lies inside the dominating region of c and is the closest to the bottom segment s_m of C_1 . However, as it is noticed in the last section, the dominating region could have various shapes which seemingly suggest that it is costly to find the next V event even if the dominating region is known. To overcome this difficulty, first it is observed that the dominating region is bounded by 45° and 135° rays and the bottom segment. From Lemmas 9 and 10, it is known that the rays of any U or V curve have fixed directions (e.g., forming 45° and 135° angles with the y axis) and their supporting lines remain the same during the whole sweeping process. This suggests that the dominating regions can be orthogonalized in 3-D space. The three dimensions of the new

Fig. 12 A dominating region is converted to a 3-D box in the orthogonalized 3-D space for MD

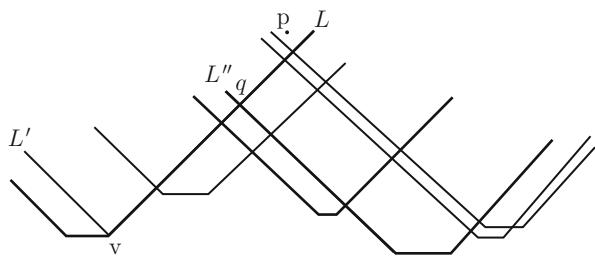

space are the orthogonal directions of the 45° and 135° lines in the sweep plane Q and the orthogonal direction of the bottom segment (or the y axis). In this way, each dominating region is converted into a (possibly unbounded) box in 3-D (see Fig. 12).

To efficiently find the next V event in the orthogonalized dominating region, the apex points of all V -shape curves are processed into a 3-D dynamic range search tree data structure MD [29, 31]. In MD, the apex point of each hidden V -shape curve is mapped into a 3-D point. Thus, for a particularly dominating region R , its orthogonalized box can be used as the query range to find the closest apex point (among all hidden V -shape curves whose apex points fall in R) to the unhidden portion of the bottom segment of a U -shape curve in $O(\log^2 N \log \log N)$ time [29].

To efficiently maintain the MD, it can be built in advance for all possible V -shape curves. In each node p of the MD tree, a mark is stored to indicate whether there is any active V -shape curve in the subtree rooted at p . A V -shape curve C is active if its corresponding 3-D cone has already been encountered by the sweep plane Q , and C has not yet changed to a U -shape curve due to a U event. In this way, it is only needed to change the marks when the status of a V -shape curve changes and therefore avoid complicate updating (such as tree rotation) to the MD.

To make use of MD, it is necessary to identify all scenarios in which it is needed to either update MD or query MD for detecting potential V events. First, it is noticed that a site event or a U event could introduce (a) a new U -shape curve C to the beach line and generate a set of unhidden portions of C and (b) a hidden V -shape curve C' . Thus, for (a), in each such event, a 3-D range query in MD is performed for each unhidden portion c_i to find the closest hidden V -shape curve to c_i in its dominating region and insert a V event into the event queue \mathcal{Q} . For (b), it is necessary to find out the exact dominating region R which contains the apex point of the newly encountered hidden V -shape curve C' (i.e., Difficulty (2)) and then insert the hidden V event into MD, since the V event of C' might be the new next V event of the unhidden portion c of R . (The idea for this challenging problem will be discussed later.) Second, after a V event, it is also necessary to perform a 3-D range query in MD to find the closest hidden V -shape curve to the new U -shape curve converted from the V -shape curve of the V event. Third, if an unhidden portion c of a U -shape curve C disappears from the beach line (e.g., a circle event), its associated V event is deleted from \mathcal{Q} , since c will never appear in the beach line again by Lemma 11.

Fig. 13 Finding the dominating region of p

The ideas for Difficulty (2) (i.e., finding the unhidden portion of the dominating region containing the apex point of a hidden V -shape curve in a site event) are discussed below. Let p be the apex point of the hidden V -shape curve. As shown in Fig. 13, finding the four rays (two 45° rays and two 135° rays) bounding p does not necessarily give us the correct dominating region. This is because the rays bounding p could be stopped by the rays bounding the actual dominating region. For example, L is stopped by L'' at point q . Thus, a ray inside a dominating region may not be a ray bounding that dominating region.

Definition 5 A ray (or a portion of a ray) is active if it bounds some dominating region and inactive otherwise.

Let l be any ray in the beach line. If starting from the bottom (i.e., the endpoint) of l and walking along it, l is active until it is stopped by some other ray and thus becomes inactive. It is easy to see that once a ray becomes inactive, it will never be active again. In Fig. 13, L is active until stopped by L'' and will no longer be active. A ray has two sides and it may not be active on both sides simultaneously. Also one side of a ray may bound more than one dominating region (L'' bounds the dominating regions generated by U -shape curves with bottom segments a and c). It is easy to see that for any ray, there is always one side bounding at most one dominating region. Otherwise, there will be an intersection between two dominating regions, thus contradicting the definition of dominating regions.

With these observations, to find out the actual dominating region of p , first the four rays bounding it are found by searching the $\mathcal{T}_{\pi/4}$ and $\mathcal{T}_{3\pi/4}$ trees. Further, it is needed to find out whether or not these rays are active on the sides containing p . To determine this, it is needed to know whether each of the four rays has been stopped by other rays. If the ray L which stops these rays can be found out, then it means that p belongs to the dominating region bounded by L . This means that for a given ray, it is needed to have a way to efficiently determine which ray stops it.

To achieve this, the $\mathcal{T}_{\pi/4}$ and $\mathcal{T}_{3\pi/4}$ trees are augmented. For each node of the trees, the z -coordinate of the lowest bottom (segment) of all rays in the subtree rooted at that node is stored. The z -coordinate of the bottom segment of a V -shape curve is the z -coordinate of its apex point minus the length of bottom segment of the

3-D V cone. With the augmented information, the ray L'' which stops a ray L can be searched in the two trees in $O(\log N)$ time.

To better understand the idea, consider the example in Fig. 13. Let L be a 45° ray with its endpoint v . A ray L'' which stops L is a 135° ray if it exists. To find L'' , another 135° ray L' with endpoint v is created. First the position of L' is searched in $\mathcal{T}_{3\pi/4}$. Then it is only needed to find the ray between L' and p (in the direction of L) with (1) lower z -coordinate than v and (2) the closest z -coordinate. This can be done by following the searching path of L' in $\mathcal{T}_{3\pi/4}$ upwards until finding a node satisfying the two conditions and then moving downwards to locate the ray L'' . In Fig. 13, the dominating region with bottom segment b dominates p .

Lemma 14 *It takes $O(\log N)$ time to find out the exact dominating region of an unhidden portion c for the apex point p of the hidden V -shape curve C' generated by the site event.*

Proof Follows from the above discussion. \square

It is not difficult to see that the augmented information can be maintained during the whole sweep process within the same time bound. With the augmented information, the exact boundary of a dominating region R for an unhidden portion c of a U -shape curve (i.e., Difficulty (3)) can also be found in $O(\log N)$ time following the same idea (i.e., finding the rays stopping the bounding rays of R).

Circle events can be handled in a way similar to the standard Voronoi diagram. More specifically, every new triple of consecutive U - or V -shape curves that appear in the beach line is checked. If such a new triple has converging breakpoints, the event is inserted into the event queue \mathcal{Q} . Furthermore, for all disappearing triples, the corresponding event is de-queued from \mathcal{Q} if it has been inserted.

2.3.5 Algorithm and Analysis

The entire plane sweep algorithm is described below. The main steps of the algorithm are as follows.

Algorithm HAUSDORFF-VORONOI-DIAGRAM(\mathcal{C})

Input. A set \mathcal{C} of axis-aligned rectangles (or geometric minimal cuts) in the plane.

Output. The Hausdorff Voronoi diagram in a doubly connected edge list \mathcal{D} .

1. Initialize the event queue \mathcal{Q} with all site events and U events; initialize empty sweep plane status structures \mathcal{T} , $\mathcal{T}_{\pi/4}$, and $\mathcal{T}_{3\pi/4}$, and an empty doubly-connected edge list \mathcal{D} ; initialize a 3-D range search tree MD for all possible V -shape curves with all nodes marked as inactive.
2. **while** \mathcal{Q} is not empty
3. **do** Remove an event with the smallest x -coordinate from \mathcal{Q} .
4. **if** the event is a site event, **then** HANDLE-SITE-EVENT.
5. **if** the event is a circle event, **then** HANDLE-CIRCLE-EVENT.
6. **if** the event is a U -event, **then** HANDLE-U-EVENT.
7. **else** the event is a V event; HANDLE-V-EVENT.

HANDLE-SITE-EVENT

1. Let C be the new curve. If the status structure is empty, insert C into it and mark the apex point in MD as active if it is a V cone. Otherwise, continue with steps 2–8.
2. If C is a V -shape curve, mark its apex point in MD as active and continue with steps 3–5.
3. Locate the position of the apex point of C in the beach line by searching $\mathcal{T}, \mathcal{T}_{\pi/4}$, and $\mathcal{T}_{3\pi/4}$.
4. If C is not hidden, insert C to the beach line by updating $\mathcal{T}, \mathcal{T}_{\pi/4}$, and $\mathcal{T}_{3\pi/4}$. This includes inserting C into the beach line, computing new breakpoints, inserting possible circle events into \mathcal{Q} , and removing all curves hidden by C from the beach line. If an unhidden portion of a U -shape curve is removed, delete its corresponding V event from \mathcal{Q} . If an unhidden portion of a U -shape curve is partially blocked by C , search for its closest hidden V -shape curve in the reduced dominating region if necessary.
5. Else if (the apex of) C is inside the dominating region an unhidden portion c of a U -shape curve C' , update the associated V event of c if needed.
6. Else if C is a U -shape curve, continue with steps 7–8.
7. Locate the position of C in the beach line by searching $\mathcal{T}, \mathcal{T}_{\pi/4}$, and $\mathcal{T}_{3\pi/4}$.
8. If C is not fully hidden, insert C into the beach line by updating $\mathcal{T}, \mathcal{T}_{\pi/4}$, and $\mathcal{T}_{3\pi/4}$. This includes computing possibly multiple breakpoints and the corresponding circle events for all its unhidden portions, removing blocked curves (similarly to Step 4), and finding the possible V event for each unhidden portion of C and partially blocked unhidden portion.

HANDLE-CIRCLE-EVENT

1. Update the beach line by updating $\mathcal{T}, \mathcal{T}_{\pi/4}$, and $\mathcal{T}_{3\pi/4}$. Delete unnecessary circle events from \mathcal{Q} involving the part disappearing from the beach line. If an unhidden portion of a U -shape curve moves out of the beach line, delete its associated V event.
2. Add the vertex to \mathcal{D} . Two new breakpoints of the beach line will be traced out.
3. Check the new triples involving the left or right neighbor of the disappearing part and insert the corresponding circle event into \mathcal{Q} , if necessary.

HANDLE-U-EVENT

1. If the V -shape curve C introduced by the V cone appeared on the beach line, the corresponding part of the beach line is changed from a V -shape curve to a U -shape curve. Update $\mathcal{T}, \mathcal{T}_{\pi/4}$, and $\mathcal{T}_{3\pi/4}$, and add vertex to \mathcal{D} . Also find the possible V event for C by querying MD, and insert it into \mathcal{Q} .
2. Mark the node in MD containing C as inactive, and update its ancestors if needed.
3. Detect the circle events and insert them into \mathcal{Q} if necessary.

HANDLE-V-EVENT

1. Update $\mathcal{T}, \mathcal{T}_{\pi/4}$, and $\mathcal{T}_{3\pi/4}$ by inserting the V -shape curve C into the beach line. Create new breakpoints, detect the possible circle event, and insert them into \mathcal{Q} .
2. For the corresponding unhidden portion c of a U -shape curve C' , break it into two unhidden portions, c' and c'' , and find possible new V event for c' and c'' , respectively by querying MD.

Theorem 4 *The L_∞ Hausdorff Voronoi diagram $HVD(\mathcal{C})$ of a set \mathcal{C} of geometric minimal cuts (or axis-aligned rectangles) can be constructed by a plane sweep algorithm in $O((N + K) \log^2 N \log \log N)$ time, where $N = |\mathcal{C}|$ and K is the complexity of the Hausdorff Voronoi diagram.*

Proof The discussion of the algorithm shows that $HVD(\mathcal{C})$ can be constructed by a plane sweep algorithm. Thus, the proof focuses on the time complexity.

First, site events are considered. Let C be a newly encountered U - or V -shape curve. If C is a V -shape curve, it is either part of the wavefront or a hidden V -shape curve. For the former case, the computation cost includes inserting C into the beach line and updating MD and \mathcal{D} . The cost for these is $O(\log^2 N \log \log N + k \log N)$, where k is the total number of breakpoints hidden by C . Since each breakpoint corresponds to a Voronoi vertex in $HVD(\mathcal{C})$, the cost of $O(k \log N)$ can be charged to the breakpoints (and their corresponding Voronoi edges). Thus, each will be charged a cost of $O(\log N)$. The cost of $(\log^2 N \log \log N)$ can be charged to each V -shape curve. For the latter case, if C is not in the dominating region of any unhidden portion of a U -shape curve, the only cost is $O(\log^2 N \log \log N)$, which can be charged to C . If C is inside the dominating region of some unhidden portion c of a U -shape curve which can be checked in $O(\log N)$ time, it is also needed to check whether C is the closest V -shape curve to c , and this can be done in $O(1)$ time. Thus, in the latter case, C is charged a cost of $O(\log^2 N \log \log N)$. If C is a U -shape curve, it could be fully hidden by the beach line, and thus, will never appear in the beach line in a later time. In this case, the total cost is $O(\log N)$, which can be charged to C . If C appears in the beach line and contributes some unhidden portions, then it is needed to update the sweep plane status structure, which takes $O(k \log N)$ time, and find the closest V -shape curve for each unhidden portion c . The cost of $O(k \log N)$ can be evenly charged to all hidden and newly created breakpoints. Thus, each of them will be charged a cost of $O(\log N)$. The closest V -shape curve to each unhidden portion c can be found by a query to MD, which takes $O(\log^2 N \log \log N)$ time and can be charged to the breakpoint bounding c . In a site event, up to two unhidden portions can be partially hidden by the newly encountered U - or V -shape curve C . In this case, each of them may need to find a new closest hidden V -shape curve in its reduced dominating region. For this, the cost of $O(\log^2 N \log \log N)$ is charged to the new breakpoint created by the two rays of C and the two unhidden portions. Thus, after processing all site events, each V -shape curve will be charged a cost of $(\log^2 N \log \log N)$, and each U -shape curve will be charged a cost of $O(\log N)$. Some breakpoints will be charged a cost of $O(\log^2 N \log \log N)$.

Clearly, each circle event can be handled in $O(\log N)$ -time, and the total number of such events is bounded by $O(K)$. Thus, the total cost for all circle events is $O(K \log N)$.

For U events, there are only $O(N)$ such events. Each event takes $O(\log^2 N \log \log N)$ time to update MD, and find the closest hidden V -shape curve to the new U -shape curve. Again, all the cost is charged to the V -shape curve.

For V events, it is clear from the algorithm, that each such event takes $O(\log^2 N \log \log N)$ time. To bound the total cost of all V events, it is needed to bound their total number. For this, it is noticed that at any moment, (1) Each unhidden portion of a U -shape curve is associated with only one hidden V -shape curve; and (2) The association of a hidden V -shape curve C and an unhidden portion c of a U -shape curve can change for only two reasons: (a) The dominating region of c changes (in a site event), and (b) a new hidden V -shape curve C' is activated and C' is closer to c than C . For (a), it means that part of c is hidden by other U - or V -shape curve C'' and the cost of de-association can be charged to the edges or vertices introduced by C'' . For (b), the cost of de-association can be charged to C' . Each V -shape will be charged no more than once. This means that computation cost of each V event can be charged to the Voronoi edge or vertex corresponding to the two breakpoints bounding the unhidden portion. Each Voronoi vertex and edge is charged a constant times with a total cost of $O(\log^2 N \log \log N)$. Thus, the total cost for all V events is $O(K \log^2 N \log \log N)$.

Putting all together, the total cost is $O((N + K) \log^2 N \log \log N)$. Thus, the theorem follows. \square

3 The MGMC Problem via Higher-Order Voronoi Diagrams

In this section, we present the iterative approach of [34] to the MGMC problem via higher-order Voronoi diagrams. A more general version of the MGMC problem is addressed in this section, where the embedded subgraph H corresponds to arbitrary polygonal shapes. The polygonal shapes are not assumed rectilinear, but they may consist of edges in arbitrary orientation. A polygonal shape is reduced to a collection of (additively) weighted line segments by means of its L_∞ medial axis. The approach is complementary to the one presented in Sect. 2 and it does not precompute any minimal cuts. On the contrary, it discovers those geometric minimal cuts that are guaranteed to participate in the final map, on the fly, by iteratively constructing variants of higher-order Voronoi diagrams. At the end of the iteration, the derived subdivision is the Hausdorff Voronoi diagram of all geometric cuts, that is, the solution to the MGMC problem. Definitions, results, and most figures in this section are reproduced from [34].

3.1 The MGMC Problem in a VLSI Layout

In a VLSI setting, the *geometric min-cut* problem is as follows [34]: We are given a collection of geometric graphs that have portions embedded on a plane (a VLSI layer) A . The embedded portions on plane A are vulnerable to random defects that may form *cuts* on the given graphs. A defect of size r is a disk of radius r . The size of a geometric cut C at a given point t is the size of the smallest defect centered at t that overlaps all elements in C , as opposed to the number of edges in C in the classic min-cut problem. Compute, for every point t on the vulnerable plane A , the

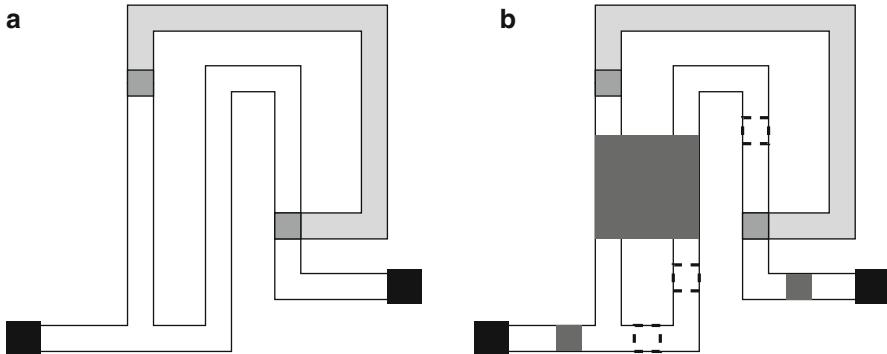

Fig. 14 (a) A net N spanning over two layers. (b) Dark defects create opens while transparent defects cause no faults

size of the minimum defect causing a geometric cut at t . The size of the minimum geometric cut at a point t is the *critical radius* for open faults at t . The resulting subdivision is referred to as the *opens Voronoi diagram*, and it corresponds to the map of the MGMC problem.

Figure 14a, reproduced from [34], illustrates an example of a simple VLSI net N spanning over two metal layers, say M1 and M2, where M2 is illustrated shaded. The two contacts illustrated as black squares are designated as *terminal shapes*. A VLSI net remains functional as long as terminal shapes remain interconnected. In Fig. 14b, defects that create open faults are illustrated as dark squares, and defects that cause no fault are illustrated hollow in dashed lines. Hollow defects do break wires of layer M1; however, they do not create opens as no terminals get disconnected.

A compact graph representation for a VLSI net N , denoted $G(N)$, can be obtained as follows: Each graph node of $G(N)$ represents a connected component of a net N on a conducting layer, and two nodes are connected by an edge if there exists at least one contact or via connecting the respective components of N . Some of the shapes constituting net N are designated as *terminal* representing the entities that the net must interconnect. A node containing terminal shapes is designated as a *terminal node*.

Given a layer A of interest, the *extended graph* of N on A , $G(N, A)$, is derived from $G(N)$ by expanding the components of N on layer A by their medial axis. Contact points between neighboring layers are approximated as points on the medial axis of the corresponding shape, called *via points*. Any via point or any portion of the medial axis corresponding to terminal shapes is identified as terminal. Figure 15a illustrates $G(N, A)$, where $A = M1$, for the net of Fig. 14; terminal points are indicated by hollow circles; dashed lines represent the original M1 polygon and they are not part of $G(N, A)$. $G(N, A)$ can be cleaned up from any trivial parts [34] by computing biconnected components, bridges, and articulation points. In the following, we assume that $G(N, A)$ is free from any trivial parts, as shown in Fig. 15b. The collection of $G(N, A)$ for all nets N involved on a layer A is the graph

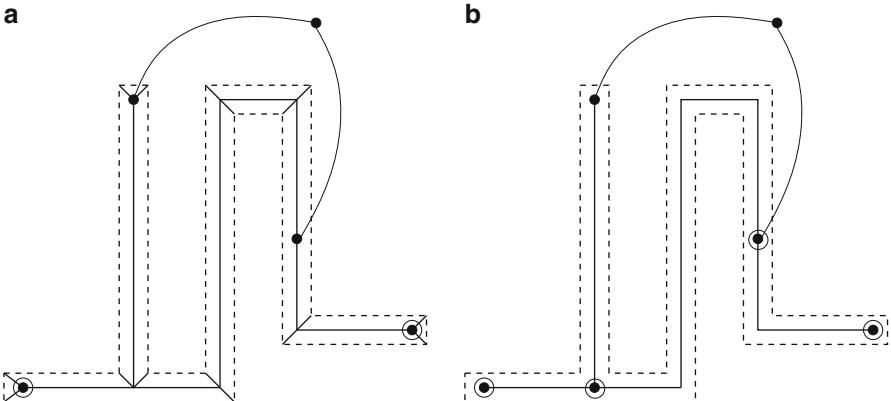

Fig. 15 The net graph of Fig. 14 before (a) and after (b) clean-up of trivial parts

of the MGMC problem, and its portion on layer A is the planar embedded subgraph H . For more details on the derivation of $G(N, A)$, see [34].

3.2 Review of Concepts on L_∞ Voronoi Diagrams

The Voronoi diagram of a set of polygonal sites in the plane is a partitioning of the plane into regions, one for each site, called *Voronoi regions*, such that the Voronoi region of a site s is the locus of points closer to s than to any other site. The Voronoi region of s is denoted as $\text{reg}(s)$ and s is called the *owner* of $\text{reg}(s)$. In the interior of a simple polygon, the Voronoi diagram is known as the *medial axis* of the polygon (a minor difference in the definition is ignored (see [26])). The boundary between two Voronoi regions is called a *Voronoi edge* and it consists of portions of *bisectors* between the owners of the neighboring regions. The bisector of two polygonal objects (such as points, segments, polygons) is the locus of points equidistant from the two objects. A point where three or more Voronoi edges meet is called a *Voronoi vertex*.

The L_∞ distance between two points $p = (x_p, y_p)$ and $q = (x_q, y_q)$ is $d(p, q) = \max\{|x_p - x_q|, |y_p - y_q|\}$. In the presence of additive weights, the (weighted) distance between p and q is $d_w(p, q) = d(p, q) + w(p) + w(q)$, where $w(p)$ and $w(q)$ denote the weights of points p and q , respectively. In case of a weighted line l , the (weighted) distance between a point t and l is $d_w(t, l) = \min\{d(t, q) + w(q), \forall q \in l\}$. The (weighted) bisector between two polygonal elements s_i and s_j is $b(s_i, s_j) = \{y \mid d_w(s_i, y) = d_w(s_j, y)\}$.

In L_∞ , any Voronoi edge or vertex can be treated as an additively weighted line segment. For brevity and in order to differentiate from ordinary line segments, the term *core segment*, more generally *core element*, is used to denote any portion of interest along an L_∞ Voronoi edge or vertex. The term *standard-45°s* is used

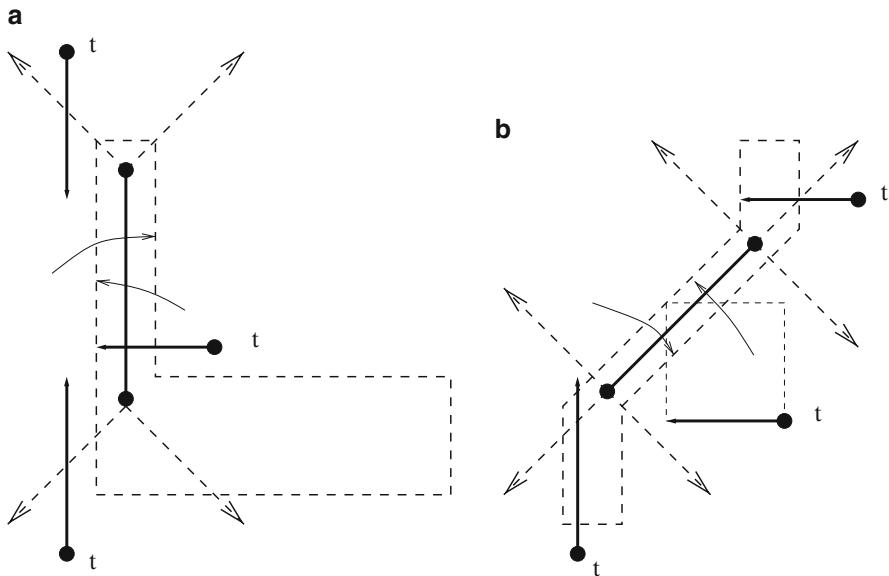

Fig. 16 The regions of influence of the core elements of a core segment: two endpoints and an open line segment. (a) an axis-parallel core segment, (b) a non-axis-parallel core segment

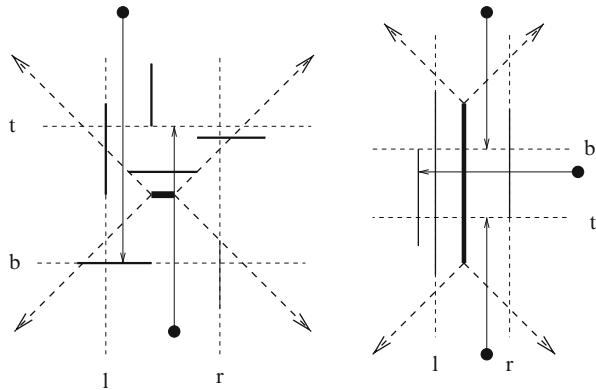

to refer to Voronoi edges of slope ± 1 that correspond to bisectors of axis-parallel lines. Figure 16 illustrates examples of core segments.

Let s be a core segment induced by the polygonal elements e_l, e_r . Every point p along a core segment s is weighted with $w(p) = d(p, e_l) = d(p, e_r)$, where e_l, e_r are the polygonal elements inducing s . The 45° rays³ emanating from the endpoints of s partition the plane into the regions of influence of either the open core segment portion or the core endpoints. In Fig. 16, the L_∞ distance is indicated by straight-line arrows emanating from various points t . In the north and south (resp. east and west) regions, the L_∞ distance simplifies to a vertical (resp. horizontal) distance. In the region of influence of a non-axis-parallel core segment, it is measured by the side of a square touching e_i as shown in Fig. 16b. In the region of influence of a core point p , distance is measured in the ordinary weighted sense, that is, for any point t , $d_w(t, p) = d(t, p) + w(p)$. In the region of influence of an open core segment s , distance, in essence, is measured according to the farthest polygonal element defining s , that is, $d_w(t, s) = d(t, e_i)$, where e_i is the polygonal element at the opposite side of s than t ; see, for example, the small arrows in Fig. 16. In L_∞ , this is equivalent to the ordinary weighted distance between t and s . For more details see [34].

The (weighted) bisector between two core elements is defined in the ordinary way, always taking the weights of the core elements into consideration. Similarly, the (weighted) Voronoi diagram of a set of core elements is defined as above,

³A 45° ray is a ray of slope ± 1 .

Fig. 17 The L_∞ farthest Voronoi diagram of axis parallel segments

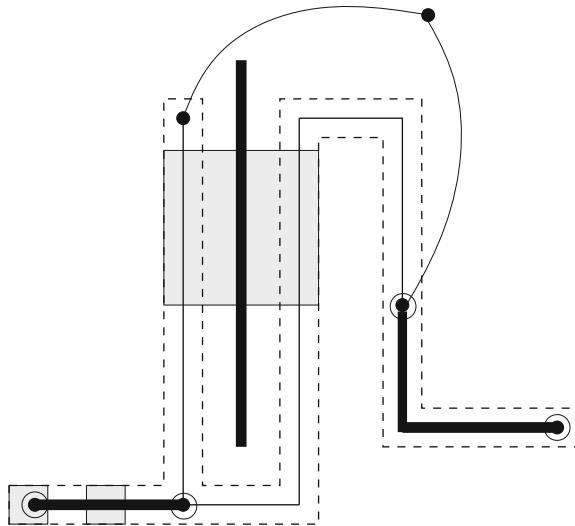

with the difference that distance between a point t and a core element s is always measured in an additive weighted sense, $d_w(t, s)$. The (weighted) Voronoi diagram of *core* medial axis segments was first introduced in [32] as a solution to the critical area computation problem for a simpler notion of an open, called *break*, that was based solely on geometric information. For Manhattan geometries, core segments are simple (additively weighted) axis-parallel line segments and points.

The *farthest Voronoi diagram* of a set of polygonal sites is a partitioning of the plane into regions, such that the *farthest Voronoi region* of a site s is the locus of points *farther away* from s than from any other site. For typical cases (e.g., points, line segments), it is a tree-like structure consisting only of unbounded regions (see, e.g., [4, 6]). In the L_∞ metric, when sites are points or axis-parallel segments, its structure is particularly simple, consisting of exactly four regions as shown in Fig. 17. In each region, the L_∞ distance to the farthest element is measured as the vertical or horizontal distance to an axis-parallel line marked by t, b, l, r , where t (resp. b) is the horizontal line through the topmost (resp. bottommost) lower (resp. upper) endpoint of all core segments and l (resp. r) is the vertical line through the leftmost (resp. rightmost) right (resp. left) endpoint of all core segments. In Fig. 17, the thin arrows indicate the farthest L_∞ distance of selected points.

3.3 Definitions and Problem Formulation

Let $\text{core}(N, A)$ denote the collection of all core elements of a net N on a layer A , that is, the collection of all medial axis vertices and edges of $G(N, A)$ on A that are of interest. For simplicity, all standard 45° edges are excluded from $\text{core}(N, A)$. The union of $\text{core}(N, A)$ for all nets N on layer A is denoted as $\text{core}(A)$. Core segments and points in $\text{core}(A)$ represent all wire segments vulnerable to defects on layer A and correspond to weighted line segments. Core segments are assumed to consist of three distinct core elements: two endpoints and an open line segment. Open faults are determined based on the connectivity information of $G(N, A)$ and the geometry information of $\text{core}(N, A)$.

Fig. 18 Generators for strictly minimal opens

Definition 6 A *minimal open* is a defect D of minimal size that breaks a net N , that is, if D is shrunk by $\epsilon > 0$, then D no longer breaks N . An *open* is any defect that entirely overlaps a minimal open. A minimal open is called *strictly minimal* if it contains no other open in its interior.

Definition 7 The center point of an open D , is called a *generator point* for D and it is weighted with the radius of D . The generator of a strictly minimal open is called *critical*. A segment formed as the union of generator points is called a *generator segment* or simply a *generator*.

In Fig. 14, strictly minimal opens are illustrated by dark shaded disks, other than the original via and contact shapes. Figure 18 illustrates the generators for strictly minimal opens for the net of Fig. 14, thickened; the shaded squares indicate strictly minimal opens. For brevity, we say that a defect D *overlaps* a core element $c \in \text{core}(A)$, but we mean that D overlaps the entire width of the wire segment induced by c .

Definition 8 A *cut* for a net N is a collection C of core elements, $C \subset \text{core}(N, A)$, such that $G(N, A) \setminus C$ is disconnected leaving nontrivial articulation or terminal points in at least two different sides. A cut C is called minimal if $C \setminus \{c\}$ is not a cut for any element $c \in C$. A defect of minimal size that overlaps all elements of cut C is called a *cut-inducing* defect. The centerpoint p of a cut-inducing defect that encloses no other defect in its interior is called a *generator point* for cut C . If, in addition, the cut-inducing defect is a strictly minimal open, then p is called *critical*. The collection of all generator points of a cut C is referred to as the *generator(s)* of C .

The generator of a cut C can consist of *critical* and *noncritical* portions. Critical portions correspond to generators of strictly minimal opens. Noncritical portions correspond to centers of cut-inducing disks that, in addition to overlapping C , may also overlap some additional cut on a layer A , and thus, although they break C , they do not correspond to strictly minimal opens.

Definition 9 Generators of minimal cuts that consist of a single core element are called *first-order generators*. Generators of minimal cuts that consist of more than one core element are called *higher-order generators*. The set of all critical generators on layer A is denoted as $G(A)$.

In Fig. 18 first-order generators are illustrated as the thickened core segments in the interior of polygons; the vertical thick segment in the exterior of polygons is a higher-order generator that involves a pair of core elements. Given $G(N, A)$, we can detect *biconnected components*,⁴ *bridges*, and *articulation points*⁵ using *depth-first search* (DFS) as described in [21, 42]. By definition, we have the following property.

Lemma 15 *The set of first-order generators on a layer A , denoted as $G_1(A)$, consists of all the bridges, terminal edges, articulation points, and terminal points of $G(N, A) \cap \text{core}(N, A)$, for all nets N . All first-order generators are critical.*

The generator of a minimal cut C that consists of more than one core element must be a subset of the L_∞ farthest Voronoi diagram of C , derived by ignoring the standard-45° edges of the diagram. For Manhattan geometries, the generator of any cut is always a single axis-parallel segment (that can degenerate to a point); see, for example, Fig. 17. Any generator point p of a cut C is weighted with $w(p) = \max\{d_w(p, c), \forall c \in C\}$. The disk D centered at p of radius $w(p)$ is clearly an open. If in addition D is strictly minimal, then p is a critical generator.

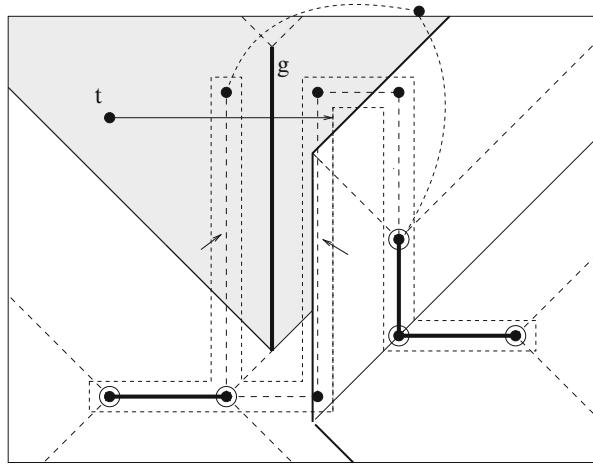

Definition 10 The *Voronoi diagram for opens* on a layer A is a subdivision of A into regions, such that the *critical radius* of any point t in a Voronoi region is determined by the owner of the region. The critical radius of a point t , $r_c(t)$, is the size (radius) of the smallest defect centered at t and causing an open.

The following theorem is easy to see by properties of Voronoi diagrams. For a proof, see [34].

⁴A biconnected component of a graph G is a maximal set of edges, such that any two edges in the set lie on a common simple cycle.

⁵An articulation point (resp. bridge) of a graph G is a vertex (resp. edge) whose removal disconnects G .

Fig. 19 The Voronoi diagram for open faults on layer A . The shaded region illustrates the Voronoi region of the higher-order generator g

Theorem 5 *The Voronoi diagram for open faults on a layer A corresponds to the (weighted) Voronoi diagram of the set $G(A)$ of all critical generators for strictly minimal opens on A , denoted as $\mathcal{V}(G(A))$.*

Figure 19 illustrates the opens Voronoi diagram for the net of Fig. 14. The shaded region illustrates the Voronoi region of a higher-order generator g , $reg(g)$. Generator g is the critical generator of a cut consisting of two core segments as indicated by two small arrows. The critical radius of a sample point t in $reg(g)$ is indicated by the arrow emanating from t .

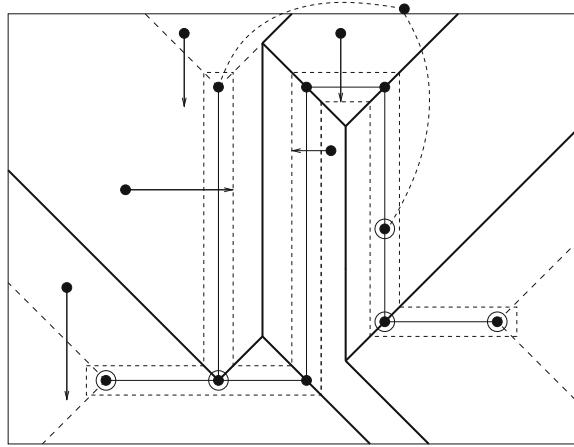

Corollary 3 *Given the opens Voronoi diagram, the critical radius of any point t in the region of a generator g is $r_c(t) = d_w(t, g)$. If g is a higher-order generator of cut C , then $r_c(t) = d_w(t, g) = \max\{d_w(t, c), \forall c \in C\}$.*

In the following section, the Voronoi diagram for opens is formulated as a special higher-order Voronoi diagram of elements in $core(A)$.

3.4 A Higher-Order Voronoi Diagram Modeling Open Faults and the MGMC Problem

Let $\mathcal{V}(A)$ denote the (weighted) Voronoi diagram of the set $core(A)$ of all core elements on a plane (layer) A . If there were no loops associated with A , then $\mathcal{V}(A)$ would provide the opens Voronoi diagram on A , and $core(A)$ would be the set of all critical generators. $\mathcal{V}(A)$ for Manhattan layouts has been defined in detail in [32]. Figure 20 illustrates $\mathcal{V}(A)$ for the net graph of Fig. 14. The arrows in Fig. 20 illustrate several minimal radii of defects that break a wire segment. Given a point t in the region of generator s , $d_w(t, s)$ gives the radius of the smallest defect centered at t

Fig. 20 The L_∞ Voronoi diagram of $\text{core}(A)$ on layer A , $\mathcal{V}(A)$

that overlaps the wire segment induced by s . Assuming no loops, $d_w(t, s)$ would be the critical radius of t .

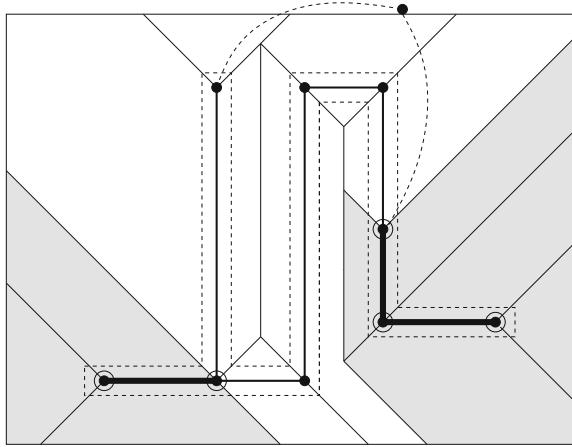

Once loops are taken into consideration, only bridges, articulation, and terminal points, among the elements of $\text{core}(A)$, correspond to critical generators. Let us augment $\mathcal{V}(A)$ with information reflecting critical generators. In particular, the regions of first-order generators get colored red reflecting the regions of critical generators. The critical radius of point t in a red region of owner s is $r_c(t) = d_w(t, s)$. In Fig. 21, red regions are shown shaded and critical generators are shown thickened.

Let us now define the order- k Voronoi diagram on the plane A , denoted as $\mathcal{V}^k(A)$. For $k = 1$, $\mathcal{V}^k(A) = \mathcal{V}(A)$. Following the standard definition of higher-order Voronoi diagrams, a region of $\mathcal{V}^k(A)$ corresponds to a maximal locus of points with the same k nearest neighbors among the core elements in $\text{core}(A)$. The open portion of a core segment and its two endpoints count as different entities. A k th-order Voronoi region, $k > 1$, belongs to a k -tuple C representing the k nearest neighbors of any point in the region of C . The region of C is denoted $\text{reg}(C)$, and it is further subdivided into finer subregions by the farthest Voronoi diagram of C . For any point $t \in \text{reg}(C)$, $d(t, C) = \max\{d(t, c), \forall c \in C\}$. If C constitutes a cut of a net N , then the region of C is colored red.

In order to appropriately model open faults, the above standard definition is slightly modified, and in certain cases fewer than k elements are allowed to own a Voronoi region of order k . In the following, the term *k-th order Voronoi diagram* implies the modified version of the diagram as follows:

- A red region corresponds to a maximal locus of points with the same r , $1 \leq r \leq k$, nearest neighbors, C , among the core elements in $\text{core}(A)$, such that C constitutes a minimal cut for some net N .
- Any time a core segment s and one of its endpoints p participate in the same set C of nearest neighbors, s is discarded from C ; this is because $d(t, p) \geq d(t, s)$

Fig. 21 The first-order opens Voronoi diagram on layer A , $\mathcal{V}^1(A)$. Shaded regions belong to first-order generators and the critical radius of any point within is determined by the region owner

$\forall t \in \text{reg}(C)$. Intuitively, a defect that destroys a core endpoint automatically also destroys all incident core segments, but not vice versa.

Figures 22 and 23 illustrate $\mathcal{V}^2(A)$ and $\mathcal{V}^3(A)$, respectively, for the net of our example. k th-order Voronoi regions are illustrated in solid lines; red regions are illustrated shaded. The darker shaded region in $\mathcal{V}^2(A)$ shows the 2nd-order red region of a pair of core segments that constitute a cut. The thick dashed lines indicate the farthest Voronoi diagram subdividing a k th-order region. In a red region, the thick dashed lines (excluding standard 45°s) correspond to critical generators. All critical generators are indicated thickened; solid ones are first-order generators and dashed ones in red regions are higher-order generators. All thin dashed lines in Figs. 21–23 can be ignored. Due to our conventions, the Voronoi region of any core endpoint p in $\mathcal{V}^1(A)$ remains present in $\mathcal{V}^2(A)$ and expands into the regions of the core segments incident to p .

Theorem 6 *The Voronoi diagram for opens on a layer A is the minimum-order m Voronoi diagram of $\text{core}(A)$, $\mathcal{V}^m(A)$, $m \geq 1$, such that all regions of $\mathcal{V}^m(A)$ are colored red. Any region $\text{reg}(H)$, where $|H| > 1$, is subdivided into finer regions by the farthest Voronoi diagram of H . The critical radius for any point t in $\text{reg}(H)$ is $r_c(t) = d_w(t, H) = \max\{d_w(t, h), h \in H\}$.*

For a proof of Theorem 6, see [34]. Figure 24 illustrates the opens Voronoi diagram, for our example; arrows indicate the critical radius of several points; all critical generators are indicated in thick solid lines. Note that in L_∞ , the Voronoi subdivision is not unique but depends on the conventions used on how to distribute regions that are equidistant from collinear elements on axis-parallel lines. Critical area calculations are immune to such differences, however, they may have an effect on the number of iterations needed to compute the opens Voronoi diagram. The adapted convention is that critical generators have priority over non-critical ones and regions equidistant from a critical and a noncritical generator are assigned to the critical one and get colored red.

Fig. 22 The second-order opens Voronoi diagram, $\mathcal{V}^2(A)$. The darker shaded region belongs to a pair of core segments forming a cut

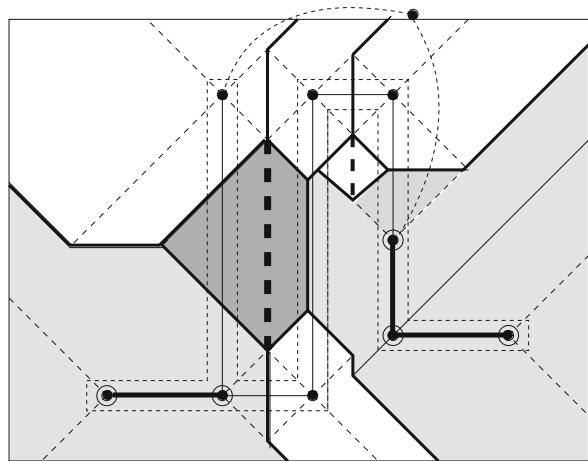

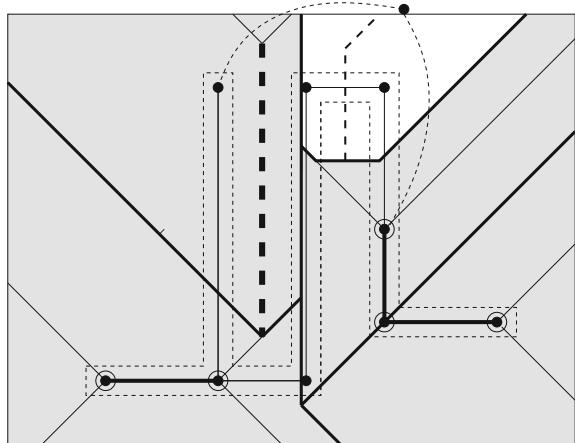

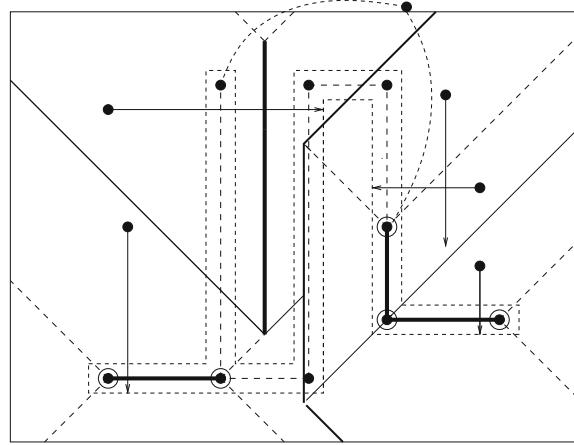

Fig. 23 The third-order opens Voronoi diagram, $\mathcal{V}^3(A)$

Corollary 4 *The higher-order critical generators on a layer A are exactly the farthest Voronoi edges and vertices, excluding the standard- 45° Voronoi edges, constituting the farthest Voronoi subdivisions in the interior of each region in $\mathcal{V}^m(A)$. All higher-order critical generators are encoded in the graph structure of $\mathcal{V}^k(A)$, for some k , $1 \leq k < m$.*

Let $G(A)$ denote the set of all critical generators on layer A , including first-order and higher-order generators. Let us classify higher-order critical generators according to the minimum-order- k Voronoi diagram they first appear in. In particular,

Fig. 24 The Voronoi diagram for open faults on a layer A . Arrows illustrate the critical radius of several points

higher-order generators encoded in $\mathcal{V}^k(A)$ are classified as $(k + 1)$ -order generators and they are denoted as $G_{k+1}(A)$, $1 \leq k < m$. Let $G(A) = \cup_{1 \leq i \leq m} G_i(A)$. By [Theorems 5 and 6](#), $\mathcal{V}(G(A))$ and $\mathcal{V}^m(A)$ are identical.

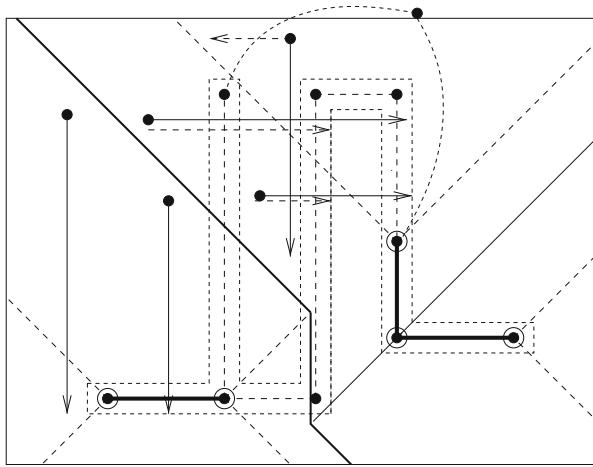

3.4.1 An Approximate Opens Voronoi Diagram

Given any subset $G'(A)$ of the set of critical generators $G(A)$, the (weighted) Voronoi diagram of $G'(A)$ can be used as an approximation to $\mathcal{V}(G(A))$. Clearly, the more critical generators are included in $G'(A)$, the more accurate the result is. In practice, we can derive $G'(A)$ as $\cup_{1 \leq i \leq k} G_i(A)$, including all i th-order generators up to a small constant k . Since the significance of critical generators reduces drastically with the increase in their order, $\mathcal{V}(G'(A))$ should be sufficient for critical area computation for all practical purposes.

Corollary 5 Let $G'(A) = \cup_{1 \leq i \leq k} G_i(A)$ be a subset of critical generators including all generators up to order k for a given constant k . The (weighted) Voronoi diagram of $G'(A)$, $\mathcal{V}(G'(A))$, can serve as an approximation to the opens Voronoi diagram. If $G'(A) = G(A)$, then the two diagrams are equivalent.

[Figure 25](#) illustrates the (weighted) Voronoi diagram of $G_1(A)$. $\mathcal{V}(G_1(A))$ reveals critical radii for opens under the (false) assumption that all loops are immune to open faults. In [Fig. 25](#), solid arrows indicate selected critical radii as derived by $\mathcal{V}(G_1(A))$, while dashed arrows indicate true critical radii. Several critical radii can be overestimated in $\mathcal{V}(G_1(A))$, resulting in underestimating the total critical area for open faults. As k increases, however, $\mathcal{V}(\cup_{1 \leq i \leq k} G_i(A))$ converges fast to $\mathcal{V}(G(A))$ (see, e.g., Sect. 8 of [34] for experimental results).

Fig. 25 $\mathcal{V}(G_1(A))$ as an approximate opens Voronoi diagram

3.5 Computing the Opens Voronoi Diagram

In this section, we give algorithmic details on how to compute $G_{k+1}(A)$ and $\mathcal{V}^{k+1}(A)$, given $\mathcal{V}^k(A)$, for $1 \leq k < m$. We also discuss how to compute $\mathcal{V}(\cup_{1 \leq i \leq m} G_i(A))$ and $\mathcal{V}(G(A))$.

The iterative process to compute higher-order generators and higher-order opens Voronoi diagrams. Let's first discuss how to identify the set $G_{k+1}(A)$ of $(k+1)$ -order generators, given $\mathcal{V}^k(A)$, for $k \geq 1$. The following property is shown in [34].

Lemma 16 *A Voronoi edge g that bounds two non-red Voronoi regions $reg(H)$ and $reg(J)$ in $\mathcal{V}^k(A)$ corresponds to a critical generator if and only if both the core elements $h \in H$ and $j \in J$ that induce g ($g \in b(h, j)$) are part of the same biconnected component B , and in addition, $H \cup J$ corresponds to a cut of B , that is, removing $H \cup J$ from B disconnects B , leaving articulation points in at least two sides. No Voronoi edge bounding a red region can be a critical generator.*

To determine if Voronoi edge g is a critical generator, we need to pose a connectivity query to biconnected component B after removing $H \cup J$. To perform connectivity queries efficiently, we can use the fully dynamic connectivity data structures of [20], which support edge insertion and deletions in $O(\log^2 n)$ -time, while they can answer connectivity queries fast. For simplicity in the implementation, instead of employing dynamic connectivity data structures, reference [34] gives a simple (almost brute force) algorithm as follows: Remove the elements of H from B and determine new nontrivial bridges, articulation points, and biconnected components of $B \setminus H$. For any Voronoi edge g bounding $reg(H)$, where g is portion of $b(h, j)$, $h \in H$, $j \in J$, g is a critical generator if and only if j is a new non-trivial

bridge or articulation point of $B \setminus H$. Generator g gets associated with the tuple of core elements $H \cup J$, simplified, in case j or h are core endpoints, by removing any core segment incident to j, h .

The above process can be considerably simplified in the special case where the biconnected component B is a simple cycle. In this case, a simple coloring scheme in the DFS tree of B can efficiently identify all cuts of B that may be associated with a second-order generator. The time complexity of determining $G_{k+1}(A)$, given $\mathcal{V}^k(A)$, is summarized in the following lemma. Note that the size of $\mathcal{V}^k(A)$ is $O(k(n - k))$ (see [26]).

Lemma 17 *The $(k + 1)$ -order generators can be determined from $\mathcal{V}^k(A)$ in time $O(kn \log^2 n)$ using the dynamic connectivity data structures of [20] or in time $O(kn^2)$ using the simple algorithm presented above. In case of biconnected components forming simple cycles, second-order generators can be determined from $\mathcal{V}(A)$ in $O(n)$ time.*

Let us now discuss how to obtain $\mathcal{V}^{k+1}(A)$ from $\mathcal{V}^k(A)$, $k \geq 1$. The following is an adaptation of the iterative process to compute higher-order Voronoi diagrams of points [26], to the case of (weighted) segments. Let $reg(H)$ be a non-red region of $\mathcal{V}^k(A)$. Let $N(H)$ denote the set of all core elements that induce a Voronoi edge bounding $reg(H)$ in $\mathcal{V}^k(A)$.

1. Compute the (weighted) L_∞ Voronoi diagram of $N(H)$ and truncate it within the interior of $reg(H)$; this gives the $(k + 1)$ -order subdivision within $reg(H)$. Each $(k + 1)$ -order subregion of $reg(H)$ is attributed to a tuple $J = H \cup \{c\}$, $c \in N(H)$. In case c is a core endpoint incident to a core segment s in H , J simplifies to $J = H \setminus \{s\} \cup \{c\}$. In case c is part of a cut C owning a neighboring red region of $\mathcal{V}^k(A)$, the subregion of J gets colored red and gets as owner the cut C .
2. Once the $(k + 1)$ -order subdivision within all non-red regions neighboring $reg(H)$ has been performed, merge any incident $(k + 1)$ -order subregions that belong to the same tuple of owners J into a maximal $(k + 1)$ -order region, $reg(J)$. The edges of $\mathcal{V}^k(A)$ included within $reg(J)$ constitute the finer subdivision of $reg(J)$ by its farthest Voronoi diagram. All $(k + 1)$ -order red subregions are merged into the neighboring red regions of $\mathcal{V}^k(A)$ forming the maximal red regions of $\mathcal{V}^{k+1}(A)$.

Using established bounds for higher-order Voronoi diagrams of points (see, e.g., [26]) we conclude the following.

Lemma 18 *$\mathcal{V}^{k+1}(A)$ can be computed from $\mathcal{V}^k(A)$ in time $O(k(n - k) \log n)$, plus the time $T(k, n)$ to determine the $(k + 1)$ -order generators, where $T(k, n)$ is as given in Lemma 17.*

3.5.1 Computing the Opens Voronoi Diagram from Critical Generators

The iterative process of Sect. 3.5 can continue until all regions are colored red and the complete opens Voronoi diagram (i.e., the map of the MGMC problem) is guaranteed to be available. By Lemmas 17 and 18, this results in

an $O(n^3 \log n (\log \log n)^3)$ -time algorithm. In practice, however, this would be unnecessarily inefficient. Note that the iterative process may continue for several rounds without any new critical generators being identified, only the regions of existing critical generators keep enlarging into neighboring non-red regions. Note also that as the number of iterations k increases, the weight of order- k critical generators (if any) increases as well, and their contribution to the total critical area drastically reduces. In practice, we can restrict the number of iterations to a small predetermined constant k , or to a small number determined adaptively, and compute only a sufficient set of critical generators $G'(A) = \cup_{1 \leq i \leq k} G_i(A)$. We can then use **Theorem 5** to report $\mathcal{V}(G'(A))$ as an approximate opens Voronoi diagram. The overall algorithm can be broken into two independent parts:

- Part I: Compute the set of critical generators $G'(A) = \cup_{1 \leq i \leq k} G_i(A)$, up to a given (or adaptively determined) order k .
- Part II: Compute the (weighted) Voronoi diagram of $G'(A)$, $\mathcal{V}(G'(A))$, as the opens Voronoi diagram.

Part I can be performed using the iterative process of [Sect. 3.5](#). Experimental results in [34] suggest that $k = 2$ is often adequate and no $k > 4$ is ever needed. Alternatively, k can be determined adaptively, for example, to the first round such that no new critical generators are determined. Part II can be performed using a plane sweep algorithm for computing $\mathcal{V}(A)$. Critical generators have similar properties to the core elements of $\text{core}(A)$, and the same plane sweep algorithm can be used to compute either (see [32, 36]). The computations of Parts I and II can be synchronized: once a generator is discovered in Part I, it can be immediately scheduled for processing in Part II. For more details on the plane sweep construction and the synchronization of Parts I and II that is important in maintaining the locality of the computation see [34]. We thus conclude:

Theorem 7 *Assuming that $G(N)$ is available for all nets under consideration and given a small constant k , the approximate opens Voronoi diagram $\mathcal{V}(G'(A))$, $G'(A) = \cup_{1 \leq i \leq k} G_i(A)$ can be computed in time $O(n \log n)$ plus the time needed to answer connectivity queries. The latter can be done in time $O(n \log^2 n)$.*

The original implementation of this method, whose experimental results are reported in [34], used a slightly different approach in order to guarantee accuracy while the locality property was preserved. Namely, the iterative process of [Sect. 3.5](#) was applied to each biconnected component independently. The advantages of considering each biconnected component independently were locality as well as the ability to run the process on each individual component to completion and guarantee the accuracy. The disadvantage was that generators produced in this manner, $G''(A)$, did not need all be critical. Including noncritical generators in the set $G''(A)$ complicates the algorithm of Part II because it amounts to computing the *Hausdorff Voronoi diagram* of corresponding geometric minimal cuts on layer A . Note that critical generators can be treated as simple additively weighted segments, having special weights, such that Voronoi regions remain connected and the entire generator is always enclosed in its Voronoi cell. This property considerably simplifies the construction of their (weighted) Voronoi diagram, which is, the Hausdorff Voronoi

diagram, which remains similar to the construction of ordinary Voronoi diagrams of line segments. Once non-critical generators are present, however, this property no longer holds and the algorithms is equivalent to constructing the Hausdorff Voronoi diagram of the corresponding cuts as presented in Sects. 2.3 and 4.

For information on critical area computation once the solution to the MGMC problem is available, see, for example, [32, 34, 36].

4 The L_∞ Hausdorff Voronoi Diagram

In this section, we review structural properties of the L_∞ Hausdorff Voronoi diagram of clusters of points, or equivalently, the L_∞ Hausdorff Voronoi diagram of rectangles, presented in [39]. The L_∞ Hausdorff Voronoi diagram of rectangles provides a solution to the MGMC problem after geometric minimal cuts have been identified. Results in this section are reproduced from [39].

Given a set S of point clusters in the plane, the *Hausdorff Voronoi diagram* of S , denoted $HVD(S)$, is a subdivision of the plane into regions, such that the *Hausdorff Voronoi region* of a cluster P , denoted $hreg(P)$, is the locus of points *closer* to P than to any other cluster in S , where distance between a point t and a cluster P is measured as the *farthest distance* between t and any point in P , $d_f(t, P) = \max\{d(t, p), p \in P\}$, $hreg(P) = \{x \mid d_f(x, P) < d_f(x, Q), \forall Q \in S\}$. It is subdivided into finer regions by the *farthest Voronoi diagram* of P , $FVD(P)$. The farthest distance $d_f(t, P)$ is equivalent to the *Hausdorff distance*⁶ $d_h(t, P)$ between t and P . In the L_∞ metric, $d_f(t, P)$ (equiv. $d_h(t, P)$) is equivalent to $d_f(t, P')$ (equiv. $d_h(t, P')$), where P' is the minimum enclosing axis-aligned rectangle of P . Thus, the L_∞ Hausdorff Voronoi diagram of S is equivalent to the L_∞ Hausdorff Voronoi diagram of the set S' of the minimum enclosing rectangles of all clusters in S . In the following, the terms cluster and rectangle are used interchangeably.

In this section, we review the tight bound on the structural complexity of the L_∞ Hausdorff Voronoi diagram given in [39]. It is shown that the structural complexity of the L_∞ Hausdorff Voronoi diagram is $\Theta(n + m)$, where n is the number of input clusters (equiv. rectangles) and m is the number of *essential pairs of crossing* clusters (see Definition 11). We also review a simple plane sweep construction in two dimensions given initially in [32] and improved in [39]. The improved algorithm consists of an $O((n + M) \log n)$ -time preprocessing step, based on *point dominance* in \mathbb{R}^3 , followed by the main plain sweep algorithm that runs in $O((n + M) \log n)$ -time and $O(n + M)$ -space, where M reflects special crossings that are *potentially essential* (see Definition 12); m, M are $O(n^2)$, $m \leq M$, but $m = M$, in the worst case. In practice, typically, $m, M \ll n^2$. For non-crossing rectangles the algorithm simplifies to optimal $O(n \log n)$ -time and $O(n)$ -space.

⁶The (directed) Hausdorff distance from a set A to a set B is $h(A, B) = \max_{a \in A} \min_{b \in B} \{d(a, b)\}$. The (undirected) Hausdorff distance between A and B is $d_h(A, B) = \max\{h(A, B), h(B, A)\}$.

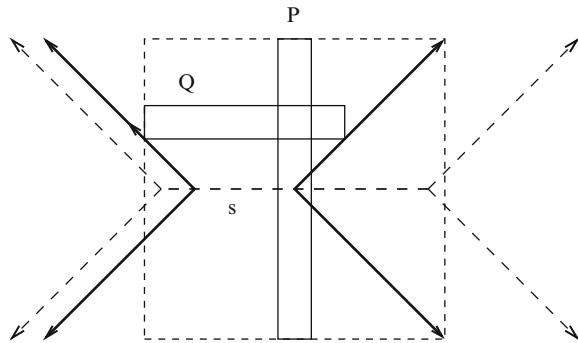

An $O(n \log n)$ -expected time algorithm can be derived in the case of non-crossing rectangles using the randomized incremental construction for abstract Voronoi diagrams [24] (see [1]). For arbitrary rectangles, however, the L_∞ Hausdorff Voronoi diagram does not fall under the umbrella of *abstract Voronoi diagrams* [23] (see, e.g., [38]). This algorithm is efficient for a relatively small number of crossing rectangles as motivated by the critical area application. For a large number of crossings, the $O(n^2)$ -time approach of [11] can be preferable. Section 2.3 presented an output-sensitive version of the plane sweep construction in three dimensions of increased space complexity.

4.1 Definitions and Structural Complexity

Let S be a set of n rectangles, or a set of n point clusters in the plane, where each cluster has been substituted by its minimum enclosing axis aligned rectangle. A pair of rectangles (P, Q) is called *crossing* if P and Q intersect in the shape of a cross. Given a crossing pair (P, Q) , P is assumed to be at least as long as Q . For a rectangle P , let P^n, P^s, P^e , and P^w denote the north, south, east, and west edges of P , respectively. P is called horizontal (resp. vertical) if P^n is longer (resp. shorter) than P^e . The axis-parallel line through edge P^i , $i = n, s, e, w$, is denoted as $l(P^i)$. The term P^i is also used to denote the main coordinate of edge P^i . The *core segment* of P is the locus of centers of all minimum enclosing squares of P , and it is given by the axis-parallel line segment of the L_∞ farthest Voronoi diagram of P . It can be viewed as an ordinary line segment s additively weighted with $w(s) = d_f(s, P)$. In Fig. 26, $FVD(P)$ is illustrated in dashed lines and the core segment is indicated by s . The L_∞ Hausdorff Voronoi diagram of S is equivalent to the (weighted) Voronoi diagram of the set of *core segments* of all clusters in S (see [32]).

The Hausdorff bisector between two clusters P, Q is $b_h(P, Q) = \{y \mid d_f(y, P) = d_f(y, Q)\}$. As shown in [38], $b_h(P, Q)$ is a subgraph of $FVD(P \cup Q)$. For a rectangle Q strictly enclosed in the interior of a minimum enclosing square of P , $b_h(P, Q)$ consists of either one (if P and Q are non-crossing) or two (if P and Q are crossing) chains, each one forming a V-shape out of the ± 1 -slope rays of $FVD(P \cup Q)$; the apex of each chain is called a *V-vertex*. A V-vertex v is incident to the core segment of P and its 90° -angle faces the portion of the plane closer to P . It is characterized as *up*, *down*, *right*, or *left*, depending on whether its 90° -angle is facing north, south, east, or west, respectively. In addition, it is characterized as *crossing*, if Q is crossing P , and *non-crossing*, otherwise. The minimum enclosing square of P centered at V-vertex v is also enclosing Q and it is denoted as $\text{square}(P, v)$. It is also denoted as $\text{square}(P, Q^i)$, where Q^i is the non-crossing edge of Q that delimits one of its edges. Figure 26 illustrates $b_h(P, Q)$ consisting of two crossing V-vertices, one right and one left; $\text{square}(P, Q^w)$ is illustrated dashed. $\text{square}(P, Q^i)$ is referred to as an *extremal minimum enclosing square* of P and Q . The V-vertices of $HVD(S)$ are referred to as *Voronoi V-vertices*.

Fig. 26 The L_∞ Hausdorff bisector of crossing rectangles

Definition 11 A pair of crossing rectangles (P, Q) is called *essential* if there is an extremal minimum enclosing square of P and Q , $\text{square}(P, Q^i)$, that is empty of any other rectangle.

The following lemma is easy to see.

Lemma 19 A pair of crossing rectangles (P, Q) induces a Voronoi V-vertex v in $\text{HVD}(S)$ if and only if (P, Q) is an essential crossing. Assuming that P is a vertical rectangle, v is a right (resp. left) V-vertex if and only if $\text{square}(P, Q_i^w)$ (resp. $\text{square}(P, Q_i^e)$) is empty of other rectangles. Similarly for a horizontal rectangle.

Combining Lemma 19 with the structural complexity results of [38], the following bound can be derived (see [39] for details).

Theorem 8 The structural complexity of the L_∞ Hausdorff Voronoi diagram of a set S of n point clusters, equivalently n rectangles, is $\Theta(n + m)$, where m is the total number of essential crossings.

Definition 12 A collection of crossings for a vertical rectangle P , (P, Q_i) , $i = 1, \dots, k$, is called a *staircase*, if $Q_i^w < Q_{i+1}^w$ and $Q_i^e < Q_{i+1}^e$, $i = 1, \dots, k$. If in addition, $\text{square}(P, Q_i^w)$ is empty of $Q_j \neq Q_i$, the staircase and its crossings are called *potentially essential*. The maximum size of a potentially essential staircase for P is the *number of potentially essential crossings* for P . Let M denote the total number of potentially essential crossings for all vertical rectangles in S , plus the number of essential crossings for all horizontal rectangles in S .

Figure 27 shows a potentially essential staircase for a vertical rectangle P . In the absence of additional rectangles, all crossings are essential, that is, they all induce Voronoi V-vertices in the Hausdorff Voronoi diagram. The shaded regions in Fig. 27 belong to $\text{hreg}(P)$.

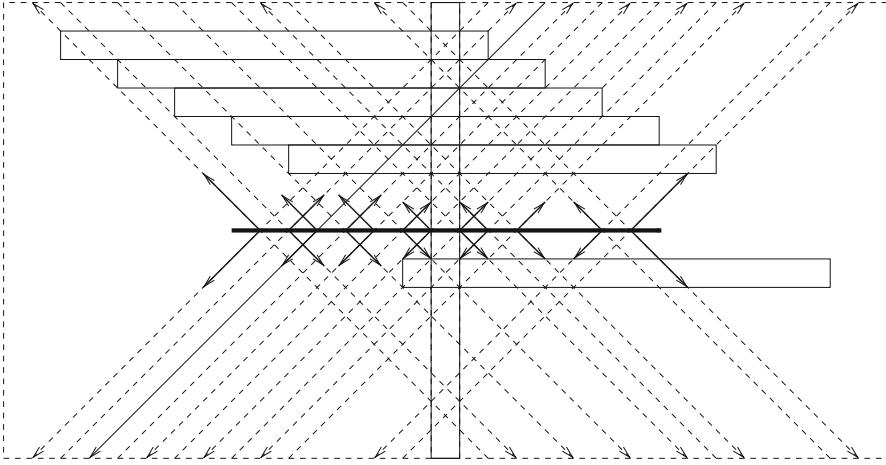

Fig. 27 Collection of essential crossings. Shaded regions belong to P

4.2 A Refined Plane Sweep Construction

In this section we present the plane sweep construction of [32, 39]. It is based on the standard plane sweep paradigm for Voronoi diagrams [8, 15], its adaptation for line segments in L_∞ [36], and the generalization to handle the special features of Hausdorff Voronoi diagrams introduced in [32, 33]. In the Hausdorff Voronoi diagram, sites need not be enclosed in their Voronoi regions and Voronoi regions may be disconnected, which are features not addressed by the standard plane sweep paradigm for Voronoi diagrams.

Assume a vertical sweep-line l_t sweeping the entire plane from left to right. At any instant t of the sweeping process, $HVD(S_t \cup l_t)$ is computed, for $S_t = \{P \in S \mid l(P^e) < t\}$. The boundary of the Voronoi region of l_t is the *wavefront* at time t . Voronoi edges and core segments incident to the wavefront are called *spike bisectors* and *spike core segments*, respectively. The combinatorial structure of the wavefront changes at specific *events* organized in a priority queue. We have four types of *site events*: *start-vertical-rectangle*, *end-vertical-rectangle*, *V-vertex* events (for brevity *V events*), and *horizontal-rectangle* events. Site events are partially similar to those for ordinary line segments [36] enhanced with additional functions to handle V-vertices and disconnected Voronoi regions. *Spike events* are caused by the intersection of incident spike bisectors, and they remain the same as in the ordinary plane sweep paradigm.

The *wave-curve* of a rectangle R is the bisector between R and the sweep line l_t , at time t , $b(R, l_t) = \{y \mid d_f(y, R) = d(y, l_t)\}$, where $d(y, l_t)$ is the ordinary distance between y and l_t . In L_∞ , it consists of two or three *waves*: a ray of slope -1 , corresponding to $b(R^s, l_t)$, a ray of slope $+1$, corresponding to $b(R^n, l_t)$, and possibly a vertical line segment corresponding to $b(R^w, l_t)$, if appropriate. The wave-curve of R can be seen equivalently as the (weighted) bisector between the

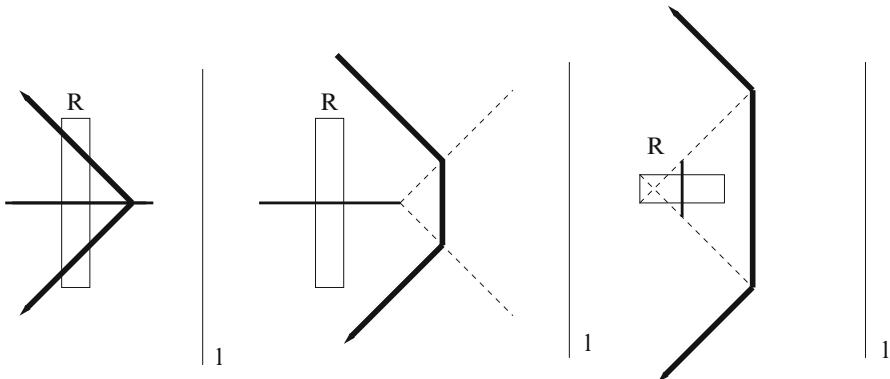

Fig. 28 The wave-curve of a rectangle R

core segment s of R and l_t , that is, $b(R, l_t) = \{y \mid d_w(y, s) = d(y, s) + w(s) = d(y, l_t)\}$. In Fig. 28, the wave-curve of several instances of rectangles is illustrated. The bold axis-aligned segment illustrates the core segment of R . The *wavefront* (equiv. the *beach line*) at time t is the lower envelope with respect to the sweep-line, of the *wave-curves* of all rectangles in S_t . Note that the term *beach line* of Sect. 2.3 is equivalent to the term *wavefront* of this section, which follows the terminology of [39]. In L_∞ , the wavefront is monotone with respect to any line of slope ± 1 . The wavefront is typically maintained as a height balanced binary tree, \mathcal{T} , ordered from bottom to top. Leaf nodes correspond to waves, while internal nodes correspond to spike bisectors and spike core segments revealing *breakpoints* between incident waves.

In [39], \mathcal{T} gets augmented with nonstandard additional information in order to efficiently answer queries regarding V-vertices. This augmentation is essential for the time complexity bound of the main plane sweep algorithm. Each node x is augmented with a *w-max* value representing the rightmost west edge of all rectangles contributing a wave to the portion of the wavefront rooted at x , and two *x-min* values (*x-min-I* and *x-min-II*) that in combination represent the minimum x -coordinate of the portion of the wavefront rooted at x . In particular, for a leaf node representing a wave of rectangle R , the *w-max* value is R^w and both *x-min* values are $+\infty$. For an internal node x , *w-max* is the maximum between the *w-max* values of its children. If node x corresponds to a horizontal (resp. ± 1 -slope) bisector, then *x-min-I* (resp. *x-min-II*) points to the breakpoint of minimum x -coordinate among its own breakpoint and the *x-min-I* (resp. *x-min-II*) values of its children; otherwise *x-min-I* (resp. *x-min-II*) points to the breakpoint of minimum x -coordinate among its children only. The minimum x -coordinate of the portion of the wavefront rooted at node x is $x\text{-min} = \min\{\text{x-min-I}, \text{x-min-II}\}$. The augmentation values *w-max*, *x-min-I*, *x-min-II* remain the same unless a combinatorial change in the wavefront (i.e., an event) takes place.

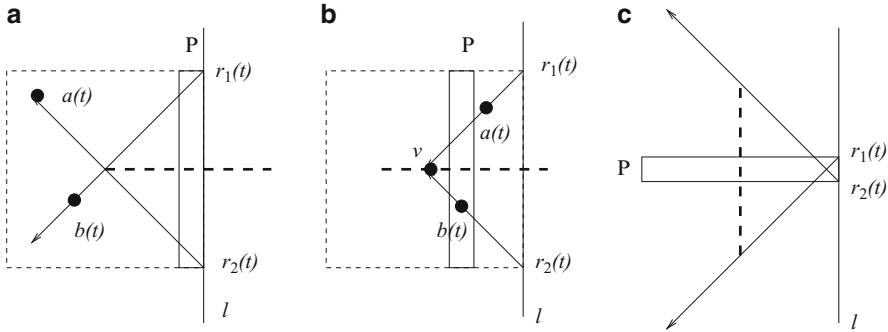

Fig. 29 (a) At $t = \text{priority}(P)$ the wavefront has not reached s . (b) An invalid event at time $t = \text{priority}(v)$. (c) A horizontal rectangle event

Any Voronoi point in $HVD(S)$ enters the wavefront at the time of its *priority*. The *priority* of a point v is the rightmost x -coordinate of the smallest square centered at v that is entirely enclosing the rectangle P that induces v . The priority of a rectangle P is denoted as $\text{priority}(P)$ and corresponds to the x -coordinate of P^e .

Let us now discuss the handling of various types of events of a rectangle P of core segment s (see Fig. 29). At time t , let $r_1(t)$ and $r_2(t)$ be the rays of slope $+1$ and -1 , respectively, emanating from $l(P^n) \cap l_t$, and $l(P^s) \cap l_t$, respectively, extending towards the left of l_t . Let $a(t)$ and $b(t)$ be the intersection points of $r_1(t)$ and $r_2(t)$ with the wavefront, respectively, at time t . Since the wavefront is ± 1 monotone, $a(t)$ and $b(t)$ can be determined by binary search in $O(\log n)$ time. In case of a wave collinear with $r_1(t)$ or $r_2(t)$, the rightmost endpoint is assigned to $a(t), b(t)$, adopting the convention that an equidistant region is assigned to the rectangle preceding P . Because the wavefront is monotone with respect to any line of slope ± 1 , in case of a vertical rectangle, the entire portion of the wavefront between $a(t)$ and $b(t)$ must be either to the left (Fig. 29a) or the right (Fig. 29b) of the intersection point of $r_1(t)$ and $r_2(t)$, and thus, it may intersect $r_1(t), r_2(t)$, or the core segment of s at most once. For a horizontal rectangle (Fig. 29c), the wavefront can intersect the vertical core segment of P a number of times.

Consider time $t = \text{priority}(P)$. There are three cases: (1) The wavefront has not reached core segment s yet (either at a start-vertical-rectangle or a horizontal-rectangle event); (2) The wavefront has already covered portion of s , where s is horizontal (start-vertical-rectangle event); and (3) The wavefront has already covered a portion of s but s is not horizontal (horizontal-rectangle event).

In case 1, the handling of the corresponding event (a start-vertical-rectangle or a horizontal-rectangle event) is similar to processing an ordinary line-segment event [32, 36]: The portion of the wavefront between $a(t)$ and $b(t)$ is finalized and gets substituted by the wave-curve of P . There is one new action to take: For any crossing V-vertex on the finalized portion of the wavefront, induced by a rectangle Q , generate a V event for the right V-vertex of $b_h(P, Q)$ and insert it to the event queue.

In case 2 (start-vertical rectangle event), a V event is generated to predict the first right V-vertex along s (if any). Given the wavefront, perform a binary search in the augmented wavefront to determine the wave between $a(t)$ and $b(t)$ with the rightmost w-max value as induced by a rectangle Q . If no other information is available, generate a V event for the right V-vertex of $b_h(P, Q)$. Note that at a start-rectangle event, Q must be non-crossing with P . Case 3 will be discussed later at a horizontal-rectangle event.

A V event v is processed similarly. If at time $t = \text{priority}(v)$ the event is *invalid*, i.e., the wavefront has already covered v , generate a new V event, given the wavefront, as described above. In particular, let Q be the rectangle inducing the wave with the rightmost w-max value among the waves between $a(t)$ and $b(t)$. If no additional information is available and assuming that Q is crossing P , generate a V event for the right V-vertex of $b_h(P, Q)$.

End-rectangle events are similar to right events of [32]. For a proof of correctness in handling vertical-rectangle events, see Lemma 2 in [39].

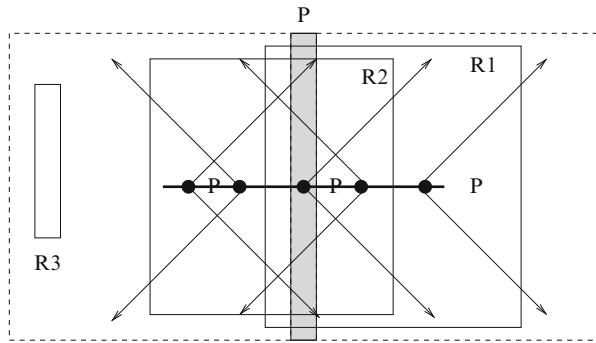

A horizontal-rectangle event is processed at time $t = \text{priority}(P)$. The problem is to identify the intersections (V-vertices) of the wavefront with the vertical core segment s (if any). Note that at time t , the wavefront may intersect s a number of times, each intersection corresponding to a V-vertex, where only the first and the last may be non-crossing V-vertices. If there are no intersections because the wavefront has not reached any portion of s yet, then we have Case 1 of $t = \text{priority}(P)$ discussed earlier. Otherwise, this is Case 3. Any portion of the wavefront to the left of s is finalized and gets substituted by the wave-curve of P as fragmented by the V-vertices and their incident spike bisectors.

To identify V-vertices efficiently, the x -min value of the augmentation is used. Let r be the breakpoint of minimum x -min value between $a(t)$ and $b(t)$. If r is to the right of s , then s must be entirely covered by the wavefront and there can be no intersections, that is, $hreg(P) = \emptyset$. Otherwise, trace the wavefront sequentially, starting at r , until the first intersections above and below r are determined. The intersection above (resp. below) corresponds to a *down* (resp. *up*) V-vertex v (resp. u). Repeat the process for the portions of the wavefront above v and below u until all intersections are determined. Any time the x -min value of a portion of the wavefront is to the right of s , this portion can be eliminated as it contains no intersections with s . The correctness of handling of a horizontal-rectangle event follows easily. A horizontal rectangle event covers also squares.

The time complexity of the plane sweep algorithm, as presented, is $O((n + m + E) \log n)$, where E is the number of invalid V events. There are two reasons for invalid V events: (1) Potentially essential staircases of vertical rectangles whose crossings are not all essential; and (2) Sequences of *strongly dominated* vertical rectangles, even in the case of non-crossing rectangles. Given a pair of vertical rectangles (P, Q) , P is said to *dominate* Q if $Q^w < P^w$ and $Q^n < P^n$, $Q^s > P^s$. If, in addition, there is a minimum enclosing square of Q that is crossing P , P is said to *strongly dominate* Q .

To eliminate source-2 of invalid V-vertex events, a preprocessing step can be added to the algorithm that precomputes *dominating sequences* of vertical

Fig. 30 The dominating sequence of rectangle P consisting of rectangles R_1, R_2, R_3

rectangles, which is described in [39]. Given the preprocessing information, the number of all V events generated is bounded by $O(n + M)$ as shown in [39].

Definition 13 The *dominating sequence* of a vertical rectangle P , denoted $ds(P)$, is a maximal collection of vertical rectangles $R_i, i = 1, \dots, k$, such that every R_i is entirely enclosed in a minimum enclosing square of P , R_1 is the rectangle with the rightmost west edge among all rectangles dominated by P , and if R_i is crossing P , $i \geq 1$, then R_{i+1} is the vertical rectangle with the rightmost west edge dominated by $\text{square}(P, R_{i-1}^e)$.

Every R_i in the *dominating sequence* of P , except possibly the last rectangle R_k , is crossing P . Rectangle R_1 in the dominating sequence of P is referred to as the *rightmost* rectangle dominated by P . In the case of non-crossing rectangles, the dominating sequence of P is R_1 (if not empty). Figure 30 shows the dominating sequence of a vertical rectangle P consisting of three rectangles R_1, R_2, R_3 . Considering only those four rectangles, the region of P is alternating with regions of R_i on the core segment of P , as shown in Fig. 30. Lemma 3 in [39] shows that the dominating sequence of P (except the last rectangle R_k , if R_k is non-crossing with P) forms a maximal staircase of vertical rectangles crossing P that is potentially essential. No vertical rectangle, other than the dominating sequence of P , may induce a right Voronoi V-vertex on the core segment of P , even when only $ds(P)$ is considered. Given the dominating sequences of vertical rectangles, every time a V event is generated, source-2 of invalid V events can be completely eliminated. The exact algorithmic details are given in [39].

Using the information of dominating sequences of vertical rectangles, the total number of V events that may be produced throughout the algorithm is shown in [39] to be $O(n + M)$. The problem of computing the dominating sequence of every vertical rectangle can be transformed into a *point dominance* problem in \mathbb{R}^3 which can be solved by plane sweep in $O((n + M) \log n)$ -time, as described in Sect. 4 of [39]. Combining with Lemma 3 of [39] we conclude.

Theorem 9 *HVD(S) can be computed by plane sweep in $O((n + M) \log n)$ -time and $O(n + M)$ -space. In the case of non-crossing rectangles, this results in optimal $O(n \log n)$ -time and $O(n)$ -space.*

For the plane-sweep algorithm to compute dominating sequences of vertical rectangles, see [39] (Sect. 4). It is based on a simple transformation to a variant of the standard *point dominance* problem in R^3 (see, e.g., [40]) and the use of an auxiliary standard *priority search tree* [28].

5 Conclusion

Given a graph $G = (V, E)$ with a subgraph H embedded in the plane, this chapter presented the problem of computing the *map of geometric minimal cuts* (MGMC) of H , as induced by axis-aligned rectangles in the embedding plane. It surveyed two different approaches for the solution of the MGMC problem [34, 47], that were based on a mix of geometric and graph-algorithm techniques. The chapter also surveyed results on the related Hausdorff Voronoi diagram, which provides a solution to the MGMC problem.

Abstract

The *max-coloring problem* is a natural generalization of the classical vertex coloring problem. The input is a vertex-weighted graph. The objective is to produce a proper coloring such that the overall weight of color classes is minimized, where the weight of each class is defined to be the *maximum weight* of vertices in that class.

Max-coloring has received significant attention over the last decade. Approximation algorithms and hardness results are now known for a number of graph classes in both the off-line and online setting. The objective of this chapter is to survey the algorithmic state of the art for the max-coloring problem.

1 Introduction

The *max-coloring problem* is a natural generalization of the classical vertex coloring problem. The input is a vertex-weighted graph. The objective is to produce a proper coloring such that the overall weight of color classes is minimized, where the weight of each class is defined to be the *maximum weight* of vertices in that class. More formally, let $G = (V, E)$ be an undirected graph and $w : V \rightarrow \mathbb{N}$ a weight function. The problem is to find a proper vertex coloring C_1, C_2, \dots, C_k of G that minimizes $\sum_{i=1}^k \max_{v \in C_i} \{w(v)\}$. Note that the special case of this problem in which $w(v) = 1$ for all $v \in V$ is simply the classical minimum coloring problem.

Max-coloring has received significant attention over the last decade. Approximation algorithms and hardness results are now known for a number of graph classes in both the off-line and online setting. The objective of this chapter is to survey the algorithmic state of the art for the max-coloring problem.

The rest of this section reviews some of the applications that motivated the study of max-coloring, introduces some notation, and describes briefly known results. Later sections discuss in more detail some key results.

1.1 Applications

The max-coloring problem arises naturally in the context of buffer management in operating systems and batch scheduling in certain manufacturing settings.

1.1.1 Buffer Minimization

Programs that run with stringent memory or timing constraints use a dedicated memory manager that provides better performance than the general purpose memory management of the operating system. An example of such programs is protocol stacks like GPRS and 3G that run on mobile devices. These protocol stacks have stringent memory requirements as well as soft real-time constraints, so a dedicated memory manager is a natural design choice. A dedicated memory manager for these

stacks must have deterministic response times and use as little memory as possible. The most commonly used memory manager design for this purpose is the *segregated buffer pool*. This consists of a fixed set of buffers of various sizes with buffers of the same size linked together in a linked list. As each memory request arrives, it is satisfied by a buffer whose size is large enough.

The assignment of buffers to memory requests can be viewed as an assignment of colors to the requests – all requests that are assigned a buffer are colored identically. Thus, the problem of determining whether a given segregated buffer pool suffices for a particular sequence of allocation requests can be formalized as follows: Let $G = (V, E)$ be a graph whose vertices are objects that need memory and whose edges connect pairs of objects that are alive at the same time. Requests which are live at the same time have to be satisfied by different buffers. Let $w : V \rightarrow \mathbb{N}$ be a weight function that assigns a natural number weight to each vertex in V . For any object v , $w(v)$ denotes the size of memory it needs. Suppose the segregated buffer pool contains k buffers with weights w_1, w_2, \dots, w_k . The problem is to determine if there is a k -coloring of G into color classes C_1, C_2, \dots, C_k such that for each i , $1 \leq i \leq k$, $\max_{v \in C_i} w(v) \leq w_i$. The optimization version of this problem is the max-coloring problem: Solving the max-coloring problem and selecting buffers according to the optimal solution lead to a segregated buffer pool that uses minimum amount of total memory. Note that this is an off-line problem. In the online version, buffers have to be allocated to requests as they arrive and without knowledge of future requests. The off-line version is also useful because designers of protocol stacks would like to estimate the size of the total memory block needed by extracting large traces of memory requests and running off-line algorithms on these traces.

When memory allocation requests are generated by *straight-line program*, (i.e., programs without loops or branching statements), each memory allocation request is made for a specific duration of time. Thus, these requests can be viewed as intervals on the real line. In this restriction to straight-line programs, the underlying graph is an interval graph. See [Sect. 6](#) for a description.

1.1.2 Batch Scheduling

In several scenarios involving the scheduling of a set of jobs on a set of machines, the jobs are partitioned into *batches*. Jobs in a batch are processed simultaneously, but batches are processed sequentially: Processing of the next batch of jobs starts only after all the jobs in the current batch are complete. Batched scheduling is common in manufacturing processes where a machine is capable of handling several types of jobs but requires a different setup for each job. In this case, all jobs of the same type can be scheduled on the machine, before changing the setup for a different type of job. For example, materials in a factory may have to be processed in a kiln, where all materials that need to be processed at the same temperature can be processed simultaneously, before starting a next batch with a different temperature. Batching thus leads to a higher utilization of the machine and hence more efficient schedules. Another application where batch scheduling is used is in scheduling jobs

on a cluster machine, where jobs that need to communicate to accomplish a task are scheduled together. A paper by Potts and Kovalyov [33] surveys recent results in batched scheduling.

Batch scheduling problems with conflicting jobs can be modeled as a max-coloring problem as follows: The input to a batch scheduling problem is a set of jobs $\mathcal{J} = \{J_1, \dots, J_n\}$ with processing times $w : \mathcal{J} \rightarrow \mathbb{N}$, and a graph G , whose vertex set is the set of jobs and edge between a pair of jobs, implies the two jobs are not compatible and hence cannot be scheduled simultaneously. A proper vertex coloring of this graph corresponds to a schedule where each color class constitutes a batch. The processing time for a batch is the maximum processing time of any job in this batch, and the processing time for the entire set of jobs is the sum of processing times of the batches. Thus, if S_1, \dots, S_k are the independent sets in a coloring, the *weight* of an independent set $w(S_i) = \max_{v \in S_i} w(v)$, and the cost of this coloring is the sum of the weights of the independent sets; That is, $\sum_{i=1}^k w(S_i)$. The problem of minimizing the makespan of this batched schedule is precisely the max-coloring problem.

In some settings, in addition to the time it takes to process the batches themselves, there is a setup time or delay d incurred by each individual batch. This is easily modeled by increasing the weight of every vertex by d .

1.2 Notations and Definitions

In this chapter, all graphs are assumed to be undirected and connected, and in all but for edge-coloring, the graphs are assumed to be simple. A graph $G = (V, E)$ is made up of a vertex set $V(G)$ and an edge set $E(G)$. The notation $n(G)$ and $m(G)$ is used to denote the cardinality of $V(G)$ and $E(G)$, respectively. The maximum degree of G will be denoted by $\Delta(G)$. (For the sake of succinctness, (G) is omitted from these quantities whenever the graph G is clear from the context.) A vertex weight function $w : V \rightarrow \mathbb{N}$ is simply an assignment of positive integer values to the vertices of the graph; similarly, an edge weight function assigns a positive integer value to every edge in the graph. Unless otherwise stated, the weight functions will be of the vertex type.

The notion of an induced subgraph is used in several places throughout the survey. For $S \subseteq V$, $G[S]$ is the vertex-induced subgraph or simply *induced subgraph*, of G that has S for vertex set and $\{(u, v) \in E : u, v \in S\}$ for edge set. Similarly, one can define an *edge-induced* subgraph, or simply *subgraph* as follows: Let $F \subseteq E$, then $G[F]$ is the edge-induced subgraph of G that has F for edge set and endpoints of edges in F for vertex set.

A proper k -coloring of the graph $G = (V, E)$ is a function $\chi : V \rightarrow \{1, \dots, k\}$ such that for every edge $(u, v) \in E$, it is the case that $\chi(u) \neq \chi(v)$. The color classes C_1, \dots, C_k of χ are defined as $C_i = \{v \in V : \chi(v) = i\}$ for each $i \in \{1, \dots, k\}$. Given a weight function w , the weight of color class C_i is defined to be

$$w(C_i) = \max_{v \in C_i} w(v)$$

and the weight of coloring χ to be

$$w(\chi) = \sum_{i=1}^k w(C_i).$$

The chromatic number of a graph G is the smallest k such that G admits a proper k -coloring; this quantity is denoted by $\chi(G)$. The *max-chromatic number*, denoted $\chi_{mc}(G)$, denotes the smallest number k such that there is an optimal max-coloring using k colors, and $\text{OPT}_{mc}(G)$ denotes the weight of an optimal max-coloring of G . Finally, $\omega(G)$ denotes the size of the largest clique in the graph; notice that $\omega(G) \leq \chi_{mc}(G)$.

Let \mathcal{A} be an algorithm for a given minimization problem, and let $\rho \geq 1$. The algorithm \mathcal{A} is said to be a ρ -approximation or that \mathcal{A} attains an approximation ratio of ρ if for all instances of the optimization problem, the solution returned by \mathcal{A} has cost at most ρ times the optimal solution. In the online context, where the instance is not revealed all at once but rather progressively, over time, here, algorithm \mathcal{A} is said to be ρ -competitive if it returns a solution whose cost is no more than ρ times the optimal solution that can be constructed after the whole instance has been revealed. A polynomial time approximation scheme (PTAS) is an algorithm such that for all $\epsilon > 0$, the algorithm returns a $1 + \epsilon$ approximate solution in $O(n^{f(\epsilon)})$, where f is an arbitrary function.

Let G be a graph, and let C_1, \dots, C_k be some proper coloring of G . The chapter always follows the convention of listing color classes in non-increasing order of their weights; that is, $w(C_1) \geq w(C_2) \geq \dots \geq w(C_k)$. Further, it is assumed without loss of generality that C_i is a *maximal independent set* in the graph induced by $\cup_{j=i}^k C_j$; indeed, otherwise, vertices can be migrated to lower indexed color classes without increasing the weight of the coloring.

1.3 Summary of Known Results

The majority of papers on max-coloring focus on solving the problem on different graph classes. These results are summarized in [Table 1](#) for the off-line setting and in [Table 2](#) for the online setting, where vertices are revealed one by one; in which case, a vertex must be assigned a color as soon as it arrives. Another line of work has studied a variant of max-coloring where the objective is to color the edges of the graph; these results are summarized in [Table 3](#). Yet another line of work has studied a variant of all these problems where there is an additional constraint on the size of the color classes used; these results are summarized in [Table 4](#).

The rest of this section briefly describes the results in [Tables 1–4](#). Later sections highlight and elaborate in more detail a selected subset of these results.

Table 1 Table for off-line max-coloring vertices of graphs. A lowerbound of $c > 1$ means that there is no $(c - \epsilon)$ -approximation unless $P = NP$. All algorithms run in polynomial time unless stated otherwise in the notes column

Graph class	Lowerbounds	Upperbounds	Notes	Section
Path	–	1 [14, 18, 19, 22]		§ Sect. 3

General multigraphs	$4/3$ [20]	$2 - \frac{2}{1.5\Delta+1}$ [4]

1.3.1 Paths

The simplest graph class imaginable is that of simple paths. It should not be surprising then to learn that max-coloring paths can be solved optimally in polynomial time. Indeed, it is not hard to see: First, note that an optimal solution

Table 4 Table for bounded max-coloring and bounded max-edge-coloring. A lowerbound of $c > 1$ means that there is no $(c - \epsilon)$ -approximation unless $P = NP$

Coloring type	Graph class	Lowerbounds	Upperbounds	Notes
Vertex	Trees	—	PTAS [2]	$O(n^{2^{1/\epsilon}})$ time
	Bipartite	4/3 [3]	17/11 [2]	
	Hereditary	—	$c + 1$ [6]	Assumes c -approx. for max-coloring
Edge	Trees	NP-hard [2]	2 [2]	
	Bipartite	7/8 [7]	e [2]	
	General	4/3 [20]	3 [2,6]	

uses at most three colors; otherwise, one can recolor the vertices in the lightest color class and decrease the cost of the solution. The algorithm guesses the weights of these three color classes (there are $O(n^3)$ possibilities to consider) and for each guess uses dynamic programming to check in linear time whether a 3-coloring with these weights exists. This is the basis of the $O(n^4)$ time algorithm of Guan et al. [18]. The running time was subsequently improved to $O(n^2)$ by Escoffier et al. [14], then to $O(n \log n)$ by Halldorsson and Schachnai [19], and finally to $O(n + S(n))$ by Kavitha and Mestre [22], where $S(n)$ is the time it takes to sort the weights. The last paper also provided a matching lower-bound of $\Omega(n \log n)$ in the algebraic computation tree model on the running time required for max-coloring a path. The algorithm of Kavitha and Mestre is covered in Sect. 3.

1.3.2 Trees

While the classic graph coloring problem is trivial on trees (any tree can be colored with at most two colors), the max-coloring problem on trees has turned out to be a challenging problem. It can be shown that on trees, an optimal max-coloring may use as many as $\lceil \log_2 n \rceil$ colors, and the best algorithm to compute an optimal max-coloring runs in quasi-polynomial time, that is, in time $2^{\text{poly} \log n}$. This quasi-polynomial time algorithm can also be used as a basis for obtaining a PTAS for the problem, and these results extend directly to graphs of bounded treewidth, provided a tree decomposition is given. These results are presented in Sect. 4. No hardness result is known for max-coloring trees. Indeed, settling its computational complexity remains an intriguing open problem.

1.3.3 Bipartite Graphs

While the max-coloring problem on trees is yet to be fully resolved, the situation is different for the class of bipartite graphs that includes trees. On bipartite graphs, it can be shown that an optimal max-coloring may use as many as $O(n)$ colors on a graph with n vertices. Pemmaraju and Raman [30] and independently Escoffier et al. [14] gave tight results for the max-coloring problem on bipartite graphs. The authors show that the problem is hard to approximate beyond $\frac{8}{7} - \epsilon$ for any $\epsilon > 0$.

unless $P = NP$, and they give a combinatorial algorithm that achieves a ratio of $\frac{8}{7}$. The surprising aspect of this algorithm is that it uses at most four colors, while an optimal max-coloring may use as many as $O(n)$ colors.

Several authors have further tried to delineate the boundary between polynomial time solvable cases and the NP-hard case for bipartite graphs. DeWerra et al. [7] prove that on P_5 -free bipartite graphs (i.e., bipartite graphs that do not have a path on five vertices as an induced subgraph), the max-coloring problem admits a polynomial time solution, while on P_8 -free bipartite graphs, the authors show that the problem becomes NP-hard.

1.3.4 Split Graphs

A Split graph is a graph $G = (K \cup S, E)$, where the vertex set V can be partitioned into a complete graph K and an independent set S . Between K and S is an arbitrary bipartite graph. Split graphs are a subclass of perfect graphs, and hence, the classic coloring problem admits a polynomial time algorithm. DeWerra et al. [7] study the max-coloring problem on split graphs. They prove the problem to be NP-complete and give a PTAS.

1.3.5 k -Colorable Graphs

Even though coloring general graphs is a very difficult problem, certain graph classes can be optimally colored or good approximations exist. It makes sense then to study how well max-coloring can be approximated in these special classes. Max-coloring is APX-hard even for bipartite graph, where an optimal coloring can be found in linear time, so one should not expect an approximation preserving reduction between the two problems. Nevertheless, being able to compute a k -coloring of the input graph is useful for approximating max-coloring. Indeed, any proper k -coloring is a k -approximation for max-coloring. Can this trivial observation be improved? Bourgeois et al. [4] considered this question and showed how to get a $\frac{k^3}{3k^2 - 3k + 1}$ approximation for max-coloring provided a k -coloring for the input graph can be computed. This result is described in Sect. 5. Here, two applications to planar graphs and triangle-free planar graphs are discussed.

The celebrated four-color theorem states that every planar graph can be vertex-colored using four colors. Robertson et al. [35] provide an $O(n^2)$ time algorithm for 4-coloring any planar graph. Using the above result, one can get a $\frac{64}{37} < 1.73$ approximation for max-coloring planar graphs. On the negative side, the hardness of graph coloring planar graphs [16] means it is NP-hard to approximate max-coloring better than $4/3 > 1.33$.

Grötzsch theorem states that every triangle-free planar graph can be 3-colored. Dvorak et al. [10] give a linear time algorithm to compute such a coloring. Using the above result, one can get a $\frac{27}{19} < 1.43$ approximation for max-coloring triangle-tree planar graphs. On the negative side, De Werra et al. [7] showed that in this class of graphs, max-coloring cannot be approximated better than $\frac{7}{6} > 1.16$.

1.3.6 Interval Graphs

Interval graphs are intersection graphs of intervals on the real line. In other words, a graph is an interval graph if and only if each vertex can be associated with an interval on the real line (closed or open) such that two intervals intersect if and only if their corresponding vertices are adjacent. Interval graphs arise in several applications from scheduling to computational biology. They are a sub-class of perfect graphs, and hence, $\chi(H) = \omega(H)$ holds for any interval graph G and induced subgraph $H \subseteq G$. Another feature that will be useful is that given a graph, one can decide in polynomial time whether it is an interval graph and, if so, construct an interval representation [5]. Hence, for these algorithms, one can assume that the interval representation is given.

Interval graphs being perfect, minimum coloring can be solved in polynomial time. However, one can compute a coloring much easier than for perfect graphs by sorting the intervals in order of their left end-points and coloring them in a greedy manner with the smallest available color at each step. (See the book by Golumbic [17] for further details.) However, the max-coloring problem is NP-hard on interval graphs. A 2-approximation was presented by Pemmaraju et al. [31]; this result appears in Sect. 6. Very recently, a PTAS has been proposed by Nonner [28], which settles the computational complexity of max-coloring in interval graphs.

1.3.7 Hereditary Graph Classes

A class of graphs \mathcal{G} is called *hereditary* if it is closed under taking vertex-induced. Hence, for all graphs $G \in \mathcal{G}$, if $H \subseteq G$ is an induced subgraph of G , this implies $H \in \mathcal{G}$ as well. Most of the graph classes considered in this survey are hereditary graph classes. Clearly, the max-coloring problem is NP-hard on hereditary graphs. However, one can show that max-coloring can be approximated as well (up to constant factors) as regular coloring. More precisely, a c -approximation algorithm for classic coloring can be used to produce an $e \cdot c$ -approximation algorithm for max-coloring on this class of graphs; here, e is the base of the natural logarithm. This result is presented in Sect. 7.

1.3.8 Online

In some application domains, the instance is not given to us all at once, but rather, vertices are revealed one by one. For instance, this is the case in the buffer minimization application described in Sect. 1.1, where memory requests depend on the actual execution path of the program that is running.

Epstein and Levin [12] studied max-coloring in the online setting. Vertices arrive one by one. When a vertex u arrives, its neighborhood (restricted to the vertices that have already arrived) is revealed. Upon u 's arrival, the algorithm must assign a valid color to u that cannot be changed later on. They showed a reduction from online max-coloring to online coloring in hereditary graph classes. Given a c -competitive algorithm for online coloring, they design a deterministic $4 \cdot c$ -competitive algorithm for max-coloring and a randomized $e \cdot c$ -competitive algorithm. This result and some applications thereof are described in Sect. 7.1.

Epstein and Levin also considered the interesting class of interval graphs. Here, they assumed that the interval representation, rather than the graph itself, is revealed. They considered two different interval arrival models: In the *list model*, intervals arrive in some arbitrary order, while in the *time model*, intervals arrive sorted by their left endpoint. In the time model, a simple greedy algorithm solves the online coloring problem optimally. Thus, the reduction for general hereditary graph classes yields 4-competitive deterministic and ϵ -competitive randomized algorithms for max-coloring interval graphs in the time model. Similar results are obtained by using the 3-competitive algorithm of Kierstead and Trotter [24] for coloring interval graphs in the list model and the 2-competitive algorithm of Epstein and Levy [13] for coloring unit interval graphs in the list model.

On the negative side, the authors show a number of lower bounds for online max-coloring interval graphs under these two models. The results are summarized in [Table 2](#).

1.3.9 Max-Edge-Coloring

An important application of max-coloring arises in the context of scheduling transmissions in optical switches. Optical switches can be modeled as a complete bipartite graph connecting n input ports and n output ports. In each time step, the switch transmits packets along a perfect matching between input and output ports. A scheduler procedure is responsible for deciding which matching to use at each time step in order to route a given traffic demand pattern. In the language of graphs, the problem is defined by an edge-weighted bipartite graph $G = (A, B, E)$, where vertices in A and B represent input and output ports, respectively; edges represent data transfers that must be carried out; and weights represent the time it takes to carry out the transfer. Transmissions occur in rounds or batches. The set of edges associated with the transmissions carried out during a single round must form a matching. The objective is to minimize the makespan of the schedule. In a sense, this is just another example of batch scheduling. However, the difference here is that colors are assigned to edges of the input graph instead of the vertices.

The problem was first studied by Kesselman and Kogan [23], who showed that a simple greedy algorithm is a 2-approximation for the problem. This was later slightly improved by Bourgeois et al. [4], who showed that taking the best between greedy and an arbitrary k -coloring is a $2 - \frac{2}{k+1}$ approximation. These algorithms are described in [Sect. 8](#). It is worth noting that for general graphs, max-edge-coloring inherits the $(\frac{4}{3} - \epsilon)$ -hardness of regular edge-coloring [20].

Max-edge-coloring remains NP-hard in planar bipartite of degree 3 with edges weights in $\{1, 2, 3\}$ in fact, this case is hard to approximate better than $\frac{7}{6}$ [7]; this is in stark contrast with regular edge-coloring, which is polynomially solvable for general bipartite graphs. Bourgeois et al. [4] give two approximation algorithms for bipartite graphs: The first one has an approximation ratio of $2 - \frac{2}{\Delta+1}$, while the second one has attained an approximation ratio of $\frac{2(\Delta+1)^3}{\Delta^3+5\Delta^2+5\Delta+3-(-1/\Delta)\Delta}$. Very recently, Lucarelli and Milis [26] gave a 1.74-approximation algorithm, the current best factor for the

problem. It is worth mentioning that this last algorithm can be adapted for general graph, however, yielding an asymptotic approximation factor of 1.74.

The complexity of max-edge-coloring trees is open, as in the case of max-(vertex)-coloring trees. As in this other case, there is PTAS for max-edge-coloring trees [26].

Max-edge-coloring can be reduced to max-(vertex)-coloring by creating a new graph, where every new vertex corresponds to an old edge and two new vertices are connected if the corresponding old edges share an endpoint; the new graph is called the *line graph* of the old graph. Since the line graph of a path is again a path, max-edge-coloring can be solved optimally in paths.

1.3.10 Bounded Max-Coloring

Consider the batch scheduling application, where each batch consists of jobs that are non-conflicting. In the language of max-coloring, each color class consists of a batch of jobs that can run simultaneously. In many applications, however, there is a fixed number of machines, m , and each job in a batch runs on a separate machine. In such applications, the number of machines is typically fixed, so the size of the batches should not exceed m ; in other words, each color class must have at most m vertices.

Coloring unweighted graphs with a bounded size on each color class is well studied, and there are results on several restricted graph classes. The problem was introduced by Baker and Coffmann [1] under the title “Mutual Exclusion Scheduling.” For permutation graphs that are a subclass of comparability graphs, Jansen [21] proved that the problem is NP-hard for $m \geq 6$. For interval graphs, Bodlaender and Jansen [3] have shown that the problem on interval graphs is NP-hard for $m \geq 4$. For $m = 2$, the problem can be solved easily in polynomial time via matching techniques, while Gardi [15] gave linear time algorithms for interval and circular-arc graphs for $m = 2$.

Clearly all the hardness results for the max-coloring problem carry over to the bounded case. The bounded case, however, seems to be harder: For some graph classes for which the max-coloring problem can be solved in polynomial time, the bounded max-coloring problem is NP-hard. On the positive side, there is an algorithm for hereditary graph classes such that given an α -approximation algorithm for the max-coloring problem, it is possible to compute an $\alpha + 1$ -approximation for the bounded max-coloring problem. Bampis et al. [2] obtained a number of results for different graphs classes, which are summarized in [Table 4](#). These results are presented in [Sect. 9](#).

2 Tools

This section develops some tools and techniques that have proved useful for attacking the max-coloring problem on various graph classes. First, consider the simple bound on $\chi_{mc}(G)$ for any graph G . Assume C_1, C_2, \dots, C_k is an optimal max-coloring of a given graph G .

Lemma 1 ([18]) *For any graph G and any weight function $w : V \rightarrow \mathbb{N}$, $\chi_{mc}(G) \leq \Delta + 1$*

Proof Let $k = \chi_{mc}(G)$. If $k > \Delta + 1$, then for each vertex $v \in C_k$, there is a color class C_i , $i < k$, such that v has no neighbors in C_i . Note that since $w(C_i) \geq w(C_k)$, when v is moved into C_i , the weight of C_i does not increase. Furthermore, when C_k becomes empty, the weight of the coloring decreases, contradicting the optimality of C_1, C_2, \dots, C_k . \square

Consider an optimal max-coloring of a graph G such that $\chi(G) = l$. The reason max-coloring uses more colors than l to color G is that coloring heavy weight vertices with the same color offsets the increase in weight due to the use of many more color classes. This relation is captured in the following lemma, which is a key property of any optimal max-coloring.

Lemma 2 *Let G be an l -colorable graph, and let C_1, \dots, C_k be an optimal max-coloring with $k > l$ colors. Then, for each $i = 1, \dots, k$, $(l - 1)w(C_i) > \sum_{j=i+1}^k w(C_j)$.*

Proof The vertices in $\cup_{j=i}^k C_j$ can be l -colored for a cost of at most $l \cdot w(C_i)$. Since k colors are used, it must be that $\sum_{j=i}^k w(C_j) < l \cdot w(C_i)$, and the result follows. \square

In the max-coloring problem, it makes sense to color the large weight vertices with the same color to avoid paying for them several times in each color class. A natural approach is to partition the vertices into groups such that within each group either the number of distinct weights is small or the variance between the largest and smallest weights is small (or both). Then one can develop algorithms that work well in this restricted setting, apply the algorithm separately to each set of the partition, and obtain a max-coloring for the entire graph. The next lemma shows that such a partition can be always found at the expense of only a small increase in the approximation factor.

Lemma 3 ([28]) *Let $G = (V, E)$ be a vertex-weighted graph with weight function $w : V \rightarrow \mathbb{N}$, and let $\epsilon > 0$ be a constant. Then, G can be partitioned into induced subgraphs G_0, G_1, \dots such that within each induced subgraph, the ratio w_{max}/w_{min} is $O(\epsilon^{-2})$, the number of distinct weights is $2^{O(1/\epsilon)}$, and optimally max-coloring each subgraph independently leads to a $(1 + \epsilon)$ approximation for G .*

Proof Let $\alpha = \alpha(\epsilon) > 1$ be a constant that depends on ϵ . Define a new weight function as follows: Let $d(v) = \lceil \log_\alpha w(v) \rceil$, and let $w'(v) = \alpha^{d(v)}$ for each $v \in V$. Hence, each vertex weight is rounded up to the nearest power of α . The graph with the new weights is called the *rounded instance*. Let $\text{OPT}_{mc}^\alpha(G)$ denote the weight of an optimal coloring with the new weights w' . Then, the following is true:

$$\text{OPT}_{mc}(G) \leq \text{OPT}_{mc}^\alpha(G) \leq \alpha \cdot \text{OPT}_{mc}(G) \quad (1)$$

The first inequality clearly holds since the weight of each vertex increases. The second inequality holds since each vertex weight increases by at most a factor of α , so using the coloring with weight $\text{OPT}_{mc}(G)$ with the new weights has cost at most $\alpha \cdot \text{OPT}_{mc}(G)$.

Now, let $\delta = \delta(\epsilon) > 0$ be a constant that depends on ϵ . Let $m = \max_{v \in V} d(v)$. Hence, m is the number of distinct weights in the rounded instance. Partition the set of vertices into $l = \delta \cdot m$ groups, each group consisting of $\frac{1}{\delta}$ contiguous weights. Assume that $\frac{1}{\delta} \in \mathbb{N}$ and that $\delta \cdot m \geq 1$; otherwise, m is already constant. The partitioning will be randomized. To this end, pick a value z uniformly at random from the range $\{1, 2, \dots, \frac{1}{\delta}\}$. Using this value z define the partition of the vertex set as follows:

$$V_i = \left\{ v \in V : \frac{i-1}{\delta} + z < d(v) \leq \frac{i}{\delta} + z \right\}, \quad i = 0, 1, \dots, l-1.$$

The graph G_i is the graph induced by the vertices in V_i for $i = 0, 1, \dots, l-1$. The idea is to compute an optimal max-coloring for each group separately, using a fresh palette for each G_i , and return the union as a max-coloring of G . It can be shown that this solution has weight that is not much more than $\text{OPT}_{mc}(G)$.

Note that the colorings produced by partitioning and solving the max-coloring problem on each group separately has the feature that each color class consists only of vertices from the same set V_i . In order to show that not much is lost by partitioning, consider an optimal max-coloring of the rounded instance of weight $\text{OPT}_{mc}^\alpha(G)$ with color classes C_1, \dots, C_k . Let $d(C_i) = \lceil \log_\alpha w(C_i) \rceil$. Define $D_{ij} = C_i \cap V_j$, for $i = 1, \dots, k$ and $j = 0, \dots, l-1$. Then, the color classes D_{ij} consist only of vertices from the set V_j . Let $S^\alpha(G)$ denote the weight of the new coloring. Then, we have

$$\begin{aligned} \mathbb{E}[S^\alpha(G)] &= \mathbb{E} \left[\sum_{i=1}^k \sum_{j=0}^{l-1} w(D_{ij}) \right], \\ &= \sum_{i=1}^k \mathbb{E} \left[\alpha^{d(C_i)} + \sum_{j: \frac{j}{\delta} + z < d(C_i)} w(D_{ij}) \right], \\ &\leq \sum_{i=1}^k \alpha^{d(C_i)} + \mathbb{E} \left[\sum_{j: \frac{j}{\delta} + z < d(C_i)} \alpha^j \right], \\ &= \sum_{i=1}^k \alpha^{d(C_i)} + \sum_{x=1}^{\frac{1}{\delta}} \mathbb{P}[z = x] \cdot \sum_{j: \frac{j}{\delta} + z < d(C_i)} \alpha^j, \end{aligned}$$

$$\begin{aligned}
&= \sum_{i=1}^k \alpha^{d(C_i)} + \delta \cdot \sum_{j < d(C_i)} \alpha^j \text{ (each } j \text{ occurs exactly once per choice of } \delta), \\
&\leq \sum_{i=1}^k \alpha^{d(C_i)} + \delta \cdot \frac{\alpha^{d(C_i)+1}}{\alpha - 1}, \text{ (sum of geometric series)} \\
&= \left(1 + \frac{\delta}{\alpha - 1}\right) \sum_{i=1}^k \alpha^{d(C_i)} = \left(1 + \frac{\delta}{\alpha - 1}\right) \cdot \text{OPT}_{mc}^\alpha(G).
\end{aligned}$$

Now from inequality (1), it follows that

$$\begin{aligned}
\mathbb{E}[S^\alpha(G)] &\leq \left(1 + \frac{\delta}{\alpha - 1}\right) \text{OPT}_{mc}^\alpha(G), \\
&\leq \alpha \cdot \left(1 + \frac{\delta}{\alpha - 1}\right) \text{OPT}_{mc}(G), \\
&= \left(\alpha + \frac{\alpha}{\alpha - 1} \cdot \delta\right) \text{OPT}_{mc}(G),
\end{aligned}$$

so setting $\alpha = 1 + \epsilon/2$ and $\delta \leq \frac{\epsilon^2/4}{1+\epsilon/2}$,

$$\begin{aligned}
&\leq \left(1 + \epsilon/2 + \frac{1 + \epsilon/2}{\epsilon/2} \cdot \frac{\epsilon^2/4}{1 + \epsilon/2}\right) \text{OPT}_{mc}(G), \\
&= (1 + \epsilon) \text{OPT}_{mc}(G).
\end{aligned}$$

Such a partition can be found deterministically by trying all possible values of z and hence de-randomize the above construction.

Finally, note that within each subgraph G_i , the ratio w_{\max}/w_{\min} is at most $\alpha^{1/\delta}$. Thus, $w_{\max}/w_{\min} = 2^{O(1/\delta)}$. \square

With Lemma 3 in hand, one can focus on developing algorithms for the max-coloring problem, where the number of distinct weights is bounded by a constant and the ratio w_{\max}/w_{\min} is bounded by a constant. This is the approach used for several graph classes such as trees, interval graphs, and hereditary graph classes.

A second useful tool is a connection between the max-coloring problem and the problem of *online coloring* of unweighted graphs. Online graph coloring has been studied for several years. For many graph classes there are good bounds on the online chromatic number and algorithms that produce good colorings. Suppose there is an online algorithm for some hereditary graph class. Using this online algorithm as a “black-box,” one can design an algorithm, MCA, for off-line max-coloring.

The MCA algorithm simply sorts the vertices of G in non-increasing order of weights and feeds the vertices in this order to an online algorithm. For any hereditary

Algorithm 1 MCA(G, w)

-
1. Sort vertices of G in non-increasing order of weights
// Let (v_1, \dots, v_n) be this ordering
 2. Present the vertices in this order to A
 3. **return** Coloring produced by A
-

class of graphs, one can give a bound on the approximation ratio achieved by MCA in terms of the *competitive ratio* of the online algorithm for this class of graphs. The algorithm MCA is described in [Algorithm 1](#).

Lemma 4 ([31]) *Let \mathcal{C} be a hereditary class of graphs, and let A be an algorithm for online graph coloring such that for some $c > 0$ and for any graph $G \in \mathcal{C}$, algorithm A k -colors G for some $k \leq c \cdot \chi(G)$. Then, for any $G \in \mathcal{C}$ and for any weight function $w : V(G) \rightarrow \mathbb{N}$, MCA produces a coloring for G whose weight is at most $c \cdot \text{OPT}_{mc}(G)$.*

Proof Let C_1, C_2, \dots, C_k be a coloring of G that is optimal for the max-coloring problem. Note that $k \geq \chi(G)$, and $\text{OPT}_{mc}(G) = \sum_{i=1}^k w(C_i)$. Let A_1, A_2, \dots, A_t be the coloring of G produced by MCA. As per convention, assume that $w(A_1) \geq w(A_2) \geq \dots \geq w(A_t)$. From the hypothesis, it follows that $t \leq c \cdot \chi(G) \leq c \cdot k$. For notational convenience, define sets $A_{t+1} = A_{t+2} = \dots = A_{c \cdot k} = \emptyset$, and let $w(A_i) = 0$ for $i, t < i \leq c \cdot k$. Suppose that for each i , $1 \leq i \leq k$, and each j , $c(i-1) < j \leq c \cdot i$, $w(C_i) \geq w(A_j)$. This implies the result sought because the coloring produced by MCA has weight

$$\begin{aligned} \sum_{\ell=1}^{c \cdot k} w(A_\ell) &= \sum_{i=1}^k \sum_{j=c(i-1)+1}^{c \cdot i} w(A_j) \\ &\leq \sum_{i=1}^k c \cdot w(C_i) \\ &\leq c \cdot \text{OPT}_{mc}(G). \end{aligned}$$

Since $w(C_1)$ is the maximum weight of any vertex in G , the supposition is trivially true for $i = 1$. For any $i \geq 2$, let $V_i \subseteq V$ be defined as $V_i = \{v : w(v) > w(C_i)\}$. The coloring C_1, C_2, \dots, C_{i-1} is an $i-1$ coloring of $G[V_i]$.

Because of the order in which vertices are presented to A , all vertices in V_i are presented to A before any vertex with weight $w(C_i)$. Therefore, by the hypothesis, algorithm A colors $G[V_i]$ with no more than $c \cdot (i-1)$ colors. Therefore, the weight of the heaviest vertex in color classes A_j for $j, c(i-1) < j \leq c \cdot i - 1$ is at most $w(C_i)$. \square

A simple and natural heuristic for online coloring a graph is called *First fit*. The algorithm is as follows: Assume that the colors are natural numbers. When a vertex is presented, color it with the *smallest* available color. Let $\chi_{FF}(G)$ denote the maximum number of colors required by First fit to color the graph G over all possible presentations of the vertices. The quantities $\chi_{mc}(G)$ to $\chi_{FF}(G)$ can be related as follows.

Lemma 5 ([18]) *Let $G = (V, E)$ be a weighted graph. Then $\chi_{mc}(G) \leq \chi_{FF}(G)$.*

Proof Let χ_{mc} be an optimal max-coloring of G , and let C_1, \dots, C_k be the color classes in this coloring. Presenting the vertices in this order, that is, all the vertices of C_1 followed by all the vertices of C_2 and so on, to the first-fit algorithm, the algorithm uses at least χ_{mc} colors. Hence, $\chi_{mc}(G) \leq \chi_{FF}(G)$. \square

The first-fit heuristic, due to its simplicity and good performance in practice, has been studied for various graph classes. Lemma 5 along with Lemma 4 immediately gives good approximation factors for max-coloring on several hereditary graph classes. For example, the first-fit algorithm is known to be 8-competitive on interval graphs, and since interval graphs are a hereditary graph class, an 8-approximation algorithm for max-coloring interval graphs follows. Similarly, the result implies nontrivial approximation ratios for k -colorable graphs even when there are no algorithm to compute a k -coloring. In particular, for 3-colorable hereditary graphs, Lemma 4 implies an $O(\sqrt{n})$ -approximation for the max-coloring problem, since the class of 3-colorable graphs can be online colored with at most $O(\sqrt{n})$ colors [37].

3 Max-Coloring Paths

This section describes a fast algorithm for max-coloring a path P . Since paths have maximum degree two, it follows from Lemma 1 that any path admits an optimal max-coloring using at most three colors. Hence, from now on, just consider finding an optimal max-3-coloring of the given input path. For ease of exposition, assume that the set of vertices with maximum weight forms an independent set (this can be checked in linear time); otherwise, any 2-coloring is an optimal max-coloring.

The algorithm works in iterations. In each iteration, it records a signature $[w_1, w_2, w_3]$ and (implicitly) a coloring $\{A_1, A_2, A_3\}$ such that $w(A_i) \leq w_i$. To that end, keep two sets L and H . The idea is to color H with colors $\{1, 2\}$ and L with all three colors $\{1, 2, 3\}$. In each iteration, transfer the heaviest vertex from L to H and thus decrease the value of w_3 until it reaches zero. At the end, the best coloring found is returned. Call this algorithm MAX-COLORING-PATHS; its pseudo-code is given in Algorithm 2. The rest of this section deals with proving the following theorem.

Theorem 1 *Algorithm MAX-COLORING-PATHS finds an optimal max-coloring of a path in $O(n + S(n))$ time, where $S(n)$ is the time it takes to sort the vertex weights.*

Algorithm 2 MAX-COLORING-PATHS(P, w)

-
1. $w_2 \leftarrow w_3 \leftarrow \max_{(u,v) \in P} \min\{w(u), w(v)\}$
 2. $w_1 \leftarrow \max_{v \in P} w(v)$
 3. $H \leftarrow \{v \in P : w(v) > w_2\}$
 4. $L \leftarrow \{v \in P : w(v) \leq w_2\}$
 5. sort vertices in L in non-increasing order of weight
 6. **for** $z \in L$ in sorted order **do**
 7. transfer z from L to H
 8. let p be the subpath of H containing z
 9. $[\alpha, \beta] \leftarrow$ optimally 2-color p
 10. $w_2 \leftarrow \max\{\beta, w_2\}$
 11. $g_i \leftarrow \max_{v \in L} w(v)$
 12. record $[w_1, w_2, w_3]$ as a candidate signature
 13. **return** coloring associated with best signature recorded
-

Proof First, it has to be shown that the algorithm can be implemented to run in the stated time. The algorithm spends $S(n)$ time in Line 5; thus, it must be shown that the rest of the algorithm runs in linear time. The only challenging steps are Lines 8 and 9; these operations can be done in $O(1)$ time by keeping some information about the set H .

Each connected component of H is a subpath of P . Let $p = (u_0, u_1, \dots, u_\ell)$ be one such component. Associated with p are the values $e(p) = \max_{u_i \in p: i \text{ even}} w(v_i)$ and $o(p) = \max_{u_i \in p: i \text{ odd}} w(v_i)$. Given this information, it is trivial to carry out Line 9, since $\alpha = \max\{e(p), o(p)\}$ and $\beta = \min\{e(p), o(p)\}$. Notice that when transferring z from L to H , a new subpath in H could be started, or u could be added to an already existing subpath, or u could merge two adjacent subpaths. In each case, $e(p)$ and $o(p)$ should be computed $e(p)$ and $o(p)$ for the new subpath. This can easily be done if in addition to $e(p)$ and $o(p)$, the parity of the length of each component p in H is kept. The information for a particular subpath p is kept at the endpoints of p . With the aid of this basic data structure, the algorithm, excluding Line 5, runs in linear time.

The correctness of the algorithm relies on the following two lemmas.

Claim 1 *Let $[w_1, w_2, w_3]$ be a signature recorded by the algorithm. Then there exists a coloring $\{A_1, A_2, A_3\}$ such that $w(A_i) \leq w_i$ for $i = 1, 2, 3$.*

Proof Let H and L be the sets of vertices the algorithm had when the signature was recorded. Notice that H can be 2-coloring with a signature $[w_1, w_2]$. This is trivially true at the start since H forms an independent set by the assumption that the maximum weight vertices form an independent set. Think of each iteration as updating this coloring for the vertices in the subpath of H containing z , the latest vertex transfer into H . This is precisely why the value of w_2 is updated in Line 10.

This 2-coloring of H is then extended to P using all three colors. The connected components of $P \setminus H$ is a collection of subpaths of P . For each subpath p , color a single vertex with 3 and then extend the coloring of H using $\{1, 2\}$ by alternating colors to get a proper 3-coloring. Clearly, in this new coloring, the weight of

the first two color classes does not change, while the third one cannot exceed $w_3 = \max_{v \in L} w(v)$. \square

Claim 2 *Let $[\alpha, \beta, \gamma]$ be the signature of an arbitrary 3-coloring of P , where $\alpha \geq \beta \geq \gamma$. And let $[w_1, w_2, w_3]$ be the last signature recorded by the algorithm such that $w_2 \leq \beta$. Then $\gamma \geq w_3$ and $\alpha = w_1$.*

Proof The last part, $\alpha = w_1$, follows trivially since in any coloring the weight of the heaviest color class must equal the maximum vertex weight in the path.

For the first part, note that the algorithm must have recorded at least one signature $[w_1, w_2, w_3]$ with $w_2 \leq \beta$ because $\beta \geq \max_{(u,v) \in P} \min\{w(u), w(v)\}$, and w_2 is initialized to this value and only gets larger with time. If $[w_1, w_2, w_3]$ is the very last signature recorded, then $w_3 = 0$, and the statement is trivially true. Otherwise, let $[w'_1, w'_2, w'_3]$ be the signature recorded immediately after $[w_1, w_2, w_3]$; notice that by definition, $w'_2 > \beta \geq w_2$. Let z be the vertex transferred by the algorithm from L to H in going from $[w_1, w_2, w_3]$ to $[w'_1, w'_2, w'_3]$, and let p be the subpath in H that z belonged to after the transfer. Notice that every vertex in p has weight $w(z)$ or more, and $w_3 = w(z)$. If $\gamma < w(z)$, then all vertices in p such be colored using $\{1, 2\}$ in the coloring $[\alpha, \beta, \gamma]$, but then, this implies that $\beta \geq w'_2$, since optimally, 2-coloring p alone requires this. This contradicts the assumption; thus, $\gamma \geq w(z) = w_3$. \square

To finish the proof, let $[\alpha, \beta, \gamma]$ be an optimal max-coloring of the input path. By Lemma 2, the algorithm must have recorded a signature $[w'_1, w'_2, w'_3]$ such that $w'_1 + w'_2 + w'_3 \leq \alpha + \beta + \gamma$. The algorithm return the coloring $\{A_1, A_2, A_3\}$ associated with the best signature $[w_1, w_2, w_3]$; that is, $w_1 + w_2 + w_3 \leq w'_1 + w'_2 + w'_3$. Furthermore, by Lemma 1, $w(A_1) + w(A_2) + w(A_3) \leq w_1 + w_2 + w_3$. Therefore, the coloring returned by the algorithm is optimal. \square

It is natural to wonder whether the sorting time $S(n)$ is really necessary in the running time of MAX-COLORING-PATHS or whether perhaps there is a linear time algorithm. Kavitha and Mestre [22] showed a lowerbound of $\Omega(n \log n)$ time in the algebraic computation tree model; this is a model where the operations $\{+, -, \times, \div, \sqrt{} = 0, \geq 0\}$ on reals can be performed at unit cost.

Theorem 2 ([22]) *The complexity of max-coloring a path with real vertex weights is $\Theta(n \log n)$ in the algebraic computation tree model.*

4 Max-Coloring Trees

The max-coloring problem on trees has turned out to be surprisingly difficult. This section starts with some simple upper bounds on $\chi_{mc}(T)$ for any tree T and then gives a quasi-polynomial time algorithm for max-coloring trees exactly. Finally, it

is shown how this algorithm can become the basis for obtaining a PTAS for the problem.

From [Lemma 2](#) on the property of optimal max-colorings of k -colorable graphs, one can obtain the following corollary for 2-colorable graphs and hence trees.

Corollary 1 *Let G be a 2-colorable graph with $\{C_1, C_2, \dots, C_k\}$ an optimal max-coloring of G . Then, $w(C_i) \geq 2w(C_{i+2})$, for $i = 1, \dots, k-2$, and hence, $w(C_1) \geq 2^{\lfloor \frac{i-1}{2} \rfloor} \cdot w(C_i)$.*

[Corollary 1](#) states that the weights of the color classes decrease geometrically. Hence, one can expect that $\chi_{mc}(T)$ may not be too large for any tree T , and this is captured by the following lemma.

Lemma 6 *Let T be a vertex-weighted tree on n vertices. Then, $\chi_{mc}(T) \leq \lfloor \log_2 n \rfloor + 1$.*

Proof Let $\{C_1, \dots, C_k\}$ be an optimal max-coloring of T with $\chi_{mc}(T)$ colors. For each vertex $v \in C_1$, let $T(v)$ denote the rooted tree with one vertex, namely, v . For each $v \in C_i$, $i > 1$, define $T(v)$ as the tree rooted at v , such that:

1. The children of v in $T(v)$ are exactly the neighbors of v in T belonging to color classes C_1, C_2, \dots, C_{i-1} .
2. For each child u of v , the subtree of $T(v)$ rooted at u is simply $T(u)$.

For each i , $1 \leq i \leq k$, let $S_i = \min\{|T(v)| \mid v \in C_i\}$. In other words, S_i is the size of a smallest tree $T(v)$ rooted at a vertex v in C_i . Recall that each C_i is a maximal independent set in the graph induced by $\cup_{j=i}^k C_j$. This means that every vertex $u \in C_i$ has at least one neighbor in C_j for all $j < i$. Therefore,

$$S_1 = 1, \text{ and}$$

$$S_i \geq \sum_{j=1}^{i-1} S_j + 1, \text{ for each } i > 1.$$

This implies that $S_i \geq 2^{i-1}$ for $1 \leq i \leq k$. Using the fact that $S_k \leq n$, one gets $\chi_{mc}(T) \leq \lfloor \log_2 n \rfloor + 1$. \square

The number of colors required by an optimal max-coloring also depends on the number of distinct weights. Indeed, if all vertex weights are the same, then the optimal max-coloring uses at most two colors. Hence, the optimal max-coloring can be bounded in terms of the number of distinct weights. This relation is stated precisely below.

Lemma 7 *Let T be a vertex-weighted tree on n vertices, and let W be the ratio of the weight of heaviest vertex to the weight of the least heavy vertex. Then, $\chi_{mc}(T) \leq \lceil \log_2 W \rceil + 1$.*

Proof Let $k = \chi_{mc}(T)$, and let C_1, C_2, \dots, C_k be an optimal max-coloring of T ; as usual, assume $w(C_1) \geq w(C_2) \geq \dots \geq w(C_k)$. Notice that $w(C_1)$ equals the weight of the heaviest vertex in the tree. Let ℓ be the smallest integer such that $w(v) \geq w_1/2^\ell$ for all $v \in V$; in other words, $\ell = \lceil \log_2 W \rceil$.

Consider the following collection of disjoint intervals $\mathcal{I} = \{I_0, I_1, \dots, I_{\ell-1}\}$:

$$I_i = \left[\frac{w(C_1)}{2^{i+1}}, \frac{w(C_1)}{2^i} \right) \text{ for } i = 1, \dots, \ell - 1, \text{ and } I_0 = \left[\frac{w(C_1)}{2}, w(C_1) \right].$$

Because of the choice of ℓ , for each vertex $v \in V(T)$, its weight $w(v)$ belongs to exactly one interval I_j . Let $V_j = \{v \in V(T) \mid w(v) \in I_j\}$, $j = 0, 1, \dots, \ell - 1$. Vertex v is said to *contribute* to a color class C_i if $v \in C_i$, and $w(v) = w(C_i)$. The *contribution* of an interval I_j is the maximum number of vertices in V_j that contribute to distinct color classes.

[Corollary 1](#) says that $w(C_i) \geq 2 \cdot w(C_{i+2})$ for $i = 1, \dots, k-2$. Therefore, no interval I_j , $j = 1, 2, \dots, \ell-1$ has a contribution of more than two. If the contribution of I_0 is three or more, then it must be the case that one can construct a 2-coloring with the same or smaller weight, compared to $\{C_1, C_2, \dots, C_k\}$. This contradicts the fact that $k = \chi_{mc}(T)$, and C_1, C_2, \dots, C_k is an optimal max-coloring of T .

Now suppose that intervals $I_{i_1}, I_{i_2}, \dots, I_{i_t}$, $0 \leq i_1 < i_2 < \dots < i_t \leq \ell - 1$ are the sequence of all intervals in \mathcal{I} , each of whose contribution is two. The following claim can be shown.

Claim 3 *For any pair of consecutive intervals I_p , $p = i_j$ and I_q , $q = i_{j+1}$, where $j < t$; it is the case that there is an interval in $\{I_{p+1}, I_{p+2}, \dots, I_{q-1}\}$ with contribution zero.*

Given this claim, one can charge the “extra” contribution of each I_{i_j} to an interval between I_{i_j} and $I_{i_{j+1}}$, whose contribution is zero. This implies that the contributing vertices in all intervals except I_t can be reassigned to a distinct interval. Since there are ℓ intervals and since the contribution of I_t is at most two, there is a total contribution of at most $\ell + 1$, implying that there are at most $\ell + 1$ color classes.

The claim is proved by contradiction, assuming that the contribution of every interval in $\{I_{p+1}, I_{p+2}, \dots, I_{q-1}\}$ is one. Let $\{x_p, x_{p+1}, \dots, x_q\} \cup \{y_p, y_q\}$ be vertices such that:

- (1) For each $j = p, p+1, \dots, q$, $x_j \in V_j$ and x_j contribute to some color class.
- (2) For each $j \in \{p, q\}$, $y_j \in V_j$ and x_j and y_j contribute to distinct color classes.

Since $x_j \in V_j$, $w(x_j) \geq \frac{w(C_1)}{2^{j+1}}$, $j = p, p+1, \dots, q$. Also, since $y_q \in V_q$, $w(y_q) \geq \frac{w(C_1)}{2^{q+1}}$. Therefore,

$$\begin{aligned}
\sum_{j=p}^q w(x_j) + w(y_q) &\geq \sum_{j=p}^q \frac{w(C_1)}{2^{j+1}} + \frac{w(C_1)}{2^{q+1}} \\
&= w(C_1) \frac{2^{q-p+1} - 1}{2^{q+1}} + \frac{w(C_1)}{2^{q+1}} \\
&= \frac{w(C_1)}{2^p} > w(y_p)
\end{aligned}$$

This contradicts [Lemma 2](#) and proves the claim. \square

The upperbounds in the preceding lemmas are all tight, as the following example shows. Let T_0, T_1, \dots be a sequence of trees, where T_0 is a single vertex, with weight 1, and $T_i, i > 0$ is constructed from T_{i-1} as follows: Let $V(T_{i-1}) = \{u_1, u_2, \dots, u_k\}$. To construct T_i , start with T_{i-1} and add a set of new vertices $\{v_1, v_2, \dots, v_k\}$, each with weight 2^i , and edges $\{u_i, v_i\}$ for all $i = 1, 2, \dots, k$. Thus, the leaves of T_i are $\{v_1, v_2, \dots, v_k\}$, and every other vertex in T_i has a neighbor v_j for some j . Now consider a tree T_n in this sequence. Clearly, $|V(T_n)| = 2^n$ and the maximum vertex degree of T_n , $\Delta(T_n) = n-1$. See [Fig. 1](#) for T_0, T_1, T_2 , and T_3 . Now consider the coloring of T_n defined by $C_i = \{\text{leaves of } T_{n+1-i}\}$, $1 \leq i \leq n+1$. Note that $w(C_i) = 2^{n+1-i}$ and therefore the weight of the coloring is $2^{n+1} - 1$. It is not hard to see that any coloring using fewer than $n+1$ colors has weight at least 2^{n+1} . Therefore,

$$\chi_{mc}(T) = n+1 = \log_2 |V(T_n)| + 1 = \Delta + 1 = \log_2 \left(\frac{2^n}{1} \right) + 1.$$

Everything is in place to describe the algorithm to find an optimal max-coloring. From [Lemma 6](#), it follows that $\chi_{mc}(T) \leq \log_2 n + 1$. Hence, there are at most $n^{O(\log n)}$ candidate weight sequences corresponding to feasible max-colorings. A candidate weight sequence consists of a sequence (W_1, \dots, W_k) of weights, with $k \leq \lceil \log_2 n \rceil$, $W_1 \geq W_2 \geq \dots \geq W_k$, and each W_i is the weight of some vertex in T . For a given candidate weight sequence (W_1, \dots, W_k) , the algorithm needs to decide if there is a coloring of T that respects this weight sequence. A coloring of T respects the given weight sequence if the coloring is proper and uses at most k colors C_1, \dots, C_k , and $\max_{v \in C_i} w(v) \leq W_i$ for each $i = 1, \dots, k$. The *feasible- k -coloring* problem asks to find, given a weighted tree T and a sequence (W_1, W_2, \dots, W_k) , a coloring satisfying the sequence (W_1, \dots, W_k) , or if such a coloring does not exist, to report so.

A simple dynamic programming algorithm solves feasible- k -coloring on trees in $O(nk)$ time. Let T be rooted at an arbitrary vertex r . Let $\text{children}(v)$ denote the set of children of v , and let $\text{parent}(v)$ denote the parent of v . For a vertex v , let $T(v)$ denote the subtree of T rooted at v . Let $[k]$ denote the set of colors $\{1, \dots, k\}$. For a vertex v , let $F(v) = \{j \mid w(v) > W_j\}$ be the set of forbidden colors, and let

$$S(v) = \{i : \text{there exists a feasible coloring of } T(v) \text{ with } \chi(v) = i\}. \quad (2)$$

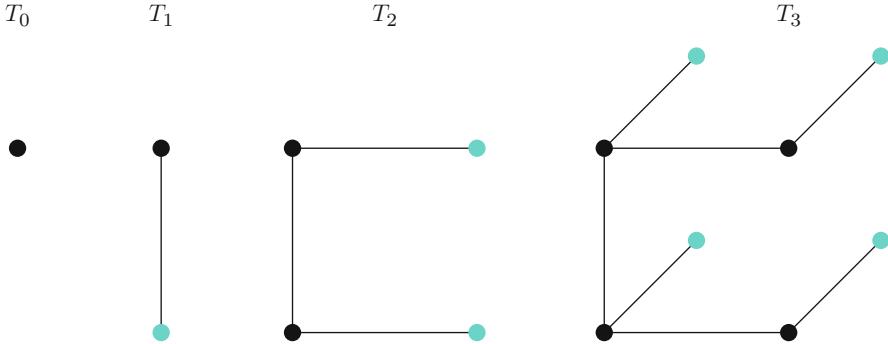

Fig. 1 Sequence of trees which show that the upperbounds of Lemmas 1, 6 and 7 are all tight. T_i is obtained by adding the *light-colored* vertices to T_{i-1} . The figure above shows the trees T_0, \dots, T_3

Algorithm 3 computes a feasible coloring, if one exists; we call this algorithm FKC. The correctness of the algorithm and the running time are easily established and are described in the lemma below.

Lemma 8 *Algorithm FKC solves the feasible- k -coloring problem in $O(nk)$ time.*

Proof Assume that the sets $S(v)$ computed by the algorithm FKC follow Eq.(2). Given this, it is trivial to see that the algorithm indeed solves the feasible- k -coloring problem. If there exists some vertex v such that $S(v) = \emptyset$, then $S(r) = \emptyset$, and clearly, there is no feasible coloring. Otherwise, for each $v \neq r$, one must argue that Line 14 can assign a valid color to v . Indeed, if $|S(v)| > 1$, this can always be done, and if $|S(v)| = 1$, then the single color present in $S(v)$ does not belong to $S(\text{parent}(v))$. Thus, Line 14 can always be carried out.

Algorithm 3 $\text{FKC}(T, w, W)$

1. Let $F(v) = \{j : w(v) > W_j\}, \forall v \in T$
 2. **for** each vertex v in a post-order traversal of T **do**
 3. Let $S(v) = [k] - F(v)$
 4. **for** each $u \in \text{children}(v)$ **do**
 5. **if** $S(u) = \emptyset$ **then**
 6. Set $S(v) = \emptyset$
 7. **if** $|S(u)| = 1$ **then**
 8. Set $S(v) = S(v) - S(u)$
 9. **if** $S(r) = \emptyset$ **then**
 10. **return** no feasible color exists
 11. **else**
 12. Pick an arbitrary $i \in S(r)$ and set $\chi(r) = i$
 13. **for** each $v \neq r$ in a pre-order traversal of T **do**
 14. Pick an arbitrary $j \in S(v) - \chi(\text{parent}(v))$
 15. Set $\chi(v) = j$
 16. **return** χ
-

Consider the following inductive argument on the height of $T(v)$ to show that the sets $S(v)$ obey (2): If the height of $T(v)$ is 0, then v is a leaf, and so, $S(v) = [k] - F(v)$, which is precisely what the algorithm returns.

Assume the claim is true for all subtrees of height $< m$. Let v be a vertex such that $T(v)$'s height is m . Suppose that v has a child u such that $S(u) = \emptyset$. By inductive hypothesis, $T(u)$ does not admit a feasible coloring and so neither does $T(v)$. Hence, the assignment $S(v) = \emptyset$ in Line 6 is correct. Now suppose that v has a child u such that $S(u) = \{c\}$. By inductive hypothesis, $S(u)$ obeys (2), and so c is the only color that can be assigned to u in any feasible coloring of $T(u)$. Hence, the c cannot be given to v , namely, $c \notin S(v)$, and so Line 8 correctly removes c from $S(v)$. For each color that remain in $S(v)$, v can be assign color and then extend the coloring to the remaining vertices in $T(v)$ by following for loop of Line 13. This finishes the proof that the $S(v)$ sets obey Eq. (2). \square

Theorem 3 *There is quasi-polynomial time algorithm for max-coloring trees that runs in $n^{O(\log n)}$ time.*

Proof Since $\chi_{mc}(T)$ is at most $\log_2 n + 1$ for any tree T , the algorithm only has to consider weight sequences (W_1, W_2, \dots, W_k) with $k \leq \log n + 1$. There are $n^{\log n + 2}$ possibilities. Each sequence can be checked for feasibility with FKC in $O(n \log n)$ time. An optimal max-coloring is simply a feasible sequence minimizing $W_1 + W_2 + \dots + W_k$. \square

The main idea underlying the PTAS is the reduction of the number of distinct weights of the vertices down to a constant. Candidates for the weights of the color classes are chosen; then for each such choice, using the algorithm for feasible- k -coloring, it can be tested if there is a legal coloring of the tree with the chosen weights for the color classes.

Let T be the input graph. Using Lemma 3, one can, with a loss of $1 + \epsilon$ in the objective, reduce the general problem to a number of smaller instances T_0, T_1, \dots such that the number of distinct to the special problem where the number of weights used in each T_i is at most $O(1/\epsilon^2)$. Together with the FKC algorithm, this means that a $(1 + \epsilon)$ approximate solution can be found in $O(n^{O(\epsilon^{-2})})$ time. Below is an alternative proof that improves the dependency on $1/\epsilon$ in the exponent.

Theorem 4 *There is a PTAS for max-coloring trees.*

Proof Let T be a tree, with weight function $w : V \rightarrow \mathbb{N}$ and an $\epsilon > 0$. Let $c > 0$ be an integer such that $(2 \log c + 3)/c \leq \epsilon$, and let $\alpha = (w_1 - 1)/c$. Let I_1, I_2, \dots, I_c be a partition of the range $[1, w_1]$, where $I_i = [1 + (i - 1)\alpha, 1 + i \cdot \alpha)$, $1 \leq i \leq c$. Let T' be a tree that is identical to T , except in its vertex weights. The tree T' has vertex weights $w' : V \rightarrow \mathbb{N}$ defined by the rule for any $v \in V$, if $w(v) \in I_j$, then $w'(v) = 1 + (j - 1) \cdot \alpha$, and if $w(v) = w_1$, then $w'(v) = w_1$. In other words, except for vertices with maximum weight w_1 , all other vertices have their weights “rounded” down. As a result, T' has $c + 1$ distinct vertex weights. Now let OPT'_{mc}

denote the weight of an optimal max-coloring of T' and let $\mathcal{C}' = C'_1, C'_2, \dots, C'_k$ be the color classes corresponding to OPT'_{mc} . Since the weights of vertices have fallen in going from T to T' , clearly, $\text{OPT}'_{mc} \leq \text{OPT}_{mc}$. The coloring \mathcal{C}' for T has weight, is at most $\text{OPT}'_{mc} + k\alpha$. Substituting $(w_1 - 1)/c$ for α and noting that $w_1 \leq \text{OPT}'_{mc}$, one can see that weight of \mathcal{C}' used as a coloring for T' is at most $(1 + \frac{k}{c})\text{OPT}'_{mc}$. It was shown that given the distribution of vertex weights of T' , $k = O(\log c)$. To see this, first observe that the weights of last three color classes C'_k, C'_{k-1} , and C'_{k-2} cannot all be identical, by Lemma 2. Also, observe that the possible vertex weights of T' are $1, 1 + \alpha, 1 + 2\alpha, \dots$. Therefore, $w(C'_{k-2}) \geq 1 + \alpha$. From Corollary 1,

$$1 + \alpha \leq w(C_{k-2}) \leq \frac{w_1}{2^{\lfloor (k-3)/2 \rfloor}}.$$

Solving this for k yields $k \leq 2 \log_2(c) + 3$. Therefore, by the choice of c ,

$$\frac{k}{c} \leq \frac{2 \log_2(c) + 3}{c} \leq \epsilon.$$

Thus, $(1 + \epsilon)\text{OPT}'_{mc}$ is an upperbound on the weight of \mathcal{C}' used as a coloring for T . Since $\text{OPT}'_{mc} \leq \text{OPT}_{mc}$, it follows that the weight of OPT'_{mc} used as a coloring for T is at most $(1 + \epsilon)\text{OPT}_{mc}$.

To construct OPT'_{mc} in polynomial time, for each $k = 1, \dots, 2 \log c + 3$, generate all $O(c^k)$ possible sequences of weights and call algorithm FKC for each subsequence and pick the coloring with the minimum weight. This gives OPT'_{mc} . Each call to FKC takes $O(nk)$ time, and we have $O(c^k)$ sequences, for $k = 1, \dots, 2 \log c + 3$. Using the fact that $(2 \log_2 c + 3)/c \leq \epsilon$, a little bit of algebra yields a running time that is linear in n and exponential in $1/\epsilon$. \square

The same algorithm can be extended to coloring graphs of bounded treewidth.

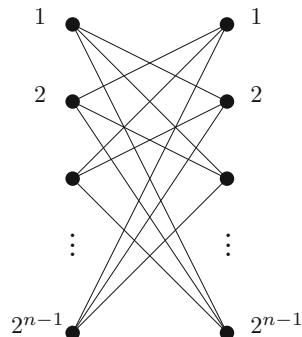

Theorem 5 ([14]) *There is a PTAS for max-coloring graphs of bounded treewidth, provided a tree-decomposition is given.*

5 Max-Coloring Bipartite and k -Colorable Graphs

The max-coloring problem on bipartite graphs, unlike the case with trees, is fully resolved. There is a $\frac{8}{7}$ -approximation algorithm and is inapproximable beyond $\frac{8}{7} - \epsilon$ for any $\epsilon > 0$ unless P = NP. Further, the approach used to max-color bipartite graphs can be extended to an approximation algorithm for coloring k -colorable graphs for which a k -coloring can be obtained in polynomial time.

Figure 2 shows that an optimal max-coloring may use as many as $O(n)$ colors. The example is a graph $G = (U \cup V, E)$, where $|U| = |V| = n$. The vertices in U

Fig. 2 An instance of max-coloring of a bipartite graph on $2n$ vertices that requires n colors in an optimal max-coloring. The weights of the vertices are powers of 2 and are shown next to the vertices. A k -coloring for any $k < n$ has weight at least 2^n , while a coloring with n colors has weight $2^n - 1$

are labeled $1, \dots, n$. and the vertices in V are labeled $1, \dots, n$. Vertex i has weight 2^{i-1} . Each vertex $i \in U$ is adjacent to all vertices in V except the vertex labeled i . A 2-coloring of G with all vertices in U colored 1 and all vertices in V colored 2 has a weight of $2^{n-1} + 2^{n-1} = 2^n$, while an optimal coloring consists of assigning color i to the vertices labeled i in both U and V , which has a weight of $2^n - 1$.

The PTAS for the max-coloring problem on trees relied on the fact that the feasible- k -coloring problem on trees can be solved in polynomial time for any k . However, feasible- k -coloring is NP-complete for bipartite graphs for $k \geq 3$ as shown by Kratochvil et al. [25]. Hence, a different approach for k -colorable graphs is needed. Consider the following algorithm that uses at most $k + 2$ colors for max-coloring a k -colorable graph.

Assume that a polynomial time algorithm is given to compute an arbitrary proper k -coloring of the input graph. The algorithm exploits the fact that an optimal max-2-coloring of a bipartite graph can be found efficiently. The basic idea is to optimally 2-color the i heaviest vertices in the graph (if possible) and then use the k -coloring algorithm to color the rest. We repeat this for each $i = 0, \dots, n$, and return the best coloring found. Call this algorithm MAX-COLORING-K-COLORABLE. Its pseudo-code is given in Algorithm 4.

Theorem 6 *Provided with a procedure for finding a proper k -coloring of the input graph, algorithm MAX-COLORING-K-COLORABLE is a $\frac{k^3}{3k^2-3k+1}$ -approximation for max-coloring.*

Proof First consider the issue of finding an optimal 2-coloring of $G[V_i]$. Notice that the graph to be colored is a collection of connected components. Each component is connected bipartite graph, which admits only two proper 2-colorings. Color each component so that the heaviest color class is 1; the resulting coloring of $G[V_i]$ is an optimal max-2-coloring. Thus, provided a k -coloring of the input graph can be computed, the algorithm MAX-COLORING-K-COLORABLE runs in polynomial time.

Algorithm 4 MAX-COLORING-K-COLORABLE(G, w)

-
1. Sort the vertices in non-increasing weight order v_1, v_2, \dots, v_n
 2. **for** $i \in \{0, n\}$ **do**
 3. $V_i \leftarrow \{v_1, \dots, v_i\}$
 4. **if** $G[V_i]$ is bipartite **then**
 5. optimally 2-color $G[V_i]$
 6. arbitrarily k -color $G[V \setminus V_i]$ using k new colors
 7. let χ_i be the resulting coloring
 8. **return** best coloring among the χ_i for $i = 1, \dots, n$
-

Second, consider the quality of the solution returned. Three different upper bounds on the value of the solution returned by the algorithm are derived. Later, it will be argued that the best of these bounds attains the desired approximation ratio of $\frac{k^3}{3k^2 - 3k + 1}$. The value of the solution found is denoted by MCKC.

Assume the vertices are sorted in non-increasing weight order v_1, v_2, \dots, v_n . Let $\{C_1, \dots, C_{k^*}\}$ be an optimal max-coloring for G . Let j_i be the smallest index such $v_{j_i} \in C_i$ for each $i = 1, \dots, n$.

Notice that when $i = 0$, the graph $G[V_i]$ is empty, so there is no cost incurred by the 2-coloring step. Hence,

$$\text{MCKC} \leq kw(C_1). \quad (3)$$

Let i be the largest index such that $w(v_i) > w(v_{j_2})$. Notice that the set V_i is independent in G . Therefore, the graph $G[V_i]$ can be colored with a single color class at the cost of $w(C_1)$. The rest of the graph $G[V \setminus V_i]$ can be colored with additional k colors at a cost of at most $kw(C_2)$. Hence,

$$\text{MCKC} \leq w(C_1) + kw(C_2). \quad (4)$$

Finally, let i be the largest index such that $w(v_i) > w(v_{j_3})$. In this case, the graph $G[V_i]$ is bipartite, and the coloring $\{C_1 \cap V_i, C_2 \cap V_i\}$ has a cost of at most $w(C_1) + w(C_2)$. The rest of the graph $G[V \setminus V_i]$ can be colored with additional k colors at a cost of at most $kw(C_3)$. Hence,

$$\text{MCKC} \leq w(C_1) + w(C_2) + kw(C_3). \quad (5)$$

Now combine these three bounds using the right multipliers: Take $\frac{(k-1)^2}{k^3}$ times (3), plus $\frac{k(k-1)}{k^3}$ times (4), plus $\frac{1}{k}$ times (5) to obtain the following equation:

$$\text{MCKC} \cdot \frac{3k^2 - 3k + 1}{k^3} \leq w(C_1) + w(C_2) + w(C_3).$$

Recall that $\{C_1, \dots, C_{k^*}\}$ was an optimal max-coloring. Thus, it was shown that MAX-COLORING-K-COLORABLE is a $\frac{k^3}{3k^2 - 3k + 1}$ approximation. \square

For bipartite graphs, the algorithm yields an $\frac{8}{7}$ -approximation that uses at most four colors. One might be tempted now to continue this and try to come up with an algorithm that uses five or more colors and obtains a better approximation ratio for bipartite graphs. Surprisingly, no such improvement is possible in polynomial time as there is a *gap introducing* reduction from the problem of *pre-coloring extension* on graphs which was shown to be NP-complete by [25].

Theorem 7 ([9], [30]) *For any $\epsilon > 0$, there is no $(8/7 - \epsilon)$ -approximation algorithm for max-coloring on bipartite graphs, unless $P = NP$.*

5.1 Planar Graphs

The four-color theorem states that every planar graph can be colored at most four colors. Robertson et al. [35] provide an $O(n^2)$ time algorithm for 4-coloring any planar graph. Using Theorem 6, one gets a $\frac{64}{37} < 1.73$ approximation for max-coloring planar graphs. On the negative side, the hardness of graph coloring planar graphs [16] means it is NP-hard to approximate max-coloring better than $4/3 > 1.33$.

Theorem 8 *Max-coloring in planar graphs can be approximated within $\frac{64}{37}$ but not within $\frac{4}{3} - \epsilon$ for any $\epsilon > 0$ unless $P = NP$.*

Grötzsch theorem states that every triangle-free planar graph can be 3-colored. Dvorak et al. [10] give a linear time algorithm to compute such a coloring. Using Theorem 6, one gets a $\frac{27}{19} < 1.43$ approximation for max-coloring triangle-free planar graphs. On the negative side, De Werra et al. [7] showed that in this class of graphs, max-coloring cannot be approximated better than $\frac{7}{6} > 1.16$.

Theorem 9 *Max-coloring in triangle-free planar graphs can be approximated within $\frac{22}{19}$ but not within $\frac{7}{6} - \epsilon$ for any $\epsilon > 0$ unless $P = NP$.*

5.2 Restricted Bipartite Graphs

DeWerra et al. [7] have attempted to further delineate the boundary between polynomial time solvable and NP-hard cases of the max-coloring problem. The authors consider bipartite graphs that do not contain an induced path on l vertices.

Theorem 10 ([7]) *Max-coloring on P_8 -free bipartite graphs is NP-complete.*

Further, they show that for P_5 -free bipartite graphs, the problem can be solved in polynomial time. There are several characterizations of P_5 -free bipartite graphs (See [7] and references therein). In particular, a bipartite graph G is P_5 -free if and

only if each connected component of G is $2K_2$ -free, that is, it does not contain edges whose vertices are nonadjacent. The authors then use this characterization to prove that any optimal max-coloring of a P_5 -free bipartite graph uses at most three colors.

Theorem 11 ([7]) *Max-coloring can be solved in polynomial time on P_5 -free bipartite graphs.*

Further, the authors observe that P_5 -free bipartite graphs have clique-width at most 5 and leave as an open question the problem of max-coloring on graphs of bounded clique-width.

5.3 Split Graphs

A graph class similar to bipartite graphs is that of split graphs. A graph $G = (K \cup S, E)$ is a split graph if its vertex set can be partitioned into two sets K and S such that K is a complete graph on n_1 vertices, and S is an independent set on n_2 vertices. The edge set of G includes an arbitrary bipartite graph between the vertices of K and S . Split graphs are a subclass of perfect graphs, and hence, classic coloring is easy. It is also easy to see that $n_1 \leq \chi(G) \leq n_1 + 1$ for any split graph. The max-coloring problem on split graphs, however, is NP-hard even with just two distinct weights as shown by Demange et al. [8].

However, a PTAS can easily be obtained as follows: Consider an optimal max-coloring of a split graph G , C_1, \dots, C_k where $k \in \{n_1, n_1 + 1\}$. There is some $i_0 \leq k + 1$ such that all color classes with index $i < i_0$ have at least one vertex from K , and the remaining color class i_0 has all the remaining vertices of S . For a fixed $\epsilon > 0$, trying all bijections between K and the first $\lceil \frac{1}{\epsilon} \rceil$ color classes, one obtains a solution which is at least as good as the first $\lceil \frac{1}{\epsilon} \rceil$ color classes.

Theorem 12 ([7]) *Max-Coloring on Split Graphs admits a PTAS.*

6 Max-Coloring Interval Graphs

An interval graph is an intersection graph of intervals on the real line. Recall that given an interval graph, an interval representation of it can be produced in polynomial time. Hence, assume that the graph is given as a set of intervals on the x -axis. Each interval has a weight w . If two intervals overlap, their corresponding vertices are adjacent. Interval graphs arise in several applications including resource allocation and scheduling and hence have been the subject of intensive study over several years. In particular, the online coloring problem on interval graphs is well studied, and it is known that the first-fit coloring algorithm is at most 8-competitive ([27, 31], G. Brightwell, H.A. Kierstead and W.T. Trotter, 2003, First-fit coloring of interval graphs, Personal communication). Applying Lemma 4 from

Algorithm 5 BETTER-MCA(G, w)

-
1. Sort the vertices of G in non-increasing order of weights
// Let (v_1, \dots, v_n) be this ordering of the vertices of G
 2. Let $k \leftarrow 1; S_k \leftarrow \emptyset$
 3. **for** $j \leftarrow 1$ **to** n **do**
 4. Insert v_j into set S_i
 5. where $i \leq k$ is the smallest value such that
 6. $S_1 \cup S_2 \cup \dots \cup (S_i \cup \{u\})$ does not contain an $(i + 1)$ -clique
 7. If no such i exists,
 8. set $k \leftarrow k + 1$ and insert v_j into S_k
 9. Use color 1 to color vertices in S_1
 10. **for** $i \leftarrow 2$ **to** k **do**
 11. Use colors $2i - 2$ and $2i - 1$ to 2-color the vertices in S_i
 12. **return** coloring
-

[Sect. 2](#) immediately gives an approximation algorithm for max-coloring with an approximation factor of 8, after noting that interval graphs form a hereditary graph class.

The best-known algorithm for online coloring interval graphs is a slight modification of the first-fit algorithm. This algorithm by Kierstead and Trotter [24] has a competitive ratio of 3, and now with [Lemma 4](#), one immediately gets a 3-approximation algorithm for max-coloring. What follows is a description of the Kierstead-Trotter algorithm, which is the basis for the 2-approximation algorithm.

The Kierstead-Trotter algorithm maintains sets S_1, S_2, \dots such that when a vertex u is presented, it finds the smallest i such that $S_1 \cup S_2 \cup \dots \cup (S_i \cup \{u\})$ does not contain an $(i + 1)$ -clique. (Recall that a maximum clique can be found in polynomial time on interval graphs.) The vertex u is then inserted into S_i . The fact that the Kierstead-Trotter algorithm is 3-competitive is a consequence of the following observations:

1. Let k be the largest index of a nonempty set S_i . Then, an interval I was placed in S_k since it induced a k -clique with intervals presented before. Hence, $k \leq \omega(G)$.
2. Let I_1, I_2, I_3 be a triple of intervals in S_i that pairwise intersect. Without loss of generality, assume that $I_3 \subseteq I_1 \cup I_2$. Then, it follows that I_3 induces an $i + 1$ -clique with intervals presented before it and hence cannot have been placed in S_i . Hence, each S_i is a disjoint union of paths.

Let k be the largest index of a nonempty set S_i . Then, $k \leq \omega(G) = \chi(G)$. Since each S_i is a disjoint union of paths, each S_i can be online 3-colored. Hence, the total number of colors used is at most $3 \cdot k \leq 3 \cdot \chi(G)$. However, since the max-coloring problem is an off-line problem, color each set S_i off-line using at most two colors. The algorithm is described in detail in [Algorithm 5](#).

Theorem 13 BETTER-MCA is a 2-approximation algorithm for the max-coloring problem on interval graphs.

Proof Let C_1, C_2, \dots, C_k be a coloring of G that is optimal for the max-coloring problem. Let $w_i = \max_{v \in C_i} w(v)$, and without loss of generality, assume that $w_1 \geq w_2 \geq \dots \geq w_k$. Now note that $k \geq \chi(G)$ and $\text{OPT}_{mc}(G) = \sum_{i=1}^k w_i$.

Suppose that at the end of Step (6) in BETTER-MCA, we have sets S_1, S_2, \dots, S_t . An element is inserted into S_t only because $S_1 \cup S_2 \cup \dots \cup (S_{t-1} \cup \{u\})$ has a t -clique. Therefore, $\chi(G) \geq t$, and it follows that $t \leq k$. Let $s_i = \max_{v \in S_i} w(v)$. The claim is that for each i , $1 \leq i \leq t$, $s_i \leq w_i$.

It is clear that $s_1 = w_1$. To obtain a contradiction, suppose that for some i , $s_i > w_i$, and let i be the smallest such value. This implies any vertex x with weight s_i or larger is in an earlier color class, C_j , for some $j < i$ in the optimal coloring. Therefore, vertices with weight s_i or larger are $(i-1)$ -colorable, so they induce a clique of size at most $i-1$, and therefore, in Step (6), no vertex with weight s_i will get inserted into S_i – a contradiction.

In Steps (9) and (10), the vertex partition S_1, S_2, \dots, S_t is converted into a coloring whose weight is at most $s_1 + 2 \cdot \sum_{i=2}^t s_i$. The following inequalities

$$s_1 + 2 \cdot \sum_{i=2}^t s_i \leq w_1 + 2 \cdot \sum_{i=2}^t w_i \leq 2 \cdot \text{OPT}_{mc}(G)$$

give the result sought. \square

Pemmaraju et al. [31] showed via a reduction from E4-set splitting that max-coloring on interval graphs is NP-hard. A simpler proof of NP-hardness was discovered by Escoffier et al. [14] and independently by Pemmaraju et al. [32] via a reduction from coloring circular-arc graphs.

Theorem 14 ([14, 32]) *Max-Coloring interval graphs is NP-hard.*

The results on NP-hardness of max-coloring interval graphs left open the question of whether there exists a PTAS for the problem. This has been answered in the affirmative recently by Nonner [28].

7 Max-Coloring on Hereditary Graphs

Recall that a class of graphs closed under taking vertex-induced subgraphs is called hereditary. Let \mathcal{G} be a hereditary class of graphs for which the classic vertex coloring admits a c -approximation algorithm. In this section, we describe approximation algorithms for the max-coloring problem on this class of graphs. The algorithm is quite natural and works by partitioning the vertices of the input graph G into *weight classes*, where each weight class consists of vertices of nearly equal weight, and solving the classic coloring problem in the subgraph induced by each weight class separately using a fresh palette for each. The section first describes how this approach leads to a 4-approximation algorithm for the max-coloring problem and

later shows how the approximation factor can be improved to e , the base of the natural logarithm.

Let $G = (V, E)$ be the input graph with weight function w . Let w_{\min} and w_{\max} denote the minimum and maximum weight vertices, respectively, and assume $w_{\min} = 1$ without loss of generality. The algorithm partitions the vertices of G into weight classes, $R_0, R_1, \dots, R_{\lceil \log_2 w_{\max} \rceil}$, where $R_i = \{v : w(v) \in [2^i, 2^{i+1})\}$, and applies the c -approximate coloring algorithm for each weight class ignoring the weights. This algorithm is called WP, for weighted partition.

Theorem 15 *Let \mathcal{G} be a hereditary class of graphs which admit a c -approximation algorithm for coloring. Then WP is a deterministic $4c$ -approximation algorithm for max-coloring for the class \mathcal{G} of graphs.*

Proof Let C_1, \dots, C_k be the color classes of OPT_{mc} . Consider a fixed color class C_i , and let $j_{\max} = \max\{j : R_j \cap C \neq \emptyset\}$. Partition C into at most $j_{\max} + 1$ classes $D_j^i = C \cap R_j$, $j = 0, \dots, j_{\max}$. Then, since this partition colors vertices in each R_i with the same color,

$$\begin{aligned} \text{WP} &\leq \sum_{i=1}^k \sum_{j=0}^{j_{\max}} c \cdot w(D_j^i) \leq c \cdot \sum_{i=1}^k \sum_{j=0}^{j_{\max}} 2^{j+1} \\ &\leq c \cdot \sum_{i=1}^k 2^{j_{\max}+2} \leq 2c \cdot \sum_{i=1}^k 2^{j_{\max}+1} \\ &\leq 4c \cdot \sum_{i=1}^k w(C_i) = 4c \cdot \text{OPT}_{mc} \end{aligned} \quad \square$$

To improve the approximation factor, the algorithm has to randomize the partitioning of the vertices into weight classes. Let q be a constant to be chosen later, and let α be chosen uniformly at random from $[0, 1]$. We now redefine the weight classes as

$$R_i = \{v : w(v) \in [q^{i+\alpha}, q^{i+1+\alpha})\}$$

Using this new partitioning and applying the c -approximation algorithm within each weight class, one obtains an ec -approximation algorithm. The algorithm, called RWP, is described in [Algorithm 6](#).

Theorem 16 *Let \mathcal{G} be a hereditary class of graphs which admit a c -approximation algorithm for coloring. Then RWP is an ec -approximation algorithm for max-coloring for the class \mathcal{G} of graphs.*

Proof Let C_1, \dots, C_k be the color classes of OPT_{mc} . For color class C_i , let $w(C_i) = q^{x_i}$. $R_i = \{i : w(v) \in [q^{i+\alpha}, q^{i+1+\alpha})\}$, for $i = 0, 1, \dots, \lceil \log_q w_{\max} \rceil$. Let $j_{\max} = \max\{j : R_j \cap C_i \neq \emptyset\}$. Then, partitioning C_i into at most $j_{\max} + 1$

Algorithm 6 RWP(G, w)

1. Choose α uniformly at random from $[0, 1)$
 2. **for** $i = 0, 1, \dots$ **do**
 3. Let $R_i = \{v \mid q^{i+\alpha} < w(v) \leq q^{i+1+\alpha}\}$
 4. Color each R_i using the c -approximation algorithm
 5. **return** Union of the individual colorings
-

color classes, D_j , where $w(v) \in R_j$, for all $v \in D_j$, there is a coloring such that each color class contains vertices from only one set R_i . However, since RWP colors each set R_i using a c -approximation algorithm,

$$\begin{aligned} \mathbb{E}[\text{RWP}] &\leq \mathbb{E}\left[c \cdot \sum_{i=1}^k \sum_{j=0}^{j_{\max}} w(D_j^i)\right] \leq c \sum_{i=1}^k \mathbb{E}\left[\sum_{j=0}^{j_{\max}} q^{j+1+\alpha}\right], \\ &\leq c \cdot \sum_{i=1}^k \mathbb{E}\left[\frac{q^{j_{\max}+1+\alpha+1}}{q-1}\right] = c \cdot \sum_{i=1}^k \frac{q^{x+1}}{q-1} \int_0^1 q^{1+\alpha-x} d\alpha, \\ &= c \cdot \sum_{i=1}^k \frac{q^{x+1}}{q-1} \frac{q-1}{\ln q} = \frac{qc}{\ln q} \sum_{i=1}^k w(C_i) \leq \frac{qc}{\ln q} \cdot \text{OPT}_{mc}. \end{aligned}$$

Since $\frac{q}{\ln q}$ is minimized at $q = e$, the base of the natural logarithm, the algorithm is an ec -approximation for max-coloring. \square

It is worth noting that RWP can be de-randomized by running the algorithm on some critical set of α values and then keeping the best solution produced. For each vertex v , there is a unique value α_v at which the vertex changes from R_i to R_{i+1} for some i . For values of α in between two consecutive critical values, the algorithm behaves the same way, so the minimum cost solution produced at these critical value is no more than the average case.

7.1 The Online Case

Even though the proof of [Theorem 15](#) provided above focused on the off-line setting, the same algorithms and the same arguments can be used to prove the following theorem about the online setting. The only difference is that one cannot de-randomize the second algorithm, so in this case, there is a gap between deterministic and randomized performance

Theorem 17 *Let \mathcal{G} be a hereditary class of graphs which admits a c -competitive algorithm for online coloring. Then WP is a deterministic $4c$ -competitive algorithm*

and RWP is a randomized ec -competitive algorithm for online max-coloring graphs in the class \mathcal{G} .

Two applications to max-coloring interval graphs are discussed to exemplify the usefulness of the above theorem. Assume that the interval representation, rather than the graph itself, is revealed. Two interval arrival models are considered: In the *list model*, intervals arrive in some arbitrary, while in the *time model*, intervals arrive sorted by their left endpoint.

First fit is a simple heuristic that assigns the lowest color available to an incoming interval. It is well known that first fit is optimal in the time model, namely, first fit is a deterministic 1-competitive algorithm in the time model. Plugging this result into [Theorem 17](#), one gets the following:

Corollary 2 *There is a 4-competitive deterministic algorithm and a e -competitive randomized algorithm for max-coloring interval graphs in the time model.*

In the list model, a different algorithm by Kierstead and Trotter [24] is 3-competitive for online coloring interval graphs. Plugging this result into [Theorem 17](#), one gets the following:

Corollary 3 *There is a 12-competitive deterministic algorithm and a $3e$ -competitive randomized algorithm for max-coloring interval graphs in the list model.*

Finally, it should be noted that better algorithms are known for restricted classes of interval graphs. Unit interval graphs are a special class of interval graph where every interval has unit length. Epstein and Levy [13] designed a 2-competitive algorithm for this special class. Thus, one gets the following result:

Corollary 4 *There is an 8-competitive deterministic algorithm and a $2e$ -competitive randomized algorithm for max-coloring unit interval graphs in the list model.*

8 Max-Edge-Coloring

This section first describes a simple approximation algorithm for max-edge-coloring a graph G . Later, it is shown how the approximation ratio can be improved slightly.

The algorithm processes the edges in non-increasing weight order. When an edge is considered, it assigns the lowest color possible so as not to create a conflict with adjacent previously colored edges. This algorithm is called GREEDY-MAX-EDGE-COLORING. Its pseudo-code is given in [Algorithm 7](#).

Every edge-coloring χ is just a collection of matchings $\{M_1, M_2, \dots, M_k\}$. As usual, these matchings are listed in non-increasing weight order; that is,

Algorithm 7 GREEDY-MAX-EDGE-COLORING(G, w)

-
1. $A(u) \leftarrow \{1, 2, \dots, 2\Delta - 1\}$, for all $u \in V$
 2. sort edge in non-increasing weight
 3. **for** $(u, v) \in E$ in sorted order **do**
 4. $\chi(u, v) = \min A(u) \cap A(v)$
 5. remove $\chi(u, v)$ from $A(u)$ and from $A(v)$
 6. **return** χ
-

$w(M_1) \geq w(M_2) \geq \dots \geq w(M_k)$. In the proofs, we will say that a coloring $\{M_1, \dots, M_k\}$ is *nice* if for all $(u, v) \in M_i$ there is no $j < i$ such that both u and v are unmatched in M_j .

For a given input instance (G, w) , denote by $\{C_1, \dots, C_{k^*}\}$ an optimal max-coloring of G ; assume $w(C_1) \geq \dots \geq w(C_{k^*})$. In addition, OPT_{mc} is used to denote the cost of this optimal solution, that is, $\text{OPT}_{mc} = \sum_{i=1}^{k^*} w(C_i)$.

Theorem 18 *The algorithm GREEDY-MAX-EDGE-COLORING is a $\min \left\{ 2 - \frac{1}{\Delta}, 2 - \frac{w_{\max}}{\text{OPT}_{mc}} \right\}$ approximation for general multigraphs, where $w_{\max} = \max_e w(e)$.*

Proof Start by showing that the algorithm indeed computes a coloring. The only subtlety that needs to be justified is that Line 4 indeed assigns a color to (u, v) . At the beginning of the algorithm, $A(u) \cap A(v) = \{1, \dots, 2\Delta - 1\}$, so initially, this is trivially feasible. By the time (u, v) is considered in the for loop, at most $\Delta - 1$ edges incident on u and another $\Delta - 1$ edges incident on v could have been colored already. Each edge can potentially disallow a distinct color; however, even after removing these $2(\Delta - 1)$ colors from $\{1, \dots, 2\Delta - 1\}$, there must remain at least one color that can be used for (u, v) .

Let $\{M_1, \dots, M_k\}$ be the coloring computed by the algorithm. For each $i = 1, \dots, k$, let e_i be the edge in M_i attaining the maximum weight in the matching (i.e., $w(e_i) = w(M_i)$) and let E_i be the edges that were colored before e_i and e_i itself. Since the coloring computed by the schedule is nice, it follows that the subgraph E_i has degree at least $\lceil \frac{i+1}{2} \rceil$ for each $i = 1, \dots, k$. All edges in E_i have weight $w(e_i)$ or larger. Hence, there must be at least $\lceil \frac{i+1}{2} \rceil$ matching in the optimal solution whose weight is at least $w(e_i)$. In other words, $w(C_{\lceil \frac{i+1}{2} \rceil}) \geq w(e_i)$. Therefore,

$$\begin{aligned} \sum_{i=1}^k w(M_i) &= \sum_{i=1}^k w(e_i) \leq \sum_{i=1}^{2\Delta-1} w(C_{\lceil \frac{i+1}{2} \rceil}) \\ &\leq w(C_1) + 2 \sum_{i=2}^{\Delta} w(C_i) \end{aligned}$$

$$\begin{aligned}
&= 2 \cdot \text{OPT}_{mc} - w(C_1) - 2 \sum_{i=\Delta+1}^{k^*} w(C_i) \\
&= \text{OPT}_{mc} \left(2 - \frac{w(C_1) + 2 \sum_{i=\Delta+1}^{k^*} w(C_i)}{\sum_{i=1}^{k^*} w(C_i)} \right) \\
&\leq \text{OPT}_{mc} \left(2 - \frac{w(C_1)}{\sum_{i=1}^{\Delta} w(C_i)} \right)
\end{aligned}$$

The proof is completed by noting that $\sum_{i=1}^{\Delta} w(C_i) \leq \Delta w(C_1)$ and $w(C_1) = w_{\max}$. \square

Recall that when edge weights are uniform, max-edge-coloring reduces to regular edge-coloring. In the uniform case, GREEDY-MAX-EDGE-COLORING returns an arbitrary nice edge-coloring. Simple examples exist showing that such a coloring can be $2 - \frac{1}{\Delta}$ away from the optimal max-coloring. However, for instances where the weights are uniform, or close to uniform, one can simply ignore the weights and approximate the underlying edge-coloring instance. The next lemma states that taking the best between these two strategies leads to an improved approximation algorithm.

Lemma 9 *Let χ be the edge-coloring returned by GREEDY-MAX-EDGE-COLORING and $\widehat{\chi}$ be an arbitrary edge-coloring that uses \widehat{k} colors. Then the best solution between these two is a $2 - \frac{2}{\widehat{k}+1}$ approximation for max-edge-coloring.*

Proof Recall that by [Theorem 18](#)

$$w(\chi) \leq \text{OPT}_{mc} \left(2 - \frac{w_{\max}}{\text{OPT}_{mc}} \right).$$

On the other hand,

$$w(\widehat{\chi}) \leq \widehat{k} \cdot w_{\max}.$$

Consider taking a convex combination of these two inequalities with coefficients $\frac{\widehat{k}}{\widehat{k}+1}$ and $\frac{1}{\widehat{k}+1}$, respectively. The result is

$$\frac{\widehat{k} \cdot w(\chi)}{\widehat{k}+1} + \frac{w(\widehat{\chi})}{\widehat{k}+1} \leq 2 \cdot \text{OPT}_{mc} \cdot \frac{\widehat{k}}{\widehat{k}+1} - \frac{\widehat{k} \cdot w_{\max}}{\widehat{k}+1} + \frac{\widehat{k} \cdot w_{\max}}{\widehat{k}+1} = \text{OPT}_{mc} \left(2 - \frac{2}{\widehat{k}+1} \right)$$

This proof is finished by noting that any convex combination of $w(\chi)$ and $w(\widehat{\chi})$ can only be larger than $\min\{w(\chi), w(\widehat{\chi})\}$. \square

Thus, if one can efficiently edge-color the input graph with few colors, then we can obtain a slightly better approximation than that offered by [Theorem 18](#). For bipartite multigraphs a Δ -edge-coloring can be computed in polynomial time [[36](#), Ch. 20]. For general simple graphs, Vizing's algorithm finds an $(\Delta + 1)$ -edge-coloring in polynomial time [[36](#), Ch. 28]. For general multigraphs, Shannon's algorithm finds a $\frac{3}{2}\Delta$ -edge-coloring in polynomial time [[36](#), Ch. 28]. From these facts, one obtains the following theorem.

Corollary 5 *There is a $2 - \frac{2}{\Delta+1}$ approximation for bipartite multigraphs, a $2 - \frac{2}{\Delta+2}$ approximation for general simple graphs, and a $2 - \frac{2}{1.5\Delta+1}$ approximation for general multigraphs.*

On the negative side, max-edge-coloring inherits the hardness of regular edge-coloring in general graphs. Unlike, regular edge-coloring, it remains hard even for bipartite graphs.

Theorem 19 ([[7, 20](#)]) *For any $\epsilon > 0$, max-edge-coloring cannot be approximated within $\frac{4}{3} - \epsilon$ in general graphs or within $\frac{7}{6} - \epsilon$ in bipartite graphs.*

9 Bounded Max-Coloring

This section studies the bounded max-coloring problem that is defined as follows. Given a graph $G = (V, E)$ with weight function $w : V \rightarrow \mathbb{N}$ on the vertices and a number $m \in \mathbb{N}$, the *bounded max-coloring* problem is to produce a proper vertex coloring of G such that if C_1, \dots, C_k are the color classes, then $|C_i| \leq m$ for $i = 1, \dots, k$, and $\sum_{i=1}^k \max_{v \in C_i} w(v)$ is minimized.

An algorithm for hereditary graph classes is presented that transforms an α -approximation algorithm for the max-coloring problem into an $\alpha + 1$ -approximation for the bounded max-coloring problem. The section first describes this generic reduction and then proceeds to discuss special graph classes.

Theorem 20 ([[6](#)]) *For a class of graphs \mathcal{G} if there is an α -approximation algorithm for the max-coloring problem, then for any $m \in \mathbb{N}$, there is an $\alpha + 1$ -approximation algorithm for the bounded max-coloring problem with a bound of m on the size of any color class.*

Proof The proof is algorithmic. Given an α -approximate solution to the max-coloring problem, an algorithm converts this solution into a feasible solution to the bounded max-coloring problem. The algorithm simply sorts the vertices in each color class in non-increasing order of weights and partitions each color class into sets of size at most m in this order. The algorithm is described in [Algorithm 8](#).

The goal is to bound the performance of Algorithm B-MAX-COLOR which we do as follows. Notice that

Algorithm 8 B-MAX-COLOR(G, w, m)

-
1. Let C_1, \dots, C_k be a max-coloring of G
 2. Let $c_i = |C_i|$
 3. **for** $i = 1, 2, \dots, k$ **do**
 4. Sort C_i in non-increasing weight order // Let v_1, \dots, v_{c_i} be this order
 5. **for** $j = 1, 2, \dots, \lceil c_i/m \rceil$ **do**
 6. Let $C_{ij} = \{v_k : \lfloor k/m \rfloor = j\}$
 7. **return** C_{ij} for all i, j as the coloring
-

$$\begin{aligned}
 \text{OPT}_{bmc}(G) &= \sum_{i,j} w(C_{ij}) \\
 &= \sum_{i=1}^k w(C_{i1}) + \sum_{i=1}^k \sum_{j=2}^{\lfloor \frac{c_i}{m} \rfloor} w(C_{ij}) \\
 &\leq \alpha \cdot \text{OPT}_{mc}(G) + \sum_{i=1}^k \sum_{j=2}^{\lfloor \frac{c_i}{m} \rfloor} w(C_{ij})
 \end{aligned} \tag{6}$$

Let $V' = V \setminus \cup_{i=1}^k C_{i1}$. The goal now is to bound the second term in the right-hand side of (6). Let $H = (V, \emptyset)$ be the weighted graph with no edges, where the vertices have the same weights as in the original graph G . An optimal bounded max-coloring of H follows by sorting the vertices in non-increasing weight order and greedily partitioning this order into sets of size m .

The color classes of an optimal bounded max-coloring of H induce a permutation π^* of V , defined as follows: The color classes of H are ordered in non-increasing weight order, and within each color class, we orders the vertices again in non-increasing weight order. This is equivalent to ordering all the vertices in non-increasing weight order by the discussion in the previous paragraph. Similarly, define a permutation π on the vertices in V' as follows. The color classes C_{ij} , $i = 1, \dots, k$, $j = 2, \dots, \lfloor c_i \rfloor$ are ordered in non-increasing weight order, where the weight of $C_{ij} = \max_{v \in C_{ij}} w(v)$, and within each color class, order the vertices in non-increasing weight order. Since a greedy partitioning is used in algorithm B-MAX-COLOR, all but at most one color class C_{ij} has size $< m$ for each i . Assume that all color classes have size m by adding dummy elements equal to the smallest element in the color class. Further, assume that ties are broken identically in π^* and π . Consider the position $\pi(u)$ of a vertex u . Next, it is shown that $\pi(u) \geq \pi^*(u)$ for all vertices $u \in V'$.

Suppose vertex $u \in V'$ is in color class C_i in the original coloring. Let $t(u)$ denote the number of color classes C_s , $s \neq i$ such that there is a vertex $v \in C_s$ that precedes u in the permutation π , that is, $\pi(v) < \pi(u)$. Let $S_{<}(u)$ and $S_{\geq}(u)$ denote the sets of vertices that have weight at most u and greater than u , respectively, in positions $1, 2, \dots, \pi(u)$. Then,

$$\pi(u) \leq |S_{<}(u)| + |S_{\geq}(u)| \quad (7)$$

Consider the number of elements in $S_{<}(u)$. Clearly, each color class C_s , $s \neq i$ contributes at most $m - 1$ elements to $S_{<}(u)$, and hence,

$$|S_{<}(u)| \leq t(u) \cdot (m - 1) \quad (8)$$

To count $|S_{\geq}(u)|$, all the vertices in π^* that appear before u are in $S_{\geq}(u)$. However, at least $t \cdot m$ vertices have been eliminated that appear in color classes C_{i1} for all i . Hence,

$$|S_{\geq}(u)| \leq \pi^*(u) - t \cdot m \quad (9)$$

Now, substituting the inequalities (8) and (9) in the inequality (7), one gets

$$\begin{aligned} \pi(u) &\leq t(u) \cdot (m - 1) + \pi^*(u) - t(u) \cdot m \\ &= \pi^*(u) - t(u) \\ &\leq \pi^*(u) \end{aligned}$$

Since $\pi(u) \leq \pi^*(u)$ for each element $u \in V'$, it follows that

$$\begin{aligned} \sum_{i=1}^k \sum_{j=2}^{\lceil \frac{C_i}{m} \rceil} w(C_{ij}) &\leq \text{OPT}_{bmc}(H) \\ &\leq \text{OPT}_{bmc}(G) \end{aligned} \quad (10)$$

Hence, plugging this into inequality (6), one gets

$$\text{OPT}_{bmc}(G) \leq (\alpha + 1)\text{OPT}_{bmc}(G) \quad \square$$

Theorem 20 gives a constant factor approximation algorithm for bounded max-coloring whenever max-coloring has a constant factor approximation. In particular, there is a constant approximations for max-coloring bipartite and interval graphs and for max-edge-coloring general graphs.

Bampis et al. [2] considered the bounded max-coloring and bounded max-edge-coloring problem in bipartite graphs and trees. In doing so, they were able to obtain better bounds than those provided by **Theorem 20**. In particular, for bipartite graphs, they get the following results.

Theorem 21 ([2]) *For bipartite graph, bounded max-coloring can be approximated within $\frac{17}{11}$, and bounded max-edge-coloring can be approximated within e .*

On the negative side, Gardi [15] showed that bounded coloring in bipartite graphs (even when all weights are uniform) cannot be approximated within $\frac{4}{3} - \epsilon$ for any $\epsilon > 0$ unless $P = NP$. For bounded max-edge-coloring, the best hardness is $\frac{7}{6} - \epsilon$ for any $\epsilon > 0$, and it is inherited from regular max-edge-coloring [7].

In the case of trees, they gave a PTAS for bounded max-coloring and a 2-approximation for bounded max-edge-coloring. Like the regular max-coloring, it is unknown whether bounded max-coloring trees is hard or not. Interestingly, bounded max-edge-coloring trees is hard.

Theorem 22 ([2]) *For trees, bounded max-coloring admits a PTAS, and bounded max-edge-coloring can be approximated within 2. The latter is NP-hard.*

10 Conclusion

This chapter has described some results on the max-coloring problem, a natural generalization of classic graph coloring. There have been several results on this problem for various graph classes, in particular, for perfect graphs and subclasses thereof. While this survey is not meant to be exhaustive, the presentation here was restricted to some representative graphs and simple algorithms. Besides the natural question of closing the gap between the known lower and upper bounds, there is one intriguing open question that deserves mentioning.

The max-coloring problem on trees admits an exact algorithm running in $2^{\text{poly log } n}$ time, and hence, there is no hope of showing NP-hardness. There are a few natural problems known that have such a property, for example, computing a minimum dominating set in a tournament or satisfiability with n clauses and $\log^2 n$ variables. For such problems, Papadimitriou and Yannakakis define the complexity classes $\log\text{-NP}$ and $\log\text{-SNP}$ [29]. It would be interesting to put the max-coloring problem on trees into one of these classes.

The max-coloring problem aims to minimize the *makespan* of a batched schedule of jobs. Another natural objective is to minimize the *average completion time* of the jobs. This objective has been considered by Epstein et al. [11], who obtain approximation algorithms for various graph classes, most notably, the class of perfect graphs and subclasses thereof. There is a third objective that is more natural and that is of the *flow-time* of the jobs. Each job comes with a release date and cannot be processed before this start date. The cost of a job is the difference between its completion time and release time, that is, the amount of time the job stays in the system. Almost nothing is known about this objective when there is an underlying conflict graph on the jobs.

Abstract

The aim of this chapter is to present an overview of the main results for a well-known optimization problem and an emerging optimization area, as well as introducing a new problem which is related to both of them. The first part of the chapter presents an overview of the main existing results for the classical maximum flow problem. The maximum flow problem is one of the most studied optimization problems in the last decades. Besides its many practical applications, it also arises as a subproblem of several other complex problems (e.g., min cost flow, matching, covering on bipartite graphs). Subsequently, the chapter introduces some problems defined on edge-labeled graphs by reviewing the most relevant results in this field. Edge-labeled graphs are used to model situations where it is crucial to represent qualitative differences (instead of quantitative ones) among different regions of the graph itself. Finally, the *maximum flow problem with the minimum number of labels* (MF-ML) problem is presented and discussed. The aim is to maximize the network flow as well as the homogeneity of the solution on a capacitated network with logic attributes.

This problem finds a practical application, for example, in the process of water purification and distribution.

1 Introduction

Network flow problems arise in several fields of inquiry, including applied mathematics, engineering, management, operations research, and computer science.

One of the most relevant network flow problems is the maximum flow problem (MFP) that can be stated as follows: given an arc-capacitated graph and two special nodes, namely, a source s and a sink t , the problem is to send as much flow as possible from s to t , by respecting the arc capacities. In the standard maximum flow problem formulation, capacities are real values, while integral and unit capacity cases reflect special scenarios.

There is a wide presence of flow networks in the real world. For instance, think about a network of pipes used to transport fluids like gas, water, or oil, in which the arcs represent the pipes and the nodes are their junctions. Other examples can be found in transportation networks, where arcs and nodes represent roads and crosses, or in communication networks, where the arcs represent cables with different bandwidths connecting a set of terminals. Whatever is the kind of the considered network, the maximum flow on them represents the maximum rate at which it is possible to ship commodities from the source to the sink. Besides its practical applications, the MFP arises as a subproblem of more complex optimization problems, such as minimum cost flow, matching, and covering on bipartite graphs as well as NP-hard network design and routing problems. This justifies the continuous efforts carried out throughout the years by researchers to improve the efficiency of the existing algorithms and to design new ones.

Extensive discussion on the maximum flow problem and its applications can be found in the books of Even [29], Ford and Fulkerson [33], Lawler [43], Papadimitriou and Steiglitz [52], Ahuja et al. [7], Tarjan [59], and in Goldberg et al., survey [38].

Recently, an NP-hard variant of the classical MFP has been introduced, namely, the maximum flow with minimum number of labels (MF-ML). MF-ML belongs to the class of problems defined on arc-labeled (or colored) graphs, which has met a growing interest in the last decade. Labeled graphs are used to model situations where it is necessary to represent qualitative differences among different regions of the graph itself. Typically, each label represents a different property (or a set of properties) to model.

The MF-ML problem consists in finding the maximum flow solution that minimizes the number of different labels on a graph where a label and a capacity are assigned to each arc. As for the original version of the problem, this variant finds real-world applications in several types of networks, although this chapter just shows an application to water purification systems.

The work is organized as follows: In Sect. 2, the maximum flow problem is formally defined, and the most relevant solution approaches for the problem are introduced. Section 3 presents an overview of the literature and the most important contributions in the emerging field of the edge-labeled graph problems. Finally, Sect. 4 addresses the *maximum flow with the minimum number of labels* (MF-ML), by presenting both mathematical formulations and metaheuristic algorithms to solve it.

2 The Maximum Flow Problem

The maximum flow problem can be defined both on directed and undirected graphs, but it is necessary to distinguish between them, although the directed and undirected variants are closely related. Ford and Fulkerson [33] provided a reduction from undirected graphs to directed graphs with comparable size and capacities. Picard and Ratli [53] gave the reduction from directed to undirected graphs, allowing to find the maximum flow value in a directed graph by solving a minimum cut problem on an undirected graph. However, a significant drawback occurs when this reduction is applied to a unit capacity instance, since it produces an instance with capacities that are proportional to the number of nodes. No efficient algorithms are available, so far, for the reduction from the unit capacity undirected problem to the unit capacity directed problem. For the sake of simplicity, from now on, only the maximum flow problem defined on directed graphs is considered.

Let $G = (V, A)$ be a directed graph where V is the *set of nodes* and A is the *set of arcs*, with $n = |V|$ and $m = |A|$. Let $u_{ij} \geq 0$ be a capacity assigned to each arc $(i, j) \in A$, and let $U = \max\{u_{ij} : u_{ij} < \infty \forall (i, j) \in A\}$. It is now made the assumption that whenever an arc (i, j) belongs to A , arc (j, i) also belongs to it; this assumption is not a limiting one, since arcs with zero capacity are allowed. Let $\delta_G^+(i) = \{(i, j) : (i, j) \in A\}$ and $\delta_G^-(i) = \{(k, i) : (k, i) \in A\}$ be the forward

star and the backward star of node $i \in V$, respectively. A graph $G' = (V', A')$ is a subgraph of G if $V' \subseteq V$ and $A' \subseteq A$. A path $P = (v_1, \dots, v_k)$ is a sequence of distinct nodes belonging to V such that, for $1 \leq i \leq k - 1$, (v_i, v_{i+1}) belongs to A . Finally, two special nodes s and t are distinguished (called source and sink, respectively). Every other node is called *intermediate*.

A function $x : A \rightarrow \mathbb{R}$ is a *feasible flow* of G with value $\hat{f} \geq 0$ if the following constraints are satisfied:

$$\sum_{(i,j) \in \delta_G^+(i)} x_{ij} - \sum_{(k,i) \in \delta_G^-(i)} x_{ki} = \begin{cases} \hat{f} & i = s \\ 0 & \forall i \in V \setminus \{s, t\} \\ -\hat{f} & i = t \end{cases} \quad (1)$$

$$0 \leq x_{ij} \leq u_{ij} \quad \forall (i, j) \in A \quad (2)$$

The variable x_{ij} represents the amount of flow sent on arc (i, j) . Flow conservation constraints (1) make sure that for each intermediate node the total ingoing flow is equal to the total outgoing flow, while the net outgoing flow of the source is equal to the net ingoing flow of the sink. Capacity constraints (2) impose that the flow sent on each arc is nonnegative and does not exceed its capacity.

The maximum flow problem consists in finding a feasible flow with the maximum value f^* , and can therefore be formulated as

$$\max \quad \hat{f} \quad (3)$$

$$s.t. \text{ (1) and (2)}$$

Note that the feasibility region of this LP problem is nonempty since $x_{ij} = 0 \quad \forall (i, j) \in A$ is a feasible solution and is bounded by constraints (2).

From now on, the expressions *feasible flow* and *flow* will be indistinguishably used since only feasibility will be considered unless differently specified.

Given a flow x of G , let the *residual network of G induced by x* , denoted as $G^x = (V, A^x)$, be a graph composed of the same set of vertices of G and the set of arcs A^x such that:

- For each $(i, j) \in A$ such that $x_{ij} = 0$, $(i, j) \in A^x$ and has capacity $r_{ij} = u_{ij}$.
- For each $(i, j) \in A$ such that $0 < x_{ij} < u_{ij}$, $(i, j) \in A^x$ and has capacity $r_{ij} = u_{ij} - x_{ij}$; moreover $(j, i) \in A^x$ with capacity $r_{ji} = x_{ij}$.

- For each $(i, j) \in A$ such that $x_{ij} = u_{ij}$, $(j, i) \in A^x$ and has capacity $r_{ji} = u_{ij}$.
- Each arc $(i, j) \in A^x$ has residual capacity $r_{ij} > 0$; this means that it is possible to send (or subtract) a positive amount of flow on (i, j) . An example of residual network is shown in Fig. 1.

An *s-t cut* of G , denoted by $[V_s, V_t]$, is a partition of its set of vertices V in two subsets V_s and V_t such that $s \in V_s$ and $t \in V_t$. Moreover, let (V_s, V_t) denote the set of forward arcs going from V_s to V_t , and let (V_t, V_s) be the set of backward arcs going from V_t to V_s . The capacity of an *s-t cut* (V_s, V_t) , denoted by $u[V_s, V_t]$, is given by the sum of the capacities of its forward arcs, that is, $u[V_s, V_t] = \sum_{(i,j) \in (V_s, V_t)} u_{ij}$.

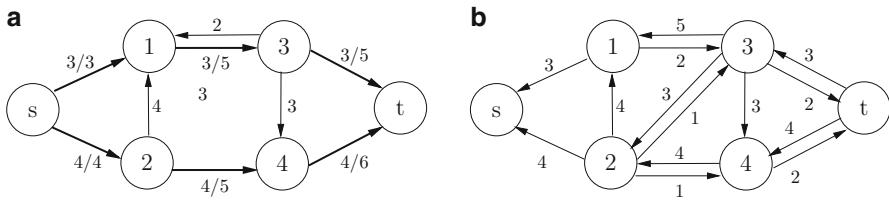

Fig. 1 (a) An example of a flow network with a maximum flow value $f^* = 7$. The source is s , and the sink t . The numbers denote flow and capacity, respectively. (b) Corresponding residual network

Now, consider the linear dual of the maximum flow formulation (10)–(12):

$$\min \sum_{(i,j) \in A} u_{ij} h_{ij} \quad (4)$$

s.t.

$$w_t - w_s = 1 \quad (5)$$

$$w_i - w_j + h_{ij} \geq 0 \quad \forall (i, j) \in A \quad (6)$$

$$h_{ij} \geq 0 \quad \forall (i, j) \in A, \quad (7)$$

Where each variable w_i corresponds to the flow conservation constraint for node i belonging to (1), and each variable h_{ij} corresponds to constraint $x_{ij} < u_{ij}$. The dual constraint (5) is associated with the primal flow variable \hat{f} , while constraints (6) are related to the variables x_{ij} . It can be noted that this dual formulation models the problem of finding the $s-t$ cut with minimum capacity. Indeed, given a feasible solution $[V_s, V_t]$, let

$$w_i = \begin{cases} 1 & \forall i \in V_t \\ 0 & \forall i \in V_s \end{cases}$$

$$h_{ij} = \begin{cases} 1 & \forall (i, j) \in (V_s, V_t) \\ 0 & \forall (i, j) \in A \setminus (V_s, V_t) \end{cases}$$

This assignment of values provides a feasible solution for the dual formulation, and the objective function value (4) is equal to the capacity value $u[V_s, V_t]$. Hence, from the weak duality theorem, it can be derived that the capacity of any cut of G is an upper bound to the maximum flow that can be sent from s to t , while as a consequence of the strong duality theorem, the following result can be stated:

Theorem 1 (Maximum Flow – Minimum Cut Theorem) *The maximum flow value in G is equal to the minimum capacity of the $s-t$ cuts of G .*

In the following sections, two general classes of algorithms to solve the maximum flow problem are presented, namely:

- **Augmenting path-based algorithms:** During their execution, these algorithms maintain the flow conservation constraints for each node of the network, and iteratively increase the value along augmenting paths from s to t .
- **Preflow-push algorithms:** Algorithms belonging to this class do not guarantee that flow conservation constraints are respected during their execution. Therefore, there could be flow *excesses* in some intermediate nodes. Preflow-push algorithms send these flow excesses toward nodes close to the sink, or close to the source when the former is not possible anymore.

2.1 Augmenting Path-Based Algorithms

The first known augmenting path procedure was introduced by Ford and Fulkerson in [31]. This algorithm is based on the concepts of residual graphs, cuts (as defined above) and augmenting paths. Given a graph G and a flow x , an augmenting path is a path (v_1, v_2, \dots, v_k) from the source s to the sink t in the residual network G^x , that is, $v_1 = s$, $v_k = t$.

The residual capacity r of an augmenting path P is defined as the minimum among all capacities of the arcs in P . From the definition of residual network, r is always a positive value. Therefore, if there is an augmenting path in G^x , then it is possible to send additional flow from s to t . Indeed, it is possible to prove that:

Theorem 2 (Ford-Fulkerson) *A flow x is maximum if and only if there is no augmenting path; that is, t is not reachable from the source s in the residual graph G^x .*

From [Theorem 2](#), the basic scheme for augmenting path algorithms is derived; that is, find an augmenting path P into the residual graph and send r flow units along P , were r is its capacity. This operation is repeated until there are no augmenting paths available in the residual graph. The steps of this generic augmenting path algorithm are subsumed in the [Algorithm 1](#).

[Algorithm 1](#) does not specify how to compute the augmenting path at each iteration. This is a crucial aspect on which the time complexity of the algorithm depends. One of the first algorithms developed to compute the augmenting path is the *labeling algorithm*, proposed by Ford and Fulkerson in [32]. This algorithm explores the residual network starting from the source s in order to find all the reachable vertices. During the exploration, vertices are divided into *labeled* (i.e., reachable from s) and *non-labeled*. The algorithm iteratively selects one of the labeled vertices, checks its forward star in the residual network, and labels all its neighbors. When the sink t is labeled, an augmenting path P is found and a flow equal to the residual capacity of P is sent along it; then, all the labels are deleted for the next iteration. If after checking the forward stars of all labeled vertices the sink

Algorithm 1 Generic augmenting path algorithm**Procedure Augmenting Path****for** each $(u, v) \in A$ **do** $x(u, v) \leftarrow 0$ **end for****while** there is a path P from s to t in G^x **do** $r \leftarrow \infty$ **for** each (u, v) in the path P **do** $r \leftarrow \min\{r, r_{uv}\}$ **end for** **for** each (u, v) in the path P **do** $x(u, v) \leftarrow x(u, v) + r$ $x(v, u) \leftarrow x(v, u) - r$ **end for****end while****return** x

is not labeled, the algorithm stops because no augmenting paths are available in the residual network. In Fig. 2 an execution of the algorithm is shown.

A worst-case time complexity analysis of the labeling algorithm is now provided. Note that each iteration except the last one increases the flow along an augmenting path, and requires $O(m)$ time. In fact, since each node is visited only if it is not labeled and is labeled after that, each forward star (and therefore each arc) is explored at most once. Sending the flow, as well as deleting all the labels, requires $O(n)$ time. Therefore, the complexity of the algorithm depends on the number of augmenting paths found. If all capacities are integer values and limited by an upper bound U , the capacity of an $s-t$ cut can be at most $(n-1)U$. The augmenting path algorithm will send at least one flow unit at each iteration; therefore, the overall time complexity of the algorithm is $O(nmU)$.

Unfortunately, there are some cases in which the Ford-Fulkerson algorithm may loop. In particular, if all the arc capacities are rational, then the Ford-Fulkerson algorithm eventually halts, but if they are irrational, the algorithm may loop forever, since it could perform an infinite sequence of small flow augmentations, and in the worst case it may not even converge to the maximum flow. Zwick [68] showed three small acyclic sample networks on which the Ford-Fulkerson procedure may fail to terminate.

Edmonds and Karp in [28] suggested two specializations of the Ford-Fulkerson algorithm. The first one consists in computing, at each iteration, the augmenting path of minimum length, which can be found by means of a breadth-first search (BFS) visit of the graph starting from s . It was proved that using shortest augmenting paths, the algorithm performs $O(nm)$ augmentations and, therefore, the whole procedure runs in $O(nm^2)$ time.

The second one is based on the idea of *scaling* that is based on computing augmenting paths with a residual capacity which is at least equal to a parameter Δ . In this way, it is guaranteed that at each iteration the flow value is increased of at

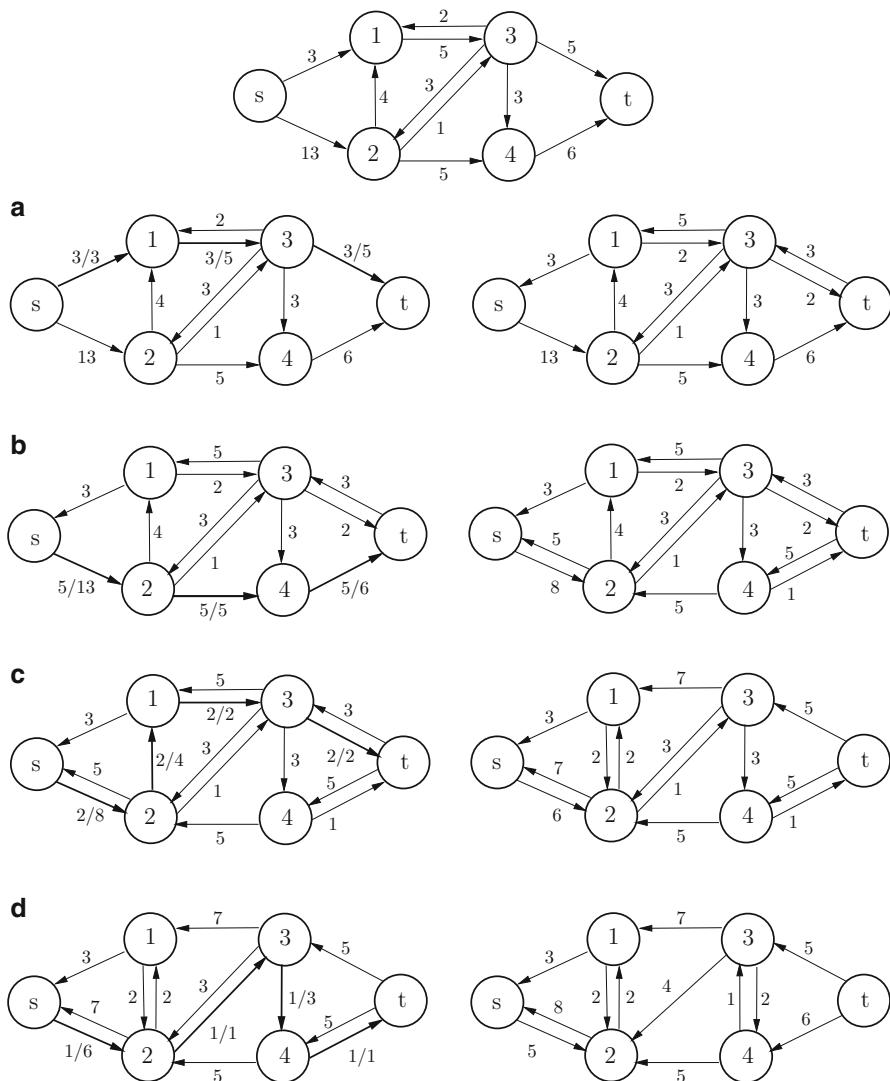

Fig. 2 Execution of the Ford-Fulkerson algorithm. (a)–(d) The *left side* figures show the augmenting path P on the residual network G^x , represented by *bold arrows*. The notation *flow/capacity* is used for each arc. The figures on the *right side* show the obtained residual graph from adding f to the current flow. The case (d) shows the residual network when there does not exist any augmenting path, and the flow x shown in (d) is therefore a maximum flow

least Δ units. To this end, the algorithm starts with $\Delta = 2^{\lfloor \log U \rfloor}$ and builds the residual network $G^{x,\Delta}$ containing only arcs with a residual capacity greater than or equal to Δ . Then, it computes an augmenting path in $G^{x,\Delta}$. If this path exists, then a quantity of flow greater than or equal to Δ is sent along this path, and the residual graph is updated. Otherwise, the algorithm sets $\Delta = \Delta/2$ and rebuilds $G^{x,\Delta}$. The algorithm stops when on the residual network $G^{x,\Delta}$, with $\Delta = 1$, no augmenting paths are found. Its time complexity is equal to $O(m^2 \log U)$.

A refinement of the shortest augmenting path algorithm was proposed by Ahuja and Orlin in [5], and it relies on the concept of *distance labels*. Given a flow x , a distance function d assigning a nonnegative integer to each node is *valid* if it satisfies the following conditions:

$$d(t) = 0 \quad (8)$$

$$d(v) \leq d(w) + 1 \quad \forall (v, w) \in A^x \quad (9)$$

As a consequence of the distance function definition, the following results can be stated:

Corollary 1 *If the distance labels are valid, the distance label $d(u)$ of a node u is a lower bound on the length of the shortest directed path from u to the sink t in the residual graph.*

Corollary 2 *If the distance labels are valid and $d(s) \geq n$, there are no paths from s to t in the residual graph.*

Corollary 1 can be easily proved by considering a path to t of length k in G^x , $(u_1, u_2, \dots, u_{k-1}, u_k, t)$. By conditions (8) and (9), it follows that

$$\begin{aligned} d(u_k) &\leq d(t) + 1 = 1 \\ d(u_{k-1}) &\leq d(u_k) + 1 \leq 2 \\ &\dots \\ d(u_1) &\leq d(u_2) + 1 \leq k \end{aligned}$$

Corollary 2 is an immediate consequence of Corollary 1.

Distance labels are defined *exact* if, for each node u , $d(u)$ is exactly the length of the shortest directed path from u to t in the residual graph. Exact distance labels can be determined in $O(m)$ time by means of a reverse breadth first search starting from t . Moreover, an arc $(u, v) \in A^x$ is defined *admissible* if $d(u) = d(v) + 1$, and a path is admissible if it is only composed of feasible arcs. It is straightforward to observe that an admissible $s-t$ path is an augmenting path with minimum length.

The improved shortest augmenting path algorithm starts by computing the exact distance labels for the nodes of G . At each iteration, it tries to build at each iteration

an admissible $s-t$ path, gradually extending an admissible path from s to some intermediate node u . If an admissible arc (u, v) exists, the path is extended (*advance* step); otherwise, the algorithm backtracks on the decision of including u in the path, and its distance label $d(u)$ is updated to $1 + \min\{d(v) : (u, v)A^x\}$ (*retreat* step). If the admissible path reaches t , an augmentation is performed using the path. The algorithm stops when $d(s) \geq n$, by returning a maximum flow in $O(n^2m)$.

In 1970, Dinitz [27] introduced his algorithm for the MFP, which became known as the *Dinic's algorithm*. Dinic's algorithm is based on the observation that many consecutive steps in the shortest path version of the augmenting path algorithm involve augmenting paths of the same length. Therefore, its aim is to push flow along all the shortest augmenting paths simultaneously. In fact, Dinic's algorithm considers the graph as a layered network, in which a given layer k contains all the vertices whose distance from the source s is k ; for example, layer 0 contains just s . The algorithm works in phases and uses the classical *breadth-first search (BFS)*. At the beginning of each phase, the algorithm constructs the residual network G^x induced by the current flow x and runs the *BFS* on it, starting from s . If the sink t is not reached, then x is maximal, and the algorithm stops. Otherwise, the *BFS* constructs a layered network L^x . When the algorithm reaches t , at distance k from s , it puts t in layer k and discards all remaining vertices. The procedure keeps in L^x all those arcs that go from one layer to the next one (discarding arcs within the same layer and backward arcs). The algorithm runs in $O(n^2m)$ time and in networks with unit capacities it terminates in $O(m\sqrt{n})$ time.

In conclusion, it is important to emphasize that the search for more efficient maximum flow algorithms led to the development of sophisticated data structures for implementing Dinic's algorithm. Some data structures were suggested by Shiloach [54] and Galil and Namaad [36]; the resulting implementations run in $O(nm \log^2 n)$ time, but the most efficient one is the *dynamic tree data structure* introduced by Sleator and Tarjan [55, 56], which yields an $O(nm \log n)$ time maximum flow algorithm.

2.2 Preflow-Push Algorithms

Given a graph G , a preflow x is a flow such that constraints (2) are satisfied whereas the net flow at node $v \in N \setminus \{s, t\}$ can be positive, that is $e(v) = \sum_{(v,w) \in \delta_G^+(v)} x_{vw} - \sum_{(k,v) \in \delta_G^-(v)} x_{kv} \geq 0$, where $e(v)$ is called the *excess flow* of node v . That is, in this class of algorithms the capacity constraints are satisfied, but the total amount of incoming flow for an intermediate vertex can exceed the total amount outgoing from it. A node with a strictly positive flow excess is defined *active*.

The first algorithm in this class is due to Karzanov [41]. The algorithm proposed by Karzanov considers layered networks, in the sense already introduced by describing the Dinic's algorithm. It starts by sending as much preflow as possible from s to its adjacent nodes (i.e., nodes in layer 1). The preflow is then propagated

Algorithm 2 Generic preflow-push algorithm

Procedure Preflow-Push

Preprocess

while there is at least an active node **do** Select active node u Push/Relabel(u)**end while**

to t : each intermediate node considers its arcs to the next layer according to a predefined order and saturates them one at a time (with the possible exception of the last considered arc), until its excess becomes zero. After this phase, defined *advance*, the algorithm considers the highest layer containing active nodes. For each of these nodes, the incoming flow is reduced until the excess is equal to 0, and all its incoming arcs are marked as closed; this phase is defined *balance*. Subsequently, a new advance phase is executed, sending as much preflow as possible on arcs that are not closed. The algorithm iterates advance and balance phases until there are no intermediate nodes with positive excess. Karzanov's algorithm runs in $O(n^3)$ time. Cherkassky [21] and Galil [35] presented further improvements of Karzanov's algorithm, which allow one to improve the time complexity to $O(n^2m^{1/2})$ and $O(n^{5/3}m^{2/3})$, respectively.

Goldberg and Tarjan [37] proposed a class of preflow-push algorithms using the concept of distance labels. These algorithms work by examining the active intermediate nodes and pushing excess from them to nodes that are estimated to be closer to the sink t , by sending flow along admissible arcs in the residual network (*push* operation). If the currently considered active node does not have any admissible arc, then its distance label is increased (*relabel* operation), in order to refine the distance approximation and to generate, as a consequence, new admissible arcs. The algorithms terminate when there are no active nodes. The steps of the generic preflow-push algorithm by Goldberg and Tarjan are presented in [Algorithm 2](#), while [Algorithm 3](#) shows the preprocess and the push/relabel subroutines. Implementing the procedure requires to specify in which order the active vertices will be visited.

The preprocess phase performs some initialization operations. More in detail, it sets the initial flow to 0 for each arc of the network, computes the exact distance labels, and sends flow from the source to its neighbors. Since all the arcs outgoing from the source are saturated, the procedure also updates the value of $d(s)$ to n , which by [Corollary 2](#) implies that the residual graph does not contain any directed path from s to t . The push-relabel operation on a generic active node u checks whether there is an admissible arc in the residual graph on which a push operation can be performed. A push along (u, v) decreases both r_{uv} and $e(u)$ and increases both $e(v)$ and r_{vu} . It is straightforward to observe that if the push operation does not saturate the selected arc, then the excess of u is reduced to 0. The relabel operation aims at creating at least one admissible arc on which the algorithm will be able to

Algorithm 3 Preprocess and push/relabel operations**Procedure Preprocess****for** each $(u, v) \in A$ **do** $x(u, v) \leftarrow 0$ **end for****for** each $u \in V$ **do** compute the exact distance label $d(u)$ **end for****for** each $(s, j) \in \delta_G^+(s)$ **do** $x(s, j) \leftarrow u_{sj}$ **end for** $d(s) \leftarrow n$ **Procedure Push/Relabel(u)****if** there is an admissible $(u, v) \in \delta_{G^x}^+(u)$ **then** *push:* $\delta \leftarrow \min\{e(u), r_{uv}\}$ $x(u, v) \leftarrow x(u, v) + \delta$ $e(u) \leftarrow e(u) - \delta$ $e(v) \leftarrow e(v) + \delta$ $r_{uv} \leftarrow r_{uv} - \delta$ $r_{vu} \leftarrow r_{vu} + \delta$ **else** *relabel:* $d(u) \leftarrow \min\{d(v) + 1 : (u, v) \in \delta_{G^x}^+(u)\}$ **end if**

perform new pushes. Eventually, no more flow can be sent to the sink, and relabeling will send flow back to the source.

When the algorithm terminates, there is no excess in the intermediate nodes, and therefore the preflow is a feasible flow. Since the algorithm maintains valid distance labels and $d(s) = n$ throughout the algorithm execution, then there are no augmenting paths from s to t in the residual graph. Therefore, the termination criterion of the augmenting path algorithm is met, and the flow sent to t is a maximum flow. Goldberg and Tarjan in [37] proved that the generic version of the preflow-push algorithm terminates in $O(n^2m)$ time. The computational time is dominated by nonsaturating pushes.

In [38], the authors have proposed an efficient implementation where each vertex v maintains a list of incident arcs, in a fixed but arbitrary order; the vertex also keeps track of its *current* arc, which will be the next one used for pushing operations originating from v . The implementation iteratively performs the *discharge* operation, shown in [Algorithm 4](#). The operation attempts iteratively to push excess of flow from an active node along its current arc. If the arc is saturated, the current arc is replaced with the next one in the list; if the last arc of the list has

Algorithm 4 Discharge operator

```

procedure Discharge(u)
let  $(u, v)$  be the current edge for  $u$ 
time_to_relabel  $\leftarrow \text{false}$ 
while  $e(v) > 0$  or  $\text{time\_to\_relabel} == \text{false}$  do
    if  $(u, v)$  is admissible then
        push on  $(u, v)$ 
    else
        if  $(u, v)$  is not the last edge of the list of  $u$  then
            update the current edge with the next one
        else
            update the current edge with the first one
            time_to_relabel  $\leftarrow \text{true}$ 
        end if
    end if
end while
if  $\text{time\_to\_relabel} == \text{true}$  then
    relabel  $u$ 
end if

```

been saturated, the current arc is updated with the first one of the list and the node is relabeled. The operation terminates when either the node is no more active or it has been relabeled.

A crucial factor for the performance of a push-relabel algorithm is the order in which active nodes are examined. Two possible orders are suggested and analyzed in [37] and [44]. In the First In, First Out selection strategy (FIFO), the data structure implemented for the set of active vertices is a queue Q ; therefore, the front vertex of Q is chosen for discharge operations, and all the new active vertices are pushed to the back of it. The other selection strategy is called largest label. According to this strategy, the vertex with the bigger distance label is selected for the discharge operation. The FIFO algorithm runs in $O(n^3)$ time, as shown by Goldberg and Tarjan in [37], while the largest label algorithm runs in $O(n^2m^{1/2})$ time as proved by Cheriyan and Maheshwari [44].

The implementation of the largest label algorithm uses an array of sets L_i , $0 \leq i \leq 2n - 1$ and an index l into the array. The set L_i is composed of all the active vertices labeled with i , which are represented as a doubly linked list. Therefore, the insertion and deletion operations take $O(1)$ time. The index l is the largest label of an active vertex. After the initialization phase, all arcs outgoing from the source are saturated, and all the resulting active vertices (i.e., the vertices adjacent to s) are inserted into L_0 , and l is set to 0. At each iteration, the algorithm removes a vertex from L_l , processes it using the discharge operation, and updates l . The algorithm loops until l becomes negative, that is, when all the vertices are not active. The steps of the process-vertex procedure by Goldberg et al. [38] are shown in [Algorithm 5](#).

Algorithm 5 Process-vertex procedure

Procedure Process-vertexremove vertex u from the current L_l $last_label \leftarrow d(u)$ *Discharge*(u)add to $L_{d(w)}$ each vertex w that became active after the discharge operation**if** $d(u) \neq last_label$ **then** $l \leftarrow d(u);$ add u to $L_l;$ **else** **if** $L_l = \emptyset$ **then** $l \leftarrow l - 1;$ **end if****end if**

This algorithm correctly maintains l , since for each node v $discharge(v)$ either relabels v or reduces to zero its excess, but doesn't do both at the same time. In the first case, v is largest distance label active vertex, and then l must be increased to $d(l)$. In the other case, if the excess at v is zero, then the excess quantity has been moved to vertices with distance labels equal to $l - 1$, so if L_l is empty, l must be decreased by one.

Cheriyan and Mehlhorn [20] presented an alternative proof that the complexity of the preflow-push method by Goldberg and Tarjan using the largest label policy is $O(n^2 m^{1/2})$. The proof is based on a potential function argument, and unlike the one in [44] does not depend on the implementation of the algorithm using current edges.

Ahuja and Orlin [4] proposed a variant of the algorithm that incorporates the concept of *excess scaling* in order to limit the number of nonsaturating pushes. This is done by pushing flow from nodes with a *sufficiently large* excess to nodes with a *sufficiently small* one, and never letting excesses to become too large. The algorithm makes use a parameter Δ called *excess dominator*, which is a power of 2 larger than any excess in the residual graph, and guarantees that each nonsaturating push sends at least $\Delta/2$ units of flow. The preflow-push algorithm with excess scaling computes a maximum flow in $O(nm + n^2 \log U)$ time, where U is a bound on arc capacities. The authors also presented a parallel implementation using the PRAM model and requiring $p = \lceil n/m \rceil$ processors that runs in $O(n^2 \log U \log p)$ time. Subsequently, Ahuja et al. [6] developed two improved versions of the excess-scaling algorithms, namely, the *stack-scaling algorithm* that runs in $O(nm + n^2 \log U / \log \log U)$ and the *wave-scaling algorithm* that runs in $O(nm + n^2 (\log U)^{1/2})$. They also demonstrated that the time complexity of the latter algorithm can be lowered to $O(nm \log((n/m)(\log U)^{1/2} + 2))$ by using dynamic trees in the implementation.

Mazzoni et al. [45] proposed an algorithm that first finds a maximum preflow (the so-called first phase), and then converts the preflow in a maximum flow (the second phase). In the first phase, the algorithm selects an active node v , detects

an augmenting path from v to t , and moves some amount of flow along such a path. Then, it repeats this process until no augmenting path exists from any active node to the sink. Once a maximum preflow is found, in the second phase, the generic algorithm sends to the source the excess flow of each active node along augmenting paths from active nodes to s .

Cerulli et al. [18] analyzed a potential drawback of the preflow-push algorithm, defined *ping pong effect*. This issue, deriving from the local nature of the choices made by the procedure, occurs when flow units are iteratively exchanged between a node u and a node v along a sequence of push-relabel operations. Interrupting this sequence might require the distance label of one of the two nodes to become greater than the one of the source, which can correspond to $\Omega(n)$ flow exchanges between the nodes and $\Omega(n^2)$ overall push operations. To overcome the ping pong effect, the authors proposed a procedure called budget algorithm. The algorithm combines the preflow-push and the augmenting path approaches in order to make sure that, starting from a node u , instead of sending flow to node v with $d(u) = d(v) + 1$, it is sent to a node v' such that $d(u) - d(v') \geq k$ for a given constant k .

3 Edge-Labeled Graphs

In the graph theory literature, a considerable amount of work has been spent to face problems related to colored (labeled) graphs. Labeled graphs, as opposed to weighted graphs, are used to model situations where it is crucial to represent qualitative differences (instead of quantitative ones) among different regions of the graph itself. Each label represent a different property (or set of properties) to model. More in detail, considering colors or labels in association to the edges of a graph, it is possible to divide the literature contributions in two main classes: The works related to the assignment of such colors (edge coloring problems), and the ones whose aim is to find homogeneous or heterogeneous substructures in the case in which such an assignment is already given (problems on edge-labeled graphs). The maximum flow problem variant presented in Sect. 4 belongs to the second class. Some of the main existing results related to this class are summarized in this section. Problems defined on edge-labeled graphs usually are stated as an input graph $G = (V, E, L)$ such that V is the set of the vertices, E is the set of the edges, and L is the set of labels in the graph. Each edge $e \in E$ has an associated label $l_e \in L$. Moreover, let $n = |V|$ and $m = |E|$. Problems belonging to this field of research have application in many fields, like communication networks, multimodal transportation networks, and molecular biology, among others.

One of the most widely studied problem in this area is the minimum labeling spanning tree problem (MLST). Given an undirected edge-labeled graph $G = (V, E, L)$, the problem consists in finding the spanning tree with the minimum number of colors. The problem was initially addressed by Broersma and Li [9]. They proved, on the one hand, that the MLST is NP-hard by reduction from the minimum dominating set problem, and, on the other hand, that the “opposite” problem of looking for a spanning tree with the maximum number of colors is polynomially solvable. Independently, Chang and Leu [19] provided a different NP-hardness proof

of the problem by reduction from the Set Covering problem. They also developed two heuristics to find feasible solutions of the problem and tested the performance of these heuristics by comparison with the results of an exponential exact approach based on an A* algorithm, reporting very good performances for one of the heuristics (the maximum vertex covering algorithm, or MVCA). Krumke and Wirth [42] presented a modification of MVCA and demonstrated that the algorithm approximates the optimal solution with a worst case ratio of at most $2 \ln n + 1$. They also showed that the other heuristic in [19] can perform arbitrarily bad and that the problem cannot be approximated within a constant factor unless $P = NP$. Wan et al. [60] provided a better analysis of the MVCA variant given in [42] by showing that its worst case performance ratio is at most $\ln(n - 1) + 1$. More recently, Xiong et al. [62] obtained the better bound of $1 + \ln(b)$, where each color appears at most b times.

The pseudocode for the procedure is given in [Algorithm 6](#). It starts from a subgraph H composed by all the nodes of G and an empty set of edges. Iteratively, it adds to the subgraph all the edges with a given label, until H is connected. At each iteration, the label whose insertion would produce the smallest number of connected components is selected.

There also exist some works in literature presenting metaheuristic comparisons for the resolution of the MLST problem, including genetic, pilot method, simulated annealing, VNS, tabu search, and GRASP [15, 23, 61, 63].

Captivo et al. [11] presented a mixed integer linear formulation for MLST based on single-commodity flow. Moreover, the authors demonstrated that by relaxing the binary variables related to the selection of the edges, an optimal solution for the original problem is always found, while the computational time required to solve the formulation by means of a solver is greatly reduced.

A variant of the problem has been studied by Brüggemann et al. [10], where the MLST with bounded color classes has been addressed, in which each color appears a maximum of r times in the graph. This special case of the MLST is polynomially solvable for $r = 2$, and NP-hard and APX-complete for r greater than or equal to 3; moreover, they showed that the problem can be approximated with a factor equal to $r/2$ through local search.

A different variant, where the edges are both labeled and weighted, was proposed by Xiong et al. [65]. The authors investigated the label-constrained minimum spanning tree problem (LCMST), where given a positive integer k , the aim to find a minimum weight spanning tree that uses at most k distinct labels. The problem was demonstrated to be NP-complete. Moreover, the authors proposed two different local search schemes, a genetic algorithm and two ILP formulations based on single-commodity and multi-commodity flow. The authors also introduced the related problem consisting in finding the spanning tree with the minimum number of labels which respects a bound on the total weight, defined cost-constrained minimum label spanning tree (CCMLST). They presented an algorithmic framework based on bisection search that, given a generic algorithm for LCMST, can be used to find heuristic solutions for CCMLST.

The minimum labeling Steiner problem is a variant of the classical Steiner problem and is an extension of the MLST that has also been object of study; in

Algorithm 6 Modified maximum vertex covering algorithm**Procedure MVCA**

return L'

this problem, a subset of *basic* nodes is considered as in the case of the Steiner tree problem, and the problem consists in finding a subgraph covering all the basic nodes using the minimum number of labels. The problem was originally proposed by Cerulli et al. [17], where the authors presented a heuristic algorithm based on MVCA and several metaheuristics, namely, VNS, reactive tabu search, simulated annealing, and pilot method. Consoli et al. [22, 24, 25] proposed GRASP, discrete particle swarm, and VNS metaheuristics, as well as a hybrid local search combining VNS and simulated annealing.

Carr et al. [12] analyzed a possible generalization of MLST, which is the problem of finding a subgraph with the minimum number of nodes that satisfies certain connectivity constraints. They called this problem the min-color generalized forest and showed that even the simplest case, in which given a couple of nodes $\{s, t\}$ the aim is to find the $s-t$ path with fewer labels (MLP), is at least as hard to approximate as the red-blue set cover problem. In the red-blue set cover problem, given two sets of elements R and B and a family $S \subseteq 2^{R \cup B}$, the aim is to find a subfamily $C \subseteq S$ that covers all elements in B and the minimum number of elements in R . Unless $P = NP$, the red-blue set cover problem cannot be approximated within $O(2^{\log^{1-\delta} |S|})$, where $\delta = 1/\log \log^c |S|$ for any $c < 1/2$.

In Yuan et al. [66] the authors took into account reliability issues related to mesh networks in scenarios when several connections can fail due to the same event, by associating colors to failures. Therefore (assuming that each failure event could occur with the same probability), they also proposed the problem of finding the $s-t$ path with the minimum number of labels, that they called minimum-color

single-path (MCSiP). Furthermore, they introduced two problems in which the aim is to find two link-disjoint $s-t$ paths that minimize either the total number of colors (minimum total color disjoint-path or MTCDiP) or the number of overlapping colors (minimum overlapping color disjoint-path or MOCDiP). MTCDiP aims at reducing the overall possibility of a failure, while MOCDiP minimizes the possibility that both paths could fail due to a single failure. The authors proved that the problems are NP-complete and proposed integer linear formulations as well as heuristic algorithms for each of them.

Other results regarding MLST and MLP can be found in Hassin et al. [39]. In this work, the authors proposed a variant of MLST where a weight is associated to each label and showed an extension of the modified MVCA that yields an approximation guarantee equal to H_{n-1} , that is, the $n - 1$ th harmonic number. Moreover, by terminating prematurely MVCA and switching to the exact algorithm proposed in [10] when each label does not appear more than twice, they obtained an algorithm with $H(r) - 1/6$ approximation for the MLST when each label appears at most r times in the graph. They also proposed an $O(\sqrt{m})$ approximation algorithm for MLP and proved that the algorithm cannot be approximated within a polylogarithmic factor unless $P = NP$.

In Zhang et al. [67], the authors investigated the minimum label $s-t$ cut problem (MLC). Given a couple of nodes $\{s, t\}$, the objective of the problem is to select a subset of labels with minimum cardinality such that the removal of the corresponding edges would disconnect s from t . The authors presented an $O(\sqrt{m})$ approximation algorithm and showed that the problem cannot be approximated within $2^{\log^{1-1/\log \log^c n} n}$. They also proved that the same approximation hardness holds for MLP, improving previous approximation results.

A variant of the classical Hamiltonian cycle problem, in which the aim is find a Hamiltonian cycle with the minimum number of colors, has also been object of studies. The problem can be considered, for instance, a variant of the traveling salesman problem in cases in which connections belong to different transportation providers adopting fixed-rate charging. The problem was introduced by Cerulli et al. [16] with the name minimum labelling Hamiltonian cycle problem (MLHC). They proved the problem to be NP-complete both on general and complete edge-colored graphs and proposed a heuristic algorithm as well as a Tabu Search metaheuristic. Independently from their work, Xiong et al. [64] introduced the same problem limiting their scope to complete graphs, with the name colorful traveling salesman problem (CTSP). This work also includes a constructive heuristic and a metaheuristic, namely, a genetic algorithm.

Couëtoux et al. [26] presented approximation algorithms and hardness approximation results for the TSP with both the maximum and the minimum number of colors on complete edge-colored graphs. Regarding the maximization version, they introduced an algorithm with $\frac{1}{2}$ -approximation based on local improvements and showed the problem to be APX-hard. The minimization version was proved to be not approximable within $n^{1-\epsilon}$ for any fixed $\epsilon > 0$, where n is the number of nodes in the graph. Moreover, the authors demonstrated that if each color does not appear more than r times, where r is an increasing function of n , the problem cannot be approximated within a factor that is less than $O(r^{1-\epsilon})$ for any $\epsilon > 0$. Finally,

for the special case where color frequency is a constant, a greedy algorithm with approximation factor equal to $\frac{r+H_r}{2}$ was shown. For each algorithm, the authors demonstrated the tightness of their analysis by means of worst-case test instances.

Similarly to what was done in [65] for the MLST problem, in [40] the authors introduced two variants of MLHC defined on graphs that have both costs and labels associated to the edges. In the first variant, a maximum cost for the tour is imposed as constraint, and the aim is to minimize the number of labels. In the second variant, the budget constraint is on the maximum number of labels that can be used, and the Hamiltonian cycle with minimum cost has to be found. The authors presented branch-and-cut optimal algorithms for MLHC and both the variants.

Monnot [50] proposed the labeled perfect matching problem in bipartite graphs. Given an input graph $G = (V, E, L)$, with $|V| = 2n$ and such that E contains a perfect matching of size n , the problem consists in finding the perfect matching with either the minimum (labeled MinPM) or the maximum (labeled MaxPM) number of colors. The author proved that on two-regular bipartite graph (i.e., consisting in a collection of pairwise disjoint cycles with even length), if each label appears at most r times, both the problems are APX-complete for each $r \geq 2$. Using reductions from MinSAT and MaxSAT, he also proved that the minimization variant is 2-approximable and the maximization one is 0.7846-approximable. On complete bipartite graphs, it was proven that the labeled MinPM is APX-complete for $r \geq 6$ and can't be approximated within a factor of $O(\log n)$. The author also proposed a greedy algorithm for labeled MinPM which selects in each iteration a monochromatic matching with maximum size and showed that it provides a $\frac{r+H_r}{2}$ -approximation. Subsequently, in Monnot [51] the author showed that labeled MinPM is not in APX whenever it is defined on a bipartite graph with maximum degree equal to 3 and that unless $P = NP$ the problem is not in polyLog-APX.

Carrabs et al. [13] presented the labeled maximum matching (LMM) problem, in which the aim is to determine the maximum matching with the minimum number of different colors. They proved that the problem is NP-complete and presented four mathematical formulations, as well as a branch-and-bound approach.

In [30] several of the above mentioned problems were analyzed in terms of parameterized complexity. More in detail, the authors considered MLST, MLHC, MLP, MLC, labeled MinPM, LMM, and the minimum label edge dominating set (MLEDS), in which the objective is the edge-dominating set that uses the minimum number of labels. When parameterized by the number of used labels, all the problems are W[2]-hard. On the other hand, when parameterized by the solution size, MLP and MLC are W[1]-hard, while all the other problems are fixed-parameter tractable.

Several other works in this area are focused on the determination of properly edge-colored subgraphs respecting a specific pattern. A subgraph $G' = (V', E', L')$ of $G = (V, E, L)$ is *properly edge-colored* if and only if $|E'| \geq 2$ and any two successive edges differ in color. A *properly edge-colored path* does not allow that two adjacent edges have the same color and vertex repetitions. A *properly edge-colored trail* does not allow edge repetitions and every successive couple of edges must differ in color.

The determination of properly edge-colored $s-t$ paths is known to be solvable in polynomial time for general graphs with two colors as showed by Bang-Jensen and Gutin [8]. Their results were extended by Szeider [58], who proved that the problem of finding a properly colored path in a graph with any number of colors can be solved in linear time. Abouelaoualim et al. proved in [1] the equivalence between properly edge-colored path and properly edge-colored trails. They also stated that the existence of properly edge-colored $s-t$ trails can be checked in polynomial time (as a straightforward consequence of the results in [58]), presenting a polynomial procedure for both of them. Finally, they proved that is NP-complete to check the existence of k pairwise vertex/edge disjoint properly edge-colored $s-t$ paths or trails in an edge-colored graph $G = (V, E, L)$ even for $k = 2$ and $|L| = O(|V|^2)$, and that these problems are still NP-complete on graphs with $|L| = O(|V|)$ that do not contain properly edge-colored cycles.

Abouelaoualim et al. [2] gave sufficient degree conditions for the existence of properly edge-colored cycles and paths in edge-colored graphs, multigraphs and random graphs. In particular, they proved that an edge-colored multigraph of order n with at least three colors and with minimum color degree greater or equal to $\lceil(n + 1)/2\rceil$ has properly edge-colored cycles of all possible lengths, including Hamiltonian cycles.

Agueda et al. [3], introduced the properly edge-colored spanning tree problem. There exist two types of properly edge-colored tree, called weak (WST) and strong (SST), respectively; the main difference among them is that in a weak tree adjacent edges may have the same color. More formally, a tree T in an edge-colored graph is a SST if every two adjacent edges differ in color, while given a root node r it is a WST if any path in T from r to a leaf is a properly edge-colored one.

The authors presented sufficient conditions for the existence of spanning trees with both patterns.

Finally, it's worth reporting the main results related to problems involving edge-colored graphs and connection (or reload) costs applied to each vertex, which depend on the colors of its adjacent edges.

The reload cost model was introduced by Wirth and Steffan [57]. In a given undirected edge-colored graph G , with edges of the same color constituting a subgraph, let a *reload cost matrix* R represent the costs of moving from one subgraph to another, that is, the cost of switching between the corresponding colors. The reload cost of a path in G is the sum of the reload costs that arise at its internal nodes from passing from the color of an incident edge to the next one. Wirth and Steffan [57] proved that the *Min-Diam* problem (i.e., the problem of looking for a spanning tree of G having a minimum diameter and taking into account the reload cost) is not approximable at all, even when the maximum degree of the graph is five. If, instead, the reload costs satisfy the triangle inequality, the problem is named Δ -*Min-Diam*. They proved that this problem is not approximable within a logarithmic bound. Galbiati [34] showed that *Min-Diam* on graphs having maximum degree 4 cannot be approximated within any constant $\epsilon < 2$, and Δ -*Min-Diam* cannot be approximated within any constant $\epsilon < 5/3$.

4 Maximum Flow with the Minimum Number of Labels (MF-ML)

In this section, a variant of the classical maximum flow problem on edge-labeled graphs, which has been introduced by Cerulli and Granata [14], will be presented, namely, the *maximum flow with the minimum number of labels* (MF-ML). Given a directed capacitated and labeled graph $G = (N, A, L)$, where a capacity and a label belonging to the set L are associated with each arc, the aim is to look for a maximum flow on G , from a source s to a sink t , using the minimum number of different labels.

A practical application of MF-ML concerns the purification of water during the distribution process. Contamination in distribution systems may result from many factors including cross connections to sewers, contamination at service reservoirs and poor hygiene practice during repairs. All the water distribution systems can be contaminated by ingress of pollutants through leaks present in the pipes, pumps, valves, or storage tanks with consequences for the public health. Therefore, it is crucial to maintain water quality and reduce the possibility to deliver water with pollutants to households. To this end, the water is collected in cisterns, before the distribution to customers, where it is subjected to a decontamination process. Now, suppose to identify each pollutant with a different color and to associate a color with the pipe of the distribution network according to the pollutant, it could be subjected to (in case of more pollution contaminations associated with a single pipe, it is possible to model the pipe with a chain of arcs labeled with different pollution colors). Minimizing the number of colors used to bring the maximum flow from sources to destinations (cistern) means to minimize the pollutions eventually involved in a possible contamination and then minimizing the number of treatments to use during the decontamination process.

In the sequel of the section, a more formal definition of the problem and an analysis of its time complexity are initially presented. Then, a mathematical model and some possible enhancements are proposed. Finally, since the problem is NP-hard, a metaheuristic procedure based on the skewed *VNS* scheme is described, and related preliminary computational results are reported.

4.1 Basic Notations and Definitions

Let $G = (N, A, L)$ be a directed graph where a label $l_{ij} \in L$ and a capacity u_{ij} are assigned to each arc $(i, j) \in A$. Two special nodes s and t in G are given. Given a feasible flow $x = \{x_{ij}\}$ on G , denote with G^x the subgraph of G containing only edges (i, j) with $x_{ij} > 0$, that is $G^x = (N, A^x, L^x)$ with $A^x = \{(i, j) \in A : x_{ij} > 0\}$ and $L^x = \{l_{ij} : (i, j) \in A^x\}$. Moreover, given a label $l \in L$, let $A^l = \{(i, j) \in A : l_{ij} = l\}$. The couple (x, \hat{f}) is used to denote a feasible flow x with value \hat{f} . From now on, denote by f^* the value of the maximum flow on G from s to t . The MF-ML problem consists in looking for, among all the admissible

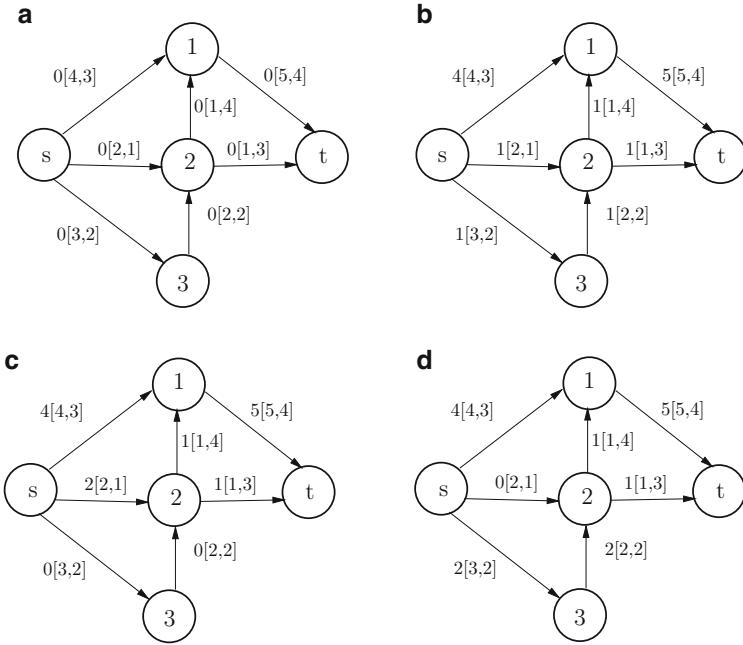

Fig. 3 (a) The starting graph G with $f^* = 6$. (b) A feasible solution with four labels $\{1, 2, 3, 4\}$. (c)–(d) Two optimal solutions with three labels, $\{1, 3, 4\}$ and $\{2, 3, 4\}$, respectively. Note that only the labels $\{3, 4\}$ are necessary as well nodes 1 and 2

flows with value f^* , a flow x such that $|L^x|$ is minimized. In the following, two useful definitions are introduced.

Definition 1 (Necessary label) A label $k \in L$ is a *necessary label* if and only if there is no feasible solution (x, f^*) in the subgraph $G_k = \{N, A_k, L \setminus \{k\}\}$ with $A_k = \{(i, j) \in A : l_{ij} \in L \setminus \{k\}\}$.

Definition 2 (Necessary node) A node $i \in N \setminus \{s, t\}$ is a *necessary node* if and only if the value of the maximum flow f_i^* on the subgraph of G induced by the nodes in $N \setminus \{i\}$ is strictly lower than f^* .

Denote by $\mathcal{CL} \subseteq L$ the set of the necessary labels and by $\mathcal{CN} \subseteq N$ the set of the necessary nodes. Moreover, let $f_i^- = f^* - f_i^* \forall i \in \mathcal{CN}$; it is straightforward to understand that for any max flow solution at least f_i^- units of flow have to pass through any necessary node i .

In the example in Fig. 3, labels $\{3, 4\}$ as well as nodes $\{1, 2\}$ are necessary. Moreover, $f_1^* = 1$ and $f_2^* = 4$.

4.2 Time Complexity

In this section, a proof that the decisional version of problem MF-ML is NP-complete is given. Consider the decisional version of the problem, namely, the *bounded labeled maximum flow problem (BLMFP)*:

Bounded Labeled Maximum Flow Problem: Given a directed, capacitated, and edge-labeled graph $G = (N, A, L)$, with a source node $s \in N$, a sink node $t \in N$, and a positive integer k , is there a maximum flow x from s to t in G such that the total number of different labels corresponding to arcs (i, j) with $x_{ij} > 0$ is less than or equal to k ?

Theorem 3 *The bounded labeled maximum flow problem is NP-complete.*

Proof It is easy to see that BLMFP is NP since it can be checked in polynomial time whether a given flow is feasible and maximum and whether the number of different labels of the arcs with a positive flow is less than or equal to k .

The theorem is proved by reduction from the minimum labeled spanning tree problem (MLST [9]). Let $G = (N, A, L)$ be an undirected and edge-labeled graph. Given an instance of MLST, let us generate a directed and arc-labeled graph $G' = (N', A', L')$ with a capacity associated with each arc and show that there exists a spanning tree of G with at most k labels if and only if there exists a maximum flow x from s to t in G' such that the total number of different labels of the arcs with a positive flow is at most $k' = k + 1$ (Fig. 4).

Let G' be the directed graph obtained from G in the following way:

- Replace any edge $(i, j) \in A$ with two directed arcs (i, j) and (j, i) having the same label of the original arc and associate a capacity $n - 1$, where $n = |N|$, with both of them.
- Add two new nodes in G' , respectively, the source node s and the sink node t ($N' = N \cup \{s, t\}$).
- Connect the source s to a generic node, say node w , by adding the arc (s, w) with capacity $n - 1$ and a new label z .
- Connect any node, but node w , to the sink node t , with z -labeled arcs, (j, t) whose capacity is equal to 1.

Therefore, G' contains $|N'| = n + 2$ vertices, $|A'| = 2|A| + n$ arcs, and $|L'| = |L| + 1$ labels. This construction can be accomplished in polynomial time. Note that the maximum flow value in G' is equal to $n - 1$, and all the z -labeled arcs must have a positive flow in each maximum flow solution.

Consider now a spanning tree T of G with at most k labels. A maximum flow in G' from s to t can be defined by sending a positive flow on all the z -labeled arcs and along the arcs of G' generated starting from the edges of T (see Fig. 4). Note that such a flow has at most $k' = k + 1$ labels. Vice versa, consider a maximum flow from s to t in G' with at most k' labels. This flow is such that all the z -labeled arcs have a positive flow and all the arcs with a positive flow whose label other than z form a spanning tree of G with at most $k = k' - 1$ labels. \square

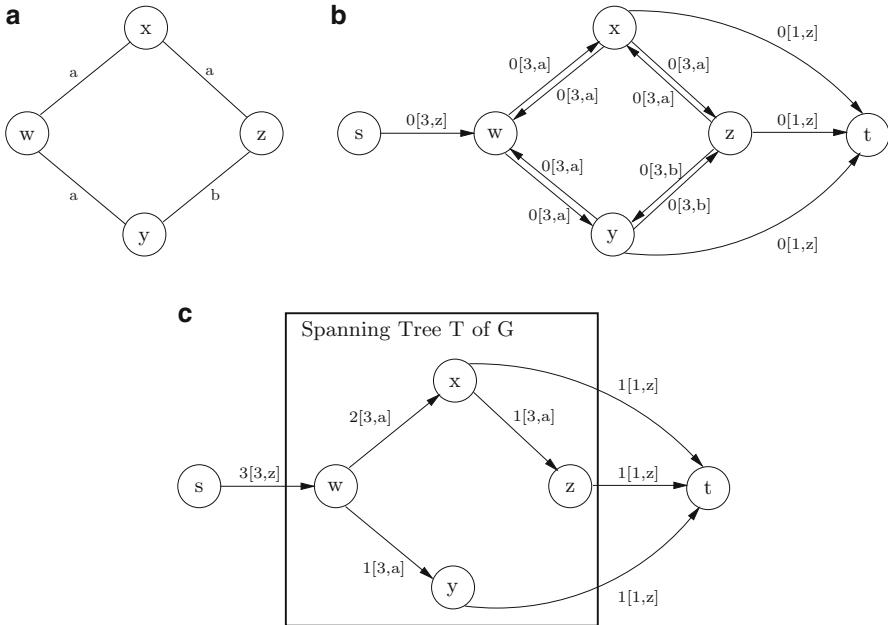

Fig. 4 (a) Graph G (generic MLST instance). (b) Graph G' obtained from G . (c) Graph G' where only arcs with positive flow and the related spanning tree T of G are shown

4.3 A Mathematical Formulation

Given a capacitated and arc-labeled directed graph $G = (N, A, L)$ and a feasible flow (x, f^*) , for each label $k \in L$, introduce a binary variable y_k whose value is equal to 1 if $k \in L^x$ and 0 otherwise. Let B be an input matrix where the entry b_{ij}^k ($(i, j) \in A$ and $k \in L$) is equal to 1 if $l(i, j) = k$ and 0 otherwise.

An integer linear programming formulation (ILP1) for MF-ML is the following:

$$(ILP1) \quad \text{ZILP1} = \min \sum_{k \in L} y_k \quad (10)$$

subject to

$$u_{ij} y_k \geq b_{ij}^k x_{ij} \quad \forall (i, j) \in A, k \in L \quad (11)$$

$$\sum_{(i,j) \in \delta_G^+(i)} x_{ij} - \sum_{(j,i) \in \delta_G^-(i)} x_{ji} = \begin{cases} f^*, & i = s; \\ 0, & \forall i \in N \setminus \{s, t\}; \\ -f^*, & i = t. \end{cases} \quad (12)$$

$$0 \leq x_{ij} \leq u_{ij} \quad \forall (i, j) \in A \quad (13)$$

$$y_k \in \{0, 1\} \quad \forall k \in L \quad (14)$$

Constraints (11) force the variable y_k to be equal to 1 if there exists at least one arc with positive flow whose associated label is k . Otherwise the variable y_k is not constrained and will be set to 0 to minimize the objective function. Constraints (12) and (13) are the classical flow conservation and capacity constraints once the flow value is fixed to f^* .

The (ILP1) formulation can be strengthened by incorporating information about the necessary nodes and labels, obtaining (ILP2):

$$(ILP2) \quad z_{ILP2} = |\mathcal{CL}| + \text{Min} \sum_{k \in L \setminus \mathcal{CL}} y_k \quad (15)$$

subject to

(12) and (13)

$$u_{ij} y_k \geq b_{ij}^k x_{ij} \quad \forall (i, j) \in A, \quad k \in L \setminus \mathcal{CL} \quad (16)$$

$$\sum_{(j,i) \in \delta_G^-(i)} x_{ji} \geq f_i^- \quad \forall i \in \mathcal{CN} \quad (17)$$

$$\sum_{(i,j) \in \delta_G^+(i)} x_{ij} \geq f_i^+ \quad \forall i \in \mathcal{CN} \quad (18)$$

$$y_k \in \{0, 1\} \quad \forall k \in L \setminus \mathcal{CL} \quad (19)$$

By introducing necessary labels, it is possible to reduce the cardinality of the set the binary variables, since variables corresponding to such labels would be always set to 1. Moreover, as already discussed, positive flow will pass through each necessary node, which brings to constraints (17) and (18).

A further improvement could be obtained by considering an additional class of valid inequalities defined as follows.

A *label cutting set* is a set of labels CS such that at least one of them is in every optimal solution. A cutting set CS is minimal if there does not exist another cutting set CS' such that $CS' \subset CS$. For example, in Fig. 3 the label set {1,2} is a minimal cutting set. Note that, by definition, a single necessary label is a minimal cutting set. Moreover, it can be also observed that for each necessary node, the set of labels belonging to its ingoing arcs as well as the ones of the outgoing arcs define two cutting sets.

For each cutting set CS, the valid inequality $\sum_{k \in CS} y_k \geq 1$ can be derived, which can be further strengthened by considering minimal cutting sets.

In order to obtain good lower bounds using the above presented formulation, one possibility is to relax the binary variables y . However, it is experimentally verified that this continuous relaxation brings to trivial lower bounds. Better lower bounds can be obtained by keeping integrality for variables y_k and by relaxing the flow conservation constraints for intermediate nodes, replacing them with

$$\sum_{(i,j) \in \delta_G^+(i)} x_{ij} - \sum_{(j,i) \in \delta_G^-(i)} x_{ji} \geq -\Delta \quad \forall i \in N \setminus \{s, t\} \quad (20)$$

$$\sum_{(i,j) \in \delta_G^+(i)} x_{ij} - \sum_{(j,i) \in \delta_G^-(i)} x_{ji} \leq \Delta \quad \forall i \in N \setminus \{s, t\} \quad (21)$$

where Δ is a positive chosen value.

4.4 Skewed Variable Neighborhood Search

Skewed variable neighborhood search (SVNS) [49] is a metaheuristic, introduced as an improvement of the simple variable neighborhood search (VNS). The idea was driven by the necessity to explore more fully valleys which are far away from the incumbent solution. Recall that the VNS is based on dynamically changing neighborhood structures during a local search process, without following a trajectory, but searching new solutions in increasingly distant neighborhoods from the current solution, jumping to the next local minimum only if it is a better solution than the incumbent one [46–48].

On the contrary, the SVNS accepts a solution close to the best one known but not necessarily better. In particular, let z be the objective function of a minimization problem (i.e., $z(x) = |L^x|$ in the MF-ML case), x be the current solution, x^* be the incumbent solution, and x'' be the local optimum of a given iteration. Then, SVNS accepts x'' if it improves the incumbent solution (i.e., $z(x'') < z(x^*)$) or if $z(x'') - \alpha\rho(x, x'') < z(x)$, where $\rho(x, x'')$ denotes a distance between the solution x and the new one x'' and α is a given parameter. Whenever the solutions are described by boolean vectors (as in the MF-ML case, by considering the boolean variables y_k), the Hamming distance can be used as a metric for evaluating the distance between the solutions. As for the value of the α parameter, after a tuning phase, in the SVNS algorithm the parameter α is set as follows: $\alpha = 0.5$ if $d \leq 0.5$ and $\alpha = 1.5$ otherwise, where d is a measure of the density of G (the computation of this measure will be discussed in Sect. 4.5).

A starting feasible solution is determined by solving the following problem, which minimizes the sum of the flows along the arcs of the network, by then recovering the corresponding number of used labels z_{UB} :

$$(UB) \quad \min \sum_{(i,j) \in A} x_{ij} \quad (22)$$

s.t. (12) and (13)

The underlying idea of this upper bound method is to find a maximum flow of G with a low number of used arcs since, intuitively, the number of used colors tends to decrease if the number of used arcs decreases as well.

Fig. 5 In this graph example, the maximum flow f can be sent using: (i) a path of two arcs $((s, 1, t)$ with $z_{UB} = 2$); (ii) a path of four arcs $((s, 2, 3, 1, t)$ with $z_{UB} = 4$; (iii) using both the paths (i) and (ii) (with $(z_{UB} = 5)$)

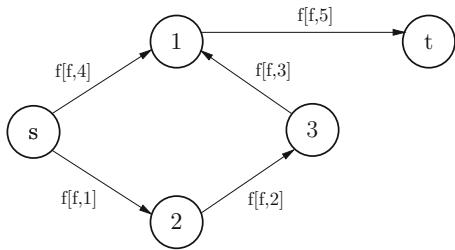

Figure 5 shows that minimizing $\sum_{(i,j) \in A} x_{ij}$ is likely to reduce the number of used arcs.

Moreover, in order to implement a SVNS procedure for the problem, a set of parametric neighborhoods have been defined. These neighborhoods are based on two integer parameters k and β :

- $N_{k,\beta}(x)$: a solution x' belongs to the neighborhood if the label set $L^{x'}$ can be obtained by removing up to k labels in $L^x \setminus \mathcal{CL}$ and adding up to k new labels, and moreover, the new labels associated with arcs which are incident to at least β nodes belonging to \mathcal{CN} .

Let $l_{\max} \in L$ be a label such that $A^{l_{\max}}$ has the maximum cardinality. The SVNS algorithm considers a neighborhood for each value of k in $\{1, \dots, |L \setminus \mathcal{CL}|\}$ and $\beta = 0$; moreover, it considers the neighborhood obtained by the previous definition by choosing $k = \lfloor |A^{l_{\max}}|/2 \rfloor$ and $\beta = 3$. That is, the SVNS algorithm takes into account a set of neighborhoods N_h , $h = 1, \dots, h_{\max}$ such that $N_1 \equiv N_{1,0}, \dots, N_{|L \setminus \mathcal{CL}|} \equiv N_{|L \setminus \mathcal{CL}|,0}$, $N_{|L \setminus \mathcal{CL}|+1} \equiv N_{\lfloor |A^{l_{\max}}|/2 \rfloor,3}$.

In Algorithm 7, the pseudocode of the SVNS procedure is given. In particular, in (a) a random solution is chosen from the current neighborhood; in (b) the algorithm tries to improve this solution by using a simple local search as described in the next subsection; in (c) is checked if the local optimum found is an improvement of the current incumbent, while in (d) it is checked if the found solution respects the SVNS criterion of acceptance.

4.4.1 Local Search Phase

Given a solution x' , at most 200 neighbors belonging to the current neighborhood $N_k(x')$ are examined. The local search phase tries to find a better solution by removing k labels and adding up to $k - 1$ new ones one at time until a new feasible solution is obtained and the β parameter is satisfied. The algorithm stops as soon as a neighbor x'' such that $z(x'') < z(x')$ is found; if no such solution is found after the considered iterations limit, the solution $x'' = x'$ is returned.

4.5 Computational Results

The instances used in the tests have been randomly generated by using three parameters: the number of nodes n , the density of the graph d , and the number of

Algorithm 7 Skewed variable neighborhood search for MF-ML

Procedure Initialize

1. Select the neighborhood structures N_k , for $k = 1, \dots, k_{max}$, where $k_{max} = |L \setminus \mathcal{CL}| + 1$ that will be used in the search;
2. find an initial solution z and its value $z(x)$;
3. $x^* \leftarrow x$
4. $z^* \leftarrow z(x)$

Procedure SVNS

1. $k \leftarrow 1$
 2. **Repeat** the following steps **until** $k = k_{max}$
 - (a) $x' \leftarrow$ Random solution $\in N_k(x)$
 - (b) $x'' \leftarrow LocalSearch(x')$
 - (c) **if** $z(x'') < z^*$ **then**
 $x^* \leftarrow x''$
 $z^* \leftarrow z(x'')$
end if

labels $|L|$. Two collections of scenarios have been generated by considering two different ranges for the value of n . In the first one (*small* instances), the value of n ranges from 20 to 80 with a step equal to 20, while in the second one (*big* instances), the value of n ranges from 100 to 200 using the same step. Parameter d varies in the set 0.2, 0.5, 0.7; the total number of arcs in a given graph is $m = dn(n - 1)$. As for parameter $|L|$, it is set to 20, 30, and 40 % m . For each scenario, three instances have been generated, for a total of 90 scenarios (36 small and 54 big scenarios, respectively) and 270 instances (108 small and 162 big instances, respectively). Tables 1 and 2 report average results for each scenario. In the tables, the first three columns report the scenario characteristics: number of nodes, number of arcs, and number of labels. Columns 4 and 5 report average values for two instance characteristics, that is, maximum flow value f^* and number of necessary labels $|\mathcal{CL}|$. In Table 1, columns with headers RF, ILP1, and ILP2 represent the average optimum values of the relaxed model and the of integer programming formulations, respectively, computed using the *CPLEX* solver. The average computational time for ILP1 and ILP2 are also reported. For each run, the time limit has been set to 3,600 s.

Since some of the small instances are not solved by the solver in the considered time limit, in those cases the best upper bounds found by the solver are used to compute the averages. In particular, it is used the notation sol^{*0} , sol^{*1} or sol^{*2} in

order to indicate whether 0, 1, or 2 instances were solved to optimality. The same notation is also used in a scenario for the relaxed model, where two instances have not been solved in the time limit; therefore, in this case, the average value reported in the table is not a certified average lower bound.

The last three columns in [Table 1](#) are related to the SVNS procedure. In particular, the average solution values are reported as well as running times and percentage gaps with respect to the optimal solution value (or the best upper bound available).

[Table 2](#) contains average results for the big instances. For these scenarios, the results obtained by CPLEX for RF, ILP1, and ILP2 are not reported; in fact, the solver was not able to find solutions within the time limit for most of the instances using these models. Therefore, the SVNS solutions are compared with the trivial lower bound given by $|CL|$.

Looking at [Table 1](#), it can be noticed that the RF formulation returns very good lower bounds. Indeed, in 6 out of 36 scenarios, it always finds certified optimal solutions, while the worst average upper bound is 13.6 % bigger than the optimum and the average gap is 3.79 %. Now, consider the two ILP formulations. It can be noticed that introducing necessary labels and nodes improves effectively the model, since in general the running times are reduced and, as a consequence, ILP2 is able to find five optimal solutions more than ILP1. In total, ILP1 fails to return a certified optimal value in 7 out of 108 instances, while ILP2 fails only twice. The SVNS also returns very good results in fast computational times. The instances with 20 and 40 nodes, it always returns optimal solutions in 52 out of 54 scenarios. In general, the maximum percentage gap is 4.92 %, and the average gap is under 1 %. The maximum average computational time is just 50.65 s.

Regarding [Table 2](#), it is possible to observe that the average gap among the very trivial lower bound $|CL|$ and the SVNS solution values is 89.13 %. This might seem a weak result. However, it should be noticed that the average gap between $|CL|$ and the optimal solution values in [Table 1](#) is 63.5 %, and therefore a good performance

of SVNS on these instances as well can be expected. Further research will be spent in finding nontrivial lower bounds for big instances.

5 Conclusion

In this chapter, the well-known maximum flow problem is reviewed, and an interesting variant on edge-labeled graphs is introduced. Since their introduction, flow problems defined on capacitated networks have been widely studied in the literature because of their great relevance. In fact, they can be used to effectively model and study many situations occurring in the real world. Furthermore, network-flow substructures are often used to model complex optimization problems. In the first part of this work, the most relevant contributions on the maximum flow problem are reviewed. In particular, the attention is focused on the description of augmenting path and preflow-push methods, which are the most commonly used classes of algorithms to face the problem. In the second part of the chapter, the maximum flow problem with the minimum number of Labels (MF-ML) is discussed, which aims at maximizing the amount of flow pushed from a given source to a given destination as well as the homogeneity of the solution on a capacitated network with logic attributes (usually known as colors or labels). This problem finds a practical application, for example, in the process of water purification and distribution. Our discussion starts with an overview of the class of optimization problems defined on labeled graphs, an area that has met a relevant interest in the last few years, in which many new problems have been defined and studied. Then the MF-ML problem is deeply explained by introducing some mathematical formulations and a skewed variable neighborhood search metaheuristic, whose efficiency is supported by a pool of preliminary computational results on randomly generated MF-ML instances.

Abstract

A network interdiction problem usually involves two players who compete in a min–max or max–min game. One player, the network owner, tries to optimize its objective over the network, for example, as measured by a shortest path, maximum flow, or minimum cost flow. The opposing player, called the interdictor, alters the owner’s network to maximally impair the owner’s objective (e.g., by destroying arcs that maximize the owner’s shortest path). This chapter

summarizes the impressive recent development of this field. The first part of this chapter emphasizes interdiction foundations, applications, and emerging research areas. The links between this field and business competition models are then developed, followed by a comparison of interdiction research with parallel developments in robust optimization and survivable network design.

1 Introduction

This chapter discusses classical and emerging network interdiction problems, along with two- and three-stage mathematical programming models and solution techniques that are often employed to solve these problems. It is useful to think of these problems in terms of defenders and attackers of a network. A defender (sometimes called an “operator” or an “owner” of the network) may be a player who wishes to protect the network from damage or optimally push flows across the network using the infrastructure that exists. An attacker (“enemy,” “interdictor,” or “adversary” is also used) seeks to disrupt the defender’s objective to the maximum extent possible. Hence, the attacker may seek to optimally impair the defender’s infrastructure to limit the defender’s overall utility from the network.

For instance, as discussed later in this chapter, a classical (though stylized) example may consist of a defender that builds a pipeline network with the intention of pushing as much flow as possible from an origin to a destination node. The attacker may attempt to destroy a strategic set of links (pipes connecting junction points), which would then minimize the defender’s maximum flow on the resulting network. As such, optimization models for this class of problems are sometimes referred to as *minimax* optimization models. Similarly, *maximin* models exist in which, for example, the attacker may wish to maximize the (optimal) cost that the defender must incur in operating its network.

Most of the standard interdiction problems that have been proposed in the literature regard Stackelberg games [65], wherein the two entities (i.e., a leader and a follower) operate in turn with full knowledge of each other’s actions. In the example given above, the defender is presumably aware of which links have been attacked in the pipeline and adjusts flow accordingly. This assumption can be rather strong, though, and several emerging research areas have targeted problems that relax this assumption within a framework where both players act simultaneously.

The role of “defender” and “attacker” is sometimes given in the context of security and antiterrorism applications, where the attacker plays the role of an adversary. However, this viewpoint is narrow with respect to the overall scope of interdiction research. For instance, it is common to model an attacker as a natural disaster such as a hurricane or earthquake, an accidental failure of infrastructure, or uncertainty about resource availability. None of these entities is, literally speaking, an intelligent and optimizing force that seeks to impede a defender. However, a defender wishing to protect itself in the worst case (restricted to whatever interdiction resources have been allocated to the attacker) must treat accidents as if they are malicious in nature. Hence, an analyst may wish to adopt the philosophy

that the worst possible event will transpire in order to guarantee a minimum level of network performance.

The defender may additionally be capable of combatting an attacker by fortifying its network infrastructure or when that is not practically achievable, installing enough redundancy in the network so that no small simultaneous collection of failures will substantially cripple the network's functionality. One can thus consider a three-stage "defender–attacker–defender" game in which the players act sequentially (again with full knowledge of each other's actions) in a Stackelberg fashion. These problems take the form of min–max–min (or max–min–max) games and are typically substantially more difficult than min–max or max–min games. The fortification actions that take place can be broadly conceived and may involve the fortification or design decisions mentioned above, a reduction of the attacker's resources, deception regarding the defender's infrastructure, and so on.

There are several additional survey treatments of interdiction in the literature. An excellent starting point was provided by Brown et al. [16, 17] in survey and tutorial articles that explain the breadth of interdiction actions, particularly from the standpoint of security. See also [55] for an introductory treatment accessible to beginning optimization researchers and [57] for a recent discussion of the interdiction area.

[Section 2](#) presents some of the founding research principles behind network interdiction, along with key examples that demonstrate common mathematical programming approaches for solving these problems. Emerging areas of interdiction are discussed in [Sect. 3](#). These areas include consideration of uncertain defense/attack strategies, uncertain or differing perceptions of network data, multi-objective interdiction, and fractional interdiction problems where defense/attack actions can be applied at intermediate levels of effectiveness. Applications of these problems pertaining to competition outside traditional interdiction application domains are presented in [Sect. 4](#). The chapter then examines robust optimization theory and survivable network design techniques in [Sect. 5](#) and compares their philosophies to that found in network interdiction studies. Finally, the chapter concludes in [Sect. 6](#).

2 Classical Interdiction Study

This section describes four general types of interdiction problems: shortest path, maximum flow, facility interdiction, and minimum cost flow. These problems are defined on a graph $G(N, A)$, where N represents the vertex set and A represents a set of directed arcs. For each arc $(i, j) \in A$, let c_{ij} represent a per-unit flow cost, and let u_{ij} represent the capacity of arc (i, j) . The *forward star* of node i is the set of arcs that leave node i . The *reverse star* of node i is the set of nodes that enter node i . Formally, the forward star $FS(i) = \{j \in N : (i, j) \in A\}$, and the reverse star $RS(i) = \{j \in N : (j, i) \in A\}$, for all $i \in N$.

In Sect. 2.1, each of the four problem types is described, formulated, and then illustrated with a numerical example. Section 2.2 includes various applications for interdiction problems.

2.1 General Problem Descriptions

First, the general formulation of a *minimax* network interdiction problem is given as follows:

$$\min_{\mathbf{x} \in \mathbf{X}} \max \mathbf{p}(\mathbf{x})^\top \mathbf{y} \quad (1a)$$

$$\text{s.t. } \mathbf{Dy} \leq \mathbf{r}(\mathbf{x}) \quad (1b)$$

$$\mathbf{y} \geq \mathbf{0}, \quad (1c)$$

where \mathbf{x} and \mathbf{y} are the leader and follower variables, respectively, and where $\mathbf{p}(\mathbf{x})$ and $\mathbf{r}(\mathbf{x})$ represent the follower's flow profits and available resources, respectively, as a function of the first-stage decisions. The \mathbf{y} -vector usually represents the flow, and $\mathbf{p}(\mathbf{x})$ and $\mathbf{r}(\mathbf{x})$ may or may not depend on the decisions made by the attacker. The constraints $\mathbf{Dy} \leq \mathbf{r}(\mathbf{x})$ usually consist of flow conservation and capacity constraints. The attacker's feasible region, \mathbf{X} , is typically of the form $\mathbf{X} = \{\mathbf{x} : f_i(\mathbf{x}) \leq b_i \text{ for } i = 1, \dots, m; \mathbf{0} \leq \mathbf{x} \leq \mathbf{e}\}$ where m is the number of constraints, f_i is a function (usually linear) of \mathbf{x} , and \mathbf{e} is a vector of ones. For instance, \mathbf{X} often consists of a single knapsack constraint, for example, an interdiction budget. The attacker is also commonly restricted to making binary decisions in which they must fully attack an arc, or not attack it at all.

2.1.1 Shortest Path Interdiction

The shortest path problem seeks a path from a source node s to a destination node t such that the sum of the arc weights on the path is minimized. In the shortest path interdiction problem, the attacker seeks to maximize the defender's shortest path cost on the network by increasing the cost of some arcs $(i, j) \in A$ from c_{ij} to $c_{ij} + d_{ij}$. Indeed, this construct permits the development of models in which either (a) the cost (or time) to traverse an arc is actually increased by d_{ij} or (b) arc (i, j) is completely destroyed by making d_{ij} a prohibitively large number that prevents traversal of (i, j) at optimality.

Define $N_0 = N \setminus \{s, t\}$ to be the set of intermediate nodes. The shortest path interdiction problem is formulated as follows:

$$\max_{\mathbf{x} \in \mathbf{X}} \min \sum_{(i,j) \in A} (c_{ij} + d_{ij} x_{ij}) y_{ij} \quad (2a)$$

$$\text{s.t. } \sum_{j \in FS(i)} y_{ij} - \sum_{j \in RS(i)} y_{ji} = \begin{cases} 1 & \text{for } i = s, \\ -1 & \text{for } i = t, \\ 0 & \text{for } i \in N_0 \end{cases} \quad (2b)$$

$$\mathbf{y} \geq \mathbf{0}, \quad (2c)$$

where \mathbf{X} again constrains the leader decisions. In the objective function, the cost of arc (i, j) is increased by $d_{ij}x_{ij}$. The constraints in (2b) represent the flow conservation constraints. In order to efficiently solve this two-stage problem, the dual of the minimization problem can be used to combine the problems into a single maximization problem:

$$\max \pi_s - \pi_t \quad (3a)$$

$$\text{s.t. } \pi_i - \pi_j - d_{ij}x_{ij} \leq c_{ij} \quad \forall (i, j) \in A \quad (3b)$$

$$\mathbf{x} \in \mathbf{X}, \boldsymbol{\pi} \text{ unrestricted.} \quad (3c)$$

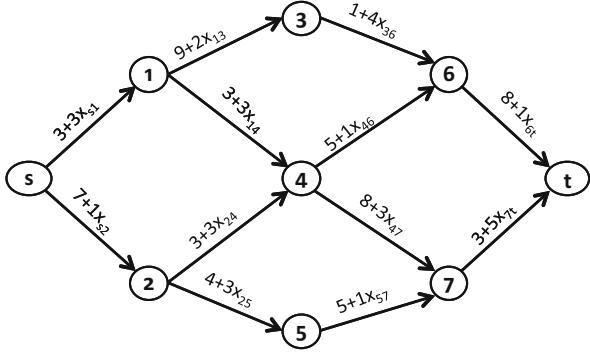

This problem is a linear program so long as \mathbf{X} contains only linear constraints on the \mathbf{x} -variables. However, the literature predominantly regards applications in which the interdictor must destroy all or none of an arc, which require the imposition of binary restrictions on the \mathbf{x} -variables.

Example 1 An evader seeks escape from a starting point s to a safe destination point t in a network, where practically speaking, t may represent a dummy node that represents the union of all safe points in a particular region. A police force seeks to maximize the evader's shortest path by blocking roads. In this example, the police force is the interdicting entity. Suppose that the police force is capable of blocking four roads, subject to some constraints, and that the decisions are binary: a roadblock can either be placed on a road or not placed. Moreover, a road block is effective in one direction on a road, which is equivalent to blocking one (directed) arc in a network. The road blocks serve to delay the evader's escape route as depicted in Fig. 1, which shows the shortest path network (with travel times labeled on each arc).

This shortest path interdiction problem is given as follows:

$$\begin{aligned} \max_{\mathbf{x} \in \mathbf{X}} \min & (3 + 3x_{s1})y_{s1} + (7 + 1x_{s2})y_{s2} + (9 + 2x_{13})y_{13} + (3 + 3x_{14})y_{14} \\ & +(3 + 3x_{24})y_{24} + (4 + 3x_{25})y_{25} + (1 + 4x_{36})y_{36} + (5 + 1x_{46})y_{46} \\ & +(8 + 3x_{47})y_{47} + (5 + 1x_{57})y_{57} + (8 + 1x_{67})y_{67} \\ & +(3 + 5x_{7y})y_{7y} \end{aligned} \quad (4a)$$

$$\text{s.t. } y_{s1} + y_{s2} = 1 \quad (4b)$$

Fig. 1 Shortest path network

$$-y_{s1} + y_{13} + y_{14} = 0 \quad (4c)$$

$$\vdots \quad (4d)$$

$$-y_{6t} - y_{7t} = -1 \quad (4e)$$

$$\mathbf{y} \geq \mathbf{0}, \quad (4f)$$

where $\mathbf{X} = \{\mathbf{x} : x_{s1} + x_{s2} \leq 1, x_{13} + x_{14} + x_{24} + x_{25} \leq 1, x_{36} + x_{46} + x_{47} + x_{57} \leq 1, x_{6t} + x_{7t} \leq 1, \mathbf{x} \in \{0, 1\}^{|A|}\}$. If the police did not set up any road blocks, the optimal path would be $s - 1 - 4 - 7 - t$ with a travel time of 17. After taking the dual of the inner minimization problem, the inner and outer problems can be combined into a single maximization problem, resulting in the following formulation:

$$\max \pi_s - \pi_t \quad (5a)$$

$$\text{s.t. } \pi_s - \pi_1 - 3x_{s1} \leq 3 \quad (5b)$$

$$\pi_s - \pi_2 - 1x_{s2} \leq 7 \quad (5c)$$

$$\vdots \quad (5d)$$

$$\pi_7 - \pi_t - 5x_{7t} \leq 3 \quad (5e)$$

$$x_{s1} + x_{s2} \leq 1 \quad (5f)$$

$$x_{13} + x_{14} + x_{24} + x_{25} \leq 1 \quad (5g)$$

$$x_{36} + x_{46} + x_{47} + x_{57} \leq 1 \quad (5h)$$

$$x_{6t} + x_{7t} \leq 1 \quad (5i)$$

$$\mathbf{x} \in \{0, 1\}^{|A|}. \quad (5j)$$

In an optimal solution, the police interdict arcs $(s, 1)$, $(1, 4)$, $(4, 6)$, and $(7, t)$, which results in a shortest travel time of 24 by changing the shortest path to $s - 1 - 3 - 6 - t$. \square

Remark 1 Note that the evader problem described here is a simplified version of the nuclear smuggling interdiction problem (see, e.g., [40, 43]). In this problem, there exist a probability a_{ij} that an evader can escape undetected through the network if arc (i, j) is not monitored and a probability b_{ij} that the evader escapes if the arc is monitored, where $0 < b_{ij} < a_{ij} < 1$. In this case, the evader seeks a *longest* path, but where this longest path distance is given by

$$\prod_{(i,j) \in A} (a_{ij} - (a_{ij} - b_{ij})x_{ij})^{y_{ij}},$$

where once again, x_{ij} is the degree to which arc (i, j) is interdicted, and y_{ij} is a flow variable that equals 1 if the evader uses arc (i, j) in its evasion path, and $y_{ij} = 0$ otherwise.

One can equivalently maximize the natural log of this function instead (noting that the natural log of a function is increasing over the domain of positive numbers). This problem's objective is given by

$$\begin{aligned} \ln \left(\prod_{(i,j) \in A} (a_{ij} - (a_{ij} - b_{ij})x_{ij})^{y_{ij}} \right) &= \sum_{(i,j) \in A} \ln ((a_{ij} - (a_{ij} - b_{ij})x_{ij})^{y_{ij}}) \\ &= \sum_{(i,j) \in A} \ln (a_{ij} - (a_{ij} - b_{ij})x_{ij}) y_{ij}, \end{aligned}$$

where each coefficient of y_{ij} in the latter expression is negative, by the assumption that $0 < a_{ij} - (a_{ij} - b_{ij})x_{ij} < 1$ for each $(i, j) \in A$ (and because $\ln(q) < 0$ for $0 < q < 1$). The optimization challenge of the evader is therefore a shortest path problem with positive costs. This exercise demonstrates that the more practical version of the evader-interdiction problem in which one minimizes the probability of escape is exactly transformable to the shortest path interdiction problem covered above. \square

2.1.2 Maximum Flow Interdiction

The maximum flow problem seeks to maximize the flow from node s to node t on a capacitated network. In the maximum flow interdiction problem, the interdictor's goal is to minimize the operator's maximum flow. Letting u_{ij} denote the capacity of arc $(i, j) \in A$ and adding a dummy arc (t, s) with $u_{ts} = \infty$, the problem is formulated as follows:

$$\min_{\mathbf{x} \in \mathbf{X}} \max_{\mathbf{y} \in \mathbf{Y}} y_{ts} \quad (6a)$$

$$\text{s.t. } \sum_{j \in FS(i)} y_{ij} - \sum_{j \in RS(i)} y_{ji} = 0, \quad \forall i \in N \quad (6b)$$

$$y_{ij} \leq u_{ij}(1 - x_{ij}) \quad \forall (i, j) \in A \setminus \{(t, s)\} \quad (6c)$$

$$\mathbf{y} \geq \mathbf{0}, \quad (6d)$$

where \mathbf{x} is the interdictor's decision vector and \mathbf{y} is the flow vector. Constraints (6b) are the flow conservation constraints, (6c) are the capacity constraints, which are a function of the interdictor's decisions, and constraints (6d) are the nonnegativity restrictions. Since the inner maximization problem is always feasible (a zero flow is always feasible), the two-stage problem can be combined into a single minimization problem by taking the dual of the inner problem. Letting α and β be dual variables corresponding to (6b) and (6c), respectively, we combine the two stages to obtain the following formulation:

$$\min \sum_{(i, j) \in A \setminus \{(t, s)\}} u_{ij}(1 - x_{ij})\beta_{ij} \quad (7a)$$

$$\text{s.t. } \alpha_i - \alpha_j + \beta_{ij} \geq 0 \quad \forall (i, j) \in A \setminus \{(t, s)\} \quad (7b)$$

$$\alpha_t - \alpha_s \geq 1 \quad (7c)$$

$$\beta \geq \mathbf{0} \quad (7d)$$

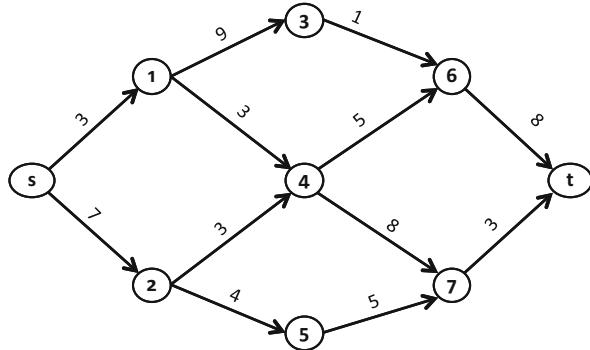

$$\mathbf{x} \in \mathbf{X}. \quad (7e)$$

Unlike the shortest path interdiction problem, this formulation is nonlinear. However, the dual variables β can be further restricted to be binary, because changing the capacity constraints by one will only change the maximum flow by either zero or one unit (i.e., β_{ij} is zero or one, $\forall (i, j) \in A \setminus \{(t, s)\}$). This allows a standard linearization technique to be used in which $x_{ij}\beta_{ij}$ is replaced by a single variable γ_{ij} and the following constraints are added: $\gamma_{ij} \leq x_{ij}$, $\gamma_{ij} \leq \beta_{ij}$, $\gamma_{ij} \geq x_{ij} + \beta_{ij} - 1$, and $\gamma_{ij} \geq 0$. In fact, only the first two constraints are needed because the bilinear terms appear in the objective function with coefficients of -1 .

Example 2 Consider a military conflict in which one of the sides (the “transporter”) has a goal of sending as much supply as possible from its base (denoted by s) to its front lines (denoted by t). The transporter has smaller, intermediate bases at which it can stop on the way to the front lines, but a limited amount of supply can be sent between each pair of points. This network is represented in Fig. 2 with the arc capacities labeled on each arc.

The opposition (interdictor) is capable of disrupting the transporter's flow by removing any arc in the network (e.g., by destroying a bridge). The goal of the

Fig. 2 Maximum flow network

interdictor is to minimize the transporter's maximum flow, and their optimization problem can be formulated as follows:

$$\min_{\mathbf{x} \in \mathbf{X}} \max_{\mathbf{y} \in \mathbf{Y}} y_{ts} \quad (8a)$$

$$\text{s.t. } y_{s1} + y_{s2} - y_{ts} = 0 \quad (8b)$$

$$\vdots \quad (8c)$$

$$-y_{6t} - y_{7t} + y_{ts} = 0 \quad (8d)$$

$$y_{s1} \leq 3(1 - x_{s1}) \quad (8e)$$

$$\vdots \quad (8f)$$

$$y_{7t} \leq 3(1 - x_{7t}) \quad (8g)$$

$$\mathbf{y} \geq \mathbf{0}, \quad (8h)$$

where $\mathbf{X} = \{\mathbf{x} : \sum_{(i,j) \in A} x_{ij} \leq 1, \mathbf{x} \in \{0, 1\}^{|A|}\}$. Without interdiction, the maximum flow is 9 units, which is obtained by sending one unit of flow on the path $s - 1 - 3 - 6 - t$, two units of flow on the path $s - 1 - 4 - 6 - t$, and three units of flow on paths $s - 2 - 4 - 6 - t$ and $s - 2 - 5 - 7 - t$. Taking the dual of the maximization problem and combining the two-stage problem into a single minimization problem gives the following:

$$\begin{aligned} \min & \quad 3(1 - x_{s1})\beta_{s1} + 7(1 - x_{s2})\beta_{s2} + 9(1 - x_{13})\beta_{13} + 3(1 - x_{14})\beta_{14} \\ & + 3(1 - x_{24})\beta_{24} + 4(1 - x_{25})\beta_{25} + 1(1 - x_{36})\beta_{36} + 5(1 - x_{46})\beta_{46} \\ & + 8(1 - x_{47})\beta_{47} + 5(1 - x_{57})\beta_{57} + 8(1 - x_{6t})\beta_{6t} + 3(1 - x_{7t})\beta_{7t} \end{aligned} \quad (9a)$$

$$\text{s.t. } \alpha_s - \alpha_1 + \beta_{s1} \geq 0 \quad (9b)$$

$$\vdots \quad (9c)$$

$$\alpha_7 - \alpha_t + \beta_{7t} \geq 0 \quad (9d)$$

$$\alpha_t - \alpha_s \geq 1 \quad (9e)$$

$$\beta \geq \mathbf{0} \quad (9f)$$

$$\mathbf{x} \in \mathbf{X}. \quad (9g)$$

Using the linearization technique discussed above, the following linear mixed-integer program is obtained:

$$\min 3(\beta_{s1} - \gamma_{s1}) + 7(\beta_{s2} - \gamma_{s2}) + 9(\beta_{13} - \gamma_{13}) + 3(\beta_{14} - \gamma_{14}) \quad (10a)$$

$$+ 3(\beta_{24} - \gamma_{24}) + 4(\beta_{25} - \gamma_{25}) + 1(\beta_{36} - \gamma_{36}) + 5(\beta_{46} - \gamma_{46}) \quad (10b)$$

$$+ 8(\beta_{47} - \gamma_{47}) + 5(\beta_{57} - \gamma_{57}) + 8(\beta_{6t} - \gamma_{6t}) + 3(\beta_{7t} - \gamma_{7t}) \quad (10c)$$

$$\text{s.t. } \gamma_{s1} \leq x_{s1} \quad (10d)$$

$$\gamma_{s1} \leq \beta_{s1} \quad (10e)$$

$$\gamma_{s2} \leq x_{s2} \quad (10f)$$

$$\gamma_{s2} \leq \beta_{s2} \quad (10g)$$

$$\vdots \quad (10h)$$

$$\gamma_{7t} \leq x_{7t} \quad (10i)$$

$$\gamma_{7t} \leq \beta_{7t} \quad (10j)$$

$$\beta \text{ binary} \quad (10k)$$

$$(9b) - (9g). \quad (10l)$$

The optimal solution for the interdictor is to interdict arc (4, 6), which reduces the maximum flow to 4 units. \square

2.1.3 Facility Assignment Interdiction

In the facility assignment problem, a set of facilities is responsible for providing some good or service to a set of demand points. The goal is to minimize the weighted distance required to supply each demand point, where the weight of each demand point may be some function of the amount of demand at the node, or the relative importance of supplying demand to that node. Assuming that the capacity of each facility is large enough to satisfy the total demand of any subset of demand points, an optimal solution is obtained by assigning each demand point to its closest facility. In the facility assignment interdiction problem, the goal is to find a subset of r facilities, which when removed, maximizes the minimum weighted facility assignment objective.

The model for this interdiction problem was introduced by Church et al. [20]. Let N denote the set of demand points (indexed by i), F denote the set of p facilities (indexed by j), a_i denote the demand at node i , d_{ij} denote the distance between facility j and node i , r denote the number of facilities to be interdicted or eliminated, and $T_{ij} = \{k \in F : d_{ik} > d_{ij}\}$ be the set of existing facilities that are farther than j from demand i . The decision variables include interdiction variables x_j , $\forall j \in F$, and assignment variables y_{ij} , $\forall i \in N$, $j \in F$. The variable x_j equals 1 if facility j is interdicted, and 0 otherwise, and y_{ij} equals 1 if demand i is assigned to facility j , and 0 otherwise. The facility assignment interdiction formulation is given as follows:

$$\max \sum_{i \in N} \sum_{j \in F} a_i d_{ij} y_{ij} \quad (11a)$$

$$\text{s.t. } \sum_{j \in F} y_{ij} = 1 \quad \forall i \in N \quad (11b)$$

$$\sum_{j \in F} x_j = r \quad (11c)$$

$$\sum_{k \in T_{ij}} y_{ik} \leq x_j \quad \forall i \in N, j \in F \quad (11d)$$

$$y_{ij} \in \{0, 1\} \quad \forall i \in N, j \in F \quad (11e)$$

$$x_j \in \{0, 1\} \quad \forall j \in F. \quad (11f)$$

The objective function (11a) is the sum of the weighted distances of the facility-demand point assignments. Constraint (11b) requires each demand point to be assigned to a facility, and constraint (11c) requires r facilities be interdicted. Constraint (11d) ensures that demand i is assigned to the closest non-interdicted facility. Constraints (11e) and (11f) give the binary restrictions. It is important to note that if the x -variables are binary, then the y -variables are binary at optimality (given a binary x , there exists an optimal solution in which each demand is fully assigned to its closest non-interdicted facility). Therefore, it is possible to reduce the number of binary variables to p —one for each facility—while equivalently relaxing (11e) to $y_{ij} \geq 0$, $\forall i \in N$, $j \in F$ (with the unitary upper bounds on y_{ij} implied by (11b)).

Example 3 An army has five primary bases that must be assigned to cover nine remote outposts. For simplicity, suppose that each outpost is assigned to the closest primary base and that the effectiveness of the army's operations is given by the sum of base-to-outpost distances. To assess the vulnerability of their coverages, the army would like to know which two large bases, if destroyed, would lead to the largest increase in minimum base-to-outpost distance assignments. Figure 3 shows the network representation along with the d -values and the optimal solution for the case in which no interdiction occurs (resulting an objective function value

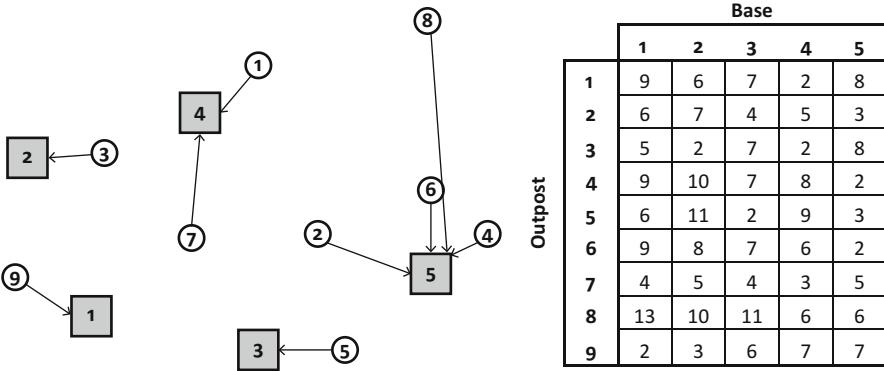

Fig. 3 Facility location example

of 24). For this particular case, $a_i = 1, \forall i = 1, \dots, 9$. The following formulation corresponds to the illustration in Fig. 3, in which $r = 2$:

$$\max \sum_{i \in N} \sum_{j \in F} d_{ij} y_{ij} \quad (12a)$$

$$\text{s.t. } y_{11} + y_{12} + y_{13} + y_{14} + y_{15} = 1 \quad (12b)$$

⋮

$$y_{91} + y_{92} + y_{93} + y_{94} + y_{95} = 1 \quad (12c)$$

$$x_1 + x_2 + x_3 + x_4 + x_5 = 2 \quad (12d)$$

$$0 \leq x_1 \quad (12e)$$

$$y_{11} + y_{13} + y_{15} \leq x_2 \quad (12f)$$

$$y_{11} + y_{15} \leq x_3 \quad (12g)$$

$$y_{11} + y_{12} + y_{13} + y_{15} \leq x_4 \quad (12h)$$

$$y_{11} \leq x_5 \quad (12i)$$

⋮

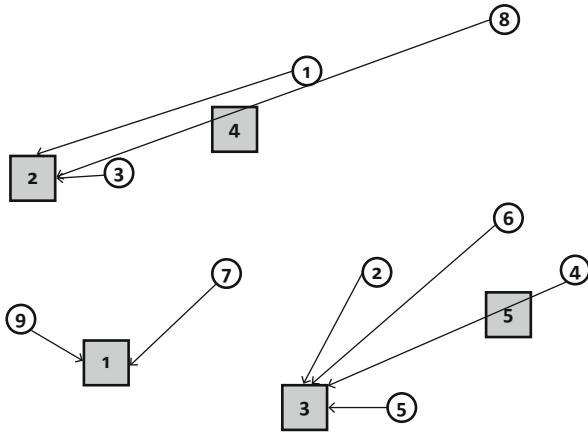

$$y_{92} + y_{93} + y_{94} + y_{95} \leq x_1 \quad (12j)$$

$$y_{93} + y_{94} + y_{95} \leq x_2 \quad (12k)$$

$$y_{94} + y_{95} \leq x_3 \quad (12l)$$

$$0 \leq x_4 \quad (12m)$$

Fig. 4 Facility location solution

$$0 \leq x_5 \quad (12n)$$

$$y_{ij} \geq 0 \quad \forall i = 1, \dots, 9, j = 1, \dots, 5 \quad (12o)$$

$$x_j \in \{0, 1\} \quad \forall j = 1, \dots, 5. \quad (12p)$$

The optimal solution has $x_4 = x_5 = 1$, resulting in an objective function value of 44. [Figure 4](#) shows the revised assignments after the interdiction.

2.1.4 Minimum Cost Flow Interdiction

The minimum cost flow problem seeks to satisfy all node demand requirements in a network at minimum cost and subsumes the cases discussed prior to now. In the minimum cost flow interdiction problem, the interdictor's goal is to maximize the follower's minimum flow cost by reducing or eliminating the capacity on some subset of arcs. Letting d_i be the supply (when positive) or demand (when negative) of node $i \in N$, the minimum cost flow interdiction model is formulated as follows:

$$\max_{\mathbf{x} \in \mathbf{X}} \min \sum_{(i,j) \in A} c_{ij} y_{ij} \quad (13a)$$

$$\text{s.t. } \sum_{j \in FS(i)} y_{ij} - \sum_{j \in RS(i)} y_{ji} = d_i \quad \forall i \in N \quad (13b)$$

$$y_{ij} \leq u_{ij}(1 - x_{ij}) \quad \forall (i, j) \in A \quad (13c)$$

$$\mathbf{y} \geq \mathbf{0}, \quad (13d)$$

where $\sum_{i \in N} d_i = 0$. The goal for the follower is to minimize cost while satisfying the flow conservation constraints (13b) and capacity constraints (13c).

Let α and $-\beta$ be the dual variables corresponding to (13b) and (13c), respectively. The dual formulation to (13) is

$$\max \sum_{i \in N} d_i \alpha_i - \sum_{(i,j) \in A} u_{ij} (1 - x_{ij}) \beta_{ij} \quad (14a)$$

$$\text{s.t. } \alpha_i - \alpha_j - \beta_{ij} \leq c_{ij} \quad \forall (i, j) \in A \quad (14b)$$

$$\beta \geq \mathbf{0} \quad (14c)$$

$$\mathbf{x} \in \mathbf{X}. \quad (14d)$$

The form of the objective function, (14a), leads to a nonlinear optimization problem that seeks to optimally interdict a minimum cost flow.

Remark 2 Unfortunately, it is not generally possible to restrict β to be binary as in the maximum flow interdiction problem because the change in the objective function value as a function of capacity is dependent on the cost vector \mathbf{c} . If \mathbf{x} is binary, then linearization is still possible with suitable upper bounds on β . Moreover, in many cases, \mathbf{X} is given by a set of constraints $\{\mathbf{x} : P\mathbf{x} = \mathbf{q}, \mathbf{0} \leq \mathbf{x} \leq \mathbf{1}\}$. If P is a totally unimodular matrix and \mathbf{q} is integral (see e.g., [4]), then in fact an optimal solution exists in which the \mathbf{x} -variables take binary values. This fact is due to the observation that, given values of α and β , problem (14) is a linear program, and an optimal solution would exist at an extreme point of \mathbf{X} . Because the extreme points of \mathbf{X} would be all binary (due to the total unimodularity of P and integrality of \mathbf{q}), \mathbf{x} is binary in some optimal solution. \square

Example 4 A company has three production facilities and three retail facilities. The company's goal is to satisfy the demand at the retail facilities with the supply from the production facilities at the lowest cost. The company would like to know the worst-case cost associated with transportation in the event that up to two of the roads may be closed (or partially closed). In the network depicted in Fig. 5, the production facilities are labeled with their supply quantities (positive values) and the retail facilities are labeled with their demands (negative values). The table shows, for each arc $(i, j) \in A$, the cost c_{ij} of sending one unit on the arc and the capacity u_{ij} on the arc. Without any road closures, an optimal solution is $y_{16} = 4$, $y_{24} = 3$, $y_{34} = 1$, and $y_{36} = 2$, with all other arcs having zero flow, and a total cost of 37. The interdiction problem is formulated as follows:

$$\begin{aligned} \max_{\mathbf{x} \in \mathbf{X}} \min & 9y_{14} + 6y_{15} + 3y_{16} + 4y_{24} + 6y_{25} + 5y_{26} \\ & + 5y_{34} + 8y_{35} + 4y_{36} + y_{54} + y_{56} \end{aligned} \quad (15a)$$

$$\text{s.t. } y_{14} + y_{15} + y_{16} = 4 \quad (15b)$$

$$\vdots \quad (15c)$$

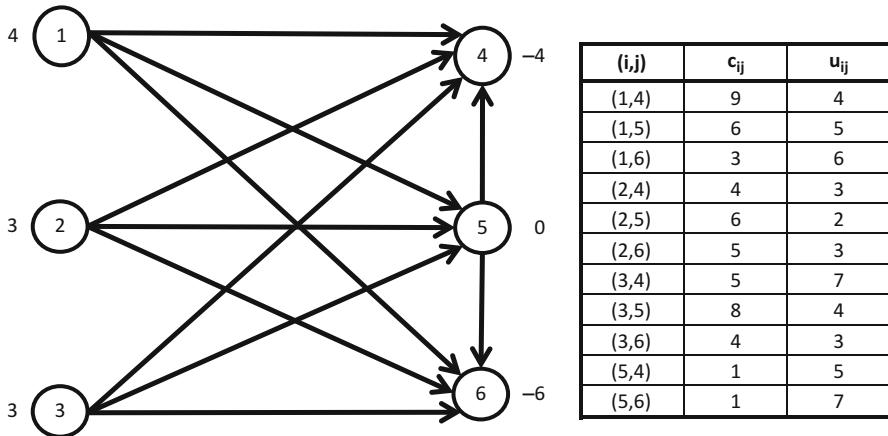

Fig. 5 Minimum cost flow network

$$-y_{16} - y_{26} - y_{36} - y_{56} = -6 \quad (15d)$$

$$y_{14} \leq 4(1 - x_{14}) \quad (15e)$$

$$\vdots \quad (15f)$$

$$y_{56} \leq 7(1 - x_{56}) \quad (15g)$$

$$\mathbf{y} \geq \mathbf{0}, \quad (15h)$$

where $\mathbf{X} = \{\mathbf{x} : \sum_{(i,j) \in A} x_{ij} \leq 2, \mathbf{0} \leq \mathbf{x} \leq \mathbf{e}\}$. After taking the dual of the minimization problem and combining it with the first-stage problem, the following maximization problem is obtained:

$$\begin{aligned} & \max 4\alpha_1 + 3\alpha_2 + 3\alpha_3 - 4\alpha_4 - 6\alpha_6 - 4(1 - x_{14})\beta_{14} \\ & -5(1 - x_{15})\beta_{15} - 6(1 - x_{16})\beta_{16} - 3(1 - x_{24})\beta_{24} - 2(1 - x_{25})\beta_{25} \\ & -3(1 - x_{26})\beta_{26} - 7(1 - x_{34})\beta_{34} - 4(1 - x_{35})\beta_{35} - 3(1 - x_{36})\beta_{36} \\ & -5(1 - x_{54})\beta_{54} - 7(1 - x_{56})\beta_{56} \end{aligned} \quad (16a)$$

$$\text{s.t. } \alpha_1 - \alpha_4 - \beta_{14} \leq 9 \quad (16b)$$

$$\vdots \quad (16c)$$

$$\alpha_5 - \alpha_6 - \beta_{56} \leq 1 \quad (16d)$$

$$\beta \geq \mathbf{0} \quad (16e)$$

$$\mathbf{x} \in \mathbf{X}. \quad (16f)$$

In this case, because the structural constraints of the set \mathbf{X} consist only of the cardinality constraint enforcing the condition that only two interdictions are allowed, along with the unit upper bounds on the x -variables, the constraints defining \mathbf{X} are totally unimodular. Hence, as explained in Remark 2, the \mathbf{x} -variables are binary, and the nonlinear product terms can be linearized. The optimal solution in this case occurs when the roads corresponding to arcs $(1, 5)$ and $(1, 6)$ are fully closed, resulting in a cost of 63. \square

2.2 Applications

This subsection presents several cases in which interdiction has been applied in real-world settings, as opposed to the simpler illustrative settings mentioned in the previous section.

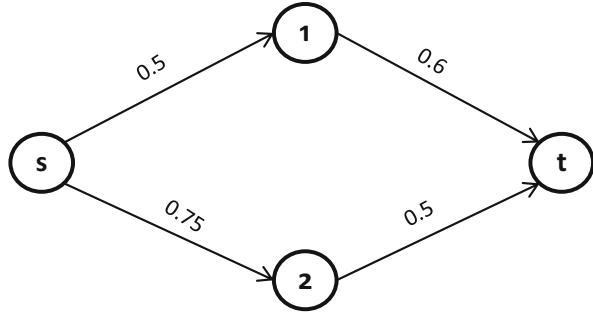

2.2.1 Nuclear Smuggling (Shortest Path Interdiction)

Morton et al. [40] give a shortest path interdiction model for a nuclear smuggling scenario. A joint effort between the United States and Russia, the goal was to determine the optimal locations for nuclear sensors to prevent the smuggling of nuclear material out of the former Soviet Union. Hence, in this case, the interdictors are the American/Russian governments, and the evaders are unknown criminals (as discussed in Remark 1). There is an underlying network on which the evaders travel, and there exists some probability of evasion on each arc. The authors developed a stochastic model in which the origin–destination pairs for evaders are unknown, but follow a known probability distribution. This results in a model where the objective of the interdictor is to minimize the maximum probability of evasion by the criminals. A directed graph $G(N, A)$ is used where $FS(i)$ is the forward star of node i and $RS(i)$ is the reverse star of node i . The interdictor has a total budget, b , with which it can install the sensors, each at a cost of c_{ij} , for all $(i, j) \in A$. Associated with each arc $(i, j) \in A$ is a probability, p_{ij} , that the evader can traverse it undetected when no sensor is installed, as well as a probability, q_{ij} , that the evader can traverse it undetected with a sensor installed. The set of scenarios is denoted by Ω , and each scenario, $\omega \in \Omega$, has a probability of p^ω and an origin–destination realization of (s^ω, t^ω) . The interdictor has one set of decision variables for which x_{ij} takes a value of 1 if a sensor is placed on arc (i, j) , and 0 otherwise. The evader has two sets of decision variables for which y_{ij} is positive only if the evader traverses arc (i, j) and a sensor is not installed, and z_{ij} is positive if the evader traverses arc (i, j) and a sensor is installed. This results in the following model:

$$\min_{\mathbf{x} \in \mathbf{X}} \sum_{\omega \in \Omega} p^\omega h(x, (s^\omega, t^\omega)) \quad (17)$$

where $\mathbf{X} = \{\mathbf{x} : \sum_{(i,j) \in AD} c_{ij} x_{ij} \leq b; x_{ij} \in \{0, 1\}, \forall (i, j) \in A\}$, and $h(x, (s^\omega, t^\omega))$ is the optimal value of

Fig. 6 Nuclear smuggling example

$$\max_{y,z} y_{t^\omega} \quad (18a)$$

$$\text{s.t. } \sum_{j \in FS(s^\omega)} (y_{s^\omega j} + z_{s^\omega j}) = 1 \quad (18b)$$

$$\sum_{j \in RS(i)} (p_{ji} y_{ji} + q_{ji} z_{ji}) = \sum_{j \in FS(i)} (y_{ij} + z_{ij}) \quad \forall i \in N \setminus \{s^\omega, t^\omega\} \quad (18c)$$

$$y_{t^\omega} = \sum_{j \in RS(t^\omega)} (p_{jt^\omega} y_{jt^\omega} + q_{jt^\omega} z_{jt^\omega}) \quad (18d)$$

$$0 \leq y_{ij} \leq 1 - x_{ij}, \quad \forall (i, j) \in A \quad (18e)$$

$$z_{ij} \geq 0 \quad \forall (i, j) \in A. \quad (18f)$$

The objective function in (17) is the expected value of evasion, taken over all possible scenarios. The optimal value of (18) is the probability of evasion given the origin–destination pair (s^ω, t^ω) . Constraint (18b) ensures that one unit of flow leaves the origin, constraint (18c) enforces flow conservation at the intermediate nodes, and constraint (18d) defines the probability of evasion, y_{t^ω} . Constraint (18e) ensures that y_{ij} must be zero if the arc is interdicted. If the evader uses an arc that is not interdicted, since $p_{ij} > q_{ij} \forall (i, j)$, the corresponding y_{ij} -variable would be positive in order to maximize evasion probability. Therefore, given a path P_{s^ω, t^ω} from s^ω to t^ω , this results in:

$$y_{t^\omega} = \prod_{(i,j) \in P_{s^\omega, t^\omega}} [p_{ij}(1 - x_{ij}) + q_{ij}x_{ij}]. \quad (19)$$

To illustrate how y_{t^ω} is calculated, consider the following example illustrated in Fig. 6 in which there is no interdiction (the p_{ij} -values are located on the arcs.) Clearly, the optimal path is $s - 2 - t$, which has an evasion probability of $(0.75)(0.5) = 0.375$. In satisfying constraint (18b), the values $y_{s1} = 0$ and $y_{s2} = 1$ are obtained. In satisfying constraint (18c) for node 2, the value $y_{2t} = 0.75$ is

obtained, and in satisfying constraint (18d), the value $y_t = 0.6y_{1t} + 0.5y_{2t} = 0 + (0.5)(0.75) = 0.375$ is obtained.

The authors also developed a model in which information is asymmetric, that is, the interdictor and the smuggler have different perceptions of the network parameters. Reformulation and duality techniques were used as well as the introduction of step inequalities to improve and tighten the formulations. CPLEX was used to solve the resulting linear mixed-integer programs. See Sect. 3 for further discussion on handling challenges posed by stochasticity and information asymmetry.

2.2.2 Electrical Grids

One highly researched area for applications of network interdiction models arises in electrical grid analysis (see, e.g., [23, 51, 52]). The goal is to determine the best way to operate a power system when the system is subject to disruptions. These disruptions may or may not be malicious. In the case of malicious disruptions, the interdictor attempts to maximize the amount of “load shedding” in the system. Load shedding occurs when the demand of the power grid exceeds the capacity, which results in significant costs to the electricity providers (as well as to those not receiving power). In [23], a two-stage model is introduced in which the interdictor (or terrorist in this case) attacks or destroys some of the power lines in the grid, and the operator attempts to minimize the amount of load shedding over the system. A simplified version of the formulation in the paper is as follows:

$$\max_v \sum_{n \in N} \Delta_n \quad (20a)$$

$$\text{s.t. } \sum_{l \in L} (1 - v_e) = M \quad (20b)$$

$$v_e \in \{0, 1\} \quad \forall e \in E, \quad (20c)$$

where E is the set of transmission lines; v_e is a binary variable that takes a value of 0 if line e is destroyed, and 1 otherwise; M is the number of lines to be destroyed; N is the set of buses; and Δ_n is the load shed at bus n , which is obtained from the operator’s load-shedding minimization problem:

$$\min_{\Delta, \mathbf{P}, \mathbf{w}, \delta} \sum_{n \in N} \Delta_n \quad (21a)$$

$$\text{s.t. } F(\mathbf{P}, \delta, \mathbf{w}, \mathbf{v}) = 0 \quad (21b)$$

$$A^\top \mathbf{P} = \Delta \quad (21c)$$

$$\mathbf{0} \leq \Delta \leq \Delta^u \quad (21d)$$

$$\mathbf{P}^l \leq \mathbf{P} \leq \mathbf{P}^u \quad (21e)$$

$$\boldsymbol{\delta}^l \leq \boldsymbol{\delta} \leq \boldsymbol{\delta}^u \quad (21f)$$

$$w_e \in \{0, 1\} \quad \forall e \in E. \quad (21g)$$

Here \mathbf{P} is the vector of variables corresponding to line power flows and generator power outputs; \mathbf{w} is the vector of variables corresponding to the binary decision of disconnecting ($w_e = 0$) or not disconnecting ($w_e = 1$) line $e \in E$; $\boldsymbol{\delta}$ is the vector of variables corresponding to the phase angles at each of the buses; Δ^u , \mathbf{P}^l , \mathbf{P}^u , $\boldsymbol{\delta}^l$, and $\boldsymbol{\delta}^u$ are vectors of lower and upper bounds for the variables; given \mathbf{v} , $F(\mathbf{P}, \boldsymbol{\delta}, \mathbf{w}, \mathbf{v})$ is a set of nonlinear functions of \mathbf{P} , $\boldsymbol{\delta}$, and \mathbf{w} , which correspond to transmission line flows; and $A^\top \mathbf{P} = \Delta$ is the set of linear constraints representing the power balance in each bus of the system.

The authors develop a Benders' decomposition technique for solving the model. Since the problem is nonconvex, the solution method incorporates multiple restarts in order to search a majority of the solution space. As a result, the algorithm is able to obtain optimal or near-optimal solutions in a reasonable amount of time.

In [16], a defender–attacker–defender model is formulated in which the operator is able to prevent interdiction on some of the lines before the interdictor is able to act. Through duality techniques, they are able to turn the three-stage formulation into a single-level master problem that is conducive to Benders' decomposition (see also the discussion in Sect. 3.1).

2.2.3 Drug Enforcement (Maximum Flow Interdiction)

In [39], a maximum flow interdiction model is used to model city-level drug enforcement decisions. In the drug trade, there is usually some multilevel hierarchy of drug dealers and drug users. Assuming that the goal of the dealer, or “enemy,” at the highest level is to maximize the flow of drugs, the optimization problem from this dealer’s point of view is a maximum flow problem. A network is used to represent the hierarchy of dealers and users with source node α that represents the “origin” of the drugs and a sink node ω that represents the sink of the flow. The origin is essentially the main dealer that supplies the city with drugs, and the sink captures all flow that reaches the users. Each dealer or user is represented in the network by a node. An arc $(i, j) \in A$ exists if the person represented by node i deals to the person represented by node j . Each arc has a capacity, and the formulation consists of the typical flow conservation and capacity constraints, with the goal of the “enemy” being to deliver as much flow from the source node to the sink node over a time horizon $1, \dots, T$. The goal of law enforcement is to minimize the maximum flow over the time horizon. One of the interesting ideas in this chapter is the way that law enforcement’s feasible region was characterized. The law enforcement officials are constrained not only by the resources of their departments but also by the real-life aspects of the drug trade. They discuss the idea that law enforcement must “climb the ladder” of the drug supply chain network in order to reach the dealers at the upper levels of the hierarchy. For example, arresting an individual may require that law enforcement officers monitor this

individual for some period of time. Also, to be able to monitor a dealer that is high up in the hierarchy, it might be necessary to arrest several of the individuals that purchase from this dealer. The resource allocation of the department is constrained as follows:

$$\sum_{(i,j) \in A} (a_{ij} w_{ijt} + b_{ij} y_{ijt}) \leq B \quad \forall t = 1, \dots, T, \quad (22)$$

where B is the number of available officers, a_{ij} is the number of officers required to arrest/remove arc (i, j) , b_{ij} is the number of officers required to monitor arc (i, j) , w_{ijt} is a binary variable representing the decision to arrest/remove arc (i, j) from the network in time period t , and y_{ijt} is a binary variable that represents the decision to monitor/target arc (i, j) in time period t . To restrict law enforcement to only be able to arrest an individual after they have been monitored for a set period of time, the following constraints are used:

$$\sum_{t'=1}^{t-1} y_{ijt'} \geq \tau_{ij} w_{ijt} \quad \forall t = 1, \dots, T \quad (23a)$$

$$(1 - z_{ijt}) \leq (1 - z_{ij,t-1}) + w_{ijt} \quad \forall t = 1, \dots, T, \quad (23b)$$

where τ_{ij} is the number of time periods that (i, j) must be targeted before it is interdicted and z_{ijt} is a binary variable representing the availability of arc (i, j) in time period t . If it is necessary to monitor the target in consecutive time periods, then the summation in (23a) can be from $t' = t - \tau_{ij}$ to $t - 1$. In order to model the fact that law enforcement may have to arrest lower-level individuals in order to start to target a higher-level individual, each dealer is actually represented with two nodes, i and i' . The capacity of the arc between them, $\mu_{ii'}$, represents the number of arrests that are necessary in order to target the dealer. This is modeled with the following constraint set:

$$\sum_{j \in A(i')} (1 - z_{jj't}) \geq \mu_{ii'} y_{ii't} \quad \forall t = 1, \dots, T, \quad (24)$$

where $A(i')$ is the adjacency list of node i' (or the set of buyers from dealer i .) The authors also detail further considerations that face law-enforcement agents in gaining cooperation from the criminals, and how these considerations affect the mathematical models they prescribe.

Through the use of duality and linearization techniques, the authors develop a single mixed-integer linear program that can be solved with a commercial solver such as CPLEX.

2.2.4 Supply Chains (Facility Assignment Interdiction)

Supply chains are vulnerable to a number of disruptions, many of them unavoidable such as hurricanes or other natural disasters. A great deal of research has focused on

designing supply chains that are resilient to these types of disruptions. Snyder et al. [61] analyze the design problem for such supply chains, including a worst-case cost model. This model takes into account various scenarios and determines a design that minimizes the worst-case cost of operating the supply chain. Let I denote the set of customers, J the set of possible facility locations, and S a set of possible failure scenarios for the facilities. Not every possible scenario belongs to S —if so, the worst-case scenario would simply consist of the failure of all facilities—because the simultaneous failure of some combination of facilities may be sufficiently unlikely and hence not worthy of consideration. Instead, this set may, for instance, only include scenarios in which no more than four facilities are disrupted. Each customer i has an annual demand of h_i units, and each unit shipped from facility j to customer i has a shipment cost of d_{ij} . There is a fixed cost f_j for opening each facility j , and a_{js} represents whether facility j was disrupted ($a_{js} = 1$) in scenario s , or not ($a_{js} = 0$). The model uses two sets of binary decisions variables: x_j which takes a value of 1 if facility j is opened, and 0 otherwise; and y_{ijs} which takes a value of 1 if customer i is assigned to facility j in scenario s , and 0 otherwise. The model is formulated as follows:

$$\min U \quad (25a)$$

$$\text{s.t. } U \geq \sum_{j \in J} f_j x_j + \sum_{i \in I} \sum_{j \in J} h_i d_{ij} y_{ijs} \quad \forall s \in S \quad (25b)$$

$$\sum_{j \in J} y_{ijs} = 1 \quad \forall i \in I, s \in S \quad (25c)$$

$$y_{ijs} \leq (1 - a_{js})x_j \quad \forall i \in I, j \in J, s \in S \quad (25d)$$

$$x_j \in \{0, 1\} \quad \forall j \in J \quad (25e)$$

$$y_{ijs} \in \{0, 1\} \quad \forall i \in I, \forall j \in J, \forall s \in S. \quad (25f)$$

The objective minimizes U , where Constraint (25b) forces U to be greater than or equal to the minimum cost of operation in each of the scenarios (the right-hand side of the constraint is forced to be the minimum cost for each scenario, since this is a minimization problem.) Constraint (25c) ensures that each customer is assigned to a facility in every scenario. Constraint (25d) ensures that customer i can only be assigned to facility j in scenario s if the facility is opened and not disrupted in that scenario. It is important to note that there are clear differences between this model and the general facility assignment interdiction model presented earlier. Instead of an interdictor acting with a goal of maximizing the cost of operating the supply chain, there is a set of possible scenarios that must be considered. However, since the supply chain designer is preparing for the worst-case scenario, this results in the same solution as if there were an interdictor choosing the worst-case from the set of possible scenarios.

3 Emerging Areas of Interdiction Research

This section describes a few research thrusts that have arisen primarily in the past decade. Fortification optimization problems are discussed in Sect. 3.1. Models and algorithms for stochastic interdiction problems are then presented in Sect. 3.2, followed by the consideration of asymmetric information in Sect. 3.3. Lastly, solution strategies are explored for multi-objective problems in Sect. 3.4.

3.1 Fortification Problems

Several fortification problems, such as those explored in [17, 19, 53, 59], seek to fortify a network in anticipation of an optimal attacker. These fortification actions are essentially taken in advance of the mathematical programming models described in Sect. 2. In many settings, it may be possible to integrate the presence of fortification actions directly within the mathematical programming interdiction model. However, for the examples mentioned here, a cutting-plane approach to solving these problems is evidently required.

In the model described by (11), Church and Scaparra [19] prescribe a two-phased algorithm to optimally fortify facilities, where a fortified facility cannot be destroyed by the interdictor. In this approach, a master problem is solved first that prescribes fortification actions and computes a lower bound on the optimal objective function value. Fortification actions are constrained by $\mathbf{w} \in \mathbf{W}$, where $\mathbf{W} = \{\mathbf{w} : \mathbf{e}^\top \mathbf{w} = q, \mathbf{w} \in \{0, 1\}^{|A|}\}$ restricts the fortification actions to be binary and enforces the condition that q fortifications are made. The approach taken is then to minimize some value function variable η , subject to $\mathbf{w} \in \mathbf{W}$, along with an exponentially sized set of affine inequalities that relate η to the fortification decisions \mathbf{w} . Sets of these inequalities are generated one at a time, as needed, from a subproblem of the form (11), which has the additional restrictions that $x_i \leq (1 - z_i)$ for each $i \in N$. To generate inequalities at iteration k of this process, consider any feasible interdiction solution \mathbf{x}^h to (11) at iteration h of the algorithm, which induces a solution \mathbf{y}^h . Define $d_i^h = \sum_{j \in F} d_{ij} y_{ij}^h$ as the distance from i to its closest non-interdicted facility in the solution given by $(\mathbf{x}^h, \mathbf{y}^h)$. If $d_{ij} < d_i^h$ for some $j \in F$, then by fortifying facility j , the total objective value may decrease by as much as $(d_i^h - d_{ij})$. Let B_i^h be the set of all closer facilities $j \in F$ such that $d_{ij} < d_i^h$. One possible valid inequality is given by

$$\eta \geq \sum_{i \in N} a_i \left(d_i^h - \sum_{j \in B_i^h} (d_i^h - d_{ij}) w_j \right),$$

but this inequality is quite weak due to the fact that for some $i \in N$, fortifying multiple facilities in $B' \subseteq B_i^h$ promises a reduction of $\sum_{j \in B'} (d_i^h - d_{ij})$ rather than the actual (maximum possible) reduction of $(d_i^h - \min_{j \in B'} \{d_{ij}\})$. To strengthen this formulation and avoid the weakness presented by the foregoing inequality, Church

and Scaparra [19] instead define additional variables v_{ij}^h at iteration h , which equal 1 if facility j is the closest facility to i in B_i^h that is fortified, and 0 otherwise. This permits the inclusion of the stronger, though larger, inequality system for every iteration h enumerated by the algorithm:

$$\eta \geq \sum_{i \in N} a_i \left(d_i^h - \sum_{j \in B_i^h} (d_i^h - d_{ij}) v_{ij}^h \right) \quad (26a)$$

$$v_{ij}^h \leq w_j \quad \forall i \in N, j \in B_i^h \quad (26b)$$

$$\sum_{j \in B_i^h} v_{ij}^h \leq 1 \quad (26c)$$

$$v_{ij}^h \in \{0, 1\} \quad \forall i \in N, j \in B_i^h. \quad (26d)$$

Even though (26) increases the number of variables and constraints for each solution h , because they are added only as needed during the two-phase process (and not in general for every possible interdiction solution), the routine is able to solve real-world instances in acceptable computational limits. The process terminates when the predicted objective η found in the master problem matches the objective computed in the subproblem.

The approach of Brown et al. [17] and Smith et al. [59] is tailored toward the more general problem of minimum cost network flow interdiction. Again letting \mathbf{W} be the feasible region for fortification actions, the objective would be to minimize $v(\mathbf{w})$ over $\mathbf{w} \in \mathbf{W}$, where $v(\mathbf{w})$ solves problem (14) with the additional objective term $-M(w_{ij} x_{ij})$ for some large number M . This term serves as a penalty function to prohibit setting $x_{ij} = 1$ at optimality when $w_{ij} = 1$. Note that the feasible region of (14) is invariant with respect to \mathbf{w} and that with \mathbf{w} fixed, (14) is a disjointly constrained mixed-integer bilinear program, assuming that \mathbf{X} contains only linear and (possibly) integrality constraints. (That is, α and β are constrained only by the polyhedron induced by (14b) and (14c), and \mathbf{x} is only constrained to lie in \mathbf{X} . If either set of variables is fixed, then assuming that \mathbf{X} is defined by a set of linear constraints, (14) becomes a linear program.) Therefore, let Θ denote the set of extreme points to (14b) and (14c), and let Λ denote the set of extreme points to \mathbf{X} (or to $\text{conv}(\mathbf{X})$ if \mathbf{X} includes binary restrictions). Because the problem is bilinear, an optimal solution lies at a combination of extreme points in Θ and Λ . Then, the interdictor's objective function can be rewritten as

$$\max_{(\alpha^k, \beta^k) \in \Theta, \mathbf{x} \in \Lambda} \sum_{i \in N} d_i \alpha_i^k - \sum_{(i, j) \in A} u_{ij} (1 - x_{ij}^k) \beta_{ij}^k - M(w_{ij} x_{ij}^k).$$

The strategy for solving this class of problems constructs a master problem and subproblem as mentioned above, where the master problem contains a value function η , and the subproblem solves (14) augmented with the fortification penalty

term. If η does not match the subproblem objective term, an optimal solution (α^*, β^*, x^*) is obtained from the subproblem and used to generate a (single) cut of the form

$$\eta \geq \sum_{i \in N} d_i \alpha_i^* - \sum_{(i,j) \in A} u_{ij} (1 - x_{ij}^*) \beta_{ij}^* - M(w_{ij} x_{ij}^*).$$

3.2 Stochastic Interdiction

Interdiction and fortification problems are further complicated in the presence of uncertainty. In practice, some of the data present in the model may be stochastic, and the success of interdiction actions may be uncertain. The former case is considered by Morton et al. [40] and Pan and Morton [44]. These papers consider an evader/interdictor, where the interdictor seeks to monitor network nodes and/or arcs with the purpose of minimizing the evader's maximum probability of escape. The origin and destination of the evader are unknown in these models, which results in an NP-hard interdiction problem even if the underlying network is bipartite [41].

Cormican et al. [21] consider a stochastic maximum flow interdiction problem, which is subject to uncertainty of interdiction actions. In their base model, the network data is known with certainty, but each interdiction action is successful only with some probability p_{ij} , for each arc (i, j) . The authors extend their results for the case in which arc capacities are also uncertain, interdiction success is varied among several discrete levels, and multiple interdiction actions are possible.

The approach taken in [21] is to consider a problem similar to the form of (6), where constraints (6c) are replaced with

$$y_{ij} \leq u_{ij} (1 - \tilde{I}_{ij} x_{ij}) \quad \forall (i, j) \in A \setminus \{(t, s)\}, \quad (27)$$

and where \tilde{I}_{ij} is a random variable that equals 1 if an interdiction on arc (i, j) would be successful (which occurs with probability p_{ij}), and otherwise equals 0 if an interdiction would be unsuccessful (occurring with probability $(1 - p_{ij})$). Both successful and unsuccessful interdiction actions contribute to the interdictor's overall budget. Hence, the interdictor is faced with the challenge of trading off the selection of arc interdictions that are maximally effective when all interdictions are successful, with those that correspond to large p_{ij} -values.

The problem is now to identify the interdiction actions $x \in S$ that minimize the network owner's maximum flow. Janjarassuk and Linderoth [34] approach this problem via sampling strategies as used in scenario-based stochastic problems. Cormican et al. [21] prescribe a sequential partitioning approach, where lower and upper bounds on the expected objective are gradually tightened over the partitioned space. The essence of the algorithm is to note that, given interdiction actions $\mathbf{x} \in \mathbf{X}$, the maximum flow problem given by (6) (which includes (27) instead of (6c)) is a

concave function over the set of possible outcomes of \tilde{I} . This problem is denoted here as SMF-1. An equivalent formulation, SMF-2, is given by

$$\min_{\mathbf{x} \in \mathbf{X}} \max y_{ts} - \sum_{(i,j) \in A} (x_{ij} \tilde{I}_{ij}) y_{ij} \quad (28a)$$

$$\text{s.t. Constraints (6b)} - \text{(6d).} \quad (28b)$$

Here, equivalence is claimed in the sense that an optimal solution to SMF-1 is also optimal to SMF-2, and although an optimal solution to SMF-2 need not be optimal to SMF-1, the optimal objective function values of the two problems match. Given a fixed interdiction action in \mathbf{X} , the inner maximum flow problem of SMF-1 is a concave function of the random variables \tilde{I} , while the inner maximum flow problem of SMF-2 is a convex function of these random variables. (Note that stochasticity occurs in the constraints of the inner problem in SMF-1 and in the objective of the inner problem in SMF-2.)

As a result, an initial lower bound (LB_0) is given by replacing the random variables with their expectation in SMF-2, and an initial upper bound (UB_0) is given by doing the same in SMF-1. These bounds are valid due to Jensen's inequality (see, e.g., Kall and Wallace [35] for a discussion of this inequality's use in stochastic programming). To refine this bound, one could partition the state space of \tilde{I} into K spaces $\mathcal{I}_1, \dots, \mathcal{I}_K$, where the probability of \tilde{I} belonging to \mathcal{I}_k is given by ρ_k , $\forall k = 1, \dots, K$. Then in the same manner above, one can compute LB_k and UB_k for each $k = 1, \dots, K$ and obtain new lower and upper bounds as

$$LB^K = \sum_{k=1}^K \rho_k LB_k \geq LB_0$$

$$UB^K = \sum_{k=1}^K \rho_k UB_k \leq UB_0.$$

Moreover, as K becomes large, LB^K and UB^K both converge to the optimal expected interdiction objective. See [21] for methods that dynamically partition the original state space into subregions and terminate once $UB^K - LB^K$ is sufficiently small.

3.3 Asymmetric Information

Bayrak and Bailey [3] and Morton et al. [40, 41] examine interdiction problems in which there exists so-called information asymmetry between the opposing players. In the context of interdiction problems, “asymmetric information” refers to the situation in which the opposing sides have different perceptions about the parameters of the model. Bayrak and Bailey [3] define c_{ij} as the length of arc (i, j) and d_{ij} as the amount that the arc length is increased if the arc is interdicted. The correct data values are known to the interdictor. The evader, on the other hand, only has estimates of these values: \bar{c}_{ij} and \bar{d}_{ij} . (Whether or not the interdictor in fact knows the correct data is immaterial, but in any case, the interdictor is optimizing

with respect to c - and d -values, with knowledge that the evader optimizes with respect to \bar{c} - and \bar{d} -values.)

Variables x_{ij} , for each $(i, j) \in A$, are the interdictor's decision variables, which take a value of 1 if arc (i, j) is interdicted, and 0 otherwise. Variables y_{ij} are the evader's decision variables, $\forall (i, j) \in A$, which take a value of 1 if arc (i, j) is on the shortest path, and 0 otherwise. The shortest path network interdiction problem with asymmetric information is formulated as follows:

$$\max_{\mathbf{x}} \sum_{(i,j) \in A} (c_{ij} + d_{ij}x_{ij})y_k^* \quad (29a)$$

$$\text{s.t. } \sum_{(i,j) \in A} b_{ij}x_{ij} \leq B \quad (29b)$$

$$x_{ij} \in \{0, 1\} \quad \forall (i, j) \in A, \quad (29c)$$

where

$$y^* \in \operatorname{argmin}_{\mathbf{y}} \left\{ \min_{\mathbf{y}} \sum_{(i,j) \in A} (\bar{c}_{ij} + \bar{d}_{ij}x_{ij})y_{ij} \right\} \quad (30a)$$

$$\text{s.t. } \sum_{j \in FS(i)} y_{ij} - \sum_{j \in RS(i)} y_{ji} = \begin{cases} 1 & \text{for } i = s, \\ -1 & \text{for } i = t, \\ 0 & \text{for } i \in N_0 \end{cases} \quad (30b)$$

$$\mathbf{y} \geq \mathbf{0}, \quad (30c)$$

and where $N_0 = N \setminus \{s, t\}$. Since the evader's problem is a linear program, it is possible to reformulate it as another linear program with no objective function and a constraint set consisting of the constraints in (30), the constraints from the dual of (30), as well as the constraint: [primal objective]=[dual objective]. This allows the two-stage problem to be formulated as a single mixed-integer program that can be linearized and solved by standard commercial solvers.

3.4 Multi-objective Interdiction

Royset and Wood [50] examine a maximum flow interdiction problem of the form (6), but with the aim of finding all *Pareto-optimal* solutions with respect to interdiction effectiveness and interdiction cost (see also the work of Rocco and Ramirez-Marquez [49], which takes an evolutionary algorithm-based approach for solving these problems). As such, the interdictor's feasible region is relaxed to contain only binary restrictions on the \mathbf{x} -variables, and the quality of an interdiction solution is measured by both the follower's maximum possible flow (measured

by y_{ts}) and the cost of interdiction, given by $\sum_{(i,j) \in A} c_{ij} x_{ij}$, where c_{ij} is the cost of interdicting arc $(i, j) \in A$. While this could be achieved by enumerating all possible budget values between 0 and R , where R is the minimum directed cut of the graph (equal to the maximum flow of the graph, see, e.g., [1]), this process would require the solution of $O(R)$ integer programming problems, and $O(R)$ itself is not a polynomial function of the problem's input size.

An alternative approach instead employs a scheme that is interpreted as Lagrangian dual optimization to identify several Pareto-optimal solutions. The scheme places objective weights on the two criteria and uses Lagrangian dual values to intelligently adjust these weights in order to compute more of the Pareto-optimal frontier. After this process has completed, a customized branch-and-bound search is then performed to compute all remaining Pareto-optimal solutions.

4 Competition, Interdiction, and Optimization Models

This section discusses the application of interdiction models to contexts involving industrial or organizational competition. The following subsection describes the view of competitive commerce problems as a class of interdiction problems. After explaining this view, the subsequent subsection explores the structure of the game-theoretic problems that result, as well as the optimization problems that must often be solved in order to characterize the actions that rational players of these games will take.

4.1 Industrial Competition as an Interdiction Problem

While the term interdiction is typically defined in warfare-related terms (e.g., contexts involving an *enemy*), this term may be applied more liberally to general competitive settings. That is, instead of defining an interdictor as an enemy in the combative sense, any competitor whose goals conflict with those of a principal operator or agent may be thought of as an interdictor. Thus, given a principal operator (referred to as an “operator”) with some set of goals, any separate party who takes action(s) that impede the operator’s ability to meet its goals may be characterized as an interdictor. As a result, given an operator organization that wishes to engage in commercial activity by selling a product or providing a service to a market of finite size, any competitor selling a substitutable product or service to that market can effectively act as an interdictor by hampering the operator’s ability to meet market demands. The concepts, models, and methods applied to network interdiction problems, therefore, often readily apply to competitive commercial operations settings. This use of warfare analogies in competitive business is hardly new. For example, Kotler and Singh [36] provide an interesting overview of the ways in which military strategies can assist in developing marketing strategies for businesses.

Cartwright [18] provided a framework discussing the elements of corporate warfare and argued that three important dimensions of corporate operational warfare strategy exist: development, defense, and attack. A competitive firm uses development strategies to create a network of relationships vital for achieving its goals. This network creates linkages among suppliers and customers to enable the flow of goods and/or services. This development phase of corporate warfare strategy is akin to the network design phase in communications or other physical network. Defense strategies focus on fortifying the network of relationships once it has been developed and may include strategic partnerships and contractual agreements that protect this network. These defense strategies are analogous to the techniques applied in survivable network design (see, e.g., Smith et al. [59]). Attack strategies are employed to disrupt a competitor's network. When a firm employs such strategies, it acts as an interdictor with respect to another firm's network. Cartwright [18] argues that the weapons employed in network development, defense, and attack (interdiction) strategies include products, information, financial capital, and human capital. Firms thus utilize information and financial and human capital to develop a network of products and alliances that enable them to compete effectively.

Numerous practical examples exist in the literature involving forms of strategic corporate warfare. For example, in response to the rise and market power of Amazon.com in the 1990s, Barnes and Noble sought to purchase its distributor, although this proposal never came to fruition as a result of opposition from the Federal Trade Commission [18]. Instead, Barnes and Noble spun off bn.com and partnered with Yahoo to enter the Internet-direct sales business. Barnes and Noble now successfully employs a dual-channel strategy using both physical stores and its web presence. Examples of competitive reaction are also prevalent in service industries. When a small start-up company called Legend Airlines began to offer 56-seat flights from Love field in Dallas, American Airlines, headquartered in Dallas, also began to offer flights using planes of the same capacity [58]. Examples of location-based competitive responses abound as well. Fast food and pharmaceutical chains often respond to competitors' strategic location decisions by building a competing store next to a newly opened store, which can undercut the original store's competitive position.

As these examples illustrate, interdiction in commerce may manifest itself in numerous ways. The most obvious and visible manifestation occurs when an operator's competitor (interdictor) introduces a product or service that is intended to compete with and take market share away from an existing product or service offered by the operator. Smith et al. [58] model product line offering decisions for an operator and an interdictor, the latter of which wishes to minimize the operator's profit. The operator must determine which among a finite set of products to offer in order to meet a set of customer needs in a market. The interdictor introduces a product line after the operator introduces its own and may thus take away customers that would have otherwise preferred a product offered by the operator. This problem is modeled as a two-stage Stackelberg game in which the operator acts first and the interdictor follows. By anticipating the interdictor's best response to its actions, the operator can effectively minimize the potential damage inflicted by the interdictor.

Competitive location-based models have a long history in the research literature, beginning with Hotelling [32] in 1929, who modeled a two-player simultaneous location game with customers uniformly distributed along a line. Since that time, researchers have modeled competitive location decisions under numerous assumptions on the potential facility locations and the factors that drive customer and competitive response to location choices (see Eiselt et al. [24] and Plastria [47] for more detailed discussions of this body of literature). This work tends to model competition based on customer preference factors, such as price, service level, and location, rather than addressing the possibility of direct attacks on a network of facilities. More recent work has taken a worst-case view of location problems that is more in line with the literature on network interdiction, identifying and fortifying the most critical locations in a facility network subject to attacks that may be man-made or natural (see Church et al. [20] and Scaparra and Church [53]).

In addition to competition based on new product/service introduction and strategic location choice, firms may engage in competitive warfare through advertising/promotions and using strategic partnerships. A well-known example of advertising competition occurred in the 1980s when Coca-Cola and Pepsi targeted each other in advertising over an extended period of time, resulting in the so-called Cola Wars (see Pearson and Irwin [46]). A recent example of an effective strategic partnership for competitive advantage can be seen in the (formerly) exclusive resale contract between AT&T and Apple for Apple's iPhone.

These are a few of the numerous ways in which firms may act in order to either fortify their strategic networks or act as an interdictor who seeks to disrupt a competitor's network. AT&T, for example, fortified their cellular phone network by partnering with Apple, while American Airlines acted as an interdictor and disrupted the network of Legend Airlines, who remained in business for only 5 years. Competitive strategic decisions such as those described can often be modeled using the tools of game theory in general and network interdiction in particular. The following subsection explores the structure of these game-theoretic models and the optimization problems that they imply.

4.2 Optimization Models for Competition with Interdiction

The vast majority of interdiction modeling efforts in the literature that deal with business operations settings assume that the “attack” comes in the form of a natural disaster, terrorist attack, or other phenomenon that is unrelated to competitors’ actions. The facility assignment and facility-to-retailer flow interdiction problems discussed in Sect. 2.1, for example, assume a diminished network capacity for flows due to a loss of a subset of facilities and transportation links, respectively. Modeling realistic competitive scenarios, on the other hand, requires a different view of interdiction. The focus on competitive models in this section assumes an absence of illegal activities such as deliberate corporate sabotage. This removes the focus of the corresponding models from the loss of facilities and transportation links

and emphasizes the ways in which firms may interfere with the profit-making goals of competitors using legal competitive strategies.

A discussion of three particular competitive models illustrates the kinds of optimization models that arise in competitive interdiction. An early example of the use of interdiction ideas in competition can be found in Parlar [45], who looked at the inventory stocking problem for two firms that stock substitutable products. He modeled a simultaneous game in which both firms make stock level decisions at the same time. Each player faces a probability distribution representing its uncertain demand, and when a firm runs out of stock, customers will seek to fill demands at the other firm if they have available stock. While the primary purpose of the paper was to characterize equilibrium stock levels when both firms seek to maximize profit (the paper demonstrates that a unique Nash equilibrium exists), it also examines the case in which one of the players acts “irrationally” in an attempt to inflict as much damage as possible on the competitor. Parlar [45] shows that when this occurs, the irrational player achieves its lowest possible profit, while the other player faces a problem that is equivalent to one without a competitor.

Smith et al. [58] provided the second illustrative model, which demonstrates how a competitor may interdict by offering a product line that competes with that of another firm. They consider two firms, both of whom can offer a subset of N candidate products that target a customer population or market, consisting of a number of market segments. Each of M market segments has an ordered preference list of a subset of the N products—customers in a given segment will choose the first available product on their ordered preference list (and if none of the products in their preference list are offered, customers from the segment will not purchase). The two firms offering the products are considered a leader and a follower in a Stackelberg game in which the leader first determines its product line offering and the follower subsequently determines which products to offer. Each firm has a limited budget and incurs a product- and firm-specific fixed cost for offering any product. If both firms offer the same product, then $100\% \times \rho_{ij}$ of the demand from market segment i for product j will go to the leader, and the remaining percentage to the follower. Each unit of product j sold to market segment i produces a revenue of r_{ij} .

The model proposed in [58] takes a worst-case approach for the leader. That is, the leader seeks to maximize its profit in the worst case (i.e., maximize its minimum profit), assuming the follower strictly seeks to introduce a set of products that minimizes the leader’s revenue. The result is a two-stage optimization model. The first-stage problem maximizes the leader’s minimum profit by determining which subset of products to offer (indicated by an N -vector \mathbf{x} of binary variables, where $x_j = 1$ if the leader offers product j). This first-stage problem encodes the follower’s product-line decision via an N -vector \mathbf{y} of binary variables, where $y_j = 1$ if the follower offers product j . The second-stage (or follower’s) problem requires the follower to choose the vector \mathbf{y} that minimizes the leader’s revenue based on the leader’s choice of the \mathbf{x} vector. Solving the leader’s problem, therefore, requires characterizing the follower’s best response to any given \mathbf{x} vector chosen by the leader and then choosing the \mathbf{x} vector that effectively minimizes the

potential damage. Smith et al. [58] show that the follower's (second-stage) problem is NP-hard in the strong sense. They thus reformulate their model as a three-stage optimization problem that requires solving a bilinear optimization problem. Using linearization and decomposition techniques (employing cutting planes), they provide an exact method for solving the problem. They also propose heuristic solution methods that can be used for solving problems of practical size.

The third example setting that illustrates interdiction in business competition is from Prince et al. [48], who consider two competitive firms that seek to secure a common raw material supply from a common supplier base. In this setting, suppliers have finite capacities and offer customers quantity discounts. An operator firm and an interdictor firm each have a supply quantity that they wish to procure from the supplier base. In addition, the operator may enter into *exclusivity* contracts with suppliers, under which the supplier agrees to provide supply only to the operator. Under an exclusivity agreement, the supplier incurs a fixed cost that is supplier dependent (which may correspond to a franchise fee paid to the supplier).

The sequence of decisions proceeds in three stages. In the first stage, the operator determines which suppliers to secure through exclusivity agreements. In the second stage, the interdictor allocates demand to available suppliers with a goal of maximizing the operator's supply cost. In the third stage, the supplier allocates its demand to the available remaining capacity in the supply base. The authors propose a two-stage reformulation of the problem in which the second stage is a bilinear integer optimization problem, and they propose a cutting-plane algorithm for the problem's solution.

Clearly numerous variants of this game are possible. For example, the exclusivity agreements may be available to the interdictor, and the interdictor may have a different objective, such as profit maximization. These variants provide a set of interesting and high-value research directions. Moreover, additional high-value directions are available at the intersection of competition and interdiction that directly consider a multitude of ways in which competitors may impede each other's ability to meet its objectives.

5 Connection to Robust Optimization and Survivable Network Design

This chapter has thus far given a sense of the breadth of interdiction application research, with a particular emphasis on network survivability (regardless of whether the networks represent physical systems or are abstractions of, e.g., supply chains or transportation operations). A natural question thus regards the relationship of interdiction models to methods designed in parallel to interdiction research over the last few decades. This subsection discusses robust and survivable network design approaches to constructing resilient networks. (Note that this discussion is *not* intended to cover the range and depth of these fields but rather to connect the interdiction literature discussed so far to the principles established in these bodies of literature.)

5.1 Robust Optimization

The theme of modern robust optimization research is to elegantly accommodate data uncertainty arising in mathematical programs. Essentially, robust optimization models define an *uncertainty set* over which data exists (as opposed to the point estimates of data in deterministic models) and seek a solution that is feasible to all constraints, regardless of the actual outcome of the data. The objective is measured according to the worst-case observation of data with respect to the given solution. For instance, if the objective is to minimize cost, then a solution's objective is the maximum possible objective function value over all objective data that belong to the uncertainty set.

The result is a fairly pessimistic model that minimizes the maximum objective function value that could arise (again in case of a minimization problem), with a guarantee of feasibility, all under the assumption that the problem data lies in the uncertainty set given above. (An alternative viewpoint is given in the field of stochastic programming (see, e.g., [15, 35]), which typically seeks a solution that is sufficiently likely to be feasible. The objective usually optimizes the expected objective function value over a given distribution of data.) In order to control the degree of robustness, the key is to strategically control the uncertainty sets that are modeled for robust optimization problems, given the actual distribution of uncertain data. See [7–10, 25, 26] for foundational work on robust optimization, an introductory chapter in [56], and the excellent recent reference book [6] and tutorial [13] treatment of the subject.

To compare the interdiction and robust optimization viewpoints, consider the following linear programming problem:

$$\min \mathbf{c}^\top \mathbf{x} \quad (31a)$$

$$\text{s.t. } A\mathbf{x} \geq \mathbf{b} \quad (31b)$$

$$\mathbf{x} \geq \mathbf{0}, \quad (31c)$$

where A is an $m \times n$ matrix and where \mathbf{c} and \mathbf{b} have conforming dimensions, but where A is uncertain. In fact, the assumption that \mathbf{c} and \mathbf{b} are deterministic, with uncertainty limited to A , can be made without loss of generality by suitable variable substitutions. (Much of the robust optimization literature assumes a lower bound l on the \mathbf{x} -variables, where l is not necessarily nonnegative; however, the brief exposition here is simplified with the assumption that \mathbf{x} is nonnegative, and moreover, any linear programming problem can easily be transformed to the form (31).) Suppose that A belongs to the uncertainty set \mathcal{U} . The *robust counterpart* formulation guarantees feasibility of \mathbf{x} to (31b) for every $A \in \mathcal{U}$, that is, by changing (31b) to $\bar{A}\mathbf{x} \geq \mathbf{b}$, $\forall \bar{A} \in \mathcal{U}$.

There is now potentially an infinite number of constraints to the problem, depending on \mathcal{U} . However, this problem can be cast as a finite optimization problem by focusing only on certain forms of the set \mathcal{U} and employing mathematical

programming techniques reminiscent of those developed for interdiction models. It is first useful to state the following observations regarding robust optimization problems:

- Let \mathbf{a}^i denote the i th row vector of A and define \mathcal{U}_i as the set of all A -matrices whose i th row is \mathbf{a}^i . Because \mathbf{x} must be feasible for any $A \in \mathcal{U}$, the following constraints are valid:

$$\mathbf{a}^i \mathbf{x} \geq b_i \quad \forall i = 1, \dots, m, \quad \mathbf{a}^i \in \mathcal{U}_i. \quad (32)$$

Therefore, optimizing over the uncertainty set \mathcal{U} is equivalent to optimizing over the possibly larger uncertainty set $\mathcal{U}_1 \times \dots \times \mathcal{U}_m$. This is referred to as row-wise uncertainty, in which randomness is independent over the rows of A .

- Similarly, optimization over \mathcal{U} is equivalent to optimization over the convex hull of \mathcal{U} and to the closure of this set (see [42]).
- If \mathcal{U} independently constrains the *columns* of A (referred to as column-wise uncertainty), then randomness is independent over both rows and columns. Randomness is thus independent over each *element* of A , and the robust counterpart replaces each element of A with its smallest possible value (in the case of \geq constraints). See [62] for an early exposition of this case. The remaining discussion in this section regards the more complex case of intercolumn dependence in \mathcal{U} .

For robust optimization problems, one can again employ minmax (or maxmin) optimization techniques as done in the context of Stackelberg games. Here, the first player (leader) selects a solution $\hat{\mathbf{x}}$. The follower will, for each row $i = 1, \dots, m$, minimize $\mathbf{a}^i \hat{\mathbf{x}}$ over all $\mathbf{a}^i \in \mathcal{U}_i$ with the aim of forcing $\hat{\mathbf{x}}$ to be infeasible. Just as in the development of the interdiction models of Sect. 2, the inner problem can be dualized to uncover a single-level optimization problem. However, the order in which the defender (now the leader) and attacker (now the follower) play is reversed. The attacker's problem is now quite simple, which admits a far simpler optimization model.

Consider the case of *budgeted uncertainty* [12], where $a_{ij} \in [\bar{a}_{ij} - \hat{a}_{ij}, \bar{a}_{ij}]$ for all elements of A and no more than some specified (nonnegative) value Γ_i of the coefficients a_{i1}, \dots, a_{in} are allowed to simultaneously deviate from \bar{a}_{ij} , for all $i = 1, \dots, m$. To minimize the left-hand side of the structural constraints, given the leader's solution $\hat{\mathbf{x}}$, the follower minimizes

$$\sum_{j=1}^n \bar{a}_{ij} \hat{x}_j - \sum_{j=1}^n \hat{a}_{ij} \hat{x}_j z_{ij} \quad \forall i = 1, \dots, m, \quad (33)$$

which is equivalent to solving

$$\max \quad \sum_{j=1}^n \hat{a}_{ij} \hat{x}_j z_{ij} \quad (34a)$$

$$\text{s.t. } \sum_{j=1}^n z_{ij} \leq \Gamma_i \quad (34\text{b})$$

$$0 \leq z_{ij} \leq 1 \quad \forall j = 1, \dots, n. \quad (34\text{c})$$

Associating the dual variable π_i with (34b) and μ_{ij} with the constraint $z_{ij} \leq 1$, $\forall j = 1, \dots, n$, the dual formulation of (34) is

$$\min \Gamma_i \pi_i + \sum_{j=1}^n \mu_{ij} \quad (35\text{a})$$

$$\text{s.t. } \pi_i + \mu_{ij} \geq \hat{a}_{ij} \hat{x}_j \quad \forall j = 1, \dots, n \quad (35\text{b})$$

$$\pi_i \geq 0, \mu_{ij} \geq 0 \quad \forall j = 1, \dots, n. \quad (35\text{c})$$

Because $\sum_{j=1}^n \hat{a}_{ij} \hat{x}_j z_{ij}$ is given by the smallest possible value of (35a) and is constrained by (35b) and (35c), each constraint (32) is equivalent to

$$\bar{a}^i x - \left(\Gamma_i \pi_i + \sum_{j=1}^n \mu_{ij} \right) \geq b_i \quad \forall i = 1, \dots, m \quad (36\text{a})$$

$$\pi_i + \mu_{ij} \geq \hat{a}_{ij} \hat{x}_j \quad \forall j = 1, \dots, n \quad (36\text{b})$$

$$\pi, \mu \geq 0. \quad (36\text{c})$$

Note that the robust counterpart is also a linear program, as opposed to the models of Sect. 2, which become nonlinear (although they can be linearized when at least one of the bilinear terms is restricted to be binary). This class of robust models is therefore considerably easier to solve than the previously developed interdiction models. However, robust models are also far more pessimistic, as they permit the attacker to essentially act not only with full knowledge of any defender design decisions but also with full knowledge of the defender's *recourse* decisions. By contrast, in the interdiction models, the defender has the capability of choosing its recourse based on the attacker's actions. The most appropriate model for a given application should therefore take into consideration to what extent recourse decisions are allowed after an attack is made. (It is worth noting that some progress has also recently been made on robust optimization with recourse, see, e.g., [2, 13, 14].)

Three other observations are relevant before continuing. First, the foregoing analysis can be applied when A belongs to a general polyhedral set. Second, much of the traditional robust optimization theory regards the case in which \mathcal{U} is ellipsoidal, and for this case, the robust counterpart becomes a nonlinear (but still convex) program. See [11] for analogous derivations of robust counterparts with respect to more general uncertainty sets. Third, when the "true" range of possible A -values

is restricted to lie in a constrained uncertainty set (e.g., budgeted or ellipsoidal uncertainty), it is possible to derive bounds on the probability that the constraint is in fact violated [6].

5.2 Survivable Network Design

Finally, it is worthwhile to note the relationship among the perspectives of other survivable network design research and interdiction studies. The survivable network design literature encompasses a broad study of network design and operations problems that remain functional in the face of failures. Hence, it is harder to put as precise a definition on this field (which some would consider to be encompassed by interdiction and/or robust optimization) than on the previously discussed lines of research.

As a starting point, one may consider the case in which robustness is defined with respect to a collection of possible failure scenarios. Each failure scenario defines a simultaneous realization of uncertain data, and design decisions must be feasible with respect to every possible failure scenario. (The objective would thus be defined as the worst-case scenario in a robust modeling framework and perhaps as an expected cost from a stochastic programming perspective.) Kouvelis and Yu [37] show that with just two scenarios, the shortest path problem with nonnegative data becomes NP-hard, in contrast to the polynomial solvability of the deterministic version of this problem. Garg and Smith [27] provide another version of this problem, in which many failure scenarios exist, each of which represents a set of possible link failures. The authors employ Benders' decomposition to mitigate the computational effort imposed by encountering a large set of failure scenarios.

Several studies, for example, [22, 33, 63], assume that network failures are rare, especially when applied to accidental failure scenarios on equipment whose functionality is very reliable but will occasionally fail. Polyhedral integer programming studies by Grötschel and Monma [30] and Grötschel et al. [31] regard connectivity problems on networks. Other network systems implicitly guarantee survivability with respect to single points of failure. In the past two decades, synchronous optical networking (SONET) ring networks [66, 67] received much research attention from the combinatorial optimization community [5, 28, 29, 38, 54, 60, 64]. These network design problems can be seen within either the interdiction or robust viewpoint. From the interdiction perspective, the attacker destroys any link in an attempt to maximize damage (dropped data), while the recourse action of the defender reroutes data in response to the attack. From the robust perspective, the design decisions build the network with the implicit understanding that *any* interdiction action can be mitigated in the future (without explicitly stating variables and constraints that prove the existence of such recourse actions).

6 Conclusion

Although network interdiction models have existed for some time, the past decade has seen an accelerated development within this field. This has resulted from a confluence of several factors. First, several major destructive events have occurred since the year 2000, including the terrorist attacks on the World Trade Center on September 11, 2001, and Hurricane Katrina in New Orleans in 2005. These events, and the state of the world in their aftermath, motivated researchers to intensify efforts on problems involving major catastrophic disruptions. Second, the operations research community and its available tools have seen advances in the development of models for handling singular events, uncertainties, and relatively large-scale network optimization problems in the past 20 years. Third, computing power and availability has increased to a degree that has permitted an ability to solve large-scale problems on desktop computers.

In a sense, however, the field of network interdiction modeling is in its early stages. The models discussed in this chapter remain somewhat limited in their abilities to handle dynamic changes in the data that drive these models. That is, the majority of the models this chapter has described take a snapshot of a problem in time and solve that snapshot or single-period version of the problem. Moreover, the limited action sets and information symmetry assumptions contained in the majority of existing models can limit their practical application. Finally, multiple interdictors with varying interdiction mechanisms serve to compound problem complexity. Accounting for a richer set of assumptions on the dynamic evolution of data, the potential actions of multiple interdictors, and various states of information will require greater modeling sophistication and computing power than currently available. Thus, while great advances have been made in both computing and operations research methods, a great deal of opportunity exists for developing models and methods for solving realistic versions of dynamic problems.

Abstract

Many real-life problems can be modeled as optimization problems in networks. Examples include finding shortest paths, scheduling classes in classrooms, and finding the vulnerability of networks to disconnection because of link and node failures. In this chapter, a number of interesting problems and their algorithms are surveyed. Some of the problems studied are matching, weighted matching, maximum flow in networks, blocking flows, minimum cuts, densest subgraphs, minimum-cost flows, multi-commodity flows, minimum spanning trees, spanners, Light approximate shortest path trees, and graph coloring. Some interesting applications of matching, namely, two processor scheduling, edge covers, and the Chinese postman problem, are also discussed.

1 Introduction

The optimization of a given objective, while working with limited resources, is a fundamental problem that occurs in all walks of life, and therefore, optimization problems have been widely studied in Computer Science and Operations Research. Problems in discrete optimization vary widely in their complexity, and efficient solutions are derived for many of these problems by studying their combinatorial structure and understanding their fundamental properties. In this chapter, a number of problems arising in networks and advanced algorithmic techniques for solving them are studied.

One of the basic topics in this field is network flow. The related optimization problems are fundamentally important. They have applications in various disciplines and provide a fundamental framework for solving problems. For example, the problem of efficiently moving entities, such as bits, people, or products, from one place to another in an underlying network, can be modeled as a network

flow problem. Applications of flow include matching, scheduling, and connectivity problems. Because of its central role in the fields of Operations Research and Computer Science, considerable emphasis has been placed on the design of efficient algorithms for solving it.

Many practical combinatorial problems such as the assignment problem, and the problem of finding the susceptibility of networks to failure due to faulty links or nodes, are special instances of the max-flow problem. There are several variations and generalizations of the max-flow problem including the vertex capacitated max-flow problem, the minimum-cost max-flow problem, the minimum-cost circulation problem, and the multi-commodity flow problem.

In this chapter, a number of interesting and important optimization problems in networks are surveyed. Some of them such as network flow and matchings have been known for several decades, while others have recent results. The chapter starts with a discussion of matchings in Sect. 2. The single-commodity maximum flow problem is introduced in Sect. 4. The minimum-cut problem is discussed in Sect. 5. In Sect. 6 some applications of network flows are discussed. Section 7 discusses an interesting application of max flows to obtain the densest subgraph of a graph. Section 8 discusses the min-cost flow problem. The multi-commodity flow problem is discussed in Sect. 9. Section 10 introduces the problem of computing optimal branchings. Section 11 discusses the problem of coloring the edges and vertices of a graph. Section 12 discusses approximation algorithms for NP-hard problems. At the end, references to current research in graph algorithms are provided.

2 The Matching Problem

First, the matching problem, which is a special case of the max-flow problem, is introduced. Then, the assignment problem, a generalization of the matching problem, is studied.

A matching is a set of edges such that no two of them are incident to the same vertex. Finding a matching of maximum cardinality within a given graph is called the matching problem. A matching is perfect if every vertex of the graph is matched. An entire book [35] has been devoted to the study of various aspects of the matching problem, ranging from necessary and sufficient conditions for the existence of perfect matchings to algorithms for solving the matching problem. Many of the basic algorithms such as breadth-first search, depth-first search, and shortest paths play important roles in developing efficient implementations for network flow and matching algorithms.

The maximum matching problem is discussed in detail only for bipartite graphs. The same principles are used to design efficient algorithms to solve the matching problem in arbitrary graphs. The algorithms for general graphs are complex due to the presence of odd-length cycles called blossoms, and the reader is referred to [38, Chap. 10] or [43, Chap. 9] for detailed treatments on how blossoms are handled.

2.1 Matching Problem Definitions

Given a graph $G = (V, E)$, a matching M is a subset of the edges such that no two edges in M share a common vertex. In other words, the problem is that of finding a set of independent edges that have no incident vertices in common. The cardinality of M is usually referred to as its size.

The following terms are defined with respect to a matching M . The edges in M are called matched edges, and edges not in M are called free edges. Likewise, a vertex is a matched vertex if it is incident to a matched edge. A free vertex is one that is not matched. The mate of a matched vertex v is its neighbor w that is at the other end of the matched edge incident to v . A matching is called perfect if all vertices of the graph are matched in it. When the number of vertices is odd, one vertex is permitted to remain unmatched. The objective of the maximum matching problem is to maximize $|M|$, the size of the matching. If the edges of the graph have weights, then the weight of a matching is defined to be the sum of the weights of its edges. A path $p = [v_1, v_2, \dots, v_k]$ is called an alternating path if the edges (v_{2j-1}, v_{2j}) , $j = 1, 2, \dots$ are free and the edges (v_{2j}, v_{2j+1}) , $j = 1, 2, \dots$ are matched. An augmenting path $p = [v_1, v_2, \dots, v_k]$ is an alternating path in which both v_1 and v_k are free vertices. Observe that an augmenting path is defined with respect to a specific matching. The symmetric difference of a matching M and an augmenting path P , $M \oplus P$, is defined to be $(M - P) \cup (P - M)$. It can be shown that $M \oplus P$ is also a matching. [Figure 1](#) shows an augmenting path $p = [a, b, c, d, g, h]$ with respect to the given matching. The symmetric difference operation can also be used as above between two matchings. In this case, the resulting graph consists of a collection of paths and cycles with alternate edges from each matching.

2.2 Matchings and Augmenting Paths

The following theorem gives necessary and sufficient conditions for the existence of a perfect matching in a bipartite graph.

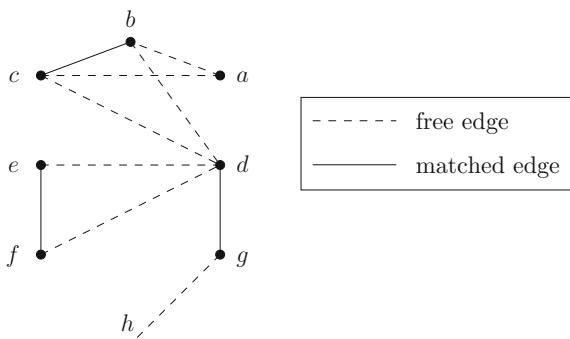

Fig. 1 An augmenting path p with respect to a matching

Theorem 1 (Hall's Theorem) A bipartite graph $G = (X, Y, E)$ with $|X| = |Y|$ has a perfect matching if and only if $\forall S \subseteq X, |N(S)| \geq |S|$, where $N(S) \subseteq Y$ is the set of vertices that are neighbors of some vertex in S .

Although the above theorem captures exactly the conditions under which a given bipartite graph has a perfect matching, it does not lead to an algorithm for finding perfect matchings directly. The following lemma shows how an augmenting path with respect to a given matching can be used to increase the size of a matching. An efficient algorithm will be described later that uses augmenting paths to construct a maximum matching incrementally.

Lemma 1 Let P be the edges on an augmenting path $p = [v_1, \dots, v_k]$ with respect to a matching M . Then, $M' = M \oplus P$ is a matching of cardinality $|M| + 1$.

Proof Since P is an augmenting path, both v_1 and v_k are free vertices in M . The number of free edges in P is one more than the number of matched edges in it. The symmetric difference operator replaces the matched edges of M in P by the free edges in P . Hence the size of the resulting matching, $|M'|$, is one more than $|M|$.

The following theorem provides a necessary and sufficient condition for a given matching M to be a maximum matching.

Theorem 2 A matching M in a graph G is a maximum matching if and only if there is no augmenting path in G with respect to M .

Proof If there is an augmenting path with respect to M , then M cannot be a maximum matching, since by Lemma 1 there is a matching whose size is larger than that of M . To prove the converse, it is shown that if there is no augmenting path with respect to M , then M is a maximum matching. Suppose that there is a matching M' such that $|M'| > |M|$. Consider the subgraph of G induced by the edges $M \oplus M'$. Each vertex in this subgraph has degree at most two, since each node has at most one edge from each matching incident to it. Hence each connected component of this subgraph is either a path or a simple cycle. For each cycle, the number of edges of M is the same as the number of edges of M' . Since $|M'| > |M|$, one of the paths must have more edges from M' than from M . This path is an augmenting path in G with respect to the matching M , contradicting the assumption that there were no augmenting paths with respect to M .

2.3 Bipartite Matching Algorithm

High-Level Description: The algorithm starts with the empty matching $M = \emptyset$ and augments the matching in phases. In each phase, an augmenting path with respect to the current matching M is found, and it is used to increase the size of the matching.

An augmenting path, if one exists, can be found in $O(|E|)$ time, using a procedure similar to breadth-first search.

The search for an augmenting path proceeds from the free vertices. At each step, when a vertex in X is processed, all its unvisited neighbors are also searched. When a matched vertex in Y is considered, only its matched neighbor is searched. This search proceeds along a subgraph referred to as the Hungarian tree.

The algorithm uses a queue to hold vertices that are yet to be processed. Initially, all free vertices in X are placed in the queue. The vertices are removed one by one from the queue and processed as follows. In turn, when vertex v is removed from the queue, all edges incident to it are scanned. If it has a neighbor in the vertex set Y that is free, then the search for an augmenting path is successful; update the matching, and the algorithm proceeds to its next phase. Otherwise, add the mates of all the matched neighbors of v to the queue if they have never been added to the queue, and continue the search for an augmenting path. If the algorithm empties the queue without finding an augmenting path, its current matching is a maximum matching, and it terminates.

2.4 Sample Execution

[Figure 2](#) shows a sample execution of the matching algorithm. It depicts a partial matching and the structure of the resulting Hungarian tree. In this example, the search starts from the free vertex b . Its neighbors are v and z , and both are matched.

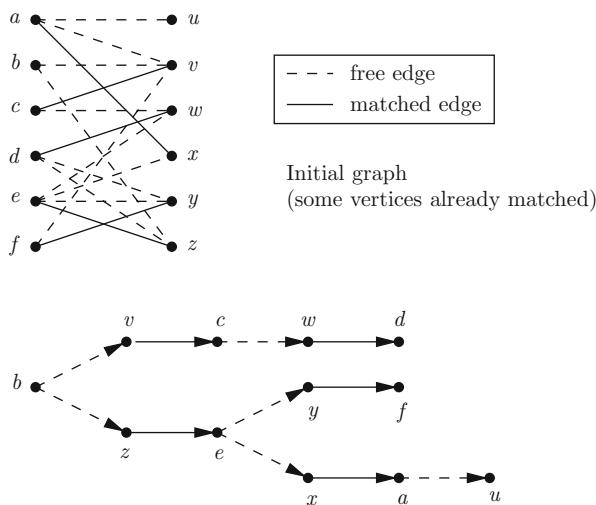

Fig. 2 Sample execution of matching algorithm

Their mates, c and e , are added to a queue Q . When c is explored, d is added to Q and then f and a . Since a has a free neighbor u , an augmenting path from vertex b to vertex u is found by the algorithm.

2.5 Analysis

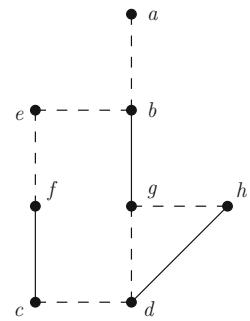

If there are augmenting paths with respect to the current matching, the algorithm will find at least one of them. Hence, when the algorithm terminates, the graph has no augmenting paths with respect to the current matching, and the current matching is optimal. Each iteration of the main while loop of the algorithm runs in $O(|E|)$ time. The construction of the auxiliary graph A and computation of the array $free$ also take $O(|E|)$ time. In each iteration, the size of the matching increases by one, and thus, there are at most $\min(|X|, |Y|)$ iterations of the while loop. Therefore, the algorithm solves the matching problem for bipartite graphs in time $O(\min(|X|, |Y|)|E|)$. Hopcroft and Karp (see [38]) showed how to improve the running time by finding a maximal set of disjoint augmenting paths in a single phase in $O(|E|)$ time. They also proved that the algorithm runs in only $O(\sqrt{|V|})$ phases, yielding a worst-case running time of $O(\sqrt{|V|}|E|)$.

2.6 The Matching Problem in General Graphs

The techniques used to solve the matching problem in bipartite graphs do not extend directly to non-bipartite graphs. The notion of augmenting paths and their relation to maximum matchings (Theorem 2) remain the same. Therefore, it is still possible to use the natural algorithm of starting with an empty matching and increasing its size repeatedly with augmenting paths until no augmenting path exists in the graph. But the problem of finding augmenting paths in non-bipartite graphs is harder. The main trouble is due to odd-length cycles known as blossoms that appear along alternating paths explored by the algorithm when it is looking for augmenting paths. This difficulty is illustrated by the example in Fig. 3. The search for an augmenting path from an unmatched vertex, such as e , could go through the following sequence of vertices $[e, b, g, d, h, g, b, a]$. Even though the augmenting path satisfies the “local” conditions for being an augmenting path, it is not a valid augmenting path since it is not simple. The reason for this is that the odd-length cycle (g, d, h, g) causes the path to “fold” on itself – a problem that does not arise in the bipartite case. In fact, the matching does contain a valid augmenting path $[e, f, c, d, h, g, b, a]$. Not all odd cycles cause this problem, but odd cycles that are as dense in matched edges as possible, that is, it depends on the current matching. By “shrinking” blossoms to single nodes, the algorithm can get rid of them [38]. Subsequent work focussed on efficient implementation of this method.

Edmonds (see [38]) gave the first polynomial-time algorithm for solving the maximum matching problem in general graphs. The current fastest algorithm for this

Fig. 3 Difficulty in dealing with blossoms

problem is due to Micali and Vazirani [36] and their algorithm runs in $O(|E|\sqrt{|V|})$ steps, which are the same bound obtained by the Hopcroft-Karp algorithm for finding a maximum matching in bipartite graphs.

2.7 Assignment Problem

In this section, the assignment problem – that of finding a maximum-weight matching in a given bipartite graph in which edges are given nonnegative weights – is studied. There is no loss of generality in assuming that the graph is a complete bipartite graph, since zero-weight edges may be added between pairs of vertices that are nonadjacent in the original graph without affecting the weight of a maximum-weight matching. The minimization version of the weighted version is the problem of finding a minimum-weight perfect matching in a complete bipartite graph. Both versions of the weighted matching problem are equivalent, and it is shown below how to reduce the minimum-weight perfect matching to maximum-weight matching. Choose a constant W that is larger than the weight of any edge, and assign each edge a new weight of $w'(e) = W - w(e)$. Observe that maximum-weight matchings with the new weight function are minimum-weight perfect matchings with the original weights.

In this section, attention is restricted to the study of the maximum-weight matching problem for bipartite graphs. Similar techniques have been used to solve the maximum-weight matching problem in arbitrary graphs (see [33, 38]).

The input is a complete bipartite graph $G = (X, Y, X \times Y)$, and each edge e has a nonnegative weight of $w(e)$. The following algorithm is known as the Hungarian method (see [1, 35, 38]). The method can be viewed as a primal-dual algorithm in the framework of linear programming [38]. No knowledge of linear programming is assumed here.

A feasible vertex-labeling ℓ is defined to be a mapping from the set of vertices in G to the real numbers such that for each edge (x_i, y_j) , the following condition holds:

$$\ell(x_i) + \ell(y_j) \geq w(x_i, y_j).$$

The following can be verified to be a feasible vertex labeling. For each vertex $y_j \in Y$, set $\ell(y_j)$ to be 0, and for each vertex $x_i \in X$, set $\ell(x_i)$ to be the maximum weight of an edge incident to x_i :

$$\begin{aligned}\ell(y_j) &= 0, \\ \ell(x_i) &= \max_j w(x_i, y_j).\end{aligned}$$

The equality subgraph, G_ℓ , is defined to be the spanning subgraph of G which includes all vertices of G but only those edges (x_i, y_j) which have weights such that

$$\ell(x_i) + \ell(y_j) = w(x_i, y_j).$$

The connection between equality subgraphs and maximum-weighted matchings is established by the following theorem.

Theorem 3 *If the equality subgraph, G_ℓ , has a perfect matching, M^* , then M^* is a maximum-weight matching in G .*

Proof Let M^* be a perfect matching in G_ℓ . By definition,

$$w(M^*) = \sum_{e \in M^*} w(e) = \sum_{v \in X \cup Y} \ell(v).$$

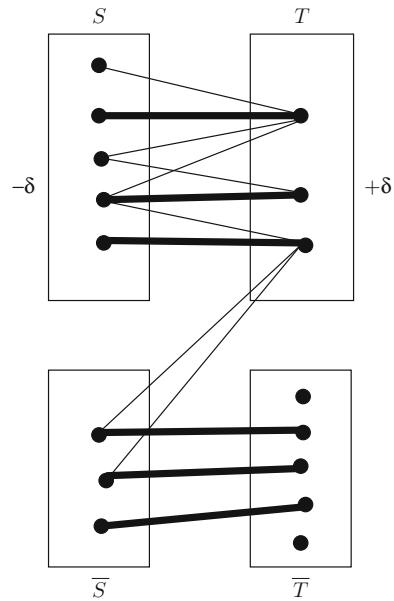

Let M be any perfect matching in G . Then,

$$w(M) = \sum_{e \in M} w(e) \leq \sum_{v \in X \cup Y} \ell(v) = w(M^*).$$

Hence, M^* is a maximum-weight perfect matching.

High-Level Description: The above theorem is the basis of the following algorithm for finding a maximum-weight matching in a complete bipartite graph. The algorithm starts with a feasible labeling, then computes the equality subgraph and a maximum cardinality matching in this subgraph. If the matching found is perfect, by [Theorem 3](#), the matching must be a maximum-weight matching, and the algorithm returns it as its output. Otherwise the matching is not perfect, and more edges need to be added to the equality subgraph by revising the vertex labels. The revision should ensure that edges from the current matching do not leave the equality subgraph. After more edges are added to the equality subgraph, the algorithm grows the Hungarian trees further. Either the size of the matching increases because an augmenting path is found, or a new vertex is added to the Hungarian tree. In the former case, the current phase terminates, and the algorithm starts a new phase since the matching size has increased. In the latter case, new nodes are added to the Hungarian tree. In $|X|$ phases, the tree includes all the nodes, and therefore, there are at most $|X|$ phases before the size of the matching increases.

Fig. 4 Sets S and T as maintained by the algorithm

It is now described in more detail how the labels are updated and which edges are added to the equality subgraph. Suppose M is a maximum matching found by the algorithm. Hungarian trees are grown from all the free vertices in X . Vertices of X (including the free vertices) that are encountered in the search are added to a set S , and vertices of Y that are encountered in the search are added to a set T . Let $\bar{S} = X - S$ and $\bar{T} = Y - T$. Figure 4 illustrates the structure of the sets S and T . Matched edges are shown in bold; the other edges are the edges in G_ℓ . Observe that there are no edges in the equality subgraph from S to \bar{T} , even though there may be edges from T to \bar{S} . The algorithm now revises the labels as follows. Decrease all the labels of vertices in S by a quantity δ (to be determined later), and increase the labels of the vertices in T by δ . This ensures that edges in the matching continue to stay in the equality subgraph. Edges in G (not in G_ℓ) that go from vertices in S to vertices in \bar{T} are candidate edges to enter the equality subgraph, since one label is decreasing and the other is unchanged. The algorithm chooses δ to be the smallest value such that some edge of $G - G_\ell$ enters the equality subgraph. Suppose this edge goes from $x \in S$ to $y \in \bar{T}$. If y is free, then an augmenting path has been found. On the other hand, if y is matched, the Hungarian tree is grown by moving y to T and its matched neighbor to S , and the process of revising labels is continued.

3 Applications of Matchings

Matchings lie at the heart of many optimization problems, and the problem has many applications. The name comes from the marriage problem, where the objective is to find a maximum number of compatible pairs of men and women for marriage,

given their pairwise compatibility information. Applications of matching include assigning workers to jobs, assigning a collection of jobs with precedence constraints to two processors such that the total execution time is minimized, determining the structure of chemical bonds in Chemistry, matching moving objects based on a sequence of snapshots, and localization of objects in space after obtaining information from multiple sensors (see [1]). A few applications of matching are discussed.

3.1 Two Processor Scheduling

First, the problem of scheduling jobs on two processors is studied. The original paper is by Fujii, Kasami, and Ninomiya [17].

There are two identical processors and a collection of n jobs that need to be scheduled. Each job requires unit time. There is a precedence graph associated with the jobs (also called the DAG). If there is an edge from i to j , then i must be finished before j is started by either processor. How should the jobs be scheduled on the two processors so that all the jobs are completed as quickly as possible. The jobs could represent courses that need to be taken (courses have prerequisites), and if a student is taking at most two courses in each semester, the question really is: How quickly can he graduate?

This is a good time to note that even though the two processor scheduling problem can be solved in polynomial time, the three processor scheduling problem is not known to be solvable in polynomial time and is known to be NP-complete. In fact, the complexity of the k processor scheduling problem when k is *fixed* is not known.

From the acyclic graph G , a *compatibility* graph G^* is constructed as follows. G^* has the same nodes as G , and there is an (undirected) edge (i, j) if there is no directed path from i to j or from j to i in G . In other words, i and j are jobs that can be done together.

A maximum matching in G^* indicates the maximum number of pairs of jobs that can be processed simultaneously. Clearly, a solution to the scheduling problem can be used to obtain a matching in G^* . More interestingly, a solution to the matching problem can be used to obtain a solution to the scheduling problem!

Suppose a maximum matching M in G^* is found. An unmatched vertex is executed on a single processor while the other processor is idle. If the maximum matching has size m^* , then $2m^*$ vertices are matched and $n - 2m^*$ vertices are left unmatched. The time to finish all the jobs will be $m^* + n - 2m^* = n - m^*$. Hence a maximum matching will minimize the time required to schedule all the jobs.

It is now shown that, given a maximum matching M^* , a schedule of size $n - m^*$ can be extracted from it. The key idea is that each matched job is scheduled in a slot together with another job (which may be different from the job it was matched to). This ensures that no more than $n - m^*$ slots are used.

Let S be the subset of vertices that have indegree 0. The following cases show how a schedule can be constructed from G and M^* . Basically, it must be ensured

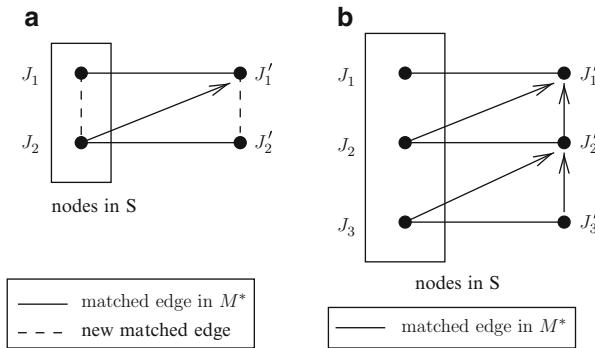

Fig. 5 (a) Changing the schedule (b) Continuing the proof

that for all jobs that are paired up in M^* , they are also paired up in the schedule. The following rules can be applied repeatedly.

1. If there is an unmatched vertex in S , schedule it and remove it from G .
2. If there is a pair of jobs in S that are matched in M^* , then schedule the pair and delete both the jobs from G .

If none of the above rules are applicable, then all jobs in S are matched; moreover each job in S is matched with a job not in S .

Let $J_1 \in S$ be matched to $J'_1 \notin S$. Let J_2 be a job in S that has a path to J'_1 . Let J'_2 be the mate of J_2 . If there is path from J'_1 to J'_2 , then J_2 and J'_2 could not be matched to each other in G^* (this cannot be an edge in the compatibility graph). If there is no path from J'_2 to J'_1 , then the matching is *changed* to match (J_1, J_2) and (J'_1, J'_2) since (J'_1, J'_2) is an edge in G^* (see Fig. 5a).

The only remaining case is when J'_2 has a path to J'_1 . Recall that J_2 also has a path to J'_1 . The above argument is repeated with J'_2 in place of J'_1 . This will yield a new pair (J_3, J'_3) , etc (see Fig. 5b). Since the graph G has no cycles at each step, a distinct pair of jobs is generated; at some point of time this process will stop (since the graph is finite). At that time a pair of jobs in S have been found that can be scheduled together.

3.2 Weighted Edge-Cover Problem

Another application of matching is the problem of finding a minimum-weight edge cover of a graph. Given a graph $G = (V, E)$ with weights on the edges, a set of edges $C \subseteq E$ form an edge cover of G if every vertex in V is incident to at least one edge in C . The weight of the cover C is the sum of the weights of its edges. The objective is to find an edge cover C of minimum weight. The problem can be reduced to the minimum-weight perfect matching problem as follows: Create an identical copy $G' = (V', E')$ of graph G , except the weights of edges in E' are all 0. Add an edge from each $v \in V$ to $v' \in V'$ with weight $w_{\min}(v) = \min_{x \in N(v)} w(v, x)$. The final graph H is the union of G and G' , together with the edges connecting the

two copies of each vertex; H contains $2|V|$ vertices and $2|E| + |V|$ edges. There exist other reductions from minimum-weight edge cover to minimum-weight perfect matching; the reduction outlined above has the advantage that it creates a graph with $O(|V|)$ vertices and $O(|E|)$ edges. The minimum-weight perfect matching problem may be solved using the techniques described earlier for the bipartite case, but the algorithm is more complex [33, 38].

Theorem 4 *The weight of a minimum-weight perfect matching in H is equal to the weight of a minimum-weight edge cover in G .*

Proof Consider a minimum-weight edge cover C in G . There is no loss of generality in assuming that a minimum-weight edge cover has no path of three edges, since the middle edge can be removed from the cover, thus reducing its weight further. Hence the edge cover C is a union of “stars” (trees of height 1). For each star that has a vertex of degree more than one, one of its leaf nodes can be made to match to its copy in G' , with weight at most the weight of the edge incident on the leaf vertex, thus reducing the degree of the star. This is repeated until each vertex has degree at most one in the edge cover, that is, it is a matching. In H , select this matching, once in each copy of G . Observe that the cost of the matching within the second copy G' is 0. Thus, given C , a perfect matching in H can be found, whose weight is no larger.

To argue the converse, it is now shown how to construct a cover C from a given perfect matching M in H . For each edge $(v, v') \in M$, add to C a least weight edge incident to v in G . Also include in C any edge of G that was matched in M . It can be verified that C is an edge cover whose weight equals the weight of M .

3.3 Chinese Postman Problem

One of the first problems to be studied in graph theory was the Euler tour problem. It asks whether a given graph has a tour that traverses each edge of the graph exactly once. Graphs that have Euler tours are called Eulerian graphs. It is well known that a graph is Eulerian if and only if it is connected and the degree of every vertex is even. Similarly, a necessary and sufficient condition for a directed graph to have an Euler tour is that it is strongly connected and the number of incoming edges at each vertex is equal to the number of outgoing edges from it. Given an Eulerian graph, whether undirected or directed, an Euler tour can be found in linear time.

A natural optimization problem, known as the Chinese postman problem (CPP), arises in non-Eulerian graphs, which are that of finding a shortest tour that traverses each edge of a given graph *at least* once. This problem and its generalizations were studied by Edmonds and Johnson [13]. CPP can be solved by using algorithms for weighted matching as follows. It is assumed that the underlying graph is connected, since otherwise, the problem is not feasible.

CPP in undirected graphs: Here, the given graph G needs to be augmented by adding additional edges such that the degree of every vertex becomes even. The subgraph that is added, known as a T-join, has odd degree at odd-degree nodes

of G and has even degree (possibly zero) at other nodes. It is easy to show that any graph has an even number of odd-degree nodes and that a minimum-weight T-join can be decomposed into a collection of edge-disjoint paths connecting odd-degree nodes. This leads us to the following algorithm for finding a shortest CPP in undirected graphs. Construct a new graph containing just the odd-degree nodes of G . Add edges connecting each pair of these nodes, with the weight of an edge being the length of a shortest path in G connecting those two nodes. Now, find a minimum-weight perfect matching in this graph. For each edge in this matching, a shortest path in G is added between its end vertices. The resulting multigraph has even degree at all nodes, and an Euler tour can be found in it.

CPP in directed graphs: In this case, it must be ensured that every node is balanced, that is, the number of outgoing edges is equal to the number of its incoming edges. For a vertex v , its imbalance, $b(v)$, is defined to be its outdegree minus its indegree. Construct an auxiliary graph with just the vertices that have $b(v) \neq 0$. In this graph, it is necessary to add as many copies of a vertex as its imbalance, that is, there are $|b(v)|$ copies of vertex v . The vertices are partitioned into those with positive imbalance (V_p) and vertices with negative imbalance (V_n). Take the complete bipartite graph between V_p and V_n , where the weight of an edge (p, n) is equal to the length of a shortest path in G from $p \in V_p$ to $n \in V_n$. Now, find a minimum-weight perfect matching M in this bipartite graph, and when G is augmented by adding the paths in G corresponding to M , the resulting multigraph is Eulerian. Note that it is also possible to solve the problem by using a solution for min-cost flow (see Sect. 8), by defining demands to be $b(v)$, by setting the weight of each edge to be its cost, and by finding a min-cost flow (without capacities) that satisfies all the demands.

4 The Network Flow Problem

A number of polynomial-time flow algorithms have been developed over the last two decades. The reader is referred to the books by Ahuja, Magnanti, and Orlin [1] and Tarjan [43] for a detailed account of the historical development of the various flow methods. An excellent survey on network flow algorithms has been written by Goldberg, Tardos, and Tarjan [23]. The book by Cormen, Leiserson, Stein, and Rivest [11] describes the preflow-push method, and to complement their coverage, an implementation of the “blocking flow” technique of Malhotra, Kumar, and Maheshwari (see [38]) is discussed here.

4.1 Network Flow Problem Definitions

Flow Network: A flow network $G = (V, E)$ is a directed graph, with two specially marked nodes, namely, the source s and the sink t . A capacity function $u : E \mapsto \mathbb{R}^+$ maps edges to positive real numbers.

Max-Flow Problem: A flow function $f : E \mapsto \mathbb{R}$ maps edges to real numbers. For an edge $e = (v, w)$, $f(v, w)$ refers to the flow on edge e , which is also called the net flow from vertex v to vertex w . This notation is extended to sets of vertices as follows: If X and Y are sets of vertices, then $f(X, Y)$ is defined to be $\sum_{x \in X} \sum_{y \in Y} f(x, y)$. A flow function is required to satisfy the following constraints:

- (Capacity constraint) For all edges e , $f(e) \leq u(e)$.
- (Skew symmetry constraint) For an edge $e = (v, w)$, $f(v, w) = -f(w, v)$.
- (Flow conservation) For all vertices $v \in V - \{s, t\}$, $\sum_{w \in V} f(v, w) = 0$.

The capacity constraint states that the total flow on an edge does not exceed its capacity. The skew symmetry condition states that the flow on an edge is the negative of the flow in the reverse direction. The flow conservation constraint states that the total net flow out of any vertex other than the source and sink is zero.

The value of the flow is defined to be the net flow out of the source vertex:

$$|f| = \sum_{v \in V} f(s, v).$$

In the maximum flow problem, the objective is to find a flow function that satisfies the above three constraints and also maximizes the total flow value $|f|$.

Remark This formulation of the network flow problem is powerful enough to capture generalizations where there are many sources and sinks (single-commodity flow) and where both vertices and edges have capacity constraints. To reduce multiple sources to a single source, add a new source vertex with edges connecting it to the original source vertices. To reduce multiple sinks to a single sink, add a new sink vertex with edges from the original sinks to the new sink. It is easy to reduce the vertex capacity problem to edge capacities by “splitting” a vertex into two vertices and making all the incoming edges come into the first vertex and the outgoing edges come out of the second vertex. An edge is added between them with the capacity of the corresponding vertex, so that the entire flow through the vertex is forced through this edge. The problem for undirected graphs can be solved by treating each undirected edge as two directed edges with the same capacity as the original undirected edge.

First, the notion of cuts is defined, and then, the max-flow min-cut theorem is introduced. Then, residual networks, layered networks, and the concept of blocking flows are introduced. It is then shown how to reduce the max-flow problem to the computation of a sequence of blocking flows. Finally an efficient algorithm for finding a blocking flow is described.

A cut is a partitioning of the vertex set into two subsets S and $V - S$. An edge crosses the cut if it connects a vertex $x \in S$ to a vertex $y \in V - S$. An $s-t$ cut of the graph is a partitioning of the vertex set V into two sets S and $T = V - S$ such that $s \in S$ and $t \in T$. If f is a flow, then the net flow across the cut is defined as $f(S, T)$. The capacity of the cut is defined as $u(S, T) = \sum_{x \in S} \sum_{y \in T} u(x, y)$. The

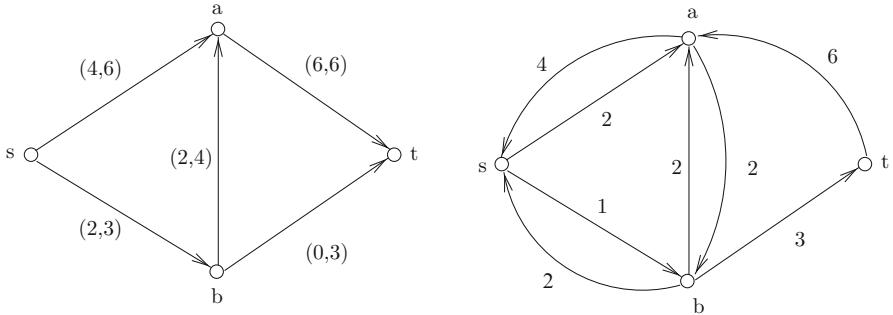

Fig. 6 A network with a given flow function and its residual network. A label of (f, c) for an edge indicates a flow of f and capacity of c

net flow across a cut includes negative flows between vertices (flow from T to S), but the capacity of the cut includes only the capacities of edges from S to T .

Using the flow conservation principle, it can be shown that the net flow across an s - t cut is exactly the flow value $|f|$. By the capacity constraint, the flow across the cut cannot exceed the capacity of the cut. Thus, the value of the maximum flow is no greater than the capacity of a minimum s - t cut. The max-flow min-cut theorem states that the two quantities are actually equal. In other words, if f^* is a maximum flow, then there is some cut (X, \bar{X}) with $s \in X$ and $t \in \bar{X}$, such that $|f^*| = u(X, \bar{X})$. The reader is referred to [11, 43] for further details.

The residual capacity of an edge (v, w) with respect to a flow f is defined as follows:

$$u'(v, w) = u(v, w) - f(v, w).$$

The quantity $u'(v, w)$ is the number of additional units of flow that can be pushed from v to w without violating the capacity constraints. An edge e is saturated if $u(e) = f(e)$, that is, if its residual capacity $u'(e) = 0$. The residual graph, $G_R(f)$, for a flow f , is the graph with vertex set V , source and sink s and t , respectively, and those edges (v, w) for which $u'(v, w) > 0$. Figure 6 shows a network on the left with a given flow function. Each edge is labeled with two values: the flow through that edge and its capacity. The figure on the right depicts the residual network corresponding to this flow.

An augmenting path for f is a path P from s to t in $G_R(f)$. The residual capacity of P , denoted by $u'(P)$, is the minimum value of $u'(v, w)$ over all edges (v, w) in the path P . The flow can be increased by $u'(P)$, by increasing the flow on each edge of P by this amount. Whenever $f(v, w)$ is changed, $f(w, v)$ is also correspondingly changed to maintain skew symmetry.

Most flow algorithms are based on the concept of augmenting paths pioneered by Ford and Fulkerson [16]. They start with an initial zero flow and augment the flow in stages. In each stage, a residual graph $G_R(f)$ with respect to the current flow function f is constructed, and an augmenting path in $G_R(f)$ is found, thus increasing the value of the flow. Flow is increased along this path until an edge in

this path is saturated. The algorithms iteratively keep increasing the flow until there are no more augmenting paths in $G_R(f)$ and return the final flow f as their output. Edmonds and Karp [14] suggested two possible improvements to this algorithm to make it run in polynomial time. The first was to choose shortest possible augmenting paths, where the length of the path is simply the number of edges on the path. This method can be improved using the approach due to Dinitz (see [43]) in which a sequence of blocking flows is found. The second strategy was to select a path which can be used to push the maximum amount of flow. The number of iterations of this method is bounded by $O(|E| \log C)$ where C is the largest edge capacity. In each iteration, a path is found through which a maximum amount of flow can be pushed. This step is implemented by a suitable modification of Dijkstra's shortest path algorithm.

The following lemma is fundamental in understanding the basic strategy behind these algorithms.

Lemma 2 *Let f be a flow and f^* be a maximum flow in G . The value of a maximum flow in the residual graph $G_R(f)$ is $|f^*| - |f|$.*

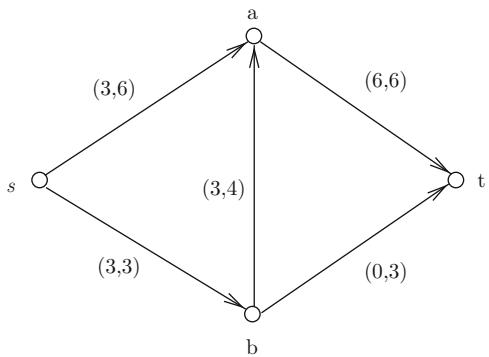

Proof Let f' be any flow in $G_R(f)$. Define $f + f'$ to be the flow $f(v, w) + f'(v, w)$ for each edge (v, w) . Observe that $f + f'$ is a feasible flow in G of value $|f| + |f'|$. Since f^* is the maximum flow possible in G , $|f'| \leq |f^*| - |f|$. Similarly define $f^* - f$ to be a flow in $G_R(f)$ defined by $f^*(v, w) - f(v, w)$ in each edge (v, w) , and this is a feasible flow in $G_R(f)$ of value $|f^*| - |f|$, and it is a maximum flow in $G_R(f)$.

Blocking Flow: A flow f is a blocking flow if every path from s to t in G contains a saturated edge. Blocking flows are also known as maximal flows. [Figure 7](#) depicts a blocking flow. Any path from s to t contains at least one saturated edge. For example, in the path $[s, a, t]$, the edge (a, t) is saturated. It is important to note that a blocking flow is not necessarily a maximum flow. There may be augmenting paths that increase the flow on some edges and decrease the flow on other edges (by increasing the flow in the reverse direction). The example in [Figure 7](#) contains an augmenting path $[s, a, b, t]$, which can be used to increase the flow by 3 units.

Layered Networks: Let $G_R(f)$ be the residual graph with respect to a flow f . The level of a vertex v is the length of a shortest path from s to v in $G_R(f)$. The level graph L for f is the subgraph of $G_R(f)$ containing vertices reachable from s and only the edges (v, w) such that $\text{level}(w) = 1 + \text{level}(v)$. L contains all shortest length augmenting paths and can be constructed in $O(|E|)$ time.

The maximum flow algorithm proposed by Dinitz starts with the zero flow and iteratively increases the flow by augmenting it with a blocking flow in $G_R(f)$ until t is not reachable from s in $G_R(f)$. At each step, the current flow is replaced by the sum of the current flow and the blocking flow. This algorithm terminates in $|V| - 1$ iterations, since in each iteration the shortest distance from s to t in the residual graph increases. The shortest path from s to t is at most $|V| - 1$, and this gives an upper bound on the number of iterations of the algorithm.

Fig. 7 Example of blocking flow – all paths from s to t are saturated. A label of (f, c) for an edge indicates a flow of f and capacity of c

An algorithm to find a blocking flow that runs in $O(|V|^2)$ time is described here (see [38] for details), and this yields an $O(|V|^3)$ max-flow algorithm. There are a number of $O(|V|^2)$ blocking flow algorithms available, some of which are described in [43].

4.2 Blocking Flows

Dinitz's algorithm finds a blocking flow as follows. The main step is to find paths from the source to the sink and push as much flow as possible on each path and thus saturate an edge in each path. It takes $O(|V|)$ time to compute the amount of flow that can be pushed on a path. Since there are $|E|$ edges, this yields an upper bound of $O(|V||E|)$ steps on the running time of the algorithm. The following algorithm shows how to find a blocking flow more efficiently.

Malhotra-Kumar-Maheshwari Blocking Flow Algorithm: The algorithm has a current flow function f and its corresponding residual graph $G_R(f)$. Define for each node $v \in G_R(f)$ a quantity $tp[v]$ that specifies its maximum throughput, that is, either the sum of the capacities of the incoming arcs or the sum of the capacities of the outgoing arcs, whichever is smaller. The quantity $tp[v]$ represents the maximum flow that could pass through v in any feasible blocking flow in the residual graph. Vertices with zero throughput are deleted from $G_R(f)$.

The algorithm selects a vertex x with least throughput. It then greedily pushes a flow of $tp[x]$ from x towards t , level by level in the layered residual graph. This can be done by creating a queue which initially contains x , which is assigned the task of pushing $tp[x]$ out of it. In each step, the vertex v at the front of the queue is removed, and the arcs going out of v are scanned one at a time, and as much flow as possible is pushed out of them until v 's allocated flow has been pushed out. For each arc (v, w) that the algorithm pushed flow through, it updates the residual capacity of the arc (v, w) and places w on a queue (if it is not already there) and increments the net incoming flow into w . Also $tp[v]$ is reduced by the amount of flow that was sent through it now. The flow finally reaches t , and the algorithm never comes across a vertex that has incoming flow that exceeds its outgoing capacity since x was chosen

as a vertex with least throughput. The above idea is repeated to pull a flow of $tp[x]$ from the source s to x . Combining the two steps yields a flow of $tp[x]$ from s to t in the residual network that goes through x . The flow f is augmented by this amount. Vertex x is deleted from the residual graph, along with any other vertices that have zero throughput.

The above procedure is repeated until all vertices are deleted from the residual graph. The algorithm has a blocking flow at this stage since at least one vertex is saturated in every path from s to t . In the above algorithm, whenever an edge is saturated, it may be deleted from the residual graph. Since the algorithm uses a greedy strategy to pump flows, at most $O(|E|)$ time is spent when an edge is saturated. When finding flow paths to push $tp[x]$, there are at most $|V|$ times (once for each vertex) when the algorithm pushes a flow that does not saturate the corresponding edge. After this step, x is deleted from the residual graph. Hence the above algorithm to compute blocking flows terminates in $O(|E| + |V|^2) = O(|V|^2)$ steps.

Karzanov (see [43]) used the concept of preflows to develop an $O(|V|^2)$ time algorithm for developing blocking flows as well. This method was then adapted by Goldberg and Tarjan (see [11]), who proposed a preflow-push method for computing a maximum flow in a network. A preflow is a flow that satisfies the capacity constraints, but not flow conservation. Any node in the network is allowed to have more flow coming into it than there is flowing out. The algorithm tries to move the excess flows towards the sinks without violating capacity constraints. The algorithm finally terminates with a feasible flow that is a max flow. It finds a max flow in $O\left(|V||E|\log \frac{|V|^2}{|E|}\right)$ time.

5 The Min-Cut Problem

Two problems are studied in this section. The first is the s - t min-cut problem: Given a directed graph with capacities on the edges and two special vertices s and t , the problem is to find a cut of minimum capacity that separates s from t . The value of a min-cut's capacity can be computed by finding the value of the maximum flow from s to t in the network. Recall that the max-flow min-cut theorem shows that the two quantities are equal. It is now shown how to find the sets S and T that provides an s - t min cut from a given s - t max flow.

The second problem is to find a smallest cut in a given graph G . In this problem on undirected graphs, the vertex set must be partitioned into two sets such that the total weight of the edges crossing the cut is minimized. This problem can be solved by enumerating over all $\{s, t\}$ pairs of vertices and finding a s - t min cut for each pair. This procedure is rather inefficient. However, Hao and Orlin [24] showed that this problem can be solved in the same order of running time as taken by a single max-flow computation. Stoer and Wagner [41] have given a simple and elegant algorithm for computing minimum cuts based on a technique due to Nagamochi and Ibaraki [37]. Recently, Karger [27] has given a randomized algorithm that runs in almost linear time for computing minimum cuts without using network flow methods.

5.1 Finding an s - t Min Cut

Let f^* be a maximum flow from s to t in the graph. Recall that $G_R(f^*)$ is the residual graph corresponding to f^* . Let S be the set of all vertices that are reachable from s in $G_R(f^*)$, that is, vertices to which s has a directed path. Let T be all the remaining vertices of G . By definition $s \in S$. Since f^* is a max flow from s to t , $t \in T$. Otherwise the flow can be increased by pushing flow along this path from s to t in $G_R(f^*)$. All the edges from vertices in S to vertices in T are saturated and form a minimum cut.

5.2 Finding All-Pair Min Cuts

For an undirected graph G with $|V|$ vertices, Gomory and Hu (see [1]) showed that the flow values between each of the $|V|(|V| - 1)/2$ pairs of vertices of G can be computed by solving only $|V| - 1$ max-flow computations. Furthermore, they showed that the flow values can be represented by a weighted tree T on $|V|$ nodes. Each node in the tree represents one of the vertices of the given graph. For any pair of nodes (x, y) , the maximum flow value from x to y (and hence the x - y min cut) in G is equal to the weight of the minimum-weight edge on the unique path in T between x and y .

6 Applications of Network Flows (and Min Cuts)

There are numerous applications of the maximum flow algorithm in scheduling problems of various kinds. It is used in open-pit mining, vehicle routing, etc. A few interesting applications of the flow problem are discussed. See [1] for further details.

6.1 Connectivity

Given a graph G , its connectivity is a measure of its susceptibility to disconnection upon the removal of some of its edges or nodes. It is an important concept in the area of telecommunication networks, where failure of nodes (called hubs) and edges (called links) can lead to network separation, resulting in millions of dollars in losses.

For two nodes v and w , define their *edge connectivity* to be the maximum number of *edge-disjoint* paths between v and w in G . Similarly, their *vertex connectivity* or simply *connectivity* is the maximum number of *vertex-disjoint* (also known as *openly disjoint*) paths connecting them. One can also define the terms using the minimum number of edges/vertices that have to be removed to disconnect v from w . Menger showed that these two definitions are equivalent: The maximum number of edge-disjoint and openly disjoint paths from v to w are, respectively, equal to the

minimum number of edges and vertices that must be removed to separate v from w in G .

Given a graph G , the edge connectivity of its vertices v and w is computed as follows. Replace each edge of G by two (antiparallel) directed edges between its end points. Assign the capacity of each edge to be 1. In the resulting flow network, find a maximum flow from v to w . The value of the maximum flow is equal to the edge connectivity of v and w in G . A min cut separating v and w is a minimum set of edges of G , whose removal separates v from w in G . For vertex connectivity, openly disjoint paths are required. This can be done by setting capacities of vertices also to be 1, which can be accomplished by replacing each vertex u by two vertices u_{in} and u_{out} , adding the edge from u_{in} to u_{out} of capacity 1. All incoming edges to u are sent to u_{in} . All outgoing edges from u are sent out of u_{out} . Now, a maximum flow from v_{out} to w_{in} gives us the maximum number of openly disjoint paths from v to w in G .

6.2 Finding a Minimum-Weight Vertex Cover in Bipartite Graphs

A vertex cover of a graph is a set of vertices that is incident to all its edges. The weight of a vertex cover is the sum of the weights of its vertices. Finding a vertex cover of minimum weight is NP-hard for arbitrary graphs (see Sect. 12 for more details). For bipartite graphs, the problem is solvable efficiently using the maximum flow algorithm.

Given a bipartite graph $G = (X, Y, E)$ with weights on the vertices, the goal is to find a subset C of vertices of minimum total weight, so that for each edge, at least one of its end vertices is in C . The weight of a vertex v is denoted by $w(v)$. Construct a flow network N from G as follows: Add a new source vertex s , and for each $x \in X$, add a directed edge (s, x) , with capacity $w(x)$. Add a new sink vertex t , and for each $y \in Y$, add a directed edge (y, t) , with capacity $w(y)$. The edges in E are given infinite capacity, and they are oriented from X to Y . Let C be a subset of vertices in G . In the following discussion, X_C denotes $X \cap C$, and Y_C denotes $Y \cap C$. Let $\bar{X}_C = X - X_C$ and $\bar{Y}_C = Y - Y_C$.

If C is a vertex cover of G , then there are no edges in G connecting \bar{X}_C and \bar{Y}_C , since such edges would not be incident to C . A cut in the flow network N , whose capacity is the same as the weight of the vertex cover, can be constructed as follows: $S = \{s\} \cup \bar{X}_C \cup Y_C$ and $T = \{t\} \cup X_C \cup \bar{Y}_C$. Each vertex cover of G gives rise to a cut whose capacity is equal to the weight of the cover. Similarly, any cut of finite capacity in N corresponds to a vertex cover of G whose weight is equal to the capacity of the cut. Hence the minimum-weight $s-t$ cut of N corresponds to a minimum-weight vertex cover of G .

6.3 Maximum-Weight Closed Subset in a Partial Order

Consider a directed acyclic graph (DAG) $G = (V, E)$. Each vertex v of G is given a weight $w(v)$ that may be positive or negative. A subset of vertices $S \subseteq V$ is said to be closed in G if for every $s \in S$, the predecessors of s are also in S .

The predecessors of a vertex s are vertices that have directed paths to s . Consider the objective of computing a closed subset S of maximum weight. This problem occurs, for example, in open-pit mining, and it can be solved efficiently by reducing it to computing the minimum cut in the following network N :

- The vertex set of $N = V \cup \{s, t\}$, where s and t are two new vertices.
- For each vertex v of negative weight, add the edge (s, v) with capacity $|w(v)|$ to N .
- For each vertex v of positive weight, add the edge (v, t) with capacity $w(v)$ to N .
- All edges of G are added to N , and each of these edges has infinite capacity.

Consider a minimum s - t cut in N . Let S be the positive weight vertices whose edges to the sink t are not in the min cut. It can be shown that the union of the set S and its predecessors is a maximum-weight closed subset.

7 Finding Densest Subgraphs

The density of a subgraph is defined as the ratio of the number of edges in the induced graph to the number of vertices in the subgraph. The problem can be extended to the weighted case when edges and vertices have positive integer weights defined by functions w' and w , respectively, by defining the density of a subgraph as the ratio of the total weight of its edges to the total weight of its vertices. Given a graph G , the objective is to find a subgraph of G , whose density is the largest among all its subgraphs. Despite the fact that there are exponentially many subgraphs, it is possible to find a maximum density subgraph in polynomial time using a procedure for the max-flow (min-cut) problem. An interesting extension of the problem is when a subset C of vertices is given, and the goal is to find a densest subgraph that must include all nodes of C .

7.1 Algorithm for Densest Subgraph Without a Specified Subset

First, the basic algorithm for finding a densest subgraph by a series of max-flow (min-cut) computations [33] is discussed. Guess α , the density of the maximum density subgraph, and then refine the guess by doing a network flow computation. Suppose a maximum density subgraph S^* has density α^* . Let the current guess be α . By appropriately defining a flow network as shown below and examining its min-cut structure, it is possible to determine if $\alpha = \alpha^*$ or $\alpha < \alpha^*$ or $\alpha > \alpha^*$. It can be verified that α^* lies between 0 and $w'(E)$ (total weight of all edges), and therefore, α^* can be found by using binary search. Since densities are rational numbers, once the interval size drops below $\frac{1}{|V|^2}$, the algorithm can stop.

The construction of the flow network for a given guess α is described below. Create a flow network G' with a source s and sink t . Each edge in G has a node in G' , and let E' be the set of these nodes of G' . In addition, each node in G also has its own node in G' , and let V' be the set of these nodes in G' . Add edges from s to

$e \in E'$ of capacity $w'(e)$ and an edge from $v \in V'$ to t with capacity $\alpha w(v)$. Add edges from $e = (x, y) \in E'$ to both $x \in V'$ and $y \in V'$ with capacity ∞ . In fact, this method works even in the case of hyper-graphs, and in this case, E' is a set of hyper-edges, and such edges are added from e to all $x \in V'$ such that $x \in e$. Since infinite capacity edges were added from e to x and y , any finite capacity (s, t) cut must have all of e , x , and y on the same side of the cut whenever e is on the same side as s . Therefore, all such finite cuts correspond to subgraphs of G .

If the problem is given without a specified subset ($C = \emptyset$), then the algorithm proceeds as follows. First, note that there is a s - t cut of value $w'(E)$. This is obtained by setting $S = \{s\}$ and $T = \{t\} \cup E' \cup V'$. Suppose the max density subset has density α^* . Suppose the guess $\alpha < \alpha^* = \frac{w'(S^*)}{w(S^*)}$, then it follows that $\alpha w(S^*) < w'(S^*)$.

Now consider an s - t cut $(s \cup V_1, t \cup V_2)$ in the flow network G' , then let $S = V_1 \cap V'$. The cut includes all the edges from nodes in S to t of capacity $\alpha w(S)$ as well as edges from s to nodes in E' that are not in V_1 . All edges $e = (x, y) \in E$ with one end in $V \setminus S$ must be in V_2 since otherwise there will be an edge of ∞ capacity across the cut. If all the edges in the induced graph formed by S are not in V_1 , a smaller cut can be found by moving such edges from V_2 to V_1 . Therefore, s - t min cuts have all edges of the induced subgraph of S in V_1 . The capacity of such a cut is exactly $w'(E \setminus E(S)) + \alpha w(S)$. Note that $w'(E \setminus E(S))$ includes the weight of all edges that are incident on some node in $E \setminus S$, and so, $w'(E \setminus E(S)) + \alpha w(S) = w'(E) - w'(S) + \alpha w(S) = w'(E) - (w'(S) - \alpha w(S))$. But for the optimal subset S^* , $w'(S^*) - \alpha w(S^*) > 0$, and thus, there is a cut whose capacity is smaller than $w'(E)$. Therefore, if the capacity of a min cut happens to be smaller than $w'(E)$, then it implies that the guess for α is smaller than α^* . Similarly, if the guess for α is greater than α^* , then the (unique) min cut has value $w'(E)$. When $\alpha = \alpha^*$, then there could be multiple min cuts of value $w'(E)$. Any min cut other than the trivial cut gives a correct solution.

7.2 Algorithm for Densest Subgraph with a Specified Subset C

It is now shown (see [40]) how to modify the above construction when $C \neq \emptyset$. In the following discussion, $w(C)$ denotes the sum of the weights of the vertices in C , and $w'(C)$ denotes the sum of the weights of edges in the induced subgraph of C . Create a new source s' and add an edge to s with capacity $w'(E) - \alpha w(C)$. In addition, remove C from V' . Again suppose that $\alpha < \alpha^*$. In this case, a subset S^* exists such that $\frac{w'(E(S^*)) + w'(C) + w'(S^*, C)}{w(S^*) + w(C)} > \alpha$. Thus, $w'(E(S^*)) + w'(C) + w'(S^*, C) - \alpha(w(S^*) + w(C)) > 0$. Replace $w'(E) - w'(\overline{E}(V \setminus (S^* \cup C)))$ for the first term. Note that $w'(\overline{E}(V \setminus (S^* \cup C)))$ includes all edges incident on nodes in $V \setminus (S^* \cup C)$ and not only the edges induced by those nodes. Hence,

$$w'(E) - w'(\overline{E}(V \setminus (S^* \cup C))) - \alpha(w(S^*) + w(C)) > 0.$$

$$(w'(E) - \alpha w(C)) - (w'(\overline{E}(V \setminus (S^* \cup C))) + \alpha w(S^*)) > 0.$$

$$(w'(E) - \alpha w(C)) > w'(\overline{E}(V \setminus (S^* \cup C))) + \alpha w(S^*).$$

This means that a min cut exists (e.g., defined by the subset S^*) that is smaller than $w'(E) - \alpha w(C)$.

So again, by looking at the min-cut structure, it is possible to know that $\alpha < \alpha^*$. If $\alpha > \alpha^*$, then the trivial min cut separating s' from the rest of the graph is unique. Again a binary search for α can be done.

Note: A simple method that does *not* work is to snap the edges to C as self loops and to then compute the densest subgraph in G with C removed. If the density of the densest subgraph found is lower than $w'(C)/w(C)$, then the algorithm just returns C as the answer. Otherwise, it returns $S \cup C$. The main problem is that the density of S could get lowered when C is added back. The level of dilution depends on the size of the densest subgraph in G with C removed; hence a subgraph with slightly lower density than the optimal solution but of much larger size could be a better choice.

8 Minimum-Cost Flows

In this section, one of the most important problems in combinatorial optimization, namely, the minimum-cost network flow problem, is studied. Some of the basic ideas behind the problem are outlined, and the reader can find a wealth of information in [1] about efficient algorithms for this problem.

The min-cost flow problem can be viewed as a generalization of the max-flow problem, the shortest path problem, and the minimum-weight perfect matching problem. To reduce the shortest path problem to the min-cost flow problem, notice that if just one unit of flow needs to be shipped, it is best to send it on a shortest path. The minimum-weight perfect matching problem on a bipartite graph $G = (X, Y, X \times Y)$ is reduced to min-cost flow as follows. Introduce a special source s and sink t , and add unit capacity edges from s to vertices in X and from vertices in Y to t . Compute a flow of value $|X|$ to obtain a minimum-weight perfect matching.

8.1 Min-Cost Flow Problem Definitions

The flow network $G = (V, E)$ is defined as before. Other than the capacity function u , a cost function $c : E \rightarrow \mathbb{R}$ is also given. The cost function specifies the cost of shipping one unit of flow through an edge. Associated with each vertex v , there is a supply $b(v)$. If $b(v) > 0$, then v is a supply node, and if $b(v) < 0$, then it is a demand node. It is assumed that $\sum_{v \in V} b(v) = 0$; if the supply exceeds the demand, an artificial sink can be added to absorb the excess flow. As before, a flow function satisfies the capacity and skew symmetry constraints. The flow conservation is rewritten to indicate that each vertex v has an outgoing flow of $b(v)$:

- (Flow Conservation) For all vertices $v \in V$, $\sum_{w \in V} f(v, w) = b(v)$.

The objective is to find a flow function that minimizes the cost of the flow,

$$\min z(f) = \sum_{e \in E} c(e) \cdot f(e).$$

Before studying any specific algorithm to solve the problem, it is noted that a feasible solution (not necessarily optimal) can be found, if one exists, by finding a max flow and ignoring costs. To see this, add two new vertices, a source vertex s and a sink vertex t . Add edges from s to all vertices v with $b(v) > 0$ of capacity $b(v)$ and edges from all vertices w with $b(w) < 0$ to t of capacity $|b(w)|$. Find a max flow of value $\sum_{b(v)>0} b(v)$. If such a flow does not exist, then the flow problem is not feasible.

The algorithm for the min-cost flow problem also uses the concept of residual networks. As before, the residual network $G_R(f)$ is defined with respect to a specific flow. Edges in the residual graph have both capacity and cost. If there is a flow $f(v, w)$ on edge $e = (v, w)$, then its capacity in the residual network is $u(e) - f(e)$ and its residual cost is $c(e)$. The reverse edge (w, v) has residual capacity $f(e)$, but its residual cost is $-c(e)$. Note that sending a unit of flow on the reverse edge actually reduces the original amount of flow that was sent, thereby decreasing the total cost, and hence its residual cost is negative. Only edges with strictly positive residual capacity are retained in the residual network.

The following theorem characterizes optimal solutions.

Theorem 5 *A feasible solution f is an optimal solution if and only if the residual network $G_R(f)$ has no directed cycles of negative cost.*

The above theorem can be used to develop an algorithm for finding a min-cost flow. As indicated earlier, a feasible flow can be found by the techniques developed in the previous section. To improve the cost of the solution, the algorithm identifies negative-cost cycles in the residual graph and pushes as much flow around them as possible and reduces the cost of the flow. This is repeated until there are no negative cycles left, and a min-cost flow has been found. A negative-cost cycle may be found by using an algorithm like the Bellman-Ford algorithm, which takes $O(|E||V|)$ time.

An important issue that affects the running time of the algorithm is the choice of a negative-cost cycle. For fast convergence, one should select a cycle that decreases the cost as much as possible but finding such a cycle is NP-hard. Goldberg and Tarjan [22] showed that selecting a cycle with minimum mean cost (the ratio of the cost of cycle to the number of arcs on the cycle) yields a polynomial-time algorithm. There is a parametric search algorithm [1] to find a min-mean cycle that works as follows. Let μ^* be the average edge weight of a min-mean cycle. Then μ^* is the largest value such that reducing the weight of every edge by μ^* does not introduce a negative-weight cycle into the graph. One can search for the value of μ^* using binary search: Given a guess μ , decrease the weight of each edge by μ and test if

the graph has no negative-weight cycles. If the smallest cycle has zero weight, it is a min-mean cycle. If all cycles are positive, the guess is increased by μ . If the graph has a negative-weight cycle, the guess is decreased by μ . Karp (see [1]) has given an algorithm based on dynamic programming for this problem that runs in $O(|E||V|)$ time.

The first polynomial-time algorithm for the min-cost flow problem was given by Edmonds and Karp [14]. Their idea is based on scaling capacities, and the running time of their algorithm is $O(|E| \log U(|E| + |V| \log |V|))$, where U is the largest capacity. The first strongly polynomial algorithm (whose running time is only a function of $|E|$ and $|V|$) for the problem was given by Tardos [42].

9 The Multi-Commodity Flow Problem

A natural generalization of the max-flow problem is the multi-commodity flow problem. In this problem, there are a number of commodities $1, 2, \dots, k$ that have to be shipped through a flow network from source vertices s_1, s_2, \dots, s_k to sink vertices t_1, t_2, \dots, t_k , respectively. The amount of demand for commodity i is specified by d_i . Each edge and each vertex has a nonnegative capacity that specifies the total maximum flow of all commodities flowing through that edge or vertex. A flow is feasible if all the demands are routed from their respective sources to their respective sinks while satisfying flow conservation constraints at the nodes and capacity constraints on the edges and vertices. A flow is an ϵ -feasible flow for a positive real number ϵ if for each demand i , it satisfies at least $\frac{d_i}{1+\epsilon}$ of that demand. There are several variations of this problem as noted below:

In the simplest version of the multi-commodity flow problem, the goal is to decide if there exists a feasible flow that routes all the demands of the k commodities through the network. The flow corresponding to each commodity is allowed to be split arbitrarily (i.e., even fractionally) and routed through multiple paths. The concurrent flow problem is identical to the multi-commodity flow problem when the input instance has a feasible flow that satisfies all the demands. If the input instance is not feasible, then the objective is to find the smallest fraction ϵ for which there is an ϵ -feasible flow. In the minimum-cost multi-commodity flow problem, each edge has an associated cost for each unit of flow through it. The objective is to find a minimum-cost solution for routing all the demands through the network. All of the above problems can be formulated as linear programs and, therefore, have polynomial-time algorithms using either the ellipsoid algorithm or the interior point method [28].

A lot of research has been done on finding approximately optimal multi-commodity flows using more efficient algorithms. There are a number of papers that provide approximation algorithms for the multi-commodity flow problem. For a detailed survey of these results, see [12, Chap. 5].

In this section, a paper that introduced a new algorithm for solving multi-commodity flow problems is discussed. Awerbuch and Leighton [3] gave a simple and elegant algorithm for the concurrent flow problem. Their algorithm is based

on the “liquid-flow paradigm.” Flow is pushed from the sources on edges based on the “pressure difference” between the end vertices. The algorithm does not use any global properties of the graph (such as shortest paths) and uses only local changes based on the current flow. Due to its nature, the algorithm can be implemented to run in a distributed network since all decisions made by the algorithm are local in nature. They extended their algorithms to dynamic networks, where edge capacities are allowed to vary [4]. The best implementation of this algorithm runs in $O(k|V|^2|E|\epsilon^{-3}\ln^3(|E|/\epsilon))$ time.

In the integer multi-commodity flow problem, the capacities and flows are restricted to be integers. Unlike the single-commodity flow problem, for problems with integral capacities and demands, the existence of a feasible fractional solution to the multi-commodity flow problem does not guarantee a feasible integral solution. An extra constraint that may be imposed on this problem is to restrict each commodity to be sent along a single path. In other words, this constraint does not allow one to split the demand of a commodity into smaller parts and route them along independent paths (see the recent paper by Kleinberg [31] for approximation algorithms for this problem). Such constraints are common in problems that arise in telecommunication systems. All variations of the integer multi-commodity flow problem are NP-hard.

9.1 Local Control Algorithm

In this section, Awerbuch and Leighton’s local control algorithm is discussed. It finds an approximate solution for the concurrent flow problem.

First, the problem is converted to the continuous flow problem. In this version of the problem, d_i units of commodity i is added to the source vertex s_i in each phase. Each vertex has queues to store the commodities that arrive at that node. The node tries to push the commodities stored in the queues towards the sink nodes. As the commodities arrive at the sinks, they are removed from the network. A continuous flow problem is stable if the total amount of all the commodities in the network at any point in time is bounded (i.e., independent of the number of phases completed). The following theorem establishes a tight relationship between the multi-commodity flow problem (also known as the static problem) and its continuous version.

Theorem 6 *A stable algorithm for the continuous flow problem can be used to generate an ϵ -feasible solution for the static concurrent flow problem.*

Proof Let R be the number of phases of the stable algorithm for the continuous flow problem at which $\frac{1}{1+\epsilon}$ fraction of each of the commodities that have been injected into the network have been routed to their sinks. It is known that R exists since the algorithm is stable. The average behavior of the continuous flow problem in these R phases generates an ϵ -feasible flow for the static problem. In other words,

the flow of a commodity through a given edge is the average flow of that commodity through that edge over R iterations, and this flow is ϵ -feasible.

In order to get an approximation algorithm using the fluid-flow paradigm, there are two important challenges. First, it must be shown that the algorithm is stable, that is, that the queue sizes are bounded. Second, the number of phases that it takes the algorithm to reach “steady state” (specified by R in the above theorem) must be minimized. Note that the running time of the approximation algorithm is R times the time it takes to run one phase of the continuous flow algorithm.

Each vertex v maintains one queue per commodity for each edge to which it is incident. Initially all the queues are empty. In each phase of the algorithm, commodities are added at the source nodes. The algorithm works in four steps:

1. Add $(1 + \epsilon)d_i$ units of commodity i at s_i . The commodity is spread equally to all the queues at that vertex.
2. Push the flow across each edge so as to balance the queues as much as possible.
If Δ_i is the discrepancy of commodity i in the queues at either end of edge e , then the flow f_i crossing the edge in that step is chosen so as to maximize $\sum_i f_i(\Delta_i - f_i)/d_i^2$ without exceeding the capacity constraints.
3. Remove the commodities that have reached their sinks.
4. Balance the amount of each commodity in each of the queues at each vertex.

The above 4 steps are repeated until $\frac{1}{1+\epsilon}$ fraction of the commodities that have been injected into the system have reached their destination.

It can be shown that the algorithm is stable and the number of phases is $O(|E|^2 k^{1.5} L \epsilon^{-3})$, where $|E|$ is the number of edges, k is the number of commodities, and $L \leq |V|$ is the maximum path length of any flow. The proof of stability and the bound on the number of rounds are not included here. The actual algorithm has a few other technical details that are not mentioned here, and the reader is referred to the original paper for further details [3].

10 Minimum Spanning and Other Light-Weight Trees

Efficient algorithms are well known for finding minimum-weight spanning trees of undirected graphs. There are several greedy algorithms known for solving the problem. The problem turns out to be more difficult to solve in directed graphs, and the greedy algorithm fails since not all maximal, acyclic subgraphs are trees in directed graphs. One solution for finding a minimum-weight branching, as minimum spanning trees are called in directed graphs, is by using an algorithm for matroid intersection, which is similar to the algorithm for weighted matching. A simpler and more efficient algorithm for finding optimal branchings is discussed.

Another well-studied problem in networks is that of finding shortest paths. One may be interested in finding shortest paths from a single-source node or

between all pairs of nodes. For the single-source case, if all edges have nonnegative weights, then the problem of finding shortest paths from the source to all nodes of the graph can be solved efficiently using Dijkstra's algorithm. The algorithm also outputs a “shortest path tree” such that for any vertex, the shortest path to it from the root is the path in the tree from the root to that vertex. In general, shortest path trees can be much heavier than minimum spanning trees. It is useful in practice if it is possible to find light subgraphs in which shortest path distances are approximately preserved with respect to the given graph. Spanners are light subgraphs in which the distance between every pair of vertices is approximately preserved. Light approximate shortest path trees (LAST) do the same for single-source shortest paths.

10.1 Minimum-Weight Branchings

A natural analog of a spanning tree in a directed graph is a branching (also called an arborescence). For a directed graph G and a vertex r , a branching rooted at r is an acyclic subgraph of G in which each vertex but r has exactly one outgoing edge, and there is a directed path from any vertex to r . This is also sometimes called an in-branching. Replacing “outgoing” in the above definition of a branching to “incoming” defines an out-branching. An optimal branching of an edge-weighted graph is a branching of minimum total weight. Unlike the minimum spanning tree problem, an optimal branching cannot be computed using a greedy algorithm. Edmonds gave the first polynomial-time algorithm to find optimal branchings (see [20]).

Let $G = (V, E)$ be an arbitrary graph, let r be the root of G , and let $w(e)$ be the weight of edge e . Consider the problem of computing an optimal branching rooted at r . In the following discussion, assume that all edges of the graph have nonnegative weights.

Two key ideas are discussed below that can be converted into a polynomial-time algorithm for computing optimal branchings. First, for any vertex $v \neq r$ in G , suppose that all outgoing edges of v are of positive weight. Let $\epsilon > 0$ be a number that is less than or equal to the weight of any outgoing edge from v . Suppose the weight of every outgoing edge from v is decreased by ϵ . Observe that since any branching has exactly one edge out of v , its weight decreases by exactly ϵ . Therefore, an optimal branching of G with the original weights is also an optimal branching of G with the new weights. In other words, decreasing the weight of the outgoing edges of a vertex uniformly leaves optimal branchings invariant. Second, suppose there is a cycle C in G consisting only of edges of zero weight. Suppose the vertices of C are combined into a single vertex and the resulting multigraph is made into a simple graph by replacing each multiple edge by a single edge whose weight is the smallest among them and by discarding self loops. Let G_C be the resulting graph. It can be shown that the weights of optimal branchings of G and G_C are the same. An optimal branching of G_C can also be converted into an optimal branching

of G by adding sufficiently many edges from C without introducing cycles. The above two ideas can be used to design a recursive algorithm for finding an optimal branching. The fastest implementation of a branching algorithm is due to Gabow, Galil, Spencer, and Tarjan [18].

10.2 Spanners

Given a graph $G = (V, E)$ and a positive number $t \geq 1$, a t -spanner is a spanning subgraph $H = (V, E')$ of G with the property that for all pairs of vertices v and w ,

$$\text{dist}_H(v, w) \leq t \cdot \text{dist}_G(v, w).$$

In other words, a spanner is a subgraph that approximates shortest paths between every pair of vertices. The factor t is called the stretch factor. The goal is to minimize the size and weight of H for a given value of t . The size of H refers to the number of edges in H , and the weight of H refers to the total weight of the edges in H . The subject of graph spanners has received much attention recently [2, 9, 39]. The following elegant algorithm computes a t -spanner [2].

```

SPANNER ( $G, t$ )
1  $H \leftarrow (V, \emptyset)$ .
2 Sort all edges in increasing weight,  $w(e_1) \leq w(e_2) \leq \dots \leq w(e_m)$ .
3 for  $i = 1$  to  $m$  do
4   let  $e_i = (v, w)$ .
5   let  $P(v, w)$  be the shortest path in  $H$  from  $v$  to  $w$ .
6   if  $w(P(v, w)) > t \cdot w(e_i)$ , then
7      $H \leftarrow H \cup e_i$ .
8   end-if
9 end-for
end-proc
```

It is not difficult to show that this algorithm outputs a t -spanner. The following property is used to establish the size of the spanner output by the algorithm.

Lemma 3 *Any cycle in the graph H output by algorithm SPANNER has at least $t + 2$ edges.*

Proof Suppose for contradiction that H contains a cycle C with at most $t + 1$ edges. Let $e_{\max} = (v, w)$ be a heaviest weight edge on the cycle C . When the algorithm considers e_{\max} , all the other edges on C have already been added. This implies that there is a path of length at most $t \cdot w(e_{\max})$ from v to w , since the path contains t edges each of weight at most $w(e_{\max})$. Thus, the edge e_{\max} is not added to H , a contradiction.

Using this property, it can be shown that H has at most $O(|V|^{1+\frac{2}{t-1}})$ edges by applying a theorem from extremal graph theory relating the number of edges in a graph and its girth (length of a shortest cycle) [8]. In a subsequent chapter, Chandra et al. [9] proved the following theorem.

Theorem 7 *Let G be a connected edge-weighted graph. For all $\epsilon > 0$, algorithm SPANNER constructs a t -spanner of G with weight $O(|V|^{\frac{2+\epsilon}{t-1}}) \cdot w(MST)$. The constant depends only on t and ϵ .*

10.3 Light Approximate Shortest Path Trees

In this section, the problem of computing light-weight spanning trees that approximate shortest paths to every vertex from a single fixed root vertex is considered.

Let G be a graph and let r be the root vertex in G . Let T_{\min} be a minimum spanning tree of G . For any vertex v , let $d(r, v)$ be the length of a shortest path from r to v in G . An (α, β) -light approximate shortest path tree $((\alpha, \beta)\text{-LAST})$ of G is a spanning tree T of G with the property that the distance from the root to any vertex v in T is at most $\alpha \cdot d(r, v)$, and the weight of T is at most β times the weight of T_{\min} .

Awerbuch, Baratz, and Peleg [5], motivated by applications in broadcast-network design, made a fundamental contribution by showing that every graph has a *shallow-light* tree – a tree whose *diameter* is at most a constant times the diameter of G and whose total weight is at most a constant times the weight of a minimum spanning tree. Cong et al. [10] studied the same problem and showed that the problem has applications in VLSI-circuit design; they improved the approximation ratios obtained in [5] and also studied variations of the problem such as bounding the *radius* of the tree instead of the diameter.

Khuller, Raghavachari, and Young [29] modified the algorithm in [5] and obtained a stronger result; they showed that the distance from the root to each vertex can be approximated within a constant factor. Their algorithm also runs in linear time if a minimum spanning tree and a shortest path tree are provided. The algorithm computes an $(\alpha, 1 + \frac{2}{\alpha-1})$ -LAST. Independently, Awerbuch, Baratz, and Peleg [6] modified their algorithm from [5]. They obtained the same algorithm as in [10] but gave a stronger analysis, proving that the algorithm computes an $(\alpha, 1 + \frac{4}{\alpha-1})$ -LAST.

The basic idea is as follows: Initialize a subgraph H to be a minimum spanning tree T_{\min} . The vertices are processed in a preorder traversal of T_{\min} . When a vertex v is processed, its distance from r in H is compared to $\alpha \cdot d(r, v)$. If the distance exceeds the required threshold, then the algorithm adds to H a shortest path in G from r to v . When all the vertices have been processed, the distance in H from r to any vertex v meets its distance requirement. A shortest path tree in H is returned by the algorithm as the required LAST. An analysis shows that the entire subgraph H satisfies the weight guarantee.

11 Coloring Problems

11.1 Vertex Coloring

A vertex coloring of a graph G is a coloring of the vertices of G such that no two adjacent vertices of G receive the same color. The objective of the problem is to find a coloring that uses as few colors as possible. The minimum number of colors needed to color the vertices of a graph is known as its chromatic number. The register allocation problem in compiler design and the map coloring problem are instances of the vertex coloring problem.

The problem of deciding if the chromatic number of a given graph is at most a given integer k is NP-complete. The problem is NP-complete even for fixed $k \geq 3$. For $k = 2$, the problem is to decide if the given graph is bipartite, and this can be solved in linear time using depth-first or breadth-first search. The vertex coloring problem in general graphs is a notoriously hard problem, and it has been shown to be intractable even for approximating within a factor of n^ϵ for some constant $\epsilon > 0$ [12, Chap. 10]. A greedy coloring of a graph yields a coloring that uses at most $\Delta + 1$ colors, where Δ is the maximal degree of the graph. Unless the graph is an odd cycle or the complete graph, it can be colored with Δ colors (known as Brooks' theorem) [20]. A celebrated result on graph coloring is that every planar graph is 4-colorable. However, checking if a planar graph is 3-colorable is NP-complete [19]. For more information on recent results on approximating the chromatic number, see [26].

In the equitable coloring problem, the objective is to find a coloring of the nodes of a graph with the additional constraint that each color class should have roughly the same cardinality. Chapter ▶A Unified Approach for Domination Problems on Different Network Topologies surveys results in this area. Coloring problems are also discussed in Chap. ▶Resource Allocation Problems.

11.2 Edge Coloring

The edge coloring problem is similar to the vertex coloring problem. In this problem, the goal is to color the edges of a given graph using the fewest colors such that no two edges incident to a common vertex are assigned the same color. The problem finds applications in assigning classroom to courses and in scheduling problems. The minimum number of colors needed to color a graph is known as its chromatic index. Since any two incident edges must receive distinct colors, the chromatic index of a graph with maximal degree Δ is at least Δ . In a remarkable theorem, Vizing (see [20]) has shown that every graph can be edge colored using at most $\Delta + 1$ colors. Deciding whether the edges of a given graph can be colored using Δ colors is NP-complete (see [12]). Special classes of graphs such as bipartite graphs and planar graphs of large maximal degree are known to be Δ -edge-colorable.

12 Approximation Algorithms for Hard Problems

Many graph problems are known to be NP-complete (see Sects. A.1 and A.2 of [19]). The area of approximation algorithms explores intractable (NP-hard) optimization problems and tries to obtain polynomial-time algorithms that generate feasible solutions that are close to optimal. In this section, a few fundamental NP-hard optimization problems in graphs that can be approximated well are discussed. For more information about approximating these and other problems, see the chapter on approximation algorithms ([►Algorithmic Aspects of Domination in Graphs](#)). We also mention several books on this topic under “Further Information and Recommended Reading” in [Sect. 13](#).

In the following discussion, $G = (V, E)$ is an arbitrary undirected graph, and k is a positive integer.

Vertex cover: A set of vertices $S \subset V$ such that every edge in E is incident to at least one vertex of S . The minimum vertex cover problem is that of computing a vertex cover of minimum cardinality. If the vertices of G have weights associated with them, a minimum-weight vertex cover is a vertex cover of minimum total weight. Using the primal-dual method of linear programming, one can obtain a 2-approximation.

Dominating set: A set of vertices $S \subset V$ such that every vertex in the graph is either in S or adjacent to some vertex in S . There are several versions of this problem such as the total dominating set (every vertex in G must have a neighbor in S , irrespective of whether it is in S or not), the connected dominating set (induced graph of S must be connected) and the independent dominating set (induced graph of S must be empty). The minimum dominating set problem is to compute a minimum cardinality dominating set. The problems can be generalized to the weighted case suitably. All but the independent dominating set problem can be approximated within a factor of $O(\log n)$. For more information on domination problems, see Chaps. [►Combinatorial Optimization Techniques for Network-Based Data Mining](#) and [►Fuzzy Combinatorial Optimization Problems](#).

Steiner tree problem: A tree of minimum total weight that connects a set of terminal vertices S in a graph $G = (V, E)$. There is a 2-approximation algorithm for the general problem. There are better algorithms when the graph is defined in Euclidean space. For more information, see [12, 25]. Gradient constrained Steiner trees are discussed in Chap. [►Online Frequency Allocation and Mechanism Design for Cognitive Radio Wireless Networks](#) and Steiner minimal trees in Chap. [►Neural Network Models in Combinatorial Optimization](#).

Minimum k -connected graph: A graph G is k -vertex-connected, or simply k -connected, if the removal of up to $k - 1$ vertices along with their incident edges leaves the remaining graph connected. It is k -edge-connected if the removal of up to $k - 1$ edges does not disconnect the graph. In the minimum k -connected graph problem, the objective is to compute a k -connected spanning subgraph of G of minimum cardinality. The problem can be posed in the context of vertex or edge connectivities, and with edge weights. The edge-connectivity problems can be approximated within a factor of 2 from optimal, and a factor smaller than 2 when the

edges do not have weights. The unweighted k -vertex-connected subgraph problem can be approximated within a factor of $1 + 2/k$, and the corresponding weighted problem can be approximated within a factor of $O(\log k)$. When the edges satisfy the triangle inequality, the vertex-connectivity problem can be approximated within a factor of about $2 + 2/k$. These problems find applications in fault-tolerant network design. For more information on approximation algorithms for connectivity problems, see [12, Chap. 6].

Traveling salesman problem (TSP): Finding a shortest tour that visits all the vertices in a given graph with weights on the edges. It has received considerable attention in the literature [34]. The problem is known to be computationally intractable (NP-hard). Several heuristics are known to solve practical instances. Considerable progress has also been made for finding optimal solutions for graphs with a few thousand vertices.

Degree constrained spanning tree: A spanning tree of maximal degree k . This problem is a generalization of the traveling salesman path problem. There is a polynomial-time approximation algorithm that returns a spanning tree of maximal degree at most $k + 1$ if G has a spanning tree of degree k (see [12, Chap. 7]).

Max cut: A partition of the vertex set into (V_1, V_2) such that the number of edges in $E \cap (V_1 \times V_2)$ (edges between a vertex in V_1 and a vertex in V_2) is maximized. It is easy to compute a partition in which at least half the edges of the graph cross the cut. This is a 2-approximation. Semi-definite programming techniques can be used to derive an approximation algorithm with a performance guarantee of about 1.15 (see [12, Chap. 11]).

13 Conclusion

Some of the recent research efforts in graph algorithms have been in the areas of dynamic algorithms, graph layout and drawing, and approximation algorithms and randomized algorithms. The methods illustrated in this chapter find use in algorithms for many optimization problems. For approximation algorithms see the books by Hochbaum [12], Vazirani [44], and Williamson and Shmoys [45]. More information on graph layout and drawing can be found in an annotated bibliography by DiBattista et al. [7].

An exciting result of Karger [27] is a randomized, near-linear time algorithm for computing minimum cuts. Finding a deterministic algorithm with similar bounds is a major open problem.

Iterative rounding [32] has emerged and has a very useful paradigm to design approximation algorithms for a collection of NP-hard optimization problems dealing with networks.

Computing a maximum flow in $O(|E||V|)$ time in general graphs is still open. Several recent algorithms achieve these bounds for certain graph densities. A recent result by Goldberg and Rao [21] breaks this barrier, by paying an extra $\log U$ factor

in the running time, when the edge capacities are in the range $[1 \dots U]$. Finding a maximum matching in time better than $O(|E|\sqrt{|V|})$ and obtaining nontrivial lower bounds are open problems.

Further Reading

The area of graph algorithms continues to be a very active field of research. There are several journals and conferences that discuss advances in the field. Some of the important meetings are “ACM Symposium on Theory of Computing (STOC)”; “IEEE Conference on Foundations of Computer Science (FOCS)”; “ACM-SIAM Symposium on Discrete Algorithms (SODA)”; “International Colloquium on Automata, Languages and Programming (ICALP)”; and the “European Symposium on Algorithms (ESA).” There are many other regional algorithms/theory conferences that carry research papers on graph algorithms. The primary journals that carry articles on current research in graph algorithms are “Journal of the ACM,” “SIAM Journal on Computing,” “SIAM Journal on Discrete Mathematics,” “ACM Transactions on Algorithms,” “Algorithmica,” “Journal of Computer and System Sciences,” “Information and Computation,” “Information Processing Letters,” “Networks,” “Internet Mathematics,” “Journal of Graph Algorithms and Applications,” and “Theoretical Computer Science.”

To find more details about some of the graph algorithms described in this chapter, the reader is referred to the books by Cormen, Leiserson, Stein, and Rivest [11]; Even [15]; Gibbons [20]; Kleinberg and Tardos [30]; and Tarjan [43]. Ahuja, Magnanti, and Orlin [1] have provided a comprehensive book on the network flow problem. The survey chapter by Goldberg, Tardos, and Tarjan [23] provide an excellent survey of various min-cost flow and generalized flow algorithms. A detailed survey describing various approaches for solving the matching and flow problems can be found in Tarjan’s book [43]. Papadimitriou and Steiglitz [38] discuss the solution of many combinatorial optimization problems using a primal-dual framework. For understanding recent methods on iterative rounding, the book by Lau, Ravi, and Singh [32] is suggested. For the area of approximation algorithms with an extensive coverage of graph algorithms, books by Hocbaum [12], Vazirani [44], and Williamson and Shmoys [45] are available.

Glossary

Assignment problem: the problem of finding a matching of maximum (or minimum) weight in an edge-weighted graph.

Augmenting path: a path used to augment (increase) the size of a matching or a flow.

Blocking flow: a flow function in which any directed path from s to t contains a saturated edge.

Blossoms: odd-length cycles that appear during the course of the matching algorithm on general graphs.

Branching: a spanning tree in a rooted graph, such that each vertex has a path to the root (also known as in-branching). An out-branching is a rooted spanning tree in which the root has a path to every vertex in the graph.

Capacity: the maximum amount of flow that is allowed to be sent through an edge or a vertex.

Chromatic index: the minimum number of colors with which the edges of a graph can be colored.

Chromatic number: the minimum number of colors needed to color the vertices of a graph.

Chinese postman problem: the problem of finding a minimum length tour that traverses each edge at least once.

Concurrent flow: a multi-commodity flow in which the same fraction of the demand of each commodity is satisfied.

Edge coloring: an assignment of colors to the edges of a graph such that no two edges incident to a common vertex receive the same color.

Euler tour: a tour of the graph that visits each of its edges exactly once.

Eulerian graph: a graph that has an Euler tour.

Integer multi-commodity flow: a multi-commodity flow in which the flow through each edge of each commodity is an integral value. The term is also used to capture the multi-commodity flow problem in which each demand is routed along a single path.

Matching: a subgraph in which every vertex has degree at most one.

Maximum flow: the maximum amount of flow that can be sent from a source vertex to a sink vertex in a given network.

Multi-commodity flow: a network flow problem involving multiple commodities, in which each commodity has an associated demand and source-sink pairs.

Network flow: an assignment of flow values to the edges of a graph that satisfies flow conservation, skew symmetry, and capacity constraints.

Traveling salesman problem: the problem of computing a minimum length tour that visits all vertices exactly once.

s-t cut: a partition of the vertex set into S and T such that $s \in S$ and $t \in T$.

Vertex coloring: an assignment of colors to the vertices of a graph such that no two adjacent vertices receive the same color.

Abstract

This chapter reviews the theory and application of artificial neural network (ANN) models with the intention of solving combinatorial optimization problems (COPs). Brief introductions to the theory of ANNs and to the classical models of ANNs applied to COPs are presented at the beginning of this chapter. Since the classical ANN models follow gradient-based search, they usually converge to a local optimal solution. To overcome this, several methods that extend the capability of ANNs to avoid the local minima have been reviewed in this chapter. Apart from that, not all the ANNs converge to a local minimum; thus, stability and/or convergence criteria of various ANNs have been addressed. The thin wafer that divides continuous and discrete optimization problems while applying ANNs to solve the COPs is highlighted. Applications of ANNs to solve the general optimization problems and to solve the discrete optimization problems have been surveyed. To conclude, issues regarding the performance behavior of the ANNs are discussed at the end of this chapter.

1 Introduction

Combinatorial optimization problems (COPs) are special problems in the field of operations research, where a real-valued mathematical function is optimized over a given domain (feasible set). Either some or all the variables of these problems are discrete in nature. The main criterion in proposing a solution method to solve the COPs is to provide a solution strategy better than the complete enumeration method. The conventional methods that are used to find the solution of a COP include branching, bounding, cutting planes, etc. Usually, COPs are NP-Hard in nature; the solution time of the conventional solution methods grows exponentially with the problem size. A curiosity to improve the solution time of finding an optimal solution of a COP directed the research toward unconventional methods. The primary unconventional methods for solving the COPs are the heuristics, and the most

prominent ones among them are the metaheuristics, such as simulated annealing, genetic and evolutionary algorithms, tabu search, and greedy randomized adaptive search procedure [15, 38, 44, 46, 53, 87, 94, 98, 115]. On the other hand, there were simultaneous research [32, 112] to use the analog circuits instead of the conventional computers for solving COPs. A method for solving the linear and the quadratic programs using resistors, diodes, transformers, current sources, and voltage sources (the basic building blocks of the analog circuit) was proposed in [32]. However, this method was impractical due to the unavailability of an ideal diode. Thus, this method remained in the theory until improved methods were proposed in [23, 62]. The first known analog circuit implementations which were capable of solving linear and quadratic programming problems were presented in [24, 131]. However, these methods were not ideal due to the use of negative resistors [131]. Later in 1985, Hopfield and Tank [121] proposed an analog circuit consisting of neurons,¹ called artificial neural networks (ANNs), to solve the COPs. This method caught the attention of many researchers, when Hopfield and Tank [121] solved some sufficiently large instances of the symmetric traveling salesman problem (TSP). The proposed method illustrated an alternate approach to solve the COPs, which is independent of the digital computers. After this illustration, many researchers were curious to utilize ANNs as a tool to solve various COPs.

1.1 Objective

The main objective of this chapter is to present different ideas of applying ANNs in solving the COPs. Furthermore, the issues related to the optimality and/or the stability analysis of various ANNs will be dealt. In addition to that, the implementation and the mapping of ANNs to solve the COPs will be illustrated by examples. Nevertheless, a brief history about the ANNs will be reviewed. In addition to that, usage of ANNs in solving the general optimization problems will be addressed.

1.2 Outline

In this chapter, ANN models which are applied in solving the COPs are described. This chapter is organized as follows: an introduction of ANNs in general and a review of the classical models in ANNs that are suitable for solving the COPs in particular are presented in Sect. 2. A systematic method, which illustrates the stability and convergence analysis of ANNs, is described in Sect. 3. Subsequently, the extensions and the improvements that can be incorporated to the classical ANN models are presented in Sect. 4. In addition to that, a methodology of mapping and

¹A term similar to the smallest processing unit in the brain, in ANNs it consist of a small independent circuit with resistors, diodes, capacitors etc.

solving some of the general optimization problems is discussed in Sect. 5. Moreover, the applications of ANNs for solving various discrete programming problems are surveyed in Sect. 6. Nonetheless, in Sect. 7, the criticism of using ANNs to solve the COPs is presented. Finally, this chapter ends with the concluding remarks in Sect. 8.

2 Review

Human brain and its functionality has been the topic of research for many years, and until now, there has been no model that could aptly imitate the human brain. Curiosity of studying human brain lead to the development of ANNs. Henceforth, ANNs are the mathematical models mimicking the interactions among the neurons² within the human brain. Initially, ANNs were developed to provide a novel solution approach to solve the problems which do not have any algorithmic solution approach. The first model that depicted a working ANN used the concept of perceptron³ [82, 101]. After the invention of perceptron, ANNs were the area of interest for many researchers for almost 10 years. However, this area of research was crestfallen due to the results shown by Minsky and Papert in [85]. Their results showed that the perceptron is incapable to model the simple logical operations. However, their work also indirectly suggested the usage of multilayer ANNs. After a decade, as a requital, this area of research became popular with Hopfield's feedback⁴ ANN [56, 57]. A pioneer practical approach to solve the COPs was presented in [58, 121]. The mathematical analysis illustrated by Hopfield demonstrated that ANNs can be used as a gradient descent method in solving optimization problems. Moreover, some instances of traveling salesman problem (TSP) were mapped and solved using ANNs. This approach kindled enthusiasm among many researchers to provide an efficient solution methodology for solving NP-Hard problems. Since then, ANNs were modified and applied in numerous ways to solve the COPs.

2.1 Artificial Neural Networks (ANNs)

Neurons are the primary elements of any ANN. They posses some memory represented by their state. The state of a neuron is represented either by a single state or a dual state (internal and external state). The state of a neuron can take any real value between the interval $[0, 1]$.⁵ Furthermore, the neurons interact with each other via links to share the available information. In general, the external state of the

²Biological neurons are the basic building blocks of the nervous system.

³A simple single-layered artificial neural network invented by Frank Rosenblatt.

⁴Feedback and feed-forward are two main classes of neural networks and will be explained in the following subsections.

⁵Some authors prefer to use the values between $[-1, 1]$; however, both the definition are interchangeable and have the same convergence behavior. Hence, in this work $[0, 1]$, representation is followed.

neuron takes part in the outer interactions, whereas the internal state of the neuron takes part in the firing⁶ decision. The intensity and sense of interactions between any two connecting neurons are represented by the weight (or synaptic⁷ weight) of the links.

A single neuron itself is incapable to process any complex information. However, it is the collective behavior of the neurons that results in the intelligent information processing. Usually, neurons update their states based on the weighted cumulative effect of the states of the surrounding neurons. The update rule for the states is

$$\mathcal{I}_i = \sum_{j=1, j \neq i}^n w_{ij} x_j - U_i \quad (1)$$

$$x_i = \Psi(\mathcal{I}_i) \quad (2)$$

where x_i and \mathcal{I}_i represent the external and internal states of an i th neuron, respectively, w_{ij} represents the weight between the i th neuron and the j th neuron, and U_i represents the threshold level of the i th neuron. Function $\Psi()$ is called the transfer function.⁸ If the collective input to the i th neuron $(\sum_{j=1, j \neq i}^n w_{ij} x_j)$ is greater than the threshold (U_i), then the neuron will fire (value of x_i is set as 1). This is the basic mechanism of any ANN. With appropriate network structure and link weights, ANNs are capable of making any logical operations.

Example 1 Consider the following neural networks:

In Fig. 1, a simple neural network, which performs logical AND and logical OR operations, is depicted. The number over the links represents the weight of the link. The number inside the neurons represents the threshold value. Each neural network has two binary input signals and one binary output signal. Similarly, in Fig. 2, another elementary logical operator XOR is presented (where XOR is logical exclusive OR operator). From this figure, it can be seen that for a specific operation, neural network may not have a unique representation.

From Figs. 1 and 2, it can be seen that although a single neuron does not possess the computation ability, collectively, they can perform any logical operations very easily. Moreover, these are just the elementary form of logical operations that can be performed using simple neural networks. ANNs can be used for the complex logical operations as well. In order to use ANNs for complex logical operations, feedback method is used. Based on the feed mechanism, ANNs can be classified as feed-forward neural networks and Feedback neural networks as shown in Fig. 3.

⁶Whether to set the value of the corresponding external state to 0 or 1

⁷The term synaptic is related to the nervous system and is used in ANNs to indicate the weight between any two neurons.

⁸This function may be continuous or discontinuous based on the type of the neuron. That is, for a discrete case, this function is similar to a signum function, whereas for continuous case, this function is similar to a sigmoidal function.

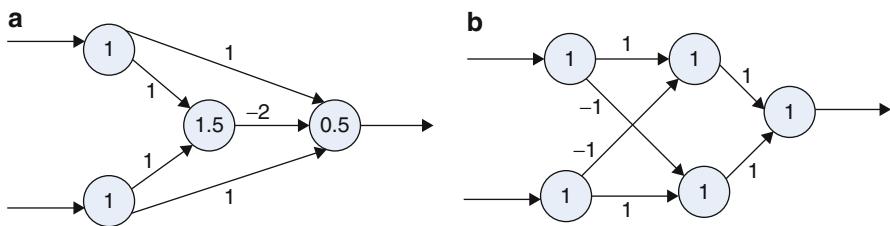

Fig. 2 Example:2 simple logical operations in ANNs. (a) XOR. (b) XOR

Fig. 3 Major categories of ANNs. (a) Feed-forward ANN. (b) Feedback ANN

In the feed-forward neural networks, information is processed only in one direction. Whereas in the case of feedback neural networks, information is processed in both the directions. From the literature, typically, there are three main types of applications of ANNs in information processing. They are categorized as:

Type 1: Pattern Recognition

- This is the most explored application of the ANNs [14, 19, 88, 89]. In pattern recognition, two sets of data, namely, *training data*, and *testing data* are given. Generally, the data sets consist of input parameters which are believed to be the cause of the output features. The aim of pattern recognition is to find a relation that maps the input parameters with the output features. This is obtained by learning, where the weights of the neural network are updated by error backpropagation. When the error between the generated features and the required output features falls below some acceptable limit, the weights are frozen or set to the current value. These weight are used to validate the performance of the obtained neural network using the testing data. This approach is used in function approximation, data prediction, curve fitting, etc.

Type 2: Associative Memory

- Advancement in the theory of ANNs from feed-forward neural networks to feedback neural networks led to this application [18, 84, 93]. In associative memory application, a neural network is set to the known target memory pattern. Later, if an incomplete or partly erroneous pattern is presented to the trained

ANN, then the ANN is capable to generate or repair the input pattern to the most resembling target pattern.

This approach is used in handwriting recognition, image processing, etc.

Type 3: Optimization

- Further extensions of associative memory approach led to the application of ANNs in solving the optimization problems. This application is fundamentally different from the pattern recognition application. In this approach, weights of the neural network are fixed, and the inputs are randomly (synchronously or asynchronously) updated such that the total energy of the network is minimized. This minimization is achieved if the network is stable. Based on the different optimality conditions, the system may converge to the local (or global) optimal solution. ANNs have been applied not only for solving the COPs [3, 43, 64, 97, 110, 111] but also for solving the optimization problems in general [39, 86, 90, 104]

In the following subsection, an example implementation of ANNs for solving a general linear programming (LP) problem is presented.

2.2 Example: Implementation

One of the conventional methods of solving any COP is to relax the problem into a series of continuous problems, and solve them until the desired discrete solution is obtained [47]. Although simplex is the most widely used method to solve the linear relaxation of COPs, it has been shown in the literature that other methods like dual-simplex, barrier methods, and interior point methods perform better than simplex on certain occasions [66, 99, 133]. Apart from that, the convergence time of simplex method is exponential in time [69], yet in practice, it performs better than polynomial time interior point method. Thus, finding a polynomial time algorithm (polynomial both in theory and in practice) for solving linear programming problems is still an attractive area of research. Therefore, it becomes an attractive choice to study the method of solving an LP problem using an ANN. Apart from that, the purpose of selecting an LP model to show the implementation of ANNs is due to the simple nature of LP models. Thus, a reader familiar with the theory of LP will find it easy to understand the analog circuit of the LP problem.

Consider a standard form of a linear programming problem described as

minimize :

$$\mathbf{c}^T \mathbf{x}$$

subject to :

$$A\mathbf{x} = \mathbf{b}$$

$$0 \leq x_i \leq x_{\max} \quad \forall i = 1, 2, \dots, n \quad (3)$$

where $\mathbf{c} \in \mathbb{R}^n$, $\mathbf{b} \in \mathbb{R}^m$, $A \in \mathbb{R}^{m \times n}$, and $\mathbf{x} \in \mathbb{R}^n$. In order to apply an ANN to solve this problem, the above stated problem has to be transformed into an unconstrained optimization problem using either a penalty function or a Lagrange function method. For the sake of simple illustration, a penalty function approach will be presented. Let $\mathbf{x}(t)$ represent the instantaneous or dynamic value of the solution vector at time t . Let $E(\mathbf{x}(t), t)$ represent the modified (penalized) objective function, which is given as

$$E(\mathbf{x}(t), t) = \frac{C_1}{2} (\mathbf{A}\mathbf{x}(t) - \mathbf{b})^T (\mathbf{A}\mathbf{x}(t) - \mathbf{b}) + C_2 \mathbf{c}^T (\bar{\mathbf{x}} + \mathbf{x}(t) e^{-C_3 t}) \quad (4)$$

where C_1 , C_2 , and C_3 represent the positive scaling parameters of the system. Let the system dynamics be defined as

$$\nabla_t \mathcal{I} = -\nabla_{\mathbf{x}(t)} E(\mathbf{x}(t), t) \quad (5)$$

where \mathcal{I} represents the internal energy of the neuron. Based on the system dynamics defined in Eq. (5), the system can be described as

$$\nabla_t \mathcal{I} = -C_1 \mathbf{A}^T \mathbf{A} \mathbf{x}(t) + C_1 \mathbf{A}^T \mathbf{b} - C_2 \mathbf{c} e^{-C_3 t} \quad (6)$$

and

$$x_i(t) = \frac{x_{\max}}{1 + e^{(-C_4 \mathcal{I}(t))}} \quad (7)$$

where C_4 is a positive scaling parameter,

$$\nabla_t \mathcal{I} = \left(\frac{d\mathcal{I}_1}{dt}, \frac{d\mathcal{I}_2}{dt}, \dots, \frac{d\mathcal{I}_n}{dt} \right)^T, \quad \mathcal{I} \in \mathbb{R}^n$$

and

$$\nabla_{\mathbf{x}(t)} E(\mathbf{x}(t), t) = \left(\frac{\partial E(\mathbf{x}(t), t)}{\partial x_1}, \frac{\partial E(\mathbf{x}(t), t)}{\partial x_2}, \dots, \frac{\partial E(\mathbf{x}(t), t)}{\partial x_n} \right)^T$$

Equations (6) and (7) are the main equations which are used to design the ANN. The first thing in designing the neural network is to know the number of neurons. Since each variable is represented by a neuron, there will be altogether n neurons required for the construction of ANN. Let \mathcal{I}_i represent the internal state of an i th neuron and x_i represent the external state of an i th neuron. At any given time, both the states of an i th neuron can be represented by $[\mathcal{I}_i(t), x_i(t)]$. The next step will be to connect the network using links. These links will have resistors, which represent the weights (synaptic weights) of the link. Based on the coefficients in Eq. (6), the weights are taken as the corresponding coefficients of the first-order term. The constant term in Eq. (6) is taken as the input bias to the neurons. From the Eq. (6), the following weight matrix and bias vector is obtained:

$$W = -C_1 \mathbf{A}^T \mathbf{A} \quad \text{and} \quad \theta(t) = C_1 \mathbf{A}^T \mathbf{b} - C_2 \mathbf{c} e^{-C_3 t} \quad (8)$$

or

$$w_{ij} = -C_1 \sum_{k=1}^m a_{ki} a_{kj} \quad \text{and} \quad \theta_i(t) = C_1 \sum k = 1^m a_{ki} b_k - C_2 c_i e^{-C_3 t} \quad (9)$$

where a_{ij} is the i th row j th column element of A and w_{ij} is the i th row j th column element of W .

Now, in order to set the appropriate weights, we use resistors. The absolute value of synaptic weight w_{ij} (between i th and j th neuron) is obtained as the ratio of the resistors R_f and R_{ij} , that is,

$$|w_{ij}| = \frac{R_f}{R_{ij}} \quad (10)$$

The next step is to assign input bias to each neuron. This can be done using the voltage E_i and the resistor R_i , given as

$$\theta_i = \frac{R_f E_i}{R_i} \quad (11)$$

The other part of the input bias, that is, $C_2 c_i e^{-C_3 t}$ is obtained by providing a discharging loop, with an additional set of capacitor C_d , and resistor R_d . The configuration is shown in Fig. 4. The values of R_d and R_f are taken arbitrarily such that $R_d \ll R_f$. The initial value of C_d is assigned as $-C_2 c_i \forall i$. Once these values are set, the other values are given as

$$R_{ij} = \frac{R_f}{w_{ij}} \quad (12)$$

$$C_3 \approx 1/(R_d C_d) \quad (13)$$

The positive (or negative) value of weight is obtained by using the x_i th terminal (or $-x_i$ th terminal) of the neuron. For the sake of simplicity, the neuron in Fig. 4 can be represented as depicted in Fig. 5. Once the structure of a single neuron is formed, it is connected to the other neurons to form the ANN which can be represented as in Fig. 6. As the time proceeds, the neurons update their internal and external energies based on the update rules and based on the dynamics of selecting the neurons for the update. If the network is stable and the dynamics is appropriate, the network will converge to a limit point(local minimum), which will give the optimal solution of the LP [39]. Applying ANNs to solve the LP problems has been studied and analyzed in [25–28, 35, 67, 100, 136].

The objective of depicting the method of developing analog circuit for solving LP was to illustrate the reader various complexities involved in the deployment of an analog ANN for solving any COP. In the following subsections, some of the classical models of the ANNs that are applied in solving COPs will be described.

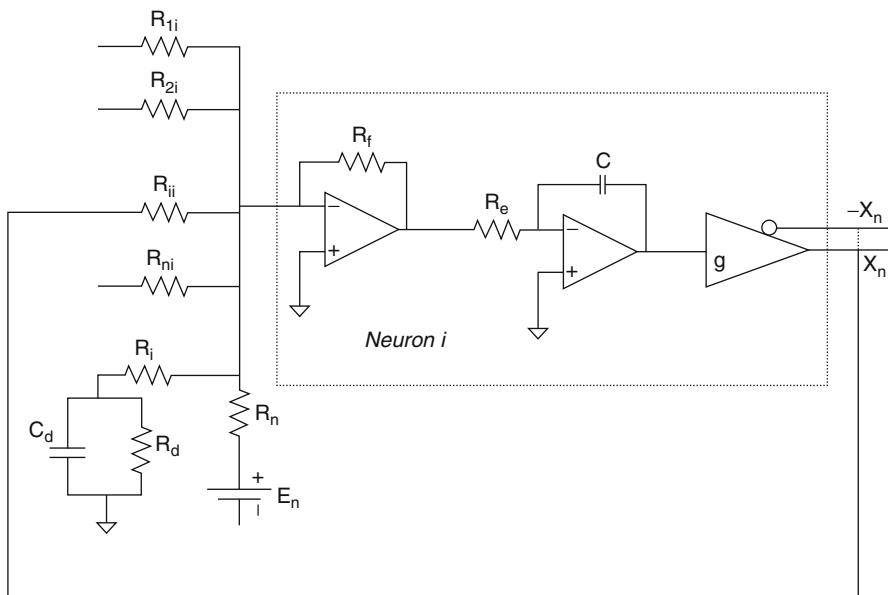

Fig. 4 Circuit representation of a neuron

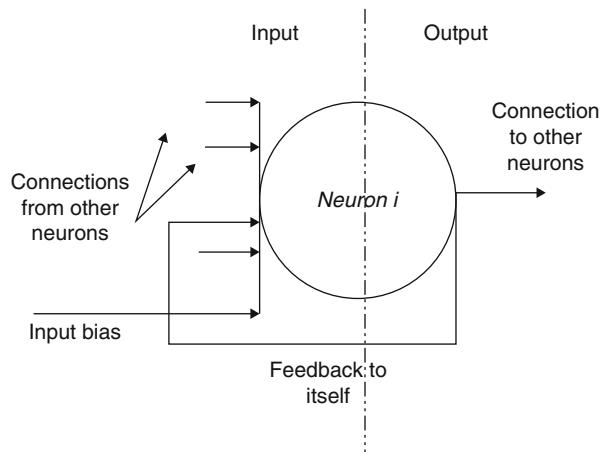

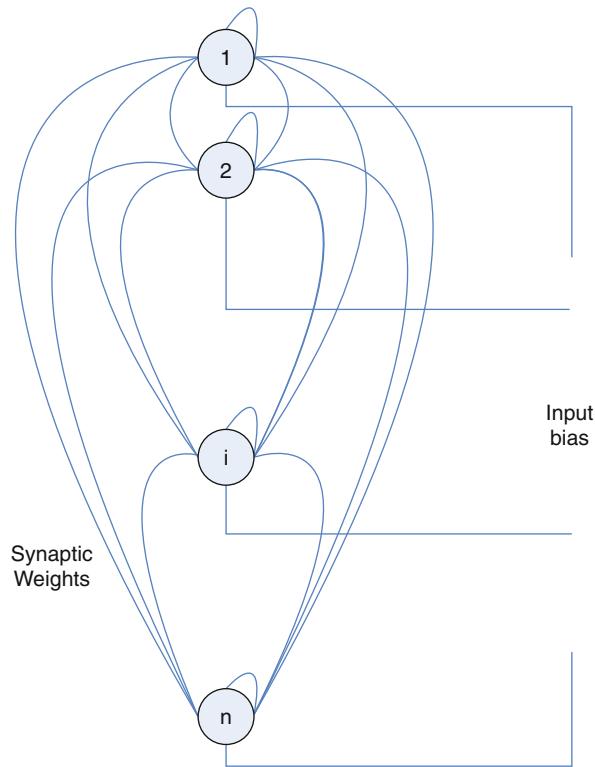

Fig. 5 Block representation of a neuron

These are the basic models proposed in 1980s–1990s as an alternate analog method to solve COPs. These models can be broadly classified as:

- Gradient-based methods
 - Hopfield and Tank's discrete and continuous models
- Self-organizing methods
 - Durbin-Willshaw's and Kohonen's models
- Projective gradient methods
 - Lagrange-based models

Fig. 6 Interconnected neurons

2.3 Hopfield and Tank (H-T) Models

In 1982, Hopfield [56] proposed a novel feedback type neural network, which is capable of performing computational tasks. Although feedback type models were proposed earlier by Anderson and Kohonen [10, 71], however, Hopfield [57] provided a complete mathematical analysis of feedback type neural networks. Thus, these feedback type neural networks were named as Hopfield networks. There are two different models proposed by Hopfield and Tank [58] for solving COPs. They are described below:

(a) *H-T's Discrete Model*

The discrete model consists of n interconnected neurons. The strength of the connection between the i th neuron and the j th neuron is represented by the weight w_{ij} . A presence of connection between any two neurons is indicated by a nonzero weight. Weights maybe positive or negative, representing the sense of connection (excitatory or inhibitory). In this model, each neuron has been assigned with the two states (external and internal states, like that in McCullough and Pitts [82] model) representing the embedded memory at each neuron. Moreover, the internal state of i th neuron I_i is continuous valued, whereas the external state x_i is binary valued. The internal and external state of a neuron are related as

$$\mathcal{I}_i(t+1) = \sum_{j=1}^n w_{ij} x_j(t) + \theta_i \quad (14)$$

$$x_i(t+1) = \Psi_d(\mathcal{I}_i) \begin{cases} 1 & \text{if } \mathcal{I}_i > U_i \\ 0 & \text{if } \mathcal{I}_i \leq U_i \end{cases} \quad (15)$$

where θ_i is a constant representing an external input bias to the i th neuron. $\Psi_d()$ represents a transfer function, which assign binary values to x_i . U_i represents the threshold value of the i th neuron. If the aggregate sum of the internal energies supplied to the i th neuron is greater than U_i , then this neuron will “fire,” that is, x_i will be set to 1. On the other hand, if the aggregate sum of the internal energies is less than the threshold, the neuron will be in a dormant or “not-firing” state. For solving the COP, w_{ij} ’s are calculated based on the objective function and the constraints of a given COP. The only decision variables of this model are x_i and \mathcal{I}_i . Unless or otherwise specified, the values of U_i ’s are taken as 0.

Initially, a random value is assigned to each external state, and the neurons update their states based on the updating rules. Usually, the neurons are selected randomly for the update (asynchronous updating). This updating rule is proven to converge to one of the stable states [83], which minimizes the energy function, provided the energy function is given by Eq. (16):

$$E_d = -\frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n w_{ij} x_i x_j - \sum_{i=1}^n \theta_i x_i \quad (16)$$

Since one of the states is binary and the update sequence of neurons is random, this model is known as a discrete model with stochastic updates. With the above details, **Algorithm 1** summarizes the mechanism of this model.

This model can be used to compute the local minimum of any quadratic function. Hopfield and Tank [58, 121] showed that the way energy function is constructed will always result in decrease of energy and the algorithm leads to one of the stable states. The algorithm proceeds as the gradient descent method, converging to a local minimum.

The main step in solving a COP using H-T’s discrete model is to convert the constrained COP into an unconstrained COP using a penalty function method (or Lagrange method). Once the unconstrained penalty objective function is obtained, it is compared with the energy function given in Eq. (16).

(b) H-T’s Continuous Model

In the subsequent research [57], H-T proposed another model in which both the states of the neuron are continuous. In addition, in this model, two additional properties have been assigned to the neurons, namely, the input capacitance C_i and the transmembrane resistance R_i . Moreover, a finite impedance R_{ij} between the

Algorithm 1 Hopfield Discrete Model

Randomly assign initial values to  $x_i$ 
termination = false
while (termination) do
    Select one neuron randomly
    Update the states  $\mathcal{I}_i$  and  $x_i$ :
     $\mathcal{I}_i(t+1) = \sum_{j=1}^n w_{ij} x_j(t) + \theta_i$ 
    if  $\mathcal{I}_i > 0$  then
         $x_i(t+1) = \Psi_d(\mathcal{I}_i) = 1$ 
    else
         $x_i(t+1) = \Psi_d(\mathcal{I}_i) = 0$ 
    end if
    Calculate the energy of the system  $E_d$ :
     $E_d = -\frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n w_{ij} x_i x_j - \sum_{i=1}^n \theta_i x_i$ 
    if termination criteria is met then
        termination = true
    end if
end while

```

i th neuron and the output x_j from j th neuron is assigned on the link ij . The main difference between the continuous model and the discrete model is in the continuous model, the external states of the neurons are continuous valued between 0 and 1. The equations of motion for this model are given as

$$\frac{d\mathcal{I}_i}{dt} = \sum_{j=1}^n w_{ij} x_j(t) - \frac{\mathcal{I}_i}{\tau} + \theta_i \quad (17)$$

$$x_i = \Psi_c(\mathcal{I}_i) \quad (18)$$

where $\tau = R_i C_i$ and usually, τ is assigned a value of 1, if the time step of any discrete time simulation is less than unity. A widely used transfer function is continuous sigmoidal function which is of the form, $\Psi_c(\mathcal{I}_i) = \frac{1}{2}(1 + \tanh(\frac{\mathcal{I}_i}{T}))$. The slope of the transfer function is controlled by parameter T . Similar to the previous model, this model will converge to a stable state which will minimize the energy function, given by Eq. (19):

$$E_c = -\frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n w_{ij} x_i x_j - \sum_{i=1}^n \theta_i x_i + \int_0^{x_i} \Psi_c^{-1}(a) da \quad (19)$$

The only decision variables in this model are x_i and \mathcal{I}_i . **Algorithm 2** describes the mechanism of this model. From this illustration, it can be seen that a continuous ANN can be applied to solve discrete optimization problems, just by tuning the parameters of the transfer function. In specific, if the value of the slope, T , in the transfer function is set to a very high value, then this model will approximately behave as the discrete model.

Algorithm 2 Hopfield Continuous Model

```

Randomly assign initial states  $x_i$ 
termination = false
while (termination) do
    Select randomly one neuron
    Update the states  $\mathcal{I}_i$  and  $x_i$ :
    
$$\frac{d\mathcal{I}_i}{dt} = \sum_{j=1}^n w_{ij} x_j(t) - \frac{\mathcal{I}_i}{\tau} + \theta_i$$

    
$$x_i(t+1) = \Psi_c(\mathcal{I}_i) = \frac{1}{2}(1 + \tanh(\frac{\mathcal{I}_i}{T}))$$

    Calculate the energy of the system  $E_d$ :
    
$$E_c = -\frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n w_{ij} x_i x_j - \sum_{i=1}^n \theta_i x_i + \int_0^{x_i} \Psi_c^{-1}(a) da$$

    if termination criteria is met then
        termination = true
    end if
end while

```

The first attempt to solve the COP using ANN was demonstrated by Hopfield and Tank [58] in 1985. They illustrated the usage of ANN by solving sufficiently large instances of the famous traveling salesman problem (TSP). After this illustration by Hopfield and Tank, numerous approaches and extensions were proposed to solve various COPs using ANNs. Most of the proposed extensions were in the direction of improving H-T's ANN model. In the following subsection, the alternative approaches which are significantly different from H-T's ANN model are presented.

2.4 Durbin-Willshaw (D-W)'s Model

In 1987, Durbin and Willshaw [34] proposed a fundamentally different approach to the H-T's approach for solving the geometric COPs. The proposed method was named as elastic nets and often referred as deformable templates. The origin of this method is the seminal work of Willshaw and Malsburg [130]. In this model, the neurons have no memory or states. Moreover, the network is not arbitrarily connected based on the values of the weights. Instead, it is connected in the form of a ring (elastic ring), where the neurons are placed on the circumference of the ring. Since this model is used to solve the geometric COPs, we will describe the model with respect to TSP.

In this model, there are M neurons on the circumference of the ring, where M is greater than N , the number of cities. The first step is to find the center of gravity of the network. This point is taken as the center for the ring, and iteratively neurons on the rings are pulled apart. In every iteration, neurons are pulled in such a way that the distance between the neurons and the closest city is minimized. However, there is another force from the ring that tries to keep the length of the ring as small as possible. Thus, in the end, when each city has been close enough to a corresponding neuron, a Hamiltonian tour is obtained. The equation describing the movement of j th neuron is given as

$$\Delta y_j = \alpha \sum_{i=1}^N w_{ij} (a_i - y_i) + \beta K (y_{j+1} + y_{j-1} - 2y_j) \quad (20)$$

where a_i is the coordinate of the i th vertex of the TSP; α , β , and K are the scaling parameters:

$$w_{ij} = \frac{\phi(d_{a_i y_j}, K)}{\sum_{k=1}^M \phi(d_{a_i y_k}, K)} \quad \forall i, j \quad (21)$$

$d_{a_i y_j}$ is the Euclidean distance between the i th city and the j th neuron; and

$$\phi(d_{a_i y_j}, K) = e^{-d_{a_i y_j}^2 / 2K^2} \quad (22)$$

α represents the scaling factor that drives the neurons toward the cities whereas β represents the scaling factor for the force that keeps the neighboring neurons on the ring closer. Parameter K is gradually decreased, so that the neurons get closer to the cities. This parameter acts like temperature in simulated annealing and requires a cooling schedule. The energy of this system is given by Eq. (23):

$$E_{dw} = -\alpha K \sum_{i=1}^N \ln \sum_{j=1}^M \phi(d_{a_i y_j}, K) + \frac{\beta}{2} \sum_{j=1}^M d_{y_j y_{j+1}}^2 \quad (23)$$

The mechanism of this model can be explained by Algorithm 3.

2.5 Kohonen Model

Another fundamentally different approach to the H-T's approach was proposed by Kohonen [72] for solving geometric COPs. This model utilizes self-organizing maps (SOMs) [70, 71] which fall under the category of the competitive neural networks. In this model, there are two layers of neurons (input and output). The input layer of the neurons are fully connected to the output layer of the neurons. In general, the neurons at the inner layer represent the input from a high-dimensional space.

Algorithm 3 Durbin-Willshaw model

Find the center of gravity of the system, and assign it as the center of the circle with M equispaced ring points.

```

termination = false
while (termination) do
    Update the coordinates  $y_i$  of ring points using equation Eq. (20)
    if ( $\min_{1,\dots,M} \{d_{a_i,y_i}\} \leq \varepsilon$ ) or ( $K < K_{min}$ ) then
        termination = true
    end if
     $K = \alpha K$   $\alpha \in (0, 1)$ 
end while

```

However, the neurons at the output layer represent output to a low-dimensional space. Therefore, the whole model act as a mapping from a higher dimensional space to a lower dimensional space. The property of self-organizing maps is to map the neurons close in the input space to the neurons that are close in the output space. The output layer of the neurons is arranged according to a topological structure, which is based on the geometry of the problem under consideration. For example: for the TSP, the output layer is arranged in a ring structure. Let $a^i = (a_1^i, a_2^i, \dots, a_n^i)^T \quad \forall i = 1, \dots, N$ be the coordinates of i th city to be visited. Let $w^j = (w_{1j}, w_{2j}, \dots, w_{Nj})^T, \quad \forall j = 1, \dots, M, \quad M \geq N$ represent the weight vector of the j th output neuron. Unlike the previous models, in this model, the weights are the decision variables. They are changed over the time using the following equation:

$$w^j = w^j + \mu f_{j,j^*}(a^i - w^j), \quad \forall j = 1, 2, \dots, M, \quad 0 < \mu < 1 \quad (24)$$

where μ is called learning rate, j^* is called winning neuron, defined as $j^* = \operatorname{argmin}_{\forall j} \{d_{a^i w_j}\}$ for a given city i , and the function $f : (j, j^*) \mapsto [0, 1]$ is a decreasing function and represents the lateral distance between output units j and j^* . This function acts like a weight of attraction between two points. Typically, the function is modified as the algorithm proceed to gradually reduce the magnitude of the weight of attraction. This method can be described by [Algorithm 4](#).

Thus, this iterative approach at the end produces a Hamiltonian tour. Since both Durbin-Willshaw's and Kohonen's models are for geometrical problems, these models have not been widely used in the application of ANNs in solving COPs.

2.6 Lagrangian Model

Another approach which is based on the Lagrange programming is presented by Zhang and Constantinides [139]. The main difference in this method when compared to the Hopfield and Tank [58] approach is that this method is not similar to the gradient descent method. In this method, the constraints and objective function are not coupled using the penalty function. Instead, two types of neurons are used

Algorithm 4 Kohonen Model

Randomly assign initial weights w_j , set $i = 0$.

termination = false

while (*termination*) **do**

 Select neuron $i, i = (i + 1) \bmod (N + 1)$

 Calculate $d_j = d_{a^i w_j} \quad \forall j = 1, \dots, M$

 Assign $j^* = \operatorname{argmin}_j \{d_j\}$ and $d_j = d_{j^*}$

 Update the weights as: $w^j = w^j + \mu f(j, j^*)(a^i - w^j), \quad \forall j = 1, \dots, M, \quad I \& 0 < \mu < 1$

if $\min_j \{d_{a^i w_j}\} \leq \varepsilon, \forall i = 1, \dots, N$ **then**

termination = true

end if

end while

(variable type, x , and Lagrangian type, λ). One type of neurons (Lagrangian) looks for a feasible solution, and the other type of neurons (variable) looks for an optimal solution.

The main advantage of this model over the previous model is that the objective function can be free from the Lyapunov function criterion and can be different from a quadratic function. That is, any type of function can be optimized, unlike the quadratic function requirements of H-T's model [58]. For example, consider any general optimization problem defined as

minimize :

$$f(\mathbf{x})$$

subject to :

$$\begin{aligned} h_i(\mathbf{x}) &= 0 \quad \forall i = 1, \dots, m \\ \mathbf{x} &\in \mathbb{R}^n \end{aligned} \tag{25}$$

where $f(\mathbf{x}), h_i(\mathbf{x}) : \mathbb{R}^n \mapsto \mathbb{R}$ are any continuous and twice differentiable functions of \mathbf{x} . The Lagrange for the problem Eq. (25) is written as

$$L(\mathbf{x}, \boldsymbol{\lambda}) = f(\mathbf{x}) + \boldsymbol{\lambda}^T h(\mathbf{x}) \tag{26}$$

The equations of motion that describe this model are

$$\nabla_t \mathbf{x} = -\nabla_x L(\mathbf{x}, \boldsymbol{\lambda}) \tag{27}$$

$$\nabla_t \boldsymbol{\lambda} = -\nabla_{\boldsymbol{\lambda}} L(\mathbf{x}, \boldsymbol{\lambda}) \tag{28}$$

where

$$\begin{aligned} \nabla_t \mathbf{x} &= \left(\frac{dx_1}{dt}, \frac{dx_2}{dt}, \dots, \frac{dx_n}{dt} \right)^T, \quad x \in \mathbb{R}^n \\ \nabla_t \boldsymbol{\lambda} &= \left(\frac{d\lambda_1}{dt}, \frac{d\lambda_2}{dt}, \dots, \frac{d\lambda_m}{dt} \right)^T, \quad \lambda \in \mathbb{R}^m \\ \nabla_x L(\mathbf{x}, \boldsymbol{\lambda}) &= \left(\frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial x_1}, \frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial x_2}, \dots, \frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial x_n} \right)^T \end{aligned}$$

and

$$\nabla_{\boldsymbol{\lambda}} L(\mathbf{x}, \boldsymbol{\lambda}) = \left(\frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial \lambda_1}, \frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial \lambda_2}, \dots, \frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial \lambda_m} \right)^T$$

The above model is iterative as described in [Algorithm 5](#), similar to that of H-T's continuous model. Both the types of neuron are the decision variables.

The mathematical properties and proofs related to convergence of ANN models will be discussed in [Sect. 3](#) of this chapter.

Algorithm 5 Lagrangian Model

Randomly assign initial states x_i and λ_i
 $\text{termination} = \text{false}$
while (termination) **do**
 Select randomly one neuron (either variable or lagrangian)
 if *ordinary variable is selected* **then**
 Update the states x_i as:
 $\nabla_x \mathbf{x} = -\nabla_x L(\mathbf{x}, \boldsymbol{\lambda})$
 else
 Update the states λ_i as:
 $\nabla_{\boldsymbol{\lambda}} \boldsymbol{\lambda} = -\nabla_{\boldsymbol{\lambda}} L(\mathbf{x}, \boldsymbol{\lambda})$
 end if
 Calculate the energy of the system $L(\mathbf{x}, \boldsymbol{\lambda})$:
 $L(\mathbf{x}, \boldsymbol{\lambda}) = f(\mathbf{x}) + \boldsymbol{\lambda}^T h(\mathbf{x})$
 if *termination criteria is met* **then**
 $\text{termination} = \text{true}$
 end if
end while

2.7 General Methodology

In the previous subsections, a brief picture of different models that can be used to solve a COP is presented with their algorithmic structure. In the following part of this subsection, general guidelines for mapping COPs onto the ANNs models will be presented.

Guidelines for H-T's Model (Discrete and Continuous)

- The output state of the neurons represents the decision variables of the COP.
- Combine the objective function and constraints using the penalty functions, such that the overall modified objective function is quadratic in nature, and it is called as the energy function of the system.
- Obtain the weights and the bias for each neuron. This is the main step that maps the COP onto ANN. This can be done by any one of the following methods:
 - Compare the coefficients of terms in energy function with the coefficients in E_d or E_c functions. This comparison will determine the weights on the links and will determine the input bias of a neuron.
 - Compare the coefficients of degree 1 in the differential update rule to the weights. Similarly, compare the constant term of differential update rule to the bias.
- Assign a random initial state to all the neurons, and proceed as described in [Algorithm 1](#) or [2](#).

Note: Only models with linear and/or quadratic objective function can be solved using the classical H-T's model. For solving the general COPs, various extensions are proposed, like the Lagrange function method.

Guidelines for Durbin-Willshaw's Model

- The decision variable of the COP is represented by the Euclidean position of the neurons.
- Find the center of gravity of the given geometry and mark it as the ring's center.
- Initially, all the neurons are placed uniformly on the circumference of the ring.
- Update the position of the neurons as described in [Algorithm 3](#).

Guidelines for Kohonen's Model

- The decision variables of the COP are represented by the weight vector.
- Initially, all the cities of the input layer are connected with all the neurons of output layer.
- Update the weights of the neurons as described in [Algorithm 4](#).

Note that only COPs which have a low-dimensional geometrical structure can be solved using the Durbin-Willshaw's model or the Kohonen's model. However, there has been extension proposed for solving other COPs, like self-organizing neural networks (SONNs) [108]. SONNs exploit the fact that solutions to many optimization problems can be seen as finding the best arrangement in the permutation matrix. The best arrangement is the one which is both feasible and optimal to the given COP.

Guidelines for Lagrangian Model

- The output state of the neurons (both Lagrangian and variable neurons) represents the decision variable of the COP.
- Combine the objective function and constraints using the Lagrange method. This overall Lagrange function is called the energy function of the system.
- Obtain the weights and the bias. This is the main step that maps COP onto ANN. This can be done by any one of the following methods:
 - Compare the coefficients of terms in energy function with the coefficients in the $L(\mathbf{x}, \lambda)$ function. This comparison will determine the weights on the links and will determine the input bias of a neuron.
 - Compare the coefficients of degree 1 in the differential update rule to the weights. Similarly, compare the constant term of differential update rule to the bias.
- Assign a random initial state to all neurons and proceed as described in [Algorithm 5](#).

In the following subsection, a detail mapping of a COP using the H-T's model will be presented.

2.8 Example: Mapping

In this subsection, an illustration of mapping a COP to the H-T's model will be presented. A symmetric traveling salesman problem (TSP) is selected for the illustration because this problem has been considered as a standard representative test problem for COPs.

Hopfield Mapping

Consider the TSP formulated as

minimize :

$$\sum_{i=1}^N \sum_{k=1, k \neq i}^N \sum_{j=1}^N d_{ik} x_{ij} (x_{k,i+1} + x_{k,i-1}) \quad (29)$$

subject to :

$$\sum_{i=1}^N x_{ij} = 1 \quad \forall j = 1, \dots, N \quad (30)$$

$$\sum_{j=1}^N x_{ij} = 1 \quad \forall i = 1, \dots, N \quad (31)$$

$$x_{ij} \in \{0, 1\} \quad \forall i, j = 1, \dots, N \quad (32)$$

where

$$x_{ij} = \begin{cases} 1 & \text{if city } i \text{ is in the position } j \\ 0 & \text{otherwise} \end{cases}$$

and d_{ik} represents the distance between the cities i and j . The first step in mapping TSP to a H-T's model will be converting the given problem into an unconstrained quadratic programming problem, using the penalty functions. Following transformations are used by Hopfield and Tank to map the problem:

- The function in Eq. (30) is transformed into

$$\sum_{i=1}^N \sum_{k=1, k \neq i}^N x_{ij} x_{kj}$$

- The function in Eq. (31) is transformed into

$$\sum_{j=1}^N \sum_{k=1, k \neq j}^N x_{ij} x_{ik}$$

- In order to preserve the equality of 1 in Eqs. (30) and (31), additional penalty is added as

$$\left(\sum_{i=1}^N \sum_{j=1}^N x_{ij} - N \right)^2$$

Thus, the penalized objective function can be written as

$$E_{\text{tsp}} = \frac{A}{2} \sum_{j=1}^N \sum_{i=1}^N \sum_{k=1, k \neq i}^N x_{ij} x_{kj} + \frac{B}{2} \sum_{i=1}^N \sum_{j=1}^N \sum_{k=1, k \neq j}^N x_{ij} x_{ik} \\ + \frac{C}{2} \left(\sum_{i=1}^N \sum_{j=1}^N x_{ij} - N \right)^2 + \frac{D}{2} \sum_{i=1}^N \sum_{k=1, k \neq i}^N \sum_{j=1}^N d_{ik} x_{ij} (x_{k,i+1} + x_{k,i-1}) \quad (33)$$

Comparing the Eq. (33) with (1), we have the following values for the synaptic weights and the input bias:

$$w_{ijkl} = -A\delta_{ik}(1 - \delta_{jl}) - B\delta_{jl}(1 - \delta_{ik}) - C - D\delta_{ik}(\delta_{l(j+1)} + \delta_{l(j-1)}) \quad (34)$$

$$\theta_{ij} = CN \quad (35)$$

where δ_{ik} is the Kronecker Delta.⁹ With the values of weight and bias, H-T's energy function can be written as

$$E_{\text{tsp}} = -\frac{1}{2} \sum_{i,j,k,l=1}^N w_{ijkl} x_{ij} x_{kl} - \sum_{i,j=1}^N \theta_{ij} x_{ij} \quad (36)$$

Thus, the system represented by Eqs. (34)–(36) can be implemented via an analog circuit or stepwise simulation on a digital computer. Although this mapping is not the best mapping (see [119] for a better mapping) for TSP, however, the purpose of this mapping was to illustrate the reader about various changes that are needed for mapping a simple COP onto a given ANN.

In this section, some of the classical models of the ANNs applied to solve the COPs were reviewed. However, the conditions under which the ANNs will converge to the optimal solution are not addressed in this section. In Sect. 3, conditions that guarantee the stability and the convergence ability of ANNs while solving the COPs will be presented.

3 Optimality Conditions

In the previous sections, it was stated that the ANNs will perform a gradient descent method. However, there were no mathematical analysis or proofs provided to support the claim. In this section, the stability and convergence analysis of ANNs will be presented. The objective of the such analysis is to prevent the network from oscillation or chaos and to guarantee its convergence to a local minimum [83, 106]. That is, to analyze that under what conditions from any arbitrary initial point, the ANN will converge to a local stable point. Although the stability term is used frequently from the electrical engineering point of view but from the view

⁹ $\delta_{ik} = 0$ if $i \neq k$; $\delta_{ik} = 1$ if $i = k$.

of optimization, these are more likely to be called as the optimality conditions. Therefore, in the following subsections, the necessary and sufficient conditions that lead the ANNs to converge at the local minima will be analyzed.

3.1 System Dynamics

The method of selecting neurons for the update in a given ANN is called its system dynamics. In the previous subsection, a random method to select a neuron for update is mentioned. However, it should be a valid question to ask, why to select a neuron randomly for the update? Why not select them in a synchronous, parallel, or consecutive way? This subsection investigates the best methods of selecting neurons. Before analyzing different update rules, in this subsection, different dynamics that can be applied to an ANN are described for a discrete state discrete dynamics system.

Consider a general form of discrete time ANN with the following dynamic equations:

$$\mathcal{I}_i(t+1) = \sum_{j=1}^n w_{ij} x_j(t) + \theta_i \quad (37)$$

$$x_i(t+1) = \Psi_d(\mathcal{I}_i) = \begin{cases} 1 & \text{if } \mathcal{I}_i > U_i \\ -1 & \text{if } \mathcal{I}_i \leq U_i \end{cases} \quad (38)$$

where x_i and \mathcal{I}_i represent the external state and internal state of an i th neuron and w_{ij} represents the weight between an i th neuron and a j th neuron. θ_i is a constant representing an external input to the i th neuron. Function $\Psi_d()$ is called as the transfer function. It assigns binary values to x_i . It should be noted that function $\Psi_d()$ is slightly different from the conventional *sign* or *signum* function. This is due to the simple observation that a single dormant neuron (i.e., not-firing neuron) will never excite itself (since $w_{ii} = 0$). U_i represents the threshold value of the i th neuron. If the aggregate sum of internal energies supplied to the i th neuron is greater than U_i , then this neuron will “fire,” that is, x_i will be set to 1. On the other hand, if the aggregate sum of internal energies is less than the threshold, the neuron will be in a dormant or “not-firing” state. Note that, here the external state of the neurons can take values of -1 or 1 . The dynamic equation of the discrete state system can be written in a compact form as

$$x_i(t+1) = \Psi_d \left(\sum_{j=1}^n w_{ij} x_j(t) + \theta_i \right) \quad (39)$$

The three main types of dynamics that can be implemented in any ANN are described as:

- Synchronous Dynamics

$$x_i(t+1) = \Psi_d \left(\sum_{j=1}^n w_{ij} x_j(t) + \theta_i \right) \quad \forall i = 1, \dots, n \quad (40)$$

- Parallel Dynamics

$$x_i(t+1) = \begin{cases} \Psi_d \left(\sum_{j=1}^n w_{ij} x_j(t) + \theta_i \right) & \forall i \in S(t) \\ x_i(t) & \text{otherwise} \end{cases} \quad (41)$$

- Consecutive Dynamics

$$x_i(t+1) = \begin{cases} \Psi_d \left(\sum_{j=1}^n w_{ij} x_j(t) + \theta_i \right) & i = K \\ x_i(t) & \text{otherwise} \end{cases} \quad (42)$$

where $S(t)$ ¹⁰ represents the set of selected neurons at time t and K ¹¹ represents the single selected vertex at time t . The above equations were defined for discrete state discrete dynamic system. That is, if the system is updated in discrete time, then the system is called as the discrete time system. Similarly, if the state (external) of the system is discrete, it is called as the discrete state system. On the other hand, if the system is updated in continuous time, it is called as the continuous time system. Moreover, if it has continuous state, it is called as the continuous state system. Thus, in general, all the ANN can be classified as discrete states discrete dynamics (DSDD), continuous state discrete dynamics (CSDD), continuous state continuous dynamics (CSCD), and discrete state continuous dynamics (DSCD). In the following sub sections, stability and optimality analysis of different systems will be presented.

3.2 Lyapunov Energy Function

When Hopfield introduced the notion of feedback type ANN, Lyapunov function was used to analyze the convergence characteristics of the H-T's model. This is

¹⁰They can be selected randomly; however, the best way to select them is considering an independent set of neurons. This will be discussed in the following subsections.

¹¹There are many ways to select the k based on the distribution function defined by:

- The gradient rule [50]
- The probabilistic-gradient rule
- The Hopfield rule [56]

However, these distribution functions are independent and have the same mean value (n) [83]. Thus, they convey the idea of random selection of the K th neuron.

done in order to prove that H-T's models are stable in nature and are capable of finding solutions to the optimization problem. Keeping the importance of Lyapunov analysis of ANNs in COPs, some of the main results from the literature will be presented in this subsection. Before proceeding for the Lyapunov analysis, some of the definitions are to be stated.

Basic Definitions:

Consider a dynamic system of the following form:

$$\nabla \mathbf{x}(t) = E(\mathbf{x}(t)), \quad \mathbf{x}(t_0) = \mathbf{x}_0 \in \mathbb{R}^n \quad (43)$$

Definition 1 A point \mathbf{x}^* is called the equilibrium point (or critical point, or steady state point) of the system described by Eq. (43) if $E(\mathbf{x}^*) = 0$.

Definition 2 A function $f : \mathbb{R}^n \mapsto \mathbb{R}$ is said to be a Lyapunov function if it holds the following properties:

- Function f is continuous and differentiable.
- The partial derivatives of function f w.r.t. any element of \mathbf{x} are continuous.
- Function f is nonnegative function over its entire domain.
- The derivative of function f w.r.t. time is nonpositive.

Definition 3 For the system described by Eq.(43), an equilibrium point \mathbf{x}^* is said to be Lyapunov stable (or stable in the sense of Lyapunov) if for any positive scalar ϵ , there exists a positive scalar δ such that

$$\|\mathbf{x}(t_0) - \mathbf{x}^*\| < \delta \implies \|\mathbf{x}(t) - \mathbf{x}^*\| < \epsilon \quad \forall t \geq t_0$$

Definition 4 An equilibrium point \mathbf{x}^* is said to be asymptotically stable (or asymptotically stable in the sense of Lyapunov) if the following conditions are satisfied:

- \mathbf{x}^* is stable.
- $\lim_{t \rightarrow \infty} \mathbf{x}(t) = \mathbf{x}^*$.

For the detailed explanation of the above definitions, see [76].

Analysis of DSDD Systems

Now, let us begin with systems of type DSDD. The two widely known Lyapunov functions for the DSDD systems can be written as

- Lyapunav 1

$$E_{\text{DDI}}(t+1) = -\langle \mathbf{x}(t+1), W\mathbf{x}(t) \rangle + \langle \boldsymbol{\theta}, (\mathbf{x}(t+1) + \mathbf{x}(t)) \rangle \quad (44)$$

or

$$E_{\text{DDI}}(t+1) = -\sum_{i=1}^n \sum_{j=1}^n w_{ij} x_i(t+1) x_j(t)$$

$$+ \sum_{i=1}^n \theta_i (x_i(t+1) + x_i(t)) \quad (45)$$

- Lyapunov 2

$$E_{DD2}(t+1) = -\frac{1}{2} \langle \mathbf{x}(t+1), W\mathbf{x}(t+1) \rangle + \langle \boldsymbol{\theta}, (\mathbf{x}(t+1)) \rangle \quad (46)$$

or

$$E_{DD2}(t+1) = -\frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n w_{ij} x_i(t+1)x_j(t+1) + \sum_{i=1}^n \theta_i (x_i(t+1)) \quad (47)$$

Theorem 1 If W is symmetric and update rule is synchronous, then a discrete system defined by Eq. (45) will converge to either a local minima or to a two-edge cycle.

Proof The change brought to the energy function given by Eq. (45) in one iteration is

$$\begin{aligned} \Delta E_{DD1}(t+1) &= (E_{DD1}(t+1)) - (E_{DD1}(t)) \\ &= \left(-\sum_{i=1}^n \sum_{j=1}^n w_{ij} x_i(t+1)x_j(t) + \sum_{i=1}^n \theta_i (x_i(t+1) + x_i(t)) \right) \\ &\quad - \left(-\sum_{i=1}^n \sum_{j=1}^n w_{ij} x_i(t)x_j(t-1) + \sum_{i=1}^n \theta_i (x_i(t) + x_i(t-1)) \right) \end{aligned} \quad (48)$$

solving Eq. (48) will lead to the following:

$$\begin{aligned} \Delta E_{DD1}(t+1) &= \left(\sum_{i=1}^n \theta_i (x_i(t+1) - x_i(t-1)) \right) \\ &\quad + \left(-\sum_{i=1}^n \sum_{j=1}^n w_{ij} x_i(t+1)x_j(t) + \sum_{i=1}^n \sum_{j=1}^n w_{ij} x_i(t)x_j(t-1) \right) \end{aligned} \quad (49)$$

Changing index in the second term and using symmetry of W matrix, following simplification is obtained:

$$\begin{aligned}\Delta E_{DD1}(t+1) = & \left(\sum_{i=1}^n \theta_i (x_i(t+1) - x_i(t-1)) \right) \\ & + \left(- \sum_{i=1}^n \sum_{j=1}^n w_{ij} x_j(t) (x_i(t+1) - x_i(t-1)) \right) \quad (50)\end{aligned}$$

Rewriting the above equation,

$$\Delta E_{DD1}(t+1) = - \sum_{i=1}^n (x_i(t+1) - x_i(t-1)) \left(\sum_{j=1}^n w_{ij} x_j(t) - \theta_i \right) \quad (51)$$

For each i th neuron, the contribution to the change in the energy function will be given by

$$(\Delta E_{DD1}(t+1))_i = -(x_i(t+1) - x_i(t-1)) \left(\sum_{j=1}^n w_{ij} x_j(t) - \theta_i \right) \quad (52)$$

or

$$(\Delta E_{DD1}(t+1))_i = (x_i(t-1) - x_i(t+1)) \mathcal{I}_i(t) \quad (53)$$

Thus, for the Lyapunov energy function given by Eq. (45), the change in energy of i th neuron is given by Eq. (3.2).

Since the update rule is synchronous, at every iteration any of the following scenarios may arise:

- If $\mathcal{I}_i(t) > 0 \Rightarrow x_i(t+1) = 1 \Rightarrow (\Delta E_{DD1}(t+1))_i \leq 0 \quad \forall i \in N.$
- If $\mathcal{I}_i(t) \leq 0 \Rightarrow x_i(t+1) = 0 \Rightarrow (\Delta E_{DD1}(t+1))_i \leq 0 \quad \forall i \in N.$

From the above implication, for every i th neuron, $(\Delta E_{DD1}(t+1))_i \leq 0$. Thus, the system is converging. At the converging limit, $(\Delta E_{DD1}(t+1))_i = 0$. This implies the following cases:

- $\mathcal{I}_i(t) = 0 \Rightarrow x_i(t) = x_i(t+1) = 0 \quad \forall i \in N$, a trivial case and can be discarded
- $x_i(t-1) - x_i(t+1) = 0 \quad \forall i \in N$.
 - $\Rightarrow x_i(t-1) = x_i(t+1) \neq x_i(t) \quad \forall i \in N \Rightarrow$ two-edge cycles.
 - $\Rightarrow x_i(t-1) = x_i(t+1) = x_i(t) \quad \forall i \in N \Rightarrow$ local minima.

Thus, the system will converge to a local minimum or to a two-edge cycle. \square

The next case to consider will be DSDD system with parallel dynamics. If a similar energy function is used, then following a similar argument, it is observed for the parallel dynamics that if $i \in S(t-1)$ and $i \notin S(t)$, then the sign of Eq. (3.2) is undetermined. Thus, there could be an increase in the energy of the system, if

parallel dynamics is followed. However, this case will not arise, if the set of neurons for parallel update is selected in a specified way and if a different energy function is used. The following theorem will give the *necessary and sufficient* condition for convergence of parallel dynamics.

Theorem 2 *If W is a symmetric matrix with zero diagonals and if the update rule is parallel, then a discrete system defined by Eq. (47) will converge to a local minima if and only if $S(t)$ contains an independent set of neurons for each iteration t . Where $S(t)$ is said to contain independent set of neurons, if $i, j \in S(t)$, then $w_{i,j} = 0$*

Proof Consider a generalized Lyapunov energy function given by Eq. (47). Let $S(t)$ be the independent set of neurons. The change in energy of the system is given by

$$\begin{aligned}\Delta E_{DD2}(t+1) &= (E_{DD2}(t+1)) - (E_{DD2}(t)) \\ &= \frac{1}{2} \left(- \sum_{i=1}^n \sum_{j=1}^n w_{ij} x_i(t+1)x_j(t+1) + \sum_{i=1}^n \theta_i(x_i(t+1)) \right) \\ &\quad - \frac{1}{2} \left(- \sum_{i=1}^n \sum_{j=1}^n w_{ij} x_i(t)x_j(t) + \sum_{i=1}^n \theta_i(x_i(t)) \right)\end{aligned}\quad (54)$$

Splitting the above equation for the cases $i, j \in S(t)$ and using symmetric property of W , we get

$$\begin{aligned}\Delta E_{DD2}(t+1) &= \frac{1}{2} \left(- \sum_{i \in S(t)} \sum_{j \notin S(t)} w_{ij} x_i(t+1)x_j(t+1) + \sum_{i=1}^n \theta_i(x_i(t+1)) \right) \\ &\quad - \frac{1}{2} \left(- \sum_{i=1}^n \sum_{j=1}^n w_{ij} x_i(t)x_j(t) + \sum_{i=1}^n \theta_i(x_i(t)) \right)\end{aligned}\quad (55)$$

Now, based on the above equation, the following two scenarios may happen:

- If $\mathcal{I}_k(t) > 0 \Rightarrow x_k(t+1) = 1 \Rightarrow \Delta E_{DD2}(t+1) \leq 0$
- If $\mathcal{I}_k(t) \leq 0 \Rightarrow x_k(t+1) = 0 \Rightarrow \Delta E_{DD2}(t+1) \leq 0$

Thus, the above system is converging. At the converging limit, $\Delta E_{DD2}(t+1) = 0$, which implies the following cases:

- $\mathcal{I}_k(t) = 0 \Rightarrow x_k(t) = x_k(t+1) = 0 \quad \forall k \in N$, a trivial case and can be discarded.
- $x_k(t) - x_k(t+1) = 0 \quad \forall k \in N \Rightarrow$ local minima.

Thus, the system will converge to a local minimum. For the proof of the converse, see [83]. \square

Theorem 3 If W is symmetric, the update rule is consecutive, then a discrete system defined by Eq. (47) will converge to a local minimum.

Proof Consider the Lyapunov energy function given by Eq. (47). The change in energy is given by

$$\begin{aligned} \Delta E_{\text{DDC}}(t+1) &= (E_{\text{DDC}}(t+1)) - (E_{\text{DDC}}(t)) \\ &= \frac{1}{2} \left(- \sum_{i=1}^n \sum_{j=1}^n w_{ij} x_i(t+1) x_j(t+1) + \sum_{i=1}^n \theta_i(x_i(t+1)) \right) \\ &\quad - \frac{1}{2} \left(- \sum_{i=1}^n \sum_{j=1}^n w_{ij} x_i(t) x_j(t) + \sum_{i=1}^n \theta_i(x_i(t)) \right) \end{aligned} \quad (56)$$

Splitting the above equation for cases when $i = K$ and when $i \neq K$ and using the property that W is symmetric, we get

$$\Delta E_{\text{DDC}}(t+1) = (x_k(t) - x_k(t+1)) \mathcal{I}_k(t) \quad (57)$$

The following two scenarios may happen:

- If $\mathcal{I}_k(t) > 0 \Rightarrow x_k(t+1) = 1 \Rightarrow \Delta E_{\text{DDC}}(t+1) \leq 0$
- If $\mathcal{I}_k(t) \leq 0 \Rightarrow x_k(t+1) = 0 \Rightarrow \Delta E_{\text{DDC}}(t+1) \leq 0$

Thus, the above system is converging. At the converging limit, $\Delta E_{\text{DDC}}(t+1) = 0$, which implies the following cases:

- $\mathcal{I}_k(t) = 0 \Rightarrow x_k(t) = x_k(t+1) = 0 \quad \forall k \in N$, a trivial case and can be discarded.
- $x_k(t) - x_k(t+1) = 0 \quad \forall k \in N \Rightarrow$ local minimum.

Thus, the system will converge to a local minimum. \square

Theorem 4 If W is symmetric positive semidefinite, then a discrete system defined by Eq. (47) will converge to a local minimum.

Proof See [83]. \square

The above analysis is performed for DSDD system. Another important class of system is CSDD system. Similar to the discrete state, three main types of dynamics can be applied for the continuous state system; they can be described as

- Synchronous Dynamics

$$x_i(t+1) = \Psi_c \left(\sum_{j=1}^n w_{ij} x_j(t) + \theta_i \right) \quad \forall i = 1, \dots, n \quad (58)$$

- Parallel Dynamics

$$x_i(t+1) = \begin{cases} \Psi_c \left(\sum_{j=1}^n w_{ij} x_j(t) + \theta_i \right) & \forall i \in S(t) \\ x_i(t) & \text{otherwise} \end{cases} \quad (59)$$

- Consecutive Dynamics

$$x_i(t+1) = \begin{cases} \Psi_c \left(\sum_{j=1}^n w_{ij} x_j(t) + \theta_i \right) & i = K \\ x_i(t) & \text{otherwise} \end{cases} \quad (60)$$

where $S(t)$ and K have the same meaning as in the DSDD case. The main difference between the above equations and the discrete state equations is the definition of the transfer function. Here the transfer function is not similar to *sign* function. However, here the transfer can be a general real valued monotonically increasing continuous function with the following properties:

$$\begin{aligned} &\text{if } a \rightarrow \infty, \Psi_c(a) \rightarrow 1 \quad \forall a \in \mathbb{R} \\ &\text{if } a \rightarrow -\infty, \Psi_c(a) \rightarrow -1 \quad \forall a \in \mathbb{R} \end{aligned} \quad (61)$$

Apart from the above properties, the following property is also incorporated to maintain an easy shift from a discrete state to a continuous state neuron. This is one of the important property of the transfer function, which adds the flexibility of using a continuous state model for solving a discrete COP.

$$\Psi_c(\mu a) \rightarrow \Psi_d(a) \quad \text{as } \mu \rightarrow \infty \quad (62)$$

Even the monotonic increasing criteria is not necessary. To be specific, any monotonic nondecreasing continuous function with the above properties may be used as the transfer function. However, the monotonic increasing continuous function is used only for the sake of simplicity and clearness [83].

There are many standard mathematical functions that appropriately fit the above restriction for the transfer function. The following are some of the widely used transfer functions:

1. $\Psi_c(a) = \tan h(a)$
2. $\Psi_c(a) = \frac{2}{\pi} \tan^{-1}(a)$
3. $\Psi_c(a) = \frac{1-e^{-a}}{1+e^{-a}}$
4. $\Psi_c(a) = \coth(a) - \frac{1}{a}$

In the following part of this section, some more theorems without proof for the CSDD systems are presented. Interested readers are directed to [83] for the detailed proofs of the following theorems.

Theorem 5 *If W is symmetric, $w_{ii} \geq 0$, and the update rule is synchronous, then a discrete system will converge to a local minima or a two-edge cycle, if the following energy function is used.*

$$\begin{aligned}
E_{\text{CDS}}(t+1) = & - \sum_{i=1}^n \sum_{j=1}^n w_{ij} x_i(t+1) x_j(t) + \\
& \sum_{i=1}^n \theta_i \left(x_i(t+1) + x_i(t) + \sum_{i=1}^n \left(\int_0^{x_i(t+1)} \Psi_{c_i}^{-1}(a) da + \int_0^{x_i(t)} \Psi_{c_i}^{-1}(a) da \right) \right)
\end{aligned} \tag{63}$$

Theorem 6 If W is symmetric and positive semidefinite, then a discrete system will converge to a local minima (irrespective of the type of dynamic used), if the following energy function is used.

$$\begin{aligned}
E_{\text{CD}}(t+1) = & -\frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n w_{ij} x_i(t+1) x_j(t) \\
& + \sum_{i=1}^n \theta_i(x_i(t+1)) + \sum_{i=1}^n \int_0^{x_i(t+1)} \Psi_{c_i}^{-1}(a) da
\end{aligned} \tag{64}$$

The restriction of positive semidefinite W can be relaxed if Ψ_c and Ψ_c^{-1} are differentiable. Let ζ_i be a scalar, defined as

$$\Psi_{c_i}' \leq \zeta_i \quad \text{and} \quad [\Psi_c^{-1}]' \geq \frac{1}{\zeta_i} \tag{65}$$

If such ζ_i 's exists, then the following theorem holds:

Theorem 7 Let $\widehat{w}_{ij} = w_{ij} + \frac{\delta_{ij}}{\zeta_j}$, where $\delta_{i,j}$ is Kronecker delta. Let the energy function be defined as

$$\begin{aligned}
E_{\text{CD}}(t+1) = & -\frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n \widehat{w}_{ij} x_i(t+1) x_j(t) \\
& + \sum_{i=1}^n \theta_i(x_i(t+1)) + \sum_{i=1}^n \int_0^{x_i(t+1)} \Psi_{c_i}^{-1}(a) da
\end{aligned} \tag{66}$$

If \widehat{W} is positive definite, then a discrete system will converge to a local minimum (irrespective of the type of dynamic used).

Furthermore, for the specific case of consecutive dynamics, a more relaxed optimality condition can be used.

Theorem 8 Let the energy function be defined as

$$\begin{aligned}
E_{CD}(t+1) = & -\frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n w_{ij} x_i(t+1) x_j(t) \\
& + \sum_{i=1}^n \theta_i(x_i(t+1)) + \sum_{i=1}^n \int_0^{x_i(t+1)} \Psi_c^{-1}(a) da
\end{aligned} \quad (67)$$

If $w_{ii} \geq 0$, $w_{ij} + \frac{1}{\zeta_j} > 0$, the update rule is consecutive, and Ψ_c & Ψ_c^{-1} are differentiable, then a discrete system will converge to a local minimum.

A similar analysis can be done for continuous dynamics. Interested readers are referred to [83] for detailed analysis. The above theorems can be easily extended to $\{0, 1\}$ systems. Continuous dynamics are usually hard to simulate on the digital computers and are mostly used in designing the analog circuits. The typical way of implementing continuous dynamics on the digital computer is to discretize the time into small steps. Nevertheless, the objective of presenting the proofs for discrete state systems is to highlight the reader that the convergence of ANNs is a critical issue. Moreover, the convergence of ANNs depends not only on the energy function but also on the systems dynamics. However, it can also be seen from the above proofs that a careful design of energy function (based on various properties of the weight matrix, W) will converge the system to a local minimum, irrespective of the dynamics.

Although Lyapunov function analysis is enough to understand that only for specific scenarios ANNs will converge to local optima. Lyapunov analysis is useful for those optimization problems whose constraints and objective function can be converted into a quadratic form. Moreover, the constraints are to be incorporated into the Lyapunov function using an appropriate penalty function. In general, it is hard to obtain a Lyapunov energy function for a given system. This does not mean that ANNs cannot be applied to these systems. Therefore, for such systems, different types of energy functions are designed.

The primary approach that replaced the usage of Lyapunov energy function analysis is the usage of a general penalty function analysis (by incorporating constraints of a given optimization problem [77]). In the following subsections, the convergence and stability criteria for penalty- and Lagrange-based ANNs will be presented.

3.3 Penalty-Based Energy Functions

Consider the following constrained optimization problem:

minimize :

$$f(\mathbf{x})$$

subject to :

$$\begin{aligned} g_i(\mathbf{x}) &\geq 0 \quad \forall i = 1, \dots, m \\ \mathbf{x} &\in \mathbb{R}^n \end{aligned} \tag{68}$$

where, $f, g_i : \mathbb{R}^n \mapsto \mathbb{R}$. It is assumed that both f, g_i are continuously differentiable functions. The above problem can be converted to an unconstrained optimization problem as

minimize :

$$\begin{aligned} E_{\text{pen}}(\mathbf{x}) \\ \text{subject to :} \\ \mathbf{x} \in \mathbb{R}^n \end{aligned} \tag{69}$$

where

$$E_{\text{pen}}(\mathbf{x}) = f(\mathbf{x}) + \sum_{i=1}^m c_i P_i(\mathbf{x}) \tag{70}$$

and $P_i(\mathbf{x})$ is the penalty function. Now, the convergence of ANNs to solve the above problem depends upon the structure of the penalty function. In this work, convergence analysis based on the penalty function of the form $P_i(\mathbf{x}) = \frac{1}{2}[\min\{0, g_i(\mathbf{x})\}]^2 \forall i = 1, \dots, m$ will be presented. One of the properties of this penalty function is that it can be converted to a continuous differentiable penalty function [77]. Consider the following transformation:

Let

$$v_i = \begin{cases} c_i g_i(\mathbf{x}) & \text{if } g_i(\mathbf{x}) < 0 \\ 0 & \text{if } g_i(\mathbf{x}) \geq 0 \end{cases} \quad \forall i = 1, \dots, m \tag{71}$$

then,

$$c_i P_i(\mathbf{x}) = \frac{c_i}{2} [\min\{0, g_i(\mathbf{x})\}]^2 = \frac{1}{2} v_i g_i(\mathbf{x}) \quad \forall i = 1, \dots, m \tag{72}$$

since $g_i, \forall i = 1, \dots, m$, is assumed to be differentiable, the above penalty function is differentiable.

The dynamics of this system¹² is defined as

$$\frac{dx_i}{dt} = -\frac{1}{C_i} \frac{\partial E(\mathbf{x})}{\partial x_i} \quad \forall i = 1, \dots, n \tag{73}$$

Thus, these systems are also called as *gradient-based systems*. These systems [77] have some of the useful properties that can be used to solve the COPs. These properties are described in the following theorems:

¹²Using Kirchoffs law, see [77]

Theorem 9 Let the system be described by Eq. (73). The isolated equilibrium point of the system is asymptotically stable if and only if it is a strict local minimizer of function E_{pen} .

Theorem 10 Let the system be described by Eq. (73). If the isolated equilibrium point of the system is stable, then it is a local minimizer of function E_{pen} .

For the gradient-based systems, assuming Lipschitz continuity, Han et al. [51] proposed many other convergence properties.

One of the difficulties in applying the penalty based method in the ANNs, is the selection of various penalty parameters. Due to the physical limits on the analog circuits, c_i cannot be set to a large value. In order to overcome the difficulties of the penalty method, and to generalize the use of ANNs, Lagrange based energy function was proposed [139]. Following subsection discuss some of the results for the Lagrange-based ANNs.

3.4 Lagrange Energy Functions

Lagrange based neural networks are inspired by the saddle point theory and the duality analysis. The focus of these networks is to search for a point that satisfies K.K.T's first order necessary conditions of optimality [12]. Therefore, analogous to the gradient descent systems, these network are also known as *projective gradient systems*.

In the following subsections, necessary and sufficient conditions related to Lagrange type energy functions will be presented. Consider the following optimization problem:

minimize :

$$f(\mathbf{x})$$

subject to :

$$h_i(\mathbf{x}) = 0 \quad \forall i = 1, \dots, m \quad (74)$$

$$\mathbf{x} \in \mathbb{R}^n$$

where, $f, h_i : \mathbb{R}^n \mapsto \mathbb{R}$. It is assumed that both, f, h_i are continuously differentiable functions. The above problem can be converted to an unconstrained optimization problem using the Lagrange function, as:

$$L(\mathbf{x}, \boldsymbol{\lambda}) = f(\mathbf{x}) + \boldsymbol{\lambda}^T h(\mathbf{x}) \quad (75)$$

In this subsection, some of the basic optimality condition in the form of theorems are stated without proof. Interested readers may refer to [12] for the complete discussion, with proofs.

Theorem 11 Let us assume that \mathbf{x}^* is a regular point (one that satisfies constraint qualification). If \mathbf{x}^* is the local minimum of problem Eq. (74), then there exists $\boldsymbol{\lambda}^* \in \mathbb{R}^m$ such that:

$$\nabla_x L(\mathbf{x}^*, \boldsymbol{\lambda}^*) = 0 \quad (76)$$

and

$$\mathbf{d}^T \nabla_{xx}^2 L(\mathbf{x}^*, \boldsymbol{\lambda}^*) \mathbf{d} \geq 0, \quad \forall \mathbf{d} \in \{\mathbf{d} : \nabla_x h(\mathbf{x}^*)^T \mathbf{d} = 0\} \quad (77)$$

Theorem 12 Let us assume that $h(\mathbf{x}^*) = 0$. If $\exists \boldsymbol{\lambda}^* \in \mathbb{R}^m$ such that:

$$\nabla_x L(\mathbf{x}^*, \boldsymbol{\lambda}^*) = 0 \quad (78)$$

and

$$\mathbf{d}^T \nabla_{xx}^2 L(\mathbf{x}^*, \boldsymbol{\lambda}^*) \mathbf{d} > 0, \quad \forall \mathbf{d} \in \{\mathbf{d} : \mathbf{d} \neq 0; \nabla_x h(\mathbf{x}^*)^T \mathbf{d} = 0\} \quad (79)$$

then \mathbf{x}^* is the local minimum of problem Eq. (74).

Similar to the case of gradient-based dynamics, Lagrange systems has the following dynamic equations:

$$\nabla_t \mathbf{x} = -\nabla_x L(\mathbf{x}, \boldsymbol{\lambda}) \quad (80)$$

$$\nabla_t \boldsymbol{\lambda} = -\nabla_{\boldsymbol{\lambda}} L(\mathbf{x}, \boldsymbol{\lambda}) \quad (81)$$

Although, the above equations are similar to the gradient-based systems, due to the difference in type of variables (ordinary variables and Lagrange variables), the system is named as *projective gradient systems*. In the presence of different types of the variables, the Lagrange will decrease w.r.t. one type of the variables and increase w.r.t. the other. This leads to the saddle point theory. For example, it is very easy to see that

$$\frac{dL(\mathbf{x}, \boldsymbol{\lambda})}{dt} \Big|_{\boldsymbol{\lambda}=\text{constant}} = \sum_{i=1}^n \frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial x_i} \frac{dx_i}{dt} = - \sum_{i=1}^n \left(\frac{dx_i}{dt} \right)^2 \leq 0 \quad (82)$$

$$\frac{dL(\mathbf{x}, \boldsymbol{\lambda})}{dt} \Big|_{\mathbf{x}=\text{constant}} = \sum_{i=1}^m \frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial \lambda_i} \frac{d\lambda_i}{dt} = \sum_{i=1}^m \left(\frac{d\lambda_i}{dt} \right)^2 \geq 0 \quad (83)$$

Thus, $(\mathbf{x}^*, \boldsymbol{\lambda}^*)$ act as a saddle point of the system.

Theorem 13 If $\nabla_{xx}^2 L(\mathbf{x}, \boldsymbol{\lambda})$ is positive definite $\forall \mathbf{x} \in \mathbb{R}^n$ and $\forall \boldsymbol{\lambda} \in \mathbb{R}^m$, then the proposed ANN is Lyapunov stable.

The proof of this theorem is presented by Zhang and Constantinides in [139]. From the above theorem, following corollaries can be obtained:

Corollary 1 \mathbf{x} tends to a limit \mathbf{x}^* at which $\nabla_x L(\mathbf{x}^*, \boldsymbol{\lambda}) = 0$.

Corollary 2 If $\nabla h_i(\mathbf{x}^*) \quad \forall i = 1, \dots, m$ are linearly independent, then $\boldsymbol{\lambda}$ converges to $\boldsymbol{\lambda}^*$.

Theorem 14 Let the network be described by Eqs. (75), (80), and (81). If the network is physically stable, then the ANN converges to a local minimum. The point of convergence is a Lagrange solution to problem Eq. (74).

The above restriction of the global convexity can be relaxed to a local convexity, and the following theorem can be stated:

Theorem 15 *Let the network be described by Eqs. (75), (80), and (81). If following conditions hold:*

1. $\exists(\mathbf{x}^*, \boldsymbol{\lambda}^*)$ such that $(\mathbf{x}^*, \boldsymbol{\lambda}^*)$ is a stationary point
2. $\nabla_{xx}^2 L(\mathbf{x}^*, \boldsymbol{\lambda}^*) > 0$
3. \mathbf{x}^* is a regular point of problem Eq. (74)

the initial point is in proximity of $(\mathbf{x}^, \boldsymbol{\lambda}^*)$, then the ANN will asymptotically converge to $(\mathbf{x}^*, \boldsymbol{\lambda}^*)$.*

In this section, different ways to study convergence and stability performance of ANNs were illustrated. Various theorems were presented to understand the critical role of the energy functions in the convergence behavior of ANNs. However, the convergence will guarantee local optimality provided suitable energy function, and dynamics are used to update the states of neurons. For obtaining global optimality, there are numerous extensions proposed in the literature. In the following section, a discussion on the methods that can be used to escape from local minima, in the hope of finding the global minimum, is presented.

4 Escaping Local Minima

The very thought of the gradient descent method will kindle the question regarding global optimality. Classical ANNs perform gradient descent method and will hardly converge to the global minimum. In order to overcome such difficulties, various extensions have been proposed. The extension methods that may converge ANNs to global minima by escaping local minima can be broadly classified as:

- Stochastic extensions
- Chaotic extensions
- Convexification
- Hybridization

Clearly, any extension that can be applied to H-T models can be easily applied to the general penalty or the Lagrange-based ANNs. Thus, in most of the cases, the extensions for the H-T's model will be reviewed. In the following part of this section, a brief discussion of the above extension methods will be presented.

4.1 Stochastic Extensions

There are basically four ways to include stochasticity in the H-T's model [107]. They are:

1. Introducing stochasticity in the transfer function
2. Introducing noise in the synaptic weights

3. Introducing noise in the input bias
4. Any combination of the above three

The prominent stochastic extensions that can be applied to the classical ANNs are discussed in the following parts of this subsection.

4.1.1 Boltzmann Machines

This is the first extension of H-T's model, which proposes a way to escape from the local minima [1, 2, 54, 55]. This is done by replacing the deterministic transfer function with a probabilistic transfer function. Let the change in energy of the i th neuron of the H-T's model be represented by ∇E_i . Then, irrespective of the previous state, the i th neuron will fire with probability p_i , which is defined as

$$p_i = \frac{1}{(1 + \exp -\nabla E_i / T)} \quad (84)$$

and

$$x_i = \Psi_{\text{Blz}}(\mathcal{I}_i) = \begin{cases} 1 & \text{with probability } p_i \\ 0 & \text{with probability } (1 - p_i) \end{cases} \quad (85)$$

where T is the parameter similar to the concept of temperature in simulated annealing.

4.1.2 Gaussian Machines

These are the extensions to the Boltzmann machines, where noise is introduced in the inputs [7]. The updating dynamics of an i th neuron in the H-T's model will be modified as

$$\mathcal{I}_i = \sum_{j=1}^n w_{ij} x_j + \theta_i + \varepsilon_i \quad (86)$$

where ε_i is the term representing the noise, which follows Gaussian distribution with mean zero and variance σ^2 . The deviation of σ depends upon the parameter T , the temperature of the Gaussian network. In addition to the noise, activation level a_i is being assigned to every neuron, which has the following dynamics:

$$\frac{da_i}{dt} = -\frac{a_i}{\tau} + \mathcal{I}_i \quad (87)$$

The external state of the i th neuron is determined by the following equation:

$$x_i = \Psi_{\text{Gss}}(a_i) = \frac{1}{2} \left(\tanh \left(\frac{a_i}{a_0} \right) + 1 \right) \quad (88)$$

where a_0 is the additional parameter added to the Gaussian network.

4.1.3 Cauchy Machines

This system is an extension of the Gaussian machines, where instead of a Gaussian noise, a Cauchy noise is added to the system [114, 116]. The reason of replacing the Gaussian noise with the Cauchy noise is based on the observation that the Cauchy noise produces both global random flights and local random flights, whereas Gaussian noise produces only local random noise. Thus, the system has a better chance of convergence to the global minimum. The probability that a neuron will fire is given as

$$p_i = \frac{1}{2} + \frac{1}{\pi} \left(\arctan\left(\frac{\mathcal{I}_i}{T}\right) \right) \quad (89)$$

and

$$x_i = \Psi_{\text{Cau}}(\mathcal{I}_i) = \begin{cases} 1 & \text{with probability } p_i \\ 0 & \text{with probability } (1 - p_i) \end{cases} \quad (90)$$

where T is the temperature of the system which has the similar meaning as in the Gaussian or Boltzmann machines. In [63], comparison of lower bounds for Boltzmann and Cauchy machines is presented.

4.2 Chaotic Extensions

Let E_{Hop} represent the general H-T's energy function. Then chaotic extensions for the H-T's model can be obtained by adding an additional function to E_{Hop} [73, 111], which can be described as

$$E_{\text{CNN}} = E_{\text{Hop}} + H(\mathbf{x}, W, \theta) \quad (91)$$

Different definitions for the function $H()$ lead to different chaotic extensions. Some of the chaotic extension methods for the H-T's model will be presented in the following subsection.

4.2.1 Chen and Ahira's Model

Chen and Ahira [20, 21] proposed a chaotic addition to the energy function, which is given as

$$H_{\text{CA}} = \frac{\lambda(t)}{2} \sum_i x_i(x_i - 1) \quad (92)$$

where $\lambda(t)$ is the decay parameter. If this term is added to H-T's energy function, then the system's dynamics is defined by the following equation:

$$\frac{d\mathcal{I}_i}{dt} = -\frac{\partial E_{\text{CNN}}}{\partial x_i} \quad (93)$$

The update rule for the internal energy of this model is given as

$$\mathcal{I}_i(t+1) = k\mathcal{I}_i(t) + \alpha \left(\sum_{j=1, j \neq i}^n w_{ij} x_j(t) + \theta_i \right) - z(t)(x_i(t) - \theta_0) \quad (94)$$

$$z(t+1) = (1 - \beta)z(t) \quad (95)$$

where $\alpha = \nabla t$, $z(t)$ is the self-feedback connection weight $z(t) = \lambda(t)\nabla t$, β is the damping factor, $\theta_0 = 1/2$, and $k = 1 - \nabla t/\tau$.

Initially, z is very high to create strong self-coupling, thereby leading to the chaotic dynamics. Chaotic dynamics acts like an exploration stage in the simulated annealing, searching for a global minima. In the later stages, z is decayed so that the system starts to converge to a stable fixed point (similar to exploitation stage in the simulated annealing).

4.2.2 Wang and Smith's Model

Wang and Smith [124] proposed the following chaotic addition to the H-T's energy function, which is given as

$$H_{WS} = (\beta^T - 1)E_c \quad (96)$$

where E_c is the original H-T's energy function and β is the parameter which takes the values between $[0, 1]$. If this term is added to H-T's energy function, then the system is defined as

$$\frac{d\mathcal{I}_i}{dt} = -\frac{\partial E_{CNN}}{\partial x_i} \quad (97)$$

The update rule of the internal energy for this model is given as

$$\mathcal{I}_i(t+1) = \left(1 - \frac{\beta^T \nabla t(0)}{\tau}\right) \mathcal{I}_i(t) + \beta^T \nabla t(0) \left(\sum_{j=1, j \neq i}^n w_{ij} x_j(t) + \theta_i \right) \quad (98)$$

$$\beta^T \nabla t(0) = \nabla t(t) \quad (99)$$

Initially, ∇t is sufficiently large to trigger chaotic search. As $t \rightarrow \infty$, ∇t gradually decreases.

4.2.3 Chaotic Noise Model

Recently, Wang et al. [125] proposed the following chaotic addition to the H-T's energy function, which is given as

$$H_\eta = - \sum_i \eta_i(t) x_i(t) \quad (100)$$

where η_i is the noise term. In general, η_i is a normalized time series. Initially, the neuron is set with the chaotic time series. If this term is added to H-T's energy function, then the system is defined as

$$\frac{d\mathcal{I}_i}{dt} = -\frac{\partial E_{\text{CNN}}}{\partial x_i} \quad (101)$$

The update rule of the internal state for this model is given as

$$\mathcal{I}_i(t+1) = \left(1 - \frac{\nabla t}{\tau}\right)\mathcal{I}_i(t) + \nabla t \left(\sum_{j=1}^n w_{ij} x_j(t) + \theta_i + \eta_i(t)\right) \quad (102)$$

This model has a linear form of function $H()$, when compared to the quadratic forms presented in the earlier models. This may be the reason for its superior optimization performance among the chaotic extension models.

4.3 Convexification

One of the important properties of a convex optimization problem is that the local minimum is the global minimum. Thus, convex reformulation of the problem and finding a local minimum of the reformulation will give the global minimum. If the actual model is nonconvex, then convexification leads to different approximations (or relaxations), which in turn may be useful in studying various bounds (lower and/or upper bound) of a given COP. Both penalty-based ANNs and Lagrange-based ANNs can be convexified. Convexification of COPs using penalty function depends upon the type of penalty function. Thus, it will not be discussed in this subsection. Nevertheless, convexification of Lagrange-based ANNs will be discussed. From the [Theorem 15](#), it can be seen that the local convexity of Lagrange systems is hard to obtain in practice. However, an augmented Lagrange method can be used to convexify any Lagrange-based ANN. In this subsection, one of the convexification methods that can be used for Lagrange-based ANN is presented. Let us assume that problem [Eq.\(74\)](#) is nonconvex, then its augmented Lagrange can be written as

$$L_{\text{Aug}}(\mathbf{x}, \boldsymbol{\lambda}) = f(\mathbf{x}) + \boldsymbol{\lambda}^T h(\mathbf{x}) + \frac{1}{2}c|h(\mathbf{x})|^2 \quad (103)$$

Using [Eq.\(103\)](#), different ANNs can be designed which are known as Augmented Lagrange Neural Networks (ALNN). The state equations can be obtained as

$$\frac{dx_i}{dt} = -\frac{\partial f}{\partial x_i} - \sum_{j=1}^m (\lambda_j + ch_j) \frac{\partial h_j}{\partial x_i} \quad \forall i = 1, \dots, n \quad (104)$$

$$\frac{d\lambda_j}{dt} = h_j, \quad \forall j = 1, \dots, m \quad (105)$$

By selecting a sufficiently large value of c , the local convexity for any Lagrange neural networks can be obtained under some restrictions (see [13]). However, due to analog circuit and implementing restrictions, the selection of c will become a critical issue [139].

4.4 Hybridization

ANNs have been coupled with metaheuristics like simulated annealing [103, 123–125], tabu search [43], and evolutionary algorithm [102, 126] for solving COPs. The main purpose of these hybridizations is to find the global optimal solution, by adding flexibility to the classical H-T's model. The usual method of coupling H-T's model with a metaheuristic is to incorporate the constraint handling technique of the ANNs in the global search technique of the metaheuristic.

Moreover, there has been research to hybridize H-T's model with SONNs (see [108]). One of the successful implementations is illustrated by Smith et al. [109]. The experimental result from the illustration indicates that a careful and appropriate hybridization of H-T's model with SONNs will result in a better solution methodology, which can be competitive to the state-of-the art optimization solvers.

5 General Optimization Problems

In this section, a discussion on applying ANNs to some of general optimization problems will be presented. For the sake of simplicity and convenience, following general optimization problem will be considered:

- Linear programming problems
- Convex programming problems
- Quadratic programming problems
- Nonlinear programming problems
- Complementarity problems
- Mixed integer programming problem

The objective of selecting mixed integer programming problem is to highlight the reader, the method of transformation between discrete and continuous variables, when applying ANNs.

5.1 Linear Programming

Linear programming (LP) is the most widely used optimization technique for solving numerous optimization problems. Dantzig [30], the father of linear programming, proposed the famous and widely used simplex method to solve LP problems. However, simplex method has an exponential complexity. A polynomial time algorithm (ellipsoid method) for solving LP problems was presented by Khachiyan [68]. Although the ellipsoid method is polynomial time algorithm, in practice simplex

outperforms ellipsoid method. Later, in 1984, Karmarkar [66] proposed a more efficient algorithm than ellipsoid method, and it outperforms simplex method in few complicated problems like scheduling, routing, and planning. Based on the solution methodology, the simplex method is categorized as exterior point method, whereas Karmarkar's algorithm is categorized as interior point method. Further studies [122] on the classification of these two fundamentally different ideas lead to a conclusion that LP problems are finite in nature. Moreover, simplex method is a finite algorithm suitable to solve LP problems. However, it was also noted that sometimes, infinite algorithms like interior point method may outperform exterior point algorithms. Thus, there has been always a curiosity among researchers to investigate the infinite algorithms. ANNs approach in solving COPs can be seen as an infinite approach.

From the demonstration of Hopfield and Tank [58], ANNs were seen as an alternative solution approaches to solve the COPs. Many studies have been conducted to solve LP problems using ANNs [25–28, 35, 67, 100, 136]. Most of these models were extensions of H-T's continuous model. As noted in Sect. 2.7, these models will have an energy function-based model for minimization. Before presenting the models, consider the following notations for LP problem in canonical LP_c and standard LP_s form:

LP_c

minimize :

$$c^T x$$

subject to :

$$g_i(x) \geq 0 \quad \forall i = 1, \dots, m$$

LP_s

minimize :

$$\tilde{c}^T x$$

subject to :

$$\tilde{g}_i(x) = 0 \quad \forall i = 1, \dots, m$$

Following are the prominent models from the literature.

5.1.1 Kennedy and Chua's Model

Kennedy and Chua's [67] model has neurons similar to the H-T's continuous model. The external states of this model are represented by x . The equations of updates for states and energy function are given as

$$\begin{aligned} \nabla x &= C^{-1}(-c - \nabla g(x) \phi(g(x))) \\ E(x(t)) &= c^T x + \sum_{j=1}^m \int_0^{g_j(x)} \phi_j(s) ds \end{aligned}$$

where C is a matrix of capacitance and is usually taken as I for most of the cases. Kennedy and Chua showed that Tank and Hopfield's model is a special case of the proposed model. Furthermore, they proved that their model will converge to a steady state, under the assumption that E is bounded from below. Selection of $\phi()$ is similar to that of a penalty function. In [80], it was shown that $\phi()$ is indeed

an implicit form of the penalty function. The most widely used representation of $\phi()$ is $s \cdot g_i^-(\mathbf{x})$, where $s > 0$ is the penalty weight. Moreover, $g_i^-(\mathbf{x})$ is same as $-\min\{g_i(\mathbf{x}), 0\}$. Based on the idea of applying penalty function, there were many extension of neural networks for LP. Some of the prominent extensions can be seen in [100, 138]. These prominent extensions will be presented in the following part of this section.

5.1.2 Rodriquez-Vazquez et al. Model

Rodriquez-Vazquez et al. [100] proposed another model for LP. This model is described as

$$\nabla \mathbf{x} = -u(\mathbf{x})\mathbf{c} - s(1 - u(\mathbf{x}))\nabla \mathbf{g}(\mathbf{x})\mathbf{v}(\mathbf{x})$$

where $\mathbf{v}(\mathbf{x}) = [v_1, \dots, v_m]^T$,

$$u(\mathbf{x}) = \begin{cases} 1 & \text{if } g_j(\mathbf{x}) \geq 0 \quad \forall j = 1, \dots, m, \\ 0 & \text{otherwise} \end{cases}$$

$$v_j(\mathbf{x}) = \begin{cases} 1 & \text{if } g_j(\mathbf{x}) \geq 0 \\ 0 & \text{otherwise} \end{cases}$$

and $s > 0$. This model can be viewed as a dynamic system, which can start from any arbitrary point. Initially, the model will move from an infeasible point to a feasible point. Once a feasible point is obtained, the model will try to move to an optimal point. In [45], the convergence analysis of Rodriquez-Vazquez et al. [100] model was performed. It was shown that if the problem is convex, network will converge. However, Zak et al. [138] proposed that discrete time implementation of Rodriquez-Vazquez et al. model with an adaptive step size may have problem in reaching feasible region. In the following paragraph, the model proposed by Zak et al. will be presented.

5.1.3 Zak et al. Model

This model differs from the earlier ANNs for the LP, as Zak et al. used the exact penalty function (non-differentiable) to formulate the energy function. This selection of penalty function eliminates the selection of very high penalty weight. Apart from that, all the earlier models were proposed for the canonical representation of LP. However, this model is applicable for both standard and canonical representation of LP. Although, in the theory, there is no difference in solving the problem in any representation. But in the case of neural networks, changing from one representation to other will increase in the number of neurons (due to slack or artificial variables) and may increase in the complexity of the ANN model. The proposed model can be described as

$$\nabla \mathbf{x} = -\nabla \mathbf{E}_{p,\rho,\gamma}(\mathbf{x})$$

$$\nabla \mathbf{E}_{p,\rho,\gamma}(\mathbf{x}) = \tilde{\mathbf{c}}^T \mathbf{x} + \rho \nabla \|\tilde{\mathbf{g}}(\mathbf{x})\|_p + \gamma \nabla \left(\sum_{i=1}^m x_i^- \right)$$

where $x_i^- = -\min\{x_i, 0\}$, $\rho > 0$, $\gamma > 0$, $1 \leq p \leq \infty$. Although the model uses exact penalty function, this penalty function is also non-differentiable and hence has few drawbacks. In [137], convergence analysis of Zak et al.'s model is performed. It was shown that the system trajectory will converge to the solution of LP under some positivity restriction on ρ , γ , p . In fact, it is shown that equilibrium points of the ANN are solutions to the corresponding LP problem [137].

These are some of the prominent models of ANNs applied to solve LP problems. Similar to the duality theory in LP, there were attempts to solve LP using dual ANNs. Interested reader may refer to [29, 81].

5.2 Convex Programming

Consider the following convex problem:

minimize :

$$f(\mathbf{x})$$

subject to :

$$g_i(\mathbf{x}) = 0 \quad \forall i = 1 \dots m$$

$$\mathbf{x} \in \mathbf{X} \tag{106}$$

where $f(\mathbf{x}), g_i(\mathbf{x}) : \mathbb{R}^n \mapsto \mathbb{R}$ are any convex functions of \mathbf{x} . In order to apply ANNs to solve this problem, the problem is reformulated into unconstrained optimization problem using penalty function. Let $\Phi()$ be the penalty function which has the following properties:

$$\Phi(\mathbf{x}) \begin{cases} = 0 & \text{if } \mathbf{x} \text{ is feasible} \\ > 0 & \text{otherwise} \end{cases} \tag{107}$$

Then, consider the following transformed convex problem:

minimize :

$$\mathbf{E}(\mathbf{x}, s)$$

subject to :

$$\mathbf{x} \in \mathbf{X}$$

where $E(\mathbf{x}, s) = f(\mathbf{x}) + s \sum_{i=1}^m \Phi(g_i(\mathbf{x}))$.

The update equation is

$$\nabla \mathbf{x} = -\eta \nabla \mathbf{E}(\mathbf{x}, s) \quad (108)$$

$$\nabla \mathbf{E}(\mathbf{x}, s) = \nabla f(\mathbf{x}) + s \sum_{i=1}^m \phi(g_i(\mathbf{x})) \nabla g_i(\mathbf{x})$$

The stability and convergence analysis of this model has been performed in [22]. It has been shown that dynamics given by Eq. (108) leads to an equilibrium point.

5.3 Quadratic Programming

Similar to the linear programming, quadratic programming problems can be modeled using ANNs. Consider the following quadratic programming problem:

minimize :

$$\mathbf{x}^T H \mathbf{x} + c^T \mathbf{x}$$

subject to :

$$A \mathbf{x} = \mathbf{b}$$

$$\mathbf{x} \in \mathbf{X} \quad (109)$$

where $\mathbf{x} \in \mathbb{R}^n$, $A, H \in \mathbb{R}^{n \times n}$. This program can be converted to an unconstrained problem using a penalty function method or a Lagrange method. A Lagrange method will be presented in the following part of this section. The Lagrange of problem Eq. (109) is written as

$$L(\mathbf{x}, \boldsymbol{\lambda}) = \mathbf{x}^T H \mathbf{x} + c^T \mathbf{x} + \boldsymbol{\lambda}^T (A \mathbf{x} - \mathbf{b}) \quad (110)$$

The equations of motion that describe this model are

$$\nabla_t \mathbf{x} = -\nabla_x L(\mathbf{x}, \boldsymbol{\lambda}) \quad (111)$$

$$\nabla_t \boldsymbol{\lambda} = -\nabla_{\boldsymbol{\lambda}} L(\mathbf{x}, \boldsymbol{\lambda}) \quad (112)$$

where

$$\nabla_t \mathbf{x} = \left(\frac{dx_1}{dt}, \frac{dx_2}{dt}, \dots, \frac{dx_n}{dt} \right)^T, \quad x \in \mathbb{R}^n$$

$$\nabla_t \boldsymbol{\lambda} = \left(\frac{d\lambda_1}{dt}, \frac{d\lambda_2}{dt}, \dots, \frac{d\lambda_m}{dt} \right)^T, \quad \lambda \in \mathbb{R}^m$$

$$\nabla_x L(\mathbf{x}, \boldsymbol{\lambda}) = \left(\frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial x_1}, \frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial x_2}, \dots, \frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial x_n} \right)^T$$

and

$$\nabla_{\lambda} L(\mathbf{x}, \boldsymbol{\lambda}) = \left(\frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial \lambda_1}, \frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial \lambda_2}, \dots, \frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial \lambda_m} \right)^T$$

The above model is iterative Lagrangian neural network. The convergence analysis of this model is presented in Sect. 3 and in [139]. Apart from that, quadratic programming problems with ANNs have been exhaustively studied in [39, 80, 134, 135].

5.4 Nonlinear Programming

Similar to the quadratic and convex programming, general nonlinear programming problems can be solved using ANNs. One of the ways is to use a penalty method approach [67]. Another approach is based on the Lagrange method, presented by Zhang and Constantinides [139]. The main differences with penalty function method and the advantages of Lagrange methods are discussed in Sect. 3 of this chapter. In the following part of this subsection, the method of writing a Lagrange for any generalized nonlinear problem will be presented.

minimize :

$$f(\mathbf{x})$$

subject to :

$$h_i(\mathbf{x}) = 0 \quad \forall i = 1 \dots m$$

$$\mathbf{x} \in \mathbb{R}^n \tag{113}$$

where $f(\mathbf{x}), h_i(\mathbf{x}) : \mathbb{R}^n \mapsto \mathbb{R}$ are any continuous and twice differentiable functions of \mathbf{x} . The Lagrange of the above COP is written as

$$L(\mathbf{x}, \boldsymbol{\lambda}) = f(\mathbf{x}) + \boldsymbol{\lambda}^T h(\mathbf{x}) \tag{114}$$

The equations of motion that describes this model are

$$\nabla_t \mathbf{x} = -\nabla_x L(\mathbf{x}, \boldsymbol{\lambda}) \tag{115}$$

$$\nabla_t \boldsymbol{\lambda} = -\nabla_{\lambda} L(\mathbf{x}, \boldsymbol{\lambda}) \tag{116}$$

where

$$\nabla_t \mathbf{x} = \left(\frac{dx_1}{dt}, \frac{dx_2}{dt}, \dots, \frac{dx_n}{dt} \right)^T, \mathbf{x} \in \mathbb{R}^n$$

$$\nabla_t \boldsymbol{\lambda} = \left(\frac{d\lambda_1}{dt}, \frac{d\lambda_2}{dt}, \dots, \frac{d\lambda_m}{dt} \right)^T, \lambda \in \mathbb{R}^m$$

$$\nabla_x L(\mathbf{x}, \boldsymbol{\lambda}) = \left(\frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial x_1}, \frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial x_2}, \dots, \frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial x_n} \right)^T$$

and

$$\nabla_{\boldsymbol{\lambda}} L(\mathbf{x}, \boldsymbol{\lambda}) = \left(\frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial \lambda_1}, \frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial \lambda_2}, \dots, \frac{\partial L(\mathbf{x}, \boldsymbol{\lambda})}{\partial \lambda_m} \right)^T$$

The above model is iterative, similar to that of H-T's continuous model. Both the types of neuron are decision variables. Lagrangian variables tend to take the solution to a feasible space, whereas the ordinary variables will take the solution to an optimal value. The mathematical properties and proofs related to convergence of this model have been discussed in [Sect. 3](#).

5.5 Complementarity Problem

5.5.1 Linear Complementarity Problem (LCP)

Given a matrix $M \in \mathbb{R}^{n \times N}$ and a vector $\mathbf{q} \in \mathbb{R}^n$, the LCP can be stated as:

find :

\mathbf{x}

subject to :

$$M\mathbf{x} + \mathbf{q} \geq 0$$

$$x^T(M\mathbf{x} + \mathbf{q}) = 0$$

$$\mathbf{x} \geq 0 \quad (117)$$

where $x \in \mathbb{R}^n$. This problem can be solved by ANNs, by converting it to a nonlinear problem by using Fischer function. Let $\phi(a, b)$ be the Fischer function, defined as $\phi(a, b) = \sqrt{a^2 + b^2} - a - b$. The purpose of using this function is that it has an important property, which can be stated as

$$\phi(a, b) = 0 \Leftrightarrow a \geq 0, b \geq 0 \text{ and } ab = 0 \quad (118)$$

Thus, this property is exploited while solving LCP using ANN. The above property mimics the LCP, which can be represented as

$$\phi_i(x_i, F_i(\mathbf{x})) = 0 \quad \forall i \quad (119)$$

where $F_i(\mathbf{x}) = x_i(M\mathbf{x} + \mathbf{q})_i$. Let $\Phi(\mathbf{x})$ represent a vector, where the i th element is $\phi_i(x_i, F_i(\mathbf{x}))$. Then, solving LCP is same as solving the following problem:

$$\begin{aligned} & \text{minimize :} \\ & F(\mathbf{x}) \end{aligned} \tag{120}$$

where

$$F(\mathbf{x}) = \frac{1}{2} \|\Phi(\mathbf{x})\|^2 \tag{121}$$

Now, the above problem can be solved by ANNs as a quadratic programming problem, using either a H-T's model or Lagrange model.

5.5.2 Nonlinear Complementarity Problem (NCP)

Given a set of functions $F_i : \mathbb{R}^n \mapsto \mathbb{R}^n$, $\forall i = 1, \dots, n$, the NCP can be stated as

find :

\mathbf{x}

subject to :

$$F_i(\mathbf{x}) \geq 0$$

$$x_i F(\mathbf{x}) = 0$$

$$\mathbf{x} \geq 0$$

(122)

where $x \in \mathbb{R}^n$ and F_i is assumed to be continuously differentiable function. ANNs can be used to solve NCP by using the idea of Fischer function [75]. Similar to the LCP case, define a vector $\Phi(\mathbf{x})$, where each i th element is represented by

$$\phi_i(x_i, F_i(\mathbf{x})) = 0 \quad \forall i \tag{123}$$

Thus, solving NCP is same as solving the following problem:

$$\begin{aligned} & \text{minimize :} \\ & E(\mathbf{x}) \end{aligned} \tag{124}$$

where

$$E(\mathbf{x}) = \frac{1}{2} \|\Phi(\mathbf{x})\|^2 \tag{125}$$

Now, this above problem can be solved by ANNs using a Lagrange model.

5.6 Mixed Integer Programming Problems (MIPs)

The difficulty in solving any optimization problems is not due to the nonlinear (or discrete) representation of the problem. The criteria that separate

difficult and easy problems are the convexity of the problem. A convex problem in a linear or nonlinear representation is tractable, whereas a nonconvex problem in any representation is difficult to solve. By presenting the example of a general MIPs, we would like to highlight the thin line that separates a continuous optimization problem from a discrete optimization problem while applying ANNs.

Consider the following MIPs defined as

minimize :

$$f(\mathbf{x}, \mathbf{y})$$

subject to :

$$g_i(\mathbf{x}, \mathbf{y}) \leq 0 \quad \forall i = 1, \dots, m$$

$$h_j(\mathbf{x}, \mathbf{y}) = 0 \quad \forall j = 1, \dots, p$$

$$l_k \leq x_k \leq u_k \quad \forall k = 1, \dots, n$$

$$y_r \in \{0, 1\} \quad \forall r = 1, \dots, q \quad (126)$$

Similar to any previous approaches, this problem can be converted to unconstrained optimization problem using either a penalty function or a Lagrange function. For the sake of completeness, both approaches are illustrated in the following part of this subsection.

5.6.1 Penalty Function Approach

The modified (penalized) energy function for problem Eq. (126) can be written as

$$\begin{aligned} E_{\text{mip}}(\mathbf{x}, \mathbf{y}) &= C_1 f(\mathbf{x}, \mathbf{y}) + C_2 \sum_{i=1}^m \Phi[g_i(\mathbf{x}, \mathbf{y})] \\ &\quad + C_3 \sum_{j=1}^p h_j^2(\mathbf{x}, \mathbf{y}) + C_4 \sum_{r=1}^q y_r(1 - y_r) \end{aligned} \quad (127)$$

where C_1 , C_2 , C_3 , and C_4 are scaling constants, used as the penalty parameters. Φ is the penalty function. The dynamics of the network defined by Eq. (127) can be described as

$$\frac{d\mathcal{I}_k^x}{dt} = -\eta_x \frac{\partial E_{\text{mip}}}{\partial x_k} \quad \forall k = 1, \dots, n \quad (128)$$

$$\frac{d\mathcal{I}_r^y}{dt} = -\eta_y \frac{\partial E_{\text{mip}}}{\partial y_r} \quad \forall r = 1, \dots, q \quad (129)$$

$$x_k = \Psi_c(\mathcal{I}_k^x) \quad \forall k = 1, \dots, n \quad (130)$$

$$y_r = \Psi_d(\mathcal{I}_r^y) \quad \forall r = 1, \dots, q \quad (131)$$

where η_x and η_y are positive scaling coefficients for the dynamics of the system. In addition to that, Ψ_d can be replaced by the tuned Ψ_c that results in the discrete values of y_r .

5.6.2 Lagrange Function Approach

The Lagrange of problem Eq. (126) can be written as

$$\begin{aligned} L_{\text{mip}}(x, y, \mu, v^1, v^2) = & f(x, y) + \sum_{i=1}^m \mu_i g_i(x, y) \\ & + \sum_{j=1}^p v_j^1 h_j(x, y) + \sum_{r=1}^q v_r^2 y_r(1 - y_r) \end{aligned} \quad (132)$$

where $\mu_i \geq 0 \quad \forall i = 1 \dots m$ and $v_j^1, v_r^2 \in \mathbb{R} \quad \forall j = 1 \dots p$ and $\forall r = 1 \dots q$. Similar to penalty function approach, the system dynamics can be described as

$$\nabla_t \mathbf{x} = -\nabla_x L_{\text{mip}}(\mathbf{x}, \mathbf{y}, \boldsymbol{\mu}, \mathbf{v}^1, \mathbf{v}^2) \quad (133)$$

$$\nabla_t \mathbf{y} = -\nabla_y L_{\text{mip}}(\mathbf{x}, \mathbf{y}, \boldsymbol{\mu}, \mathbf{v}^1, \mathbf{v}^2) \quad (134)$$

$$\nabla_t v^1 = \nabla_{v^1} L_{\text{mip}}(\mathbf{x}, \mathbf{y}, \boldsymbol{\mu}, \mathbf{v}^1, \mathbf{v}^2) \quad (135)$$

$$\nabla_t v^2 = \nabla_{v^2} L_{\text{mip}}(\mathbf{x}, \mathbf{y}, \boldsymbol{\mu}, \mathbf{v}^1, \mathbf{v}^2) \quad (136)$$

$$\frac{d\mu_i}{dt} = \begin{cases} 0 & \text{for } \mu_i = 0 \text{ \& } \frac{\partial L_{\text{mip}}(\mathbf{x}, \mathbf{y}, \boldsymbol{\mu}, \mathbf{v}^1, \mathbf{v}^2)}{\partial \mu_i} < 0 \\ \frac{\partial L_{\text{mip}}(\mathbf{x}, \mathbf{y}, \boldsymbol{\mu}, \mathbf{v}^1, \mathbf{v}^2)}{\partial \mu_i} & \text{otherwise} \end{cases} \quad \forall i \quad (137)$$

In [127], penalty-based approach is applied to solve factory allocation problem, and to solve the unit commitment problem. Direct use of inequality constraints in Lagrange programming ANNs have been introduced in [61, 79]. In Eq. (137), a simple method of update for inequality constrained is illustrated from [79]. A primitive way to deal with the inequality constraints is to transform them into equality constraints. Another novel approach for direct usage of inequality constraints is to use the square of the Lagrange multiplier for the inequality constraints [61].

From this section, it should be clear that ANNs are not limited for solving either a linear or a quadratic programming problem. With development of penalty- and Lagrange-based methods for the ANNs, they can be applied to any typical optimization problem. With the ease of transformation from continuous to discrete variable space, they can be appropriately designed for any COPs. In the following section, some of the applications of ANNs in solving discrete optimization problems will be surveyed.

6 Discrete Optimization Problems

Discrete optimization problems find their application in the problems related to transportation, scheduling, sorting, networking, etc. In this section, various methods of mapping the discrete optimization problems to the ANNs will be presented.

6.1 Graph Problems

Graph problems are one of the extensively studied and applied problems in operations research. The goal of this subsection is to discuss these problems and their mapping onto ANNs [96].

6.1.1 Graph Partitioning Problem (GPP)

Problem Statement: Given a graph $G = (V, E)$, where V represents the vertices, $|V| = n$ and E represents the edges, $|E| = m$. Let w_i be the weight on each vertex. Let e_{ij} be the weight on the link connecting i th and j th vertices. The problem is to partition the graph into two partitions of nearly equal weights, such that the cut-size is minimized. In other words, the problem is to bisect the graph, such that the sum of weights of the vertices assigned to the partitions is nearly equal, while the sum of weights on the links connecting the partitions is minimum.

Solution Methodology: A continuous H-T's model was used to solve this Problem [9]. Let x_i represent the external state of the neuron, which can take any values between 0 and 1. All the neurons that have the value of 0 are assigned to the first partition. The others neurons, which have the value of 1, were assigned to the second partition. The objective function for GPP is given as

$$E_{\text{GPP}} = \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n e_{ij} (x_i + x_j - 2x_i x_j) + \sum_{i=1}^n \sum_{j=1}^n w_i w_j (1 - x_i - x_j + 2x_i x_j) \quad (138)$$

The first term of the objective function aims at minimizing the weighted sum of the edges which belong to the cut, whereas the second term of the objective function aims at balancing the weights in both the partitions. When the E_{GPP} is compared with E_c , the following values for the synaptic weights and the input bias are obtained:

$$W_{ij} = 2e_{ij} - 4w_i w_j \quad \text{and} \quad \theta_i = - \sum_{j=1}^n e_{ij} + 2w_i \sum_{j=1}^n w_j \quad (139)$$

Thus, the H-T's model is complete. The above system is solved to get the solution of GPP.

6.1.2 Graph K-Partitioning Problem (GKP)

Problem Statement: Given a graph $G = (V, E)$, where V represents the vertices, $|V| = n$ and E represents the edges, $|E| = m$. Let w_i be the weight on each vertex. Let e_{ij} be the weight on the link connecting i th and j th vertices. This problem is a generalized version of GPP, where the objective is to partition given graph with similar description as GPP into K partitions. In general, K is not the multiple of 2.

Solution Methodology: This problem can be formulated as an assignment problem, where each node is assigned to only one partition. Since there are K partitions and n nodes, there will be $N = nK$ number of variables. Since, in H-T's model, each variable represents a neuron, there will be altogether N neurons. Let x_{ij} be the external state of the neuron, which can take value between 0 and 1.

The objective function with penalty parameters is written as

$$\begin{aligned} E_{\text{GKP}} = & \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^K \sum_{k=1, k \neq j}^K x_{ij} x_{jk} + \frac{1}{2} \left(\sum_{i=1}^n \sum_{j=1}^K x_{ij} - n \right)^2 \\ & + \frac{1}{2} \sum_{i,j=1}^n \sum_{k,l=1}^K e_{ij} (x_{ik} + x_{jl} - 2x_{ik}x_{jl}) \\ & + \sum_{k=1}^K \sum_{i=1}^n \sum_{j=1}^n x_{ik} x_{jk} w_i w_j \end{aligned} \quad (140)$$

When the E_{GKP} is compared with E_d , the following values for the weights and input bias are obtained:

$$W_{ij,kl} = -\delta_{ij}(1 - \delta_{ij}) - 1 + 2e_{ij} - 2w_i w_j \quad \text{and} \quad \theta_i = +n - \sum_{j=1}^n e_{ij} \quad (141)$$

where $W_{ij,kl}$ is the synaptic weight between neuron ij ¹³ and neuron kl . Thus, with the above mapping, the H-T's model is complete. The above system is solved by using [Algorithm 1](#) to get the solution of GKP. A higher order ANNs for solving GKP was presented in [40].

6.1.3 Vertex Cover Problem (VCP)

Problem Definition: Given a graph $G = (V, E)$, where V represents the vertices, $|V| = n$ and E represents the edges, $|E| = m$. Let A be the adjacency matrix, where $a_{ij} = 1$ if there is an edge between i th and j th vertices, otherwise $a_{ij} = 0$. A subset C of the vertices V of the graph G is called the *vertex cover* if all the edges

¹³neuron ij corresponds to variable x_{ij}

of G are adjacent to at least one vertex in the set C . The VCP is to find the *vertex cover*, such that the cardinality of set C is minimum.

Solution Methodology: Let

$$x_i = \begin{cases} 1 & \text{if vertex } i \in C \\ 0 & \text{otherwise} \end{cases} \quad (142)$$

Since there are $|V| = n$ vertices in G , there will be n neurons used to design the model. The modified objective function designed for H-T's model will be

$$E_{\text{VCP}} = C_1 \left(\sum_{i=1}^n \sum_{j=1}^n x_i x_j \right) - \frac{C_2}{2} \left(\sum_{i=1}^n \sum_{j=1}^n (1 - x_i)(1 - x_j) a_{ij} \right) \quad (143)$$

where C_1 and C_2 are penalty terms whose values decide the relative importance of the constraints and the objective function. The first term in E_{VCP} ensures the minimality of the cover. The second term (is the penalty term) will be zero if the nodes which are not in the *vertex cover* have no edges between them. By comparing the coefficients of E_{VCP} and E_d , the synaptic weights and the input bias are obtained as

$$W_{ij} = -2C_1 - C_2 a_{ij} \quad \text{and} \quad \theta_i = C_2 \sum_{j=1}^n a_{ij} \quad (144)$$

Thus, with the above mapping, the H-T's model is complete. The above system is solved by using [Algorithm 1](#) to get the solution of GKP.

6.1.4 Maximum Independent Set Problem (MISP)

Problem Definition: Given a graph $G = (V, E)$, where V represents the vertices, $|V| = n$ and E represents the edges, $|E| = m$. Let A represent the adjacency matrix, where $a_{ij} = 1$ if there is an edge between i th and j th vertices, otherwise $a_{ij} = 0$. A subset I of the vertices V of the graph G is called the *independent set* if there is no edge between any pair of vertices which belong to I . The MISP is to find an *independent set* with the maximum cardinality.

Solution Methodology: Let

$$x_i = \begin{cases} 1 & \text{if vertex } i \in I \\ 0 & \text{otherwise} \end{cases} \quad (145)$$

Since there are $|V| = n$ vertices in G , there will be n neurons used to design the model. The modified objective function designed for H-T's model will be

$$E_{\text{MISP}} = -C_1 \left(\sum_{i=1}^n \sum_{j=1}^n x_i x_j \right) + \frac{C_2}{2} \left(\sum_{i=1}^n \sum_{j=1}^n x_i x_j a_{ij} \right) \quad (146)$$

where C_1 and C_2 are penalty terms whose values decide the relative importance of the constraints and the objective function. The first term in E_{MISP} minimizes cardinality of the set I . The second term will ensure that the set I forms an *independent set*. By comparing the coefficients of E_{MISP} and E_d , the synaptic weights and the input bias are obtained as

$$W_{ij} = 2C_1 - C_2 a_{ij} \quad \text{and} \quad \theta_i = 0 \quad (147)$$

Thus, with the above mapping, the H-T's model is complete. The above system is solved by using [Algorithm 1](#) to get the solution of MISP.

6.1.5 Maximum Clique Set Problem (MCSP)

Problem Definition: Given a graph $G = (V, E)$, where V represents the vertices, $|V| = n$ and E represents the edges, $|E| = m$. Let A represent the adjacency matrix, where $a_{ij} = 1$ if there is an edge between i th and j th vertices, otherwise $a_{ij} = 0$. A subset of the vertices V of the graph G is called *clique* if every pair of vertices in the subset is connected by an edge. The MCSP is to find a *clique* with the maximum cardinality.

Solution Methodology: Let

$$x_i = \begin{cases} 1 & \text{if vertex } i \in \text{clique} \\ 0 & \text{otherwise} \end{cases} \quad (148)$$

Since there are $|V| = n$ vertices in G , there will be n neurons used to design the model. Let $a_{ij}^c = 1 - a_{ij}$, then with this modification, MCSP will be same as MISP. The modified objective function designed for H-T's model will be

$$E_{\text{MCSP}} = -C_1 \left(\sum_{i=1}^n \sum_{j=1}^n x_i x_j \right) + \frac{C_2}{2} \left(\sum_{i=1}^n \sum_{j=1}^n x_i x_j a_{ij}^c \right) \quad (149)$$

where C_1 and C_2 are penalty terms whose values decide the relative importance of the constraints and the objective function. The first term in E_{MCSP} minimizes cardinality of the clique set. The second term will ensure that the selected set forms a clique. By comparing the coefficients of E_{MCSP} and E_d , the synaptic weights and the input bias are obtained as

$$W_{ij} = 2C_1 - C_2 a_{ij}^c \quad \text{and} \quad \theta_i = 0 \quad (150)$$

Thus, with the above mapping, the H-T's model is complete. The above system is solved by using [Algorithm 1](#) to get the solution of MCSP.

6.1.6 Graph Coloring Problem (GCP)

Problem Definition: Given a graph $G = (V, E)$, where V represents the vertices, $|V| = n$ and E represents the edges, $|E| = m$. Let A represent the adjacency matrix, where $a_{ij} = 1$ if there is an edge between i th and j th vertices, otherwise $a_{ij} = 0$. The GCP is to find the minimum number of subsets of V such that no two adjacent vertices (two vertices connected by an edge) belong to the same subset. In other words, find the minimum number of different colors needed to color the graph such that no two adjacent vertices are of the same color.

Solution Methodology: Let

$$x_{ij} = \begin{cases} 1 & \text{if vertex } i \text{ is colored in the color } j \\ 0 & \text{otherwise} \end{cases} \quad (151)$$

Since there are $|V| = n$ vertices in G , from the graph theory, the maximum number of different colors needed to color the graph will be one plus the maximum degree of any vertex. Let v represent the maximum number of different colors. Thus, there will be nv neurons used to design the model. The modified objective function designed for H-T's model will be

$$E_{\text{GCP}} = \frac{1}{2} \left(\sum_{k=1}^v \sum_{i=1}^n \sum_{j=1}^n x_{ik} x_{jk} a_{ij} \right) - \left(\sum_{k=1}^v \sum_{i=1}^n \sum_{j=1}^n x_{ik} x_{jk} \right) \quad (152)$$

By comparing the coefficients of E_{GCP} and E_d , the synaptic weights and the input bias are obtained as

$$W_{ij} = 1 - a_{ij}/2 \quad \text{and} \quad \theta_i = 0 \quad (153)$$

Thus, with the above mapping, the H-T's model is complete. The above system is solved by using [Algorithm 1](#) to get the solution of GCP.

6.1.7 Graph Matching Problem (GMP)

Problem Definition: Given a graph $G = (V, E)$, where V represents the vertices, $|V| = n$ and E represents the edges, $|E| = m$. Let B be the incidence matrix, where $b_{ij} = 1$ if j th edge is incident on i th vertex, otherwise $b_{ij} = 0$. A subset M of the edges E of the graph G is called *matching* if there are no two edges in M that share a common node. The GMP is to find a *matching* with the maximum cardinality.

Solution Methodology: Let

$$x_i = \begin{cases} 1 & \text{if edge } i \in M \\ 0 & \text{otherwise} \end{cases} \quad (154)$$

Since there are $|E| = m$ vertices in G , there will be m neurons used to design the model. The modified objective function designed for H-T's model will be

$$E_{\text{GMP}} = - \left(\sum_{i=1}^m x_i \right) + \left(\sum_{i=1}^m \sum_{j=1}^m x_i x_j \sum_{k=1}^n b_{ki} b_{kj} \right) \quad (155)$$

By comparing the coefficients of E_{GMP} and E_d , the synaptic weights and the input bias are obtained as

$$W_{ij} = -2 \sum_{k=1}^n b_{ki} b_{kj} \quad \text{and} \quad \theta_i = 1 \quad (156)$$

Thus, with the above mapping, the H-T's model is complete. The above system is solved by using [Algorithm 1](#) to get the solution of GMP.

6.2 Shortest Path Problems

Problem Description: Given a network $G = (V, E)$, where V represents the vertices or cities, $|V| = n$ and E represents the edges or paths, $|E| = m$. Let the distance between the cities be represented by a distance matrix D , where d_{ij} represents the distance between the i th city and the j th city. The problem is to find the shortest path between two given pair of cities. Let s be the origin and e be the destination.

Solution Methodology: Let

$$x_{ij} = \begin{cases} 1 & \text{if edge } (i, j) \text{ is in the path} \\ 0 & \text{otherwise} \end{cases} \quad (157)$$

Since there are n cities, there will be n neurons used to design the model. The modified objective function designed for H-T's model will be

$$E_{\text{SPP}}(t) = C_1 \left(\sum_{i=1}^n \sum_{j \neq i} d_{ij} \exp^{-t/\tau} x_{ij} \right) + \frac{C_2}{2} \sum_{i=1}^n \left(\sum_{k \neq i} x_{ik} - \sum_{l \neq i} x_{li} - \delta_{is} + \delta_{ie} \right) \quad (158)$$

By comparing the coefficients of E_{SPP} and E_c , the synaptic weights and input bias are obtained as

$$W_{ij} = 2 * C_2 \quad \text{and} \quad \theta_i = -2 * C_2 \quad (159)$$

Thus, with the above mapping, the H-T's model is complete. The above system is solved by using [Algorithm 2](#) to get the solution of SPP.

6.3 Number Partitioning Problems (NPP)

Problem Definition: Given a set of n numbers $a_1, a_2, \dots, a_n \in S$, partition the set S into two sets S_1 and S_2 such that the following cost function is minimized:

$$C(S_1, S_2) = \left| \sum_{i \in S_1} a_i - \sum_{i \in S_2} a_i \right| \quad (160)$$

Solution Methodology: Let

$$x_i = \begin{cases} 1 & \text{if edge } i \in S_2 \\ 0 & \text{if edge } i \in S_1 \end{cases} \quad (161)$$

Since there are n numbers, there will be n neurons used to design the model. The modified objective function designed for H-T's model will be

$$E_{\text{NPP}} = \left(\sum_{i=1}^n \sum_{j=1}^n (1 + 2x_i x_j - x_i - x_j) a_i a_j \right) \quad (162)$$

The term $(1 + 2x_i x_j - x_i - x_j)$ ensures that only numbers which belong to the same partition will contribute to the sum. By comparing the coefficients of E_{GMP} and E_d , the synaptic weights and input bias are obtained as

$$W_{ij} = -4a_i a_j \quad \text{and} \quad \theta_i = \sum_{i=1}^n a_i \quad (163)$$

Thus, with the above mapping, the Hopfield model is complete. The above system is solved by using [Algorithm 1](#) to get the solution of GMP.

6.4 Assignment Problems

Problem Definition: Given n entities, n cells, and the cost c_{ij} of assigning i th entity to j th cell. The linear assignment problem (LAP) is to assign each entity to one cell, such that the assignment cost is minimized.

Solution Methodology: Since there are n entities and n cells, there will be altogether n^2 neurons used for designing ANN. Let x_{ij} represent the external state of H-T's model. Let \mathcal{I}_{ij} represent the internal state of H-T's neuron, such that

$$x_{ij} = \begin{cases} 1 & \text{if entity } i \text{ is assigned to cell } j \\ 0 & \text{otherwise} \end{cases} \quad (164)$$

The dynamics of this system is given as

$$\frac{d\mathcal{I}_{ij}(t)}{dt} = -C_1 \sum_{k=1}^n v_{kj}(t) - C_1 \sum_{k=1}^n v_{ik}(t) + 2C_1 - C_2 c_{ij} \exp(-t/\tau) \quad (165)$$

$$x_{ij}(t) = f_{ij}(\mathcal{I}_{ij}(t)) \quad (166)$$

From the above equations, the weights and input bias of H-T's model are defined as

$$w_{ij} = \delta_{ij} 2C_1 + (1 - \delta_{ij})C_1 \quad \text{and} \quad \theta_{ij} = 2C_1 \quad (167)$$

Thus, with the above mapping, the H-T's model is complete. The above system is solved by using [Algorithm 2](#) to get the solution of LAP.

6.5 Sorting Problems

Problem Definition: Given n real numbers a_1, a_2, \dots, a_n , the problem is to order them in ascending, descending, or biotonic order (where both the ends have higher numbers).

This problem can be formulated as an assignment problem, that is, given n numbers that are to be assigned to n cells. The cost c_{ij} of assigning i th number to j th cell is given by $c_{ij} = a_i c_j$, where c_j is an arbitrary sequence of real numbers, which are selected based on the sense of sorting (ascending, descending, or biotonic).

Solution Methodology: Since there are n numbers and n cells, there will be altogether n^2 neurons used for designing ANN. Let x_{ij} represent the external state of H-T's continuous model. Let \mathcal{I}_{ij} represent the internal state of H-T's model such that

$$x_{ij} = \begin{cases} 1 & \text{if entity } i \text{ is assigned to cell } j \\ 0 & \text{otherwise} \end{cases} \quad (168)$$

The energy function and dynamics of this system are given as

$$\begin{aligned} E_{SP}(x(t), t) &= C_1 \left(\sum_{i=1}^n \sum_{j=1}^n a_i c_j \exp(-t/\tau) x_{ij} \right) \\ &\quad + \sum_{i=1}^n \frac{C_2^i}{2} \left(\sum_{j=1}^n x_{ij} - 1 \right)^2 \end{aligned}$$

$$+ \sum_{j=1}^n \frac{C_2^j}{2} \left(\sum_{i=1}^n x_{ij} - 1 \right)^2 \quad (169)$$

$$\begin{aligned} \frac{d\mathcal{I}_{ij}(t)}{dt} = & -C_2^j \sum_{k=1}^n v_{kj}(t) - C_2^i \sum_{k=1}^n v_{ik}(t) \\ & + C_2^j + C_2^i - C_1 a_i c_j \exp(-t/\tau) \end{aligned} \quad (170)$$

$$x_{ij}(t) = f_{ij}(\mathcal{I}_{ij}(t)) \quad (171)$$

From the above equations, the weights of H-T's model can be obtained as

$$w_{ij} = -\delta_{ij}(C_2^j + C_2^i) - (1 - \delta_{ij})C_2^i \quad \text{and} \quad \theta_{ij} = C_2^j + C_2^i \quad (172)$$

Thus, with the above mapping, the H-T's model is complete. The above system is solved by using [Algorithm 2](#) to get the solution of SPP.

6.6 Traveling Salesman Problems (TSP)

Problem Definition: Given n cities with the Euclidean distance between them, d_{ij} . A path that starts from a given city, passing through all the cities (without visiting a city twice), and returning to the first city is called a *tour*. The TSP problem can be defined as finding the shortest tour for the given cities.

Solution Methodology: In [Sect. 2](#), a detailed mapping of TSP onto H-T's model was shown. However, in this subsection, one of the improved TSP mappings [[119](#)] will be presented. This is the modification of H-T's approach, which can be described as

$$E_{\text{tsp}}^{\text{mod}} = E_{\text{tsp}} + E_{\text{cns}} + E_{\text{drv}} \quad (173)$$

where E_{tsp} is same as defined in [Eq. \(33\)](#),

$$E_{\text{cns}} = \frac{C1}{2} \sum_i \left(\sum_j x_{ij} - 1 \right)^2 + \frac{C2}{2} \sum_j \left(\sum_i x_{ij} - 1 \right)^2 \quad (174)$$

$$E_{\text{drv}} = \frac{C3}{2} \sum_i \sum_j x_{ij} (1 - x_{ij}) + \frac{C4}{2} \left(\frac{N^2}{4} - \sum_j \sum_i \left(x_{ij} - \frac{1}{2} \right)^2 \right) \quad (175)$$

and $C1$, $C2$, $C3$, and $C4$ are new penalty parameters that are used for scaling the respective penalty terms. E_{cns} represents a better way of mapping the TSP constraints, whereas E_{drv} represents the penalty that deflects the external state of the neurons to take the value of 0 or 1.

There are numerous COPs in the literature, and presenting ANNs model for each of them will be a cumbersome task. However, a similar approach (like the above models) can be followed for any discrete optimization problem. Moreover, the above mappings were based on H-T's model with penalty approach. As seen in Sect. 3, the capability of ANNs to solve COPs can be extended by using the Lagrange approach. Thus, any discrete optimization problem (linear or nonlinear) can be modeled using the techniques given in Sect. 5. In the following part of this section, a survey of some of the recent models in ANNs is cited.

A recent survey that presents the usage of ANNs in mathematical programming problems is conducted in [128]. Apart from the theoretical COPs, there has been many practical problems that have been mapped onto ANNs. For example, some of the recent applications of ANNs within the past 2 years are

- Resource allocation in wireless communication [17, 78]
- Scheduling in wireless sensors [105]
- Scheduling in packet radio networks [113]
- Scheduling via H-T's model [31]
- Scheduling in water pumps [49]
- Scheduling to minimize earliness and tardiness [8]
- Small-world nature of H-T's model [141]
- Constrained least absolute deviation problem [60]
- Hybrid approach with genetic algorithms [5]
- Hybrid approach with particle swarm optimization [33]
- Hybrid approach with ant colony optimization [129]
- Parameter setting for the GCP [118]
- Placement of electronic circuit problem [36]
- Edge detection in wood logs [95]
- Economic load dispatching problem [48]
- Hybrid routing algorithm [11]
- Data envelopment analysis [59]
- Water system management problem [120]
- Graphs isomorphism discernment problem [140]
- Nonlinear vector encoding problem [41]

7 Criticism

After the eye-catching implementation of applying ANNs in solving TSP, H-T's model caught the attention of many researchers [92]. However, this method had two drawbacks at that time. It has a lot of parameters to select, and it performs a gradient descent method while solving COPs. In [132], it was illustrated that H-T's model does not perform well. In fact, the results in [132] raised serious questions about the validity of this method. Thus, it drifted many researchers away from the use of ANNs in solving COPs. However, some of the researchers were inclined to improve the method proposed by Hopfield and Tank. One of the direction of improvements was to develop a method of optimally selecting the parameters in Hopfield and

Tank's energy function [37, 52, 65, 74, 117]. Recently, in [119], a systematic way of selecting optimal parameters for various TSP is presented. Apart from that, an enhanced method of mapping TSP onto an ANN is illustrated, and convergence and stability analysis is presented. From the results shown in [119], it can be concluded that by proper construction of energy function and by proper selection of parameters (penalty parameters), there can be a significant difference in the performance of ANNs while solving COPs.

Another direction of improvement in Hopfield and Tank's ANN was to free the algorithm from gradient descend method, that is, to avoid falling into the local minima. One of the methods, that was adopted by many researchers, was to modify Hopfield and Tank's objective function [4, 16]. However, some of the successful methods were to use hybrid techniques like convexification, improve choice of penalty function, and use hill-climbing techniques [123]. In [109], a novel approach that combines self-organizing neural networks and H-T's model is presented. Convergence of such networks is analyzed. The algorithm was tested on car-sequencing problem. From the results, it was concluded that hybrid method of ANN is better than MINOS¹⁴ solver. The results from this study showed that proper application of ANNs to solve COPs will prove better than the conventional solution methods of COPs.

Moreover, there were many stochastic and metaheuristic methods that were incorporated in H-T's model. Some of the studies showed that global convergence can be obtained with ANNs if they are properly coupled with metaheuristic methods like simulated annealing [91]. Apart from that, sophisticated penalty methods and Lagrange methods made the use of ANNs more general (i.e., not only applied to linear and quadratic but can be applied to any nonlinear optimization problems). Among the use of penalty methods, in [6, 42], subspace and hyperplane approaches were used. These were the pioneer approaches that modified the use of penalty function, by incorporating the feasibility issues of the system into a single penalty parameter. In [43], the capability of ANNs were demonstrated based on polyhedral combinatorics. It was one of the novel methods in ANNs that proposed the use of memory (like tabu search) to overcome the entrapment of algorithm at the polyhedral vertices. However, not many studies have actually tried to compare performance of ANNs with other conventional or heuristic methods for solving COPs. Thus, it is very hard to conclude if ANNs perform better or worse than other methods. Apart from that, most of the implementations were simulations of ANNs on the digital computers. Thus, the computing limitations of digital computer may hinder the performance of ANNs. Nevertheless, it should be noted that ANNs can overcome the limitations of digital computers since they can be implemented on the analog circuits.

¹⁴A standard nonlinear programming problem solver

8 Conclusion

In this chapter, a simple and brief introduction of ANNs is presented, which is followed by addressing the usage of ANNs in solving COPs. Our focus throughout this chapter was not only to highlight the application of ANNs in solving COPs but also to present the theoretical aspects of ANNs in solving COPs. At the beginning of this chapter, some of the classical ANN models that were used in solving COPs were illustrated. Along with these illustration, a methodology of implementing an LP to analog circuit is depicted. Moreover, a detail method of mapping TSP on one of the classical ANNs is presented. In addition to that, some of the stability and convergence analysis of ANNs is studied. Lastly, examples from literature on solving general optimization problems and discrete optimization problems using ANNs were presented.

It can be seen that unlike other metaheuristics, based on appropriate conditions, ANNs do converge to local and/or global optima. Simple methods that are used to define such optimality conditions were shown with proofs in Sect. 3 of this chapter. The aim in presenting these proofs was to highlight the importance of selecting proper energy function and the type of dynamics (i.e., consecutive, parallel, or synchronous). Apart from that, methods to extend the classical models (which can solve only linear or quadratic problems) by using penalty functions, Lagrange functions, or hybrid approaches were presented. Through various illustration, it was shown that a continuous model can be used to solve discrete problem very easily. It was underlined that the only change in solving a discrete problem and continuous problem is the adjustment in the transfer function and the adjustment in the energy function for the discrete variables.

Since the first implementation of ANN in 1980s until the present, there are handful analog implementations of ANNs in solving COPs. Due to the limitations of performance comparison of ANNs with other solution procedures, a concrete conclusion regarding the advantage or disadvantage of ANNs in solving COPs cannot be presented at this point. However, proper implementation of the analog circuit and systematic study in deployment of these circuits to solve real world problems will demonstrate the true potential of ANN.

Abstract

Graph coloring is an important branch in graph theory, since it has come from the famous Four-Color Problem and is of many applications in time tabling, sequencing, scheduling, coding, frequency channel assignment, and other practical problems. Since this area includes quite a number of subjects and there exist too many interesting problems, only several interested subjects are selected in this chapter. An introduction of concepts and symbols on graph coloring is given in Sect. 1. Section 2 is devoted to discussing the classical vertex-coloring problem, involving the general upper bound of the vertex chromatic number, and the colorability and choosability of planar graphs and graphs embeddable in a surface. Section 3 investigates the acyclic vertex coloring and acyclic edge coloring of graphs as well as various generalizations such as star coloring, linear coloring, and acyclic improper coloring. Section 4 focus on some recent progresses on vertex-distinguishing edge-weighting problems. Two types of edge-weighting, that is, proper edge-weighting and non-proper edge-weighting, are mentioned respectively. The $L(p, q)$ -labeling problem of graphs will be finally investigated in Sect. 5, including the $L(2, 1)$ -labeling, the coloring of the square of a graph, the injective coloring, the backbone coloring, and the $(d, 1)$ -total labeling. In each section, a somewhat detailed survey on the recent advance of the related direction and some open problems are provided.

1 Introduction

Many real-world situations can conveniently be described by means of a diagram consisting of a set of points together with lines connecting certain pairs of these points. For example, the points may represent people, with lines connecting pairs of friends, or the points may be communication centers, with lines representing communication links. Notice that in such diagrams, one is mainly interested in whether two given points are connected by a line; the manner in which they are connected is immaterial. A mathematical abstraction of situations of this type gives rise to the graph concept. The basic concepts of graph theory are simple and can be used to express problems from many different subjects.

Graph coloring is an important branch in graph theory. It has a central position in discrete mathematics and is of interest for its applications. Graph coloring deals with the fundamental problem of partitioning a set of objects into classes, according to certain rules. Time tabling, sequencing, and scheduling problems, in their many forms, are basically of this nature.

Most of graph coloring problems come from the famous Four-Color Problem which states that any map in a plane can be colored using four colors in such a way that regions sharing a common boundary (other than a single point) have distinct colors. This was a question which Francis Guthrie asked his brother Frederick Guthrie, who was a student of De Morgan in mathematics. In 1878, the Four-Color

Problem was formally declared by Cayley in Mathematics Conference in London, and thus, it received much attention. A proposed solution by Kempe [224] in 1879 stood for more than a decade until it was refuted by Heawood [187] in 1890 in his first paper. In 1976, the Four-Color Problem was proved by Appel and Haken [27] using computer. The proof was based on the same basic idea as Kempe's proof, that is, to find a set of unavoidable and reducible configurations. Since then, the Four-Color Problem has been changed into the Four-Color Theorem.

In this chapter, some coloring problems of graphs are studied. The organization is as follows. Firstly, an introduction of graph coloring and planar graphs in the rest of this section is given. Then, Sect. 2 is devoted to presenting some general upper bounds on chromatic number of graphs. In particular, the coloring problems of graphs that are embeddable in a surface are also considered in this section. Section 3 is concerned with the study of acyclic coloring and acyclic edge coloring of graphs. One interesting problem is to prove or disprove the Acyclic Edge-Coloring Conjecture, which has attracted considerable much attention in recent years. Some positive evidences about this challenging conjecture are collected. Moreover, some related colorings such as star coloring, linear coloring, frugal coloring, and improper coloring are also discussed in this section. Section 4 focuses on some recent progresses on vertex-distinguishing edge-weighting problems. Two types of edge-weightings, that is, proper edge-weighting and non-proper edge-weighting, are the main topics in this section. Finally, $L(p, q)$ -labeling problem of graphs is discussed in Sect. 5. Several well-known conjectures such as Griggs and Yeh's Conjecture, Wegner's Conjecture, and Havet and Yu's Conjecture are mentioned.

Simple graphs with n vertices, m edges, maximum degree Δ , minimum degree δ , clique number $\omega(G)$, and girth $g(G)$ (i.e., the length of a shortest cycle in G) are considered throughout this chapter. For all graph theoretic concepts, definitions, symbols, and graph classes inclusions not given in this chapter are referred either to [126] or the related references.

1.1 Definitions

A *vertex k -coloring* of a graph G is an assignment π of integers $1, 2, \dots, k$ (as colors) to the vertices of G . The coloring π is said to be *proper* if $\pi(u) \neq \pi(v)$ for any pair of adjacent vertices u and v of G . Obviously, in a proper vertex coloring, each color class induces an *independent* set of vertices; that is, no two of them are joined by an edge. The *chromatic number*, denoted by $\chi(G)$, is the least integer k such that G has a proper k -coloring. The graph G is called *k -chromatic* if $\chi(G) = k$.

A *t -improper k -coloring* of a graph G (sometimes called generalized, defective, or relaxed coloring) or simply a $(k, t)^*$ -coloring is a k -coloring of G in which every color class has a bounded degree t . The *t -improper chromatic number* of G is therefore defined as the smallest integer k such that G is $(k, t)^*$ -colorable. Notice that 0-improper coloring corresponds to the ordinary notion of proper coloring.

So a $(k, 0)^*$ -coloring of G is a proper k -coloring of G , and the 0-improper chromatic number of G is the chromatic number of G .

The smallest integer k , such that the edges of a graph G can be colored with k colors in such a way that any two adjacent edges have distinct colors, is called the *chromatic index* or *edge chromatic number* of G , denoted by $\chi'(G)$. Such a coloring is called a *proper edge-coloring* of G . Note that $\chi'(G) = \chi(L(G))$, where $L(G)$ denotes the line graph of a graph G .

L is called an *assignment* for the graph G if it assigns a list $L(v)$ of possible colors to each vertex v of G . If G has a proper coloring π such that $\pi(v) \in L(v)$ for all vertices v , then G is *L -colorable* or π is called an *L -coloring* of G . The graph G is *k -choosable* (or *list k -colorable*) if it is L -colorable for every assignment L satisfying $|L(v)| \geq k$ for all vertices v . The *list chromatic number* of G , denoted $\chi^l(G)$, is the smallest integer k such that G is k -choosable.

The concept of list coloring was introduced by both Vizing [341] in 1976 and Erdős et al. [140] in 1979. Note that $\chi^l(G) \geq \chi(G)$, and $\chi^l(G)$ can be arbitrarily larger than $\chi(G)$.

1.2 Planar Graphs and Basic Known Facts

A graph G is *planar* if it has a drawing without crossings in the plane. Such a drawing is a *planar embedding* of G . A *plane graph* is a particular embedding of a planar graph. A planar embedding of a graph G cuts the plane into a number of arcwise-connected open sets. These sets are called the *faces* of G , denoted by $F(G)$. Each plane graph has exactly one unbounded face, called the *outer face* and others called *internal faces*. The *dual graph* G^* of a plane graph G is a plane graph whose vertices correspond to the faces of G . Two vertices in G^* are adjacent if the corresponding faces in G are adjacent.

The next lemma may be regarded as a dual version of the Handshake Lemma.

Lemma 1 *If G is a plane graph with m edges, then*

$$\sum_{f \in F(G)} d(f) = 2m.$$

There is a celebrated formula relating the numbers of vertices, edges, and faces in a connected plane graph. It was first established for polyhedral graphs by Euler in 1752 and is known as Euler's formula, which plays a key role in the proof of results on planar graphs that use the powerful discharging method.

Theorem 1 (Euler's Formula) *Let G be a connected plane graph with n vertices, m edges, and f faces. Then*

$$n - m + f = 2. \quad (1)$$

Corollary 1 can be easily obtained by the Euler's formula.

Corollary 1 *If G is a planar graph with girth $g \geq 3$ and order $n \geq 3$, then*

$$m \leq \frac{g}{g-2}(n-2). \quad (2)$$

In particular, if G is a simple connected planar graph, then

$$m \leq 3n - 6. \quad (3)$$

The most elegant result about planar graphs should be the Kuratowski's Theorem [242] which characterizes completely planar graphs in terms of forbidden subgraphs. The first relatively simple proof on this theorem was published in 1954 by Dirac and Schuster [130]. Other alternative proofs can be seen in [266, 326, 327].

A *subdivision* of a graph G is obtained by replacing each edge of G with a path. A k -*subdivision* of G is such that any path replacing an edge of G has at most k internal vertices.

Theorem 2 (Kuratowski's Theorem) *A graph is planar if and only if it does not contain a subdivision of K_5 or $K_{3,3}$ as a subgraph.*

2 Classical Vertex Coloring

The problem of the classical vertex coloring of graphs is considered in this section. Some important results and recent progresses in this direction will be surveyed. Usually, the coloring considered in this section is proper unless otherwise stated.

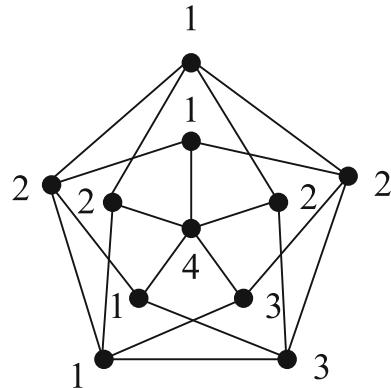

2.1 General Upper Bounds

Classical graph coloring or, more precisely, the task of finding an optimal proper vertex coloring, is an NP-hard problem [159]. Indeed, this type of problem still remains NP-hard even in spite of strong restrictions imposed on the class of graphs which are taken into consideration and on the number of colors used. Recently, a proof of the NP-hardness of 4-coloring of tripartite graphs was presented in [225]. Furthermore, the problem of determining whether a given planar graph with a degree not exceeding 4 is 3-colorable is also NP-hard [160]. In order to determine a simple bound on the graph chromatic number in the general case, it is sufficient to observe that an empty graph is 1-colorable, while the complete graph K_n has the chromatic number n . A well-known result is stated as follows:

Theorem 3 *A graph has chromatic number at most 2, that is, is bipartite, if and only if it contains no odd cycles.*

On the one hand, the proof of Theorem 3 yields an efficient (in fact, linear time) algorithm for determining if G is bipartite. On the other hand, it is NP-complete

Fig. 1 The Grötzsch graph:
a 4-chromatic and
triangle-free graph

to determine if G is of the chromatic number 3. Hence, determining the chromatic number of a graph G precisely seems difficult. However, there are a number of results yield simple bounds on the chromatic number of G . Among of them, a trivial lower bound is easy to obtain.

Recall that a *clique* is a set of pairwise adjacent vertices. Let $\omega(G)$ denote the *clique number* of G , that is, the number of vertices in the largest clique of G . It is still unknown if there exists an algorithm for determining $\omega(G)$ in the general case, because this problem is NP-hard.

Theorem 4 *For any graph G , $\chi(G) \geq \omega(G)$.*

Notice that this bound is best possible for complete graphs, bipartite graphs, and interval graphs. However, there are also many graphs whose chromatic number exceeds their clique number such as the Petersen graph and the odd cycles of length 5 or more. As it is about to see, the chromatic number of a graph can be considerably larger than its clique number.

For instance, the graph G , depicted in Fig. 1, is triangle-free (and so $\omega(G) = 2$) but $\chi(G) = 4$. So $\chi(G)$ exceeds $\omega(G)$ by 2 in this case. This graph is the famous Grötzsch graph. It is known to be the unique smallest graph (in terms of order) that is 4-colorable and triangle-free. The fact that a graph can be triangle-free and yet have a large chromatic number has been established by a number of mathematicians, including Descartes [125], Kelly and Kelly [223], Mycielski [289], and Zykov [402].

Theorem 5 *For every positive integer k , there exists a triangle-free k -chromatic graph.*

Most upper bounds on the chromatic number come from algorithms that produce colorings. For example, assigning distinct colors to the vertices yields $\chi(G) \leq |G|$, where $|G|$ usually denotes the order of G . This bound is tight, since $\chi(K_n) = n$, but it holds with equality only for complete graphs. The following upper bound can be directly derived from the definition of the chromatic number:

Proposition 1 Every graph G with m edges satisfies

$$\chi(G) \leq \frac{1}{2} + \sqrt{2m + \frac{1}{4}}.$$

Clearly, $\chi(G) \leq |G|$ uses nothing about the structure of G . Yet, it can do better by coloring the vertices in some order and always using the *least available* color.

The *greedy coloring* [379] relative to a vertex ordering v_1, v_2, \dots, v_n of $V(G)$ is obtained by coloring vertices in the order v_1, v_2, \dots, v_n , assigning to v_i the smallest indexed color not already used on its lower-indexed neighbors.

Theorem 6 $\chi(G) \leq \Delta + 1$ for every graph G .

Proof First, give a random ordering of vertices. Clearly, each vertex has at most Δ vertices as (early) neighbors. So the greedy coloring cannot be forced to use more than $\Delta + 1$ colors. \square

Theorem 7 If a graph G has degree sequence d_1, d_2, \dots, d_n , then $\chi(G) \leq 1 + \max_i \{\min\{d_i, i - 1\}\}$.

Observe that the upper bound in Theorem 7 is always at most $\Delta + 1$. So this is at least as good as Theorem 6. On the other hand, Szekeres and Wilf [324] in 1968 showed a relationship between chromatic number and minimum degree.

Theorem 8 If G is a graph, then $\chi(G) \leq 1 + \max_{H \subseteq G} \{\delta(H)\}$.

The bound $\chi(G) \leq \Delta + 1$ holds with equality for complete graphs and odd cycles. By choosing the vertex ordering more carefully, it can be shown that there are essentially the only such graphs. To avoid unimportant complications, it suffices to give the statement for connected graphs. It extends to all graphs because the chromatic number of a graph is the maximum chromatic number of its components.

Theorem 9 (Brooks' Theorem) If G is a connected graph other than a complete graph or an odd cycle, then $\chi(G) \leq \Delta$.

For the proof of Brooks' Theorem, one may refer to [258]. Notice that for some special class of graphs, $\chi(G)$ is far from Δ . Such a situation occurs for stars $K_{1,m}$. Obviously, $K_{1,m}$ has chromatic number exactly 2, while the discussed bound implies that $\chi(K_{1,m}) \leq m$. But the bound Δ can be improved when G has no large clique. Brooks' Theorem states that $\chi(G) \leq \Delta$ whenever $3 \leq \omega(G) \leq \Delta$. Borodin and Kostochka [75] conjectured that $\omega(G) < \Delta$ implies $\chi(G) < \Delta$ if $\Delta \geq 9$ (an example shows that the condition $\Delta \geq 9$ is needed). Reed [301] proved that this conjecture holds when $\Delta \geq 10^{14}$. Moreover, Reed [300] proved the following:

Theorem 10 If G is a graph, then $\chi(G) \leq \lceil \frac{\Delta+1+\omega(G)}{2} \rceil$.

2.2 Hajós Conjecture and Hadwiger Conjecture

Notice that the clique number $\omega(G)$ of a graph G is a lower bound for $\chi(G)$. **Theorem 5** states that for every integer $k \geq 3$, there is a graph G such that $\chi(G) = k$ and $\omega(G) = 2$. Indeed, every odd cycle of order at least 5 is 3-chromatic but none of these graphs contains K_3 as a subgraph. But all of these do contain a subdivision of K_3 . Since every 3-chromatic graph contains an odd cycle, it follows that if G is a graph with $\chi(G) \geq 3$, then G must contain a subdivision of K_3 . In 1952, Dirac [128] showed that the corresponding result is true as well for graphs having chromatic number of at least 4.

Theorem 11 *If G is a graph with $\chi(G) \geq 4$, then G contains a subdivision of K_4 .*

Therefore, for $2 \leq k \leq 4$, every k -chromatic graph contains a subdivision of K_k . In 1961, Hajós [176] conjectured that this is true for every integer $k \geq 2$.

Conjecture 1 (Hajós Conjecture) *If G is a k -chromatic graph, where $k \geq 2$, then G contains a subdivision of K_k .*

In 1979, Catlin [95] constructed a family of graphs that showed that Hajós Conjecture is false for every integer $k \geq 7$. A graph G is called *perfect* if $\chi(H) = \omega(H)$ for every induced subgraph H of G . Then a class of perfect graphs can be obtained from a given perfect graph. Let G be a graph with $v \in V(G)$. Then the *replication graph* $R_v(G)$ of G (with respect to v) is the graph obtained from G by adding a new vertex v' to G and joining v' to the vertices in the closed neighborhood $N[v]$ of v .

In 1972, Lovász [257] obtained the following result.

Theorem 12 *Let G be a graph where $v \in V(G)$. If G is perfect, then $R_v(G)$ is perfect.*

Recently, Thomassen [333] showed that there is a connection between perfect graphs and Hajós' Conjecture.

Theorem 13 *A graph G is perfect if and only if $R_v(G)$ satisfies Hajós Conjecture.*

A graph H is a *minor* of a graph G if H can be obtained from G by a sequence of edge contractions, edge deletions, and vertex deletions (in any order). Since Hajós Conjecture does not hold for the case $k \geq 7$, a k -chromatic graph need not contain a subdivision of K_k . But this fact does not imply that a k -chromatic graph need not contain K_k as a minor. Before Hajós Conjecture was made, in 1942, Hadwiger posed the following conjecture:

Conjecture 2 (Hadwiger Conjecture) *Every k -chromatic graph contains K_k as a minor.*

Hadwiger Conjecture holds trivially for $k \leq 1$. Dirac [128] proved the conjecture for $k = 3$. The case $k = 4$ is significantly more challenging. The Four-Color

Conjecture is clearly implied by Hadwiger Conjecture for the case $k = 4$, as it is well known that any graph with a K_5 -minor is non-planar. In fact, Wagner [345] showed that in this case Hadwiger Conjecture is equivalent to the Four-Color Conjecture. In 1980, Albertson and Hutchinson [15] showed that Hadwiger Conjecture is true if $k = 6$ and the graph is the Klein bottle. Recently, by the Four-Color Theorem, Robertson, Seymour, and Thomas [305] confirmed Hadwiger Conjecture for the case $k = 6$. Hence, Hadwiger Conjecture remains open for all larger values of k .

One may check that the complete graph is a perfect graph, since every subgraph of a complete graph is also complete. Moreover, it was proved in [275] that the bipartite graph and the complement of bipartite graph are both perfect graphs. It means that if a graph G is either a complete graph or a bipartite graph, then G and \overline{G} are both perfect. Indeed, in 1961, Berge made the following conjecture.

Conjecture 3 (Perfect Graph Conjecture) *A graph is perfect if and only if its complement is perfect.*

In 1972, Lovász [257] showed that this conjecture is, in fact, true.

Theorem 14 (Perfect Graph Theorem) *A graph is perfect if and only if its complement is perfect.*

It is easy to observe that the perfect graph cannot contain a subgraph H which is an induced odd cycle with more than five vertices. If that is indeed the case, then $\chi(H) = 3$ and $\omega(H) = 2$. Denote $H = C_{2k+1}$, where $k \geq 2$. One may easily check that $\chi(\overline{H}) = k+1$ and $\omega(\overline{H}) = k$. Basing on these observations, Berge [48] proposed the following famous conjecture:

Conjecture 4 (Strong Perfect Graph Conjecture) *A graph G is perfect if and only if neither G nor \overline{G} contains an induced odd cycle of length 5 or more.*

This challenging conjecture was recently solved by Chudnovsky, Robertson, Seymour, and Thomas [114] by a long and technical proof.

Theorem 15 (Strong Perfect Graph Theorem) *A graph G is perfect if and only if neither G nor \overline{G} contains an induced odd cycle of length 5 or more.*

2.3 Coloring Graphs Embedded in a Surface

This section is concerned with the vertex coloring of graphs embedded in a given (closed) surface. Motivated by the Four-Color Problem, coloring problems on graphs embedded in various surfaces have been studied extensively in the literature. Surfaces can be classified according to their genus and colorability (choosability). The *orientable surfaces* are the sphere with g handles S_g , where $g \geq 0$. For example, cylinder and torus are both orientable surfaces.

The *non-orientable surfaces* are the surfaces Π_h ($h \geq 1$) obtained by taking the sphere with h holes and attaching h Möbius bands along their boundary to the boundaries of the holes. For example, Π_1 is the projective plane and Π_2 is the Klein bottle. An embedding of a graph G in a surface S is called a *2-cell embedding* if each face of G is homeomorphic to an open unit disk. The *Euler characteristic* $\varepsilon(S) = 2 - 2g$ of a surface S is equal to $|V(G)| - |E(G)| + |F(G)|$ for any multigraph G that is 2-cell embedded in S . When $\varepsilon(S) = 2$, S denotes the Euclidean plane and G is a plane graph. When $\varepsilon(S) = 0$, S denotes the torus or the Klein bottle.

Among all those graphs embedded in the surfaces, the most interested one is the *toroidal graph*. A graph G is *toroidal* if it can be embedded in the torus. In other words, the graph's vertices can be placed in a torus such that no edges cross. Usually, it is assumed that G is also non-planar. For example, the Heawood graph, the complete graph K_7 (and hence K_5 and K_6), the Petersen graph, and all Möbius ladders are toroidal. More generally, any graph with crossing number 1 is toroidal. But some graph with greater crossing numbers is also toroidal, that is, the Möbius-Kantor graph has crossing number 4 and is also toroidal.

The well-known Four-Color Theorem [27] asserts that every plane graph G is 4-colorable. In 1890, Heawood [187] established an upper bound for the vertex chromatic number of graphs embedded in a surface S of genus $g \geq 1$. This upper bound was called the Heawood number $h(S) = \lfloor \frac{7 + \sqrt{49 - 24\varepsilon(S)}}{2} \rfloor$.

Theorem 16 *If G is a graph embedded in a surface S of genus $g \geq 1$, then $\chi(G) \leq h(S)$.*

Almost a century later, Ringel [302] and Ringel and Youngs [303] proved that the Heawood number $h(S)$ is in fact the maximum chromatic number as well as the maximum clique number of graphs embedded in a surface of genus $g \geq 1$ besides the Klein bottle, which is 6-colorable (showing by Franklin [156]) but has $h(S) = 7$.

In 1956, Dirac [129] refined this by showing that the upper bound $h(S)$ is attained only if a graph G contains $K_{h(S)}$ as a subgraph except for three surfaces. Albertson and Hutchinson [14] settled these excluded cases in 1979. This result is nowadays known as Dirac's Map-Color Theorem. Later, Böhme, Mohar, and Stiebitz [53] extended Dirac's Map-Color Theorem to the case of choosability by showing that G is $(h(S) - 1)$ -choosable unless G contains $K_{h(S)}$ as a subgraph for genera $g \geq 1$ and $g \neq 3$. For the left case $g = 3$, it was then solved by Král and Škrekovski [238].

By Theorem 16, if G is a graph embedding in a surface with $\varepsilon(S) = 0$, then $\chi(G) \leq 7$. It follows that every toroidal graph is 7-colorable. This result is best possible, since the complete graph K_7 has chromatic number 7. Dirac [128] showed that every 7-chromatic toroidal graph contains K_7 as a subgraph. In 1999, Böhme, Mohar, and Stiebitz [53] further generalized these two results to the list-coloring situation:

Theorem 17 *Every toroidal graph G is 7-choosable and $\chi^l(G) = 7$ if and only if $K_7 \subseteq G$.*

Characterizing k -colorable toroidal graphs with $k = 3, 4, 5$ turns out to be an interesting problem. It has received much attention in the past years, even before 1990. A cycle C of a graph G embedded in a surface S is called *contractible* if, when viewed as a closed curve on S , it is homotopic to a point; otherwise, it is called *noncontractible*. By considering noncontractible cycles with given length, Albertson and Stromquist [16] proved the following result.

Theorem 18 *If G can be embedded in the torus such that noncontractible cycles have length at least 8, then $\chi(G) \leq 5$.*

Let G_1 and G_2 be graphs. Their *union* $G_1 \cup G_2$ is the graph with vertex set $V(G_1) \cup V(G_2)$ and edge set $E(G_1) \cup E(G_2)$. The *join* of G_1 and G_2 is the graph $G_1 \vee G_2$ obtained from $G_1 \cup G_2$ by adding an edge v_1v_2 for each vertex v_1 of G_1 and each vertex v_2 of G_2 . A graph is called *Hajós- n -constructible* if it can be obtained from complete graphs K_n by repeated application of the following two operations:

- (a) Let G_1 and G_2 be already obtained disjoint graphs with edges x_1y_1 and x_2y_2 . Remove x_1y_1 and x_2y_2 , identify x_1 and x_2 , and join y_1 and y_2 by a new edge.
- (b) Identify independent vertices (i.e., apply a homomorphism).

Let H_7 be the graph with seven vertices obtained by applying Hajós' construction to two copies of K_4 (only operation (a)). Let T_{11} be a special triangulation with 11 vertices of the torus. In 1994, Thomassen [330] gave a new sufficient condition for toroidal graphs to be 5-colorable.

Theorem 19 *Every toroidal graph is 5-colorable unless it contains one of the following four subgraphs: (1) K_6 , (2) T_{11} , (3) $C_3 \vee C_5$, and (4) $K_2 \vee H_7$.*

If a toroidal graph G is 6-regular, then the above theorem implies the following:

Corollary 2 *Every 6-regular toroidal graph is 5-colorable unless it contains either K_6 or T_{11} .*

Recently, the 4-colorable 6-regular toroidal graphs have been studied by many authors. Combining their results in [22, 118, 389], all 4-colorable 6-regular toroidal graphs have been completely characterized.

As an effort to understand graphs embedded in orientable surfaces of nonnegative characteristic, one has studied k -colorable toroidal graphs without some specific short cycles or with given girth. In 1972, Kronk and White [240] proved the following:

Theorem 20 *Let G be a toroidal graph with girth g :*

- (1) *If $g \geq 4$, then $\chi(G) \leq 4$.*
- (2) *If $g \geq 6$, then $\chi(G) \leq 3$.*

The second conclusion in **Theorem 20** has been strengthened in two aspects. On the one hand, the girth requirement was reduced to 5 by Thomassen [329]. On the other hand, Cai et al. [91] proved that every toroidal graph G of girth at least 6 is 3-choosable. Moreover, they proposed the following conjecture:

Conjecture 5 *Every toroidal graph of girth at least 5 is 3-choosable.*

In a slightly different approach, Cai et al. [91] considered the coloring of toroidal graphs without specific cycles. Suppose that G is a toroidal graph without k -cycles. Then the following result was proved in [91]:

$$\chi^l(G) \leq \begin{cases} 4, & \text{if } k \in \{3, 4, 5\}; \\ 5, & \text{if } k = 6; \\ 6, & \text{if } k = 7. \end{cases}$$

Observe that toroidal graphs without 6-cycles (e.g., K_5) may not be 4-choosable. However, K_5 seems to be the only obstacle for such graphs to be 4-choosable. Basing on these observations, Cai et al. [91] proposed the following problem:

Conjecture 6 *Let G be a toroidal graph without 6-cycles. If G is K_5 -free, then $\chi^l(G) \leq 4$.*

For other 3-colorable graphs embedded in surfaces, one classical result of Heawood and Kempe states that every Eulerian triangulation of the plane is 3-colorable. Note that the condition that the graph be embedded in the plane is essential. For example, K_7 can be embedded as an Eulerian triangulation of the torus but has chromatic number 7. On the other hand, it is recently proved by Hutchinson et al. [208] that every Eulerian triangulation G of an orientable surface is 4-colorable if every noncontractible cycle of G is sufficiently large.

2.4 Coloring Planar Graphs

As it is mentioned in the previous section, Vizing [341] and Erdős et al. [140] independently introduced the concepts of list coloring and choosability. By the Four-Color Theorem [27], every planar graph G has a partition (V_1, V_2, V_3, V_4) such that each V_i induces an independent set. However, Wegner [377] showed that there exists a planar graph which cannot be partitioned into (V_1, V_2, V_3) such that V_1 and V_2 are independent sets and V_3 is a forest, and even earlier, Chartrand and Kronk [101] showed that there exists a planar graph which cannot be partitioned into two forests. On the other hand, Voigt [342] and Mirzakhani [268], independently, proved that not all planar graphs are 4-choosable. All of these facts imply that it is impossible to strengthen the Four-Color Theorem.

However, it is evident that every planar graph is 6-choosable, which follows from the fact that every planar graph contains a vertex of degree at most 5. In 1979, Erdős et al. [140] conjectured that there exists a planar graph G such that $\chi^l(G) = 5$ and that there is no planar graph G such that $\chi^l(G) = 6$. The second conjecture was confirmed by Thomassen [328] in 1994.

Theorem 21 *Every planar graph is 5-choosable.*

The bound in [Theorem 21](#) is best possible, since Voigt [342] and Mirzakhani [268] independently proved the following theorem:

Theorem 22 *There exists a planar graph G such that $\chi^l(G) = 5$.*

The graph presented in the original proof given by Voigt [342] has 238 vertices. In [343], she further constructed a planar graph G of order 130 with $\chi(G) = 3$ and $\chi^l(G) = 5$. This gives a negative answer to the question whether $\chi^l(G) - \chi(G) \leq 1$ for every planar graph G . The smallest known so far planar graph G with $\chi^l(G) = 5$ was constructed by Mirzakhani [268]. This graph has 63 vertices and chromatic number 3.

If all vertices of degree 1 are removed recursively from a graph G , then the final graph has no vertices of degree 1 and is called the *core* of G . A graph is called a $Q_{2,2,p}$ -graph if it consists of two vertices x and y and three internally disjoint paths of lengths 2, 2 and p joining x and y . For example, $\theta_{2,2,2}$ is isomorphic to $K_{2,3}$. Using these two concepts, Erdős et al. [140] established the following characterization for the 2-choosability of a graph.

Theorem 23 *A connected graph is 2-choosable if and only if the core of G is isomorphic to K_1 , C_{2m+2} , or $\theta_{2,2,2m}$ for some $m \geq 1$.*

So characterizing 3- or 4-choosable planar graphs becomes one of the most interesting problems in investigating the choosability of planar graphs. However, Gutner [173] proved that both these problems are NP-complete.

2.4.1 4-Choosable Planar Graphs

A graph G is k -degenerate if every subgraph H of G has a vertex of degree at most k in H . It is well known that every k -degenerate graph is $(k + 1)$ -choosable. It is easy to prove that every planar triangle-free graph is 3-degenerate by Euler's formula. Wang and Lih [359] proved that planar graphs without 5-cycles are 3-degenerate, while Fijavž et al. [155] showed that planar graphs without 6-cycles are also 3-degenerate. The lack of 4-cycles does not imply the 3-degeneracy of a planar graph, for example, the line graph of a dodecahedron. However, Lam et al. [244] proved that planar graphs without 4-cycles are 4-choosable. Recently, Farzad [144] proved the conjecture proposed by Fijavž et al. [155] and independently by Wang and Lih [358] that planar graphs without 7-cycles are 4-choosable.

These facts together summarize the following theorem:

Theorem 24 *If G is a planar graph without i -cycles for some fixed $i \in \{3, 4, 5, 6, 7\}$, then G is 4-choosable.*

Borodin and Ivanova [66] improved the above-mentioned result in [244] by showing that every planar graph without 4-cycles adjacent to 3-cycles is 4-choosable. By considering the distance of two triangles, Wang and Lih [360] proved the following

Theorem 25 *Every planar graph without intersecting triangles is 4-choosable.*

Recently, Luo [261] extends the result to all graphs embeddable in an orientable surface of non-negative Euler's characteristic by showing the following.

Theorem 26 *Every toroidal graph without intersecting triangles is 4-choosable.*

Two triangles, that is, two 3-cycles, are *intersecting* if they share at least one common vertex. Two triangles are *adjacent* if they share at least one common edge.

The following challenging conjecture was proposed in [360]:

Conjecture 7 *Every planar graph without adjacent triangles is 4-choosable.*

This conjecture remains open. However, a $(4, 1)^*$ -choosability of planar graphs without adjacent triangles is indeed the case by Xu and Zhang [384]. A graph G is called $(k, d)^*$ -*choosable* if, for every list assignment L satisfying $|L(v)| = k$ for all $v \in V(G)$, there is an L -coloring of G such that each vertex of G has at most d neighbors colored with the same color as itself. The notion of list improper coloring was introduced independently by Škrekovski [320] and by Eaton and Hull [137]. They proved that every planar graph is $(3, 2)^*$ -choosable and every outerplanar graph is $(2, 2)^*$ -choosable.

In fact, Xu and Zhang [384] extended such a list coloring to any toroidal graph. Their main result is the following:

Theorem 27 *Every toroidal graph without adjacent triangles is $(4, 1)^*$ -choosable.*

Note that this result is best possible in the sense that K_7 is a non- $(3, 1)^*$ -choosable toroidal graph.

2.4.2 Steinberg's Conjecture

In 1958, Grötzsch [170] proved that planar graphs without 3-cycles are 3-colorable. But not every triangle-free planar graph is 3-choosable. The first example of such graphs was provided by Voigt [343]. However, Škrekovski [319] proved that every planar graph without 3-cycles is $(3, 1)^*$ -choosable. Alon and Tarsi [20] proved that every planar bipartite graph is 3-choosable. Moreover, Thomassen [331] proved that planar graphs with girth at least 5 are 3-choosable. As early as 1969, Havel [180] asked if there existed a constant C such that each planar graph with the minimal distance between triangles at least C is 3-colorable. In 1976, Aksionov and Mel'nikov [11] and, independently, Steinberg [322] proved that $d \geq 4$. Moreover, Steinberg [322] proposed the following conjecture:

Conjecture 8 *Every planar graph without 4-cycles and 5-cycles is 3-colorable.*

This challenging conjecture still remains unsolved. In 1990, Erdős suggested the following relaxation of Steinberg's conjecture:

Question 1 *What is the smallest integer k such that every planar graph without i -cycles for $4 \leq i \leq k$ is 3-colorable?*

In [1], Abbott and Zhou showed that such k exists and $k \leq 11$. This result was improved to $k \leq 9$ by Borodin [57] and independently by Sanders and Zhao [310], and then it was further reduced to $k \leq 7$ by Borodin et al. [65]. Recently, Borodin et al. [79], and independently Wang et al. [364], strengthened this result by showing that every planar graph without adjacent cycles of lengths at most 7 is 3-colorable.

2.4.3 3-Choosable Planar Graphs

To answer Erdős's question, many authors considered some restricted planar graphs, that is, without some cycles of four lengths; see [108, 263, 314, 354, 398, 399]. Strengthening results of these types, Wang and Chen [353] proved that every planar graph without 4-, 6-, and 8-cycles is 3-colorable; Lu et al. [259] proved that every planar graph without 4-, 7-, and 9-cycles is 3-colorable; Borodin et al. [64] proved that every planar graph without 5-cycles, 7-cycles, and adjacent 3-cycles is 3-colorable, which implies that every planar graph without 4-, 5-, and 7-cycles is 3-colorable.

Naturally, a similar question on choosability of planar graphs is stated as follows:

Question 2 *What is the smallest integer k^* such that every planar graph without j -cycles for $4 \leq j \leq k^*$ is 3-choosable?*

Notice that it is impossible to extend Steinberg's conjecture to list coloring by the example given by Voigt [344] and independently, by Montassier [277]. Hence $k^* \geq 6$. The best known upper bound is $k^* \leq 9$ obtained by Borodin [57] in 1996, that is, every planar graph without $\{4, 5, \dots, 9\}$ -cycles is 3-choosable.

These results have also been improved by showing that forbidding four cycles of certain size would lead to 3-choosability of planar graphs. These results are summarized in the following theorem:

Theorem 28 *A planar graph is 3-choosable if it has no*

- (Zhang and Wu [398]) 4-, 5-, 7-, and 9-cycles
- (Zhang and Wu [399]) 4-, 5-, 6-, and 9-cycles
- (Chen et al. [105]) 4-, 6-, 7-, and 9-cycles
- (Shen and Wang [314]) 4-, 6-, 8-, and 9-cycles
- (Wang et al. [375]) 4-, 7-, 8-, and 9-cycles
- (Wang et al. [362]) 4-, 5-, 8-, and 9-cycles

As it can be seen, it is really not easy to reduce the value of k to answer Question 2. Lih et al. [249] gave the following result on improper choosability of planar graphs without some short cycles, which may be regarded as a solution to a weakened form of Steinberg's conjecture:

Theorem 29 *Every planar graph without 4-cycles and l -cycles for some $l \in \{5, 6, 7\}$ is $(3, 1)^*$ -choosable.*

Since every triangle-free planar graph is 3-colorable, it seems to be interesting to discuss the 3-choosability of such planar graph which contains no other short cycles.

There are many possible combinations of cycles one may try to forbid. These results are collected as follows:

Theorem 30 *A triangle-free planar graph is 3-choosable if it has no*

- (Lam et al. [243]) 5- and 6-cycles
- (Zhang et al. [401]) 8- and 9-cycles
- (Dvořák et al. [135]) 6- and 7-cycles
- (Dvořák et al. [136]) 7- and 8-cycles

By investigating planar graphs with sparse triangles and without short cycles, Montassier et al. [283] proved the following two results.

Theorem 31 *Every planar graph without 4- and 5-cycles, and without two triangles at distance less than 4 is 3-choosable.*

Theorem 32 *Every planar graph without 4-, 5-, and 6-cycles and without two triangles at distance less than 3 is 3-choosable.*

Moreover, they constructed a non-3-choosable planar graph which contains no 4-cycles, 5-cycles and intersecting triangles. So the following problem may be of interest.

Problem 1 *Is a planar graph without 4- and 5-cycles and without triangles at distance less than k ($1 \leq k \leq 3$) 3-choosable?*

3 Acyclic Coloring

This section is devoted to dealing with the acyclic coloring of graphs. This direction includes many interesting results and open problems.

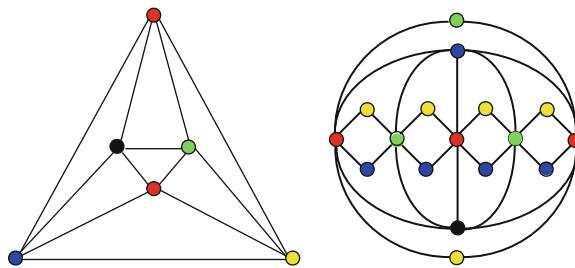

3.1 Acyclic Vertex Coloring

A proper vertex coloring of a graph G is *acyclic* if there is no bicolored cycle in G . Namely, the union of any two color classes induces a forest. The *acyclic chromatic number*, denoted by $\chi_a(G)$, of a graph G is the smallest integer k such that G has an acyclic k -coloring. It is obvious that $\chi(G) \leq \chi_a(G)$ for any graph G .

The notion of acyclic coloring of graphs was introduced by Grünbaum [171] in 1973. It is not difficult to show that if G is a graph with $\Delta \leq 1$, then $\chi_a(G) \leq 2$; if G is a graph with $\Delta \leq 2$, then $\chi_a(G) \leq 3$ and the upper bound value 3 is tight. Moreover, using a greedy coloring procedure, it is easy to verify that for any graph G , $\chi_a(G) \leq \Delta^2 + 1$.

Obviously, determining $\chi_a(G)$ is a hard problem. Actually, Kostochka [231] proved that it is an NP-complete problem to decide for a given graph G whether $\chi_a(G) \leq 3$, and Coleman and Cai [117] showed that it is NP-hard when restricted to bipartite graphs.

Fig. 2 Example of Grünbaum and example of Kostochka and Mel'nikov

3.1.1 Planar Graphs

Grünbaum [171] proved that every planar graph is acyclically 9-colorable and conjectured that 5 is sufficient. This conjecture was studied by many people, for example, Mitchem [269], Albertson, and Berman [12], and Kostochka [229]. In 1979, Borodin [55] settled eventually this conjecture:

Theorem 33 *Every planar graph is acyclically 5-colorable.*

The bound in [Theorem 33](#) is sharp. In 1973, Grünbaum [171] gave an example of a 4-regular planar graph which is not acyclically 4-colorable; furthermore, bipartite planar graphs which are not acyclically 4-colorable were constructed in [233]; see [Fig. 2](#).

Borodin, Kostochka, and Woodall [78] reduced this upper bound 5 by considering planar graphs with large girth.

Theorem 34 *Let G be a planar graph with girth g :*

1. *If $g \geq 5$, then $\chi_a(G) \leq 4$.*
2. *If $g \geq 7$, then $\chi_a(G) \leq 3$.*

More recently, Angelini and Frati [25] investigated the acyclic 3-colorability of some subclasses of planar graphs. They showed the following three results:

Theorem 35 *There exist infinitely many cubic and subcubic planar graphs that admit no acyclic 3-coloring.*

Recall that the 1-subdivision of a graph G is the graph obtained by replacing each edge of G with a path of length at most 2.

Theorem 36 *Every planar graph has a 1-subdivision that admits an acyclic 3-coloring. Such a coloring can be constructed in linear time.*

A graph G is called a *series-parallel* graph if G can be obtained from K_2 by applying a sequence of operations, where each operation is either to duplicate an edge (i.e., replace an edge with two parallel edges) or to subdivide an edge (i.e., replace an edge with a path of length 2).

Theorem 37 *There exists a linear-time algorithm for deciding whether every 3-coloring of a series-parallel graph is acyclic.*

A planar graph is *1-planar* if it can be drawn on the plane in such a way that every edge crosses at most one other edge. Borodin et al. [76] showed the following:

Theorem 38 *Every 1-planar graph is acyclically 20-colorable.*

3.1.2 Graphs Embedded in a Surface

Alon, Mohar, and Sanders [18] proved that every projective planar graph is acyclically 7-colorable. Borodin et al. (see [212]) conjectured that the acyclic chromatic number of any surface but the plane is the same as its chromatic number. Unfortunately, this conjecture is false. An easy counterexample may be referred to the Klein bottle which is 6-colorable [156] but has the acyclic chromatic number at least 7 [18].

Alon et al. [18] presented a more general upper bound of any graph embedded in a surface.

Theorem 39 *The acyclic chromatic number of an arbitrary surface with Euler characteristic $\chi = -\gamma$ is at most $O(\gamma^{\frac{4}{7}})$.*

Notice that this upper bound is nearly tight, since for every $\gamma > 0$, there are graphs embeddable in surfaces of Euler characteristic $-\gamma$ whose acyclic chromatic number is at least $\Omega(\gamma^{\frac{4}{7}}/(\log \gamma)^{\frac{1}{7}})$.

There are two widely recognized notions of *local planarity*, that is, large edge width and large face width (see [275]). For coloring problems, the natural one is the large edge-width condition, meaning that all noncontractible cycles of an embedded graph are large. Recently, acyclic colorings of locally planar graphs have been studied by Mohar [272]. The *nonseparating edge width*, denoted $\text{new}(G)$, is the length of a shortest surface-nonseparating cycle in an embedded graph G . The following theorem was established by Mohar [272].

Theorem 40 *For every surface S , there is a constant c such that every graph G embedded in S with $\text{new}(G) \geq c$ is acyclically 8-colorable.*

Note that the constant c is depending on the genus g of the surface. It is shown to be of order $O(g^3 2^g)$.

More recently, Kawarabayashi and Mohar [222] proved that every graph embedded in a fixed surface with sufficiently large edge width is acyclically 7-colorable. Furthermore, it was shown in [222] that for every surface S , there exists an integer $w = w(S)$ such that every graph embedded in S with edge width at least w is acyclically 7-colorable.

3.1.3 Graphs with a Fixed Maximum Degree

Concerning graphs with a fixed maximum degree, certain results come from Alon, McDiarmid, and Reed [17] using a probabilistic method and the Lovász Local Lemma [45]. Two results in the following were established in [17]:

Theorem 41 *If G has maximum degree Δ , then $\chi_a(G) = O(\Delta^{4/3})$ as $\Delta \rightarrow \infty$.*

Theorem 42 *There exists a graph G such that $\chi_a(G) = \Omega\left(\frac{\Delta^{4/3}}{(\log \Delta)^{1/3}}\right)$ as $\Delta \rightarrow \infty$.*

Notice that [Theorem 41](#) settled a conjecture, due to Erdős, which says that $\chi_a(G) = O(\Delta^2)$ for any graph G of maximum degree Δ . These results show that there are graphs G with maximum degree Δ whose acyclic chromatic numbers are significantly larger than Δ . It turns out that such graphs must contain certain complete bipartite graphs. The proofs of these results rely heavily on probabilistic arguments.

Alon et al. [17] presented a polynomial-time greedy algorithm to acyclically color any graph G with maximum degree Δ using $\Delta^2 + 1$ colors. This was later improved by Albertson et al. [13] to that $\chi_a(G) \leq \Delta(\Delta - 1) + 2$.

For the graphs with a smaller maximum degree Δ , it was shown that every subcubic graph G is acyclically 4-colorable by Grünbaum [171] and independently by Skulrattanakulchai [321]. Observe that four colors are necessary because of K_4 . Moreover, Skulrattanakulchai [321] constructed a linear-time algorithm for acyclically coloring any subcubic graphs:

Theorem 43 *Every subcubic graph G is acyclically 4-colorable; moreover, the vertices of G can be acyclically colored using four colors in $O(n)$ time.*

The acyclic chromatic number of graphs with maximum degree at most 4 has been studied by Buršteín [90] in 1979. He proved that every graph of maximum degree 4 is acyclically 5-colorable (this bound is sharp because of K_5). Recently, Yadava et al. [385] obtained the same result as in [90], by presenting a linear-time algorithm for acyclically coloring any graph of maximum degree 4:

Theorem 44 *The vertices of any graph G of degree at most 4 can be acyclically colored using five colors in $O(n)$ time, where n is the number of vertices.*

The upper bound $\Delta(\Delta - 1) + 2$ [13] for any graph G seems to be not tight. In fact, this bound was later improved to $\frac{\Delta(\Delta-1)}{2}$ by Fertin and Raspaud [148] if $\Delta \geq 5$. They also constructed an $O(n\Delta^2)$ algorithm to acyclically color any graph of maximum degree Δ . More specifically, they proved the following two results:

Theorem 45 *There exists an $O(n\Delta^2)$ time algorithm to acyclically color any graph of order n and maximum degree Δ . This algorithm uses at most:*

1. $\frac{\Delta(\Delta-1)}{2} + 1$ colors when Δ is even and $\Delta \geq 4$.
2. $\frac{\Delta(\Delta-1)}{2}$ colors when Δ is odd and $\Delta \geq 5$.

Theorem 46 *There exists an $O(n\Delta^2)$ time algorithm to acyclically color any graph of order n and having $\Delta \geq 6$. This algorithm uses at most:*

1. $\frac{\Delta(\Delta-1)}{2}$ colors when Δ is even.
2. $\frac{\Delta(\Delta-1)}{2} - 1$ colors when Δ is odd.

By a deep study for the $\Delta = 5$ case, Fertin and Raspaud also showed that every graph G of maximum degree 5 has acyclic chromatic number at most 9, which has been recently improved to 8 by Hocquard and Montassier [193] and independently

by Yadava et al. [386]. Moreover, in [386], the authors gave a linear-time algorithm to achieve this bound as follows:

Theorem 47 *Every $\Delta = 5$ graph G with n vertices can be acyclically colored using 8 colors in $O(n)$ time.*

In 2009, Varagani et al. [337] proved that every graph G with $\Delta = 6$ can be acyclically colored using at most 12 colors in $O(n)$ time, which improves the result of [148] by reducing 15–12.

3.1.4 Products of Graphs

Given two graphs G_1 and G_2 , the *Cartesian product* $G_1 \times G_2$ of G_1 and G_2 is defined to be the graph G with $V(G) = V(G_1) \times V(G_2)$, and $E(G)$ contains the edge joining (u_1, u_2) and (v_1, v_2) if and only if either $u_1 = v_1$ and $(u_2, v_2) \in E(G_2)$ or $u_2 = v_2$ and $(u_1, v_1) \in E(G_1)$.

Let $d \in N$ and $(n_1, n_2, \dots, n_d) \in N^d$, with $n_i \geq 2$ for any $1 \leq i \leq d$. The d -dimensional grid of lengths n_1, n_2, \dots, n_d , denoted by $G_d(n_1, n_2, \dots, n_d)$, is the following graph:

- $V(G_d(n_1, n_2, \dots, n_d)) = [1, n_1] \times [1, n_2] \times \dots \times [1, n_d]$.
- $E(G_d(n_1, n_2, \dots, n_d)) = \{(u, v) | u = (u_1, u_2, \dots, u_d), v = (v_1, v_2, \dots, v_d), \text{ and there exists } i_0 \text{ such that } |u_{i_0} - v_{i_0}| = 1\}$.

Fertin, Godard, and Raspaud [147] discussed the acyclic coloring of d -dimensional grids $G_d(n_1, n_2, \dots, n_d)$, with each $n_i \geq 2$. The following theorem gives one of their main results:

Theorem 48 *Let $(n_1, n_2, \dots, n_d) \in N^d$ with $n_i \geq 2$ for any $1 \leq i \leq d$. For any grid $G_d(n_1, n_2, \dots, n_d)$ of dimension d , $\chi_a(G_d(n_1, n_2, \dots, n_d)) \leq d$.*

Jamison et al. [211] considered the Cartesian product of trees by showing the following:

Theorem 49 *Let $G = T_1 \times T_2 \times \dots \times T_d$ be a product of trees T_1, T_2, \dots, T_d . Then*

$$\left\lceil \frac{d+3}{2} \right\rceil \leq \chi_a(G) \leq d+1.$$

For an arbitrary graph, Jamison and Matthews [209] gave a simple but very useful lower bound on the acyclic chromatic number.

Theorem 50 *For any graph G with n vertices and m edges, $\chi_a(G) > \frac{m}{n} + 1$.*

Proof Assume that φ is an acyclic coloring of G using k colors. Denote the color classes of φ by C_1, C_2, \dots, C_k , and set $|C_i| = n_i$. Since G has no bichromatic cycles, the subgraph of G induced by any two color classes C_i and C_j is a forest T_{ij} . Clearly, $|E(T_{ij})| \leq n_i + n_j - 1$. Thus,

$$\begin{aligned} m &= \sum_{1 \leq i < j \leq k} |E(T_{ij})| \leq \sum_{1 \leq i < j \leq k} n_i + n_j - 1 = (k-1) \sum_{i=1}^k n_i - \binom{k}{2} \\ &= (k-1)n - \binom{k}{2}. \end{aligned}$$

So $\frac{m}{n} \leq (k-1) - \frac{\binom{k}{2}}{n}$, and hence, $k \geq \frac{m}{n} + 1 + \frac{\binom{k}{2}}{n}$. Since $\frac{\binom{k}{2}}{n} > 0$, it follows that $\chi_a(G) > \frac{m}{n} + 1$. \square

The following corollary is an immediate consequence of [Theorem 50](#).

Corollary 3 *Let G_1, G_2, \dots, G_d be graphs. Then*

$$\chi_a(G_1 \times G_2 \times \dots \times G_d) > \sum_{i=1}^d \frac{|E(G_i)|}{|V(G_i)|} + 1.$$

By applying [Corollary 3](#), the following result is easy to obtain.

Corollary 4 *Let P_m be a path on m vertices and C_n be a cycle on n vertices. Then $\chi_a(P_m \times C_n) \geq 3$ and $\chi_a(C_m \times C_n) \geq 4$.*

It is easy to see that $P_m \times C_n$ is a cylinder graph and $C_m \times C_n$ is a toroidal graph. In fact, in [209], the acyclic chromatic number of these two types of graphs was completely characterized:

Theorem 51

$$\chi_a(C_m \times C_n) = \begin{cases} 5, & \text{if } m = n = 3; \\ 4, & \text{otherwise.} \end{cases}$$

Theorem 52

$$\chi_a(P_m \times C_n) = \begin{cases} 4, & \text{if } n = 4; \\ 3, & \text{otherwise.} \end{cases}$$

Let $H(s_1, s_2, \dots, s_t)$ denote the Hamming graph, defined by $K_{s_1} \times K_{s_2} \times \dots \times K_{s_t}$ with the dimension t , and assume $2 \leq s_1 \leq s_2 \leq \dots \leq s_t$. For simplicity, write $\chi_a(s_1, s_2, \dots, s_t)$ for $\chi_a(H(s_1, s_2, \dots, s_t))$. Jamison and Matthew [210] considered the acyclic coloring of Hamming graphs by showing the following:

Theorem 53 *Suppose that $t \geq 3$ and define $B(s_1, s_2, \dots, s_t) = \sum_{i < j} s_i s_j - (t-2)(\sum_{i=1}^t s_i) + \frac{t(t-3)}{2}$. Then*

$$\chi_a(s_1, s_2, \dots, s_t) \leq B(s_1, s_2, \dots, s_t) \leq \binom{t}{2} s_t^2.$$

Moreover,

$$\chi_a(s, s, \dots, s) \leq \binom{t}{2} s^2 - t(t-2)(s - \frac{1}{2})$$

provided $t \geq 3$.

In the same paper [210], Jamison and Matthew investigated the t -dimensional hypercube, defined by $Q_t = K_2 \times K_2 \times \dots \times K_2$. Determining the acyclic chromatic

number of the hypercube is mentioned as an open problem in [147], where it is shown that $\lfloor \frac{t}{2} \rfloor + 2 \leq \chi_a(Q_t) \leq t + 1$ (see Theorem 4 in [147] or Theorem 2.1 in [211]). The authors in [147, 211] observed that the exact value may be equal to the lower bound. It was shown in [210] that this is indeed the case if $t + 3$ is a Fermat prime. In addition, they obtained an improved upper bound in a number of other cases.

Theorem 54 Assume that $a \leq b$ and $1 \leq c, d \leq 4$. Then

$$\chi_a(Q_{2^a+2^b-c-d}) = \begin{cases} 2^b, & \text{if } a < b; \\ \beta(2^b), & \text{if } a = b. \end{cases}$$

Next, by [Theorem 54](#), the exact acyclic chromatic number of hypercubes of dimensions related to the Fermat primes can be obtained.

Corollary 5 The acyclic chromatic number of the hypercube of dimension $t = 2^{r+1} - 2$ satisfies

$$2^r + 1 \leq \chi_a(Q_{2^{r+1}-2}) \leq NP(2^r).$$

In particular, if $2^r + 1$ is a Fermat prime, then $\chi_a(Q_{2^{r+1}-2}) = 2^r + 1$.

More recently, Joshi and Kothapalli [215] investigated the acyclic coloring of grid-like graphs. A graph is *chordal* if each of its cycles of four or more vertices has a chord, which is an edge joining two vertices that are not adjacent in the cycle. An equivalent definition is that any chordless cycles have at most three vertices. Gebremedhin et al. [162] showed that every coloring of a chordal graph is also an acyclic coloring. Since recognizing and optimally coloring chordal graphs can be done in linear time, this result immediately implies a linear-time algorithm for the acyclic coloring problem on chordal graphs.

3.2 Acyclic List Coloring

Given an assignment $L = \{L(v)|v \in V(G)\}$ of colors to the vertices of a graph G , G is *acyclically L -colorable* if there is an acyclic coloring π of the vertices such that $\pi(v) \in L(v)$ for every vertex v . If G is acyclically L -colorable for any list assignment L with $|L(v)| \geq k$ for all $v \in V$, then G is *acyclically k -choosable* or *acyclically list k -colorable*. The *acyclic list chromatic number* of G , denoted by $\chi_a^l(G)$, is the smallest integer k such that G is acyclically k -choosable.

3.2.1 Acyclic List 5-Coloring

In 2002, Borodin et al. [62] first investigated the acyclic list coloring of planar graphs. They proved that every planar graph is acyclically 7-choosable and put forward the following challenging conjecture:

Conjecture 9 *Every planar graph is acyclically 5-choosable.*

This conjecture has attracted much attention in recent years. If [Conjecture 9](#) is true, then it would strengthen the Borodin's Acyclic 5-Color Theorem [55] and the Thomassen's 5-Choosable Theorem [328] about planar graphs. Evidently, it is very hard to settle this conjecture. As yet, it has been verified only for several restricted classes of planar graphs: those of girth at least 5 [279], without 4- and 5-cycles or without 4- and 6-cycles [284], without 4-cycles and without triangles at distance less than 3 [113], and with neither 4-cycles nor chordal 6-cycles [400]. In particular, in [67], Borodin and Ivanova proved that a planar graph G is acyclically 5-choosable if G does not contain an i -cycle adjacent to a j -cycle where $3 \leq j \leq 5$ if $i = 3$ and $4 \leq j \leq 6$ if $i = 4$. This result absorbs most of the previous work in this direction.

Wang and Chen [355] proved that every planar graph without 4-cycles is acyclically 6-choosable. To attack [Conjecture 9](#), in [113], the authors proposed the following weaker version of [Conjecture 9](#):

Conjecture 10 *Every planar graph without 4-cycles is acyclically 5-choosable.*

Recently, Chen and Raspaud [106] proved that every planar graph with neither 4-cycles nor intersecting triangles is acyclically 5-choosable. This result partially confirms [Conjecture 10](#). Lately, Conjecture 10 has been verified by Borodin and Ivanova [68].

3.2.2 Acyclic List 4-Coloring

Some sufficient conditions for a planar graph to be acyclically 4-choosable (or colorable) have been obtained in the past decade. It was proved in [59] that $\chi_a(G) \leq 4$ if G contains no $\{4, 5\}$ -cycles. Moreover, $\chi_a^l(G) \leq 4$ was confirmed in each of the following cases: (i) if $g(G) \geq 5$ [278], which extends two results in [78, 279]; (ii) if G has no $\{4, 5, 6\}$ -cycles, or without $\{4, 5, 7\}$ -cycles, or without $\{4, 5\}$ -cycles and intersecting 3-cycles [282], or without $\{4, 7, 8\}$ -cycles [107], or with neither 4-cycles nor 6-cycles adjacent to a triangle [74]. In addition, in [282], Montassier et al. proposed the following conjecture which is still unsettled:

Conjecture 11 (Domaine de la Solitude 2000 Conjecture) *Every planar graph without 4-cycles is acyclically 4-choosable.*

Recently, Chen and Raspaud [111], independently Borodin and Ivanova [71], proved that every planar graph without 4- and 5-cycle is acyclically 4-choosable. This result is a new approach to [Conjecture 11](#) and is the best possible in the sense that there are planar graphs without 4- and 5-cycles that are not 3-choosable (see [344]).

3.2.3 Acyclic List 3-Coloring

In 1999, Borodin et al. [78] proved that every planar graph with girth at least 7 is acyclically 3-colorable. Ten years later, Borodin et al. [61] further generalized this result to the list-coloring version by showing that every planar graph with girth

at least 7 is acyclically 3-choosable. Recently, the similar question of Erdős was studied in the acyclic choosability case:

Question 3 *What is the smallest integer i such that every planar graph without cycles of lengths 4 to i is acyclically 3-choosable?*

Borodin [58], and independently Hocquard and Montassier [192], proved that such i exists and $i \leq 12$.

Let $d_\Delta(G)$ denote the minimum distance between triangles in a given graph G . Based on this concept, Hocquard et al. [194] established some new sufficient conditions for a planar graph to be acyclically 3-choosable. More precisely, they proved the following:

Theorem 55 *If a planar graph G satisfies one of the following conditions, then G is acyclically 3-choosable:*

1. *No cycles of length 4 to 10, and $d_\Delta(G) \geq 2$.*
2. *No cycles of length 4 to 9, and $d_\Delta(G) \geq 3$.*
3. *No cycles of length 4 to 8, and $d_\Delta(G) \geq 5$.*
4. *No cycles of length 4 to 7, and $d_\Delta(G) \geq 7$.*

The following three interesting questions were supplied in [194]:

Question 4 *Is every planar graph without 4-, 5-, 6-cycles acyclically 3-choosable?*

Question 5 *Is every planar graph with girth 6 acyclically 3-choosable?*

Question 6 *Does there exist a constant d such that every planar graph G without 4-, 5-, and 6-cycles and $d_\Delta(G) \geq d$ is acyclically 3-choosable?*

3.3 Acyclic Edge Coloring

An *acyclic edge-coloring* of a graph is a proper edge-coloring without bichromatic cycles. The *acyclic chromatic index* or *acyclic edge chromatic number* of a graph G , denoted by $\chi'_a(G)$, is the least integer k such that G admits an acyclic edge-coloring using k colors. The concept of acyclic edge-coloring is a very natural extension of acyclic vertex coloring, which was first investigated by Fiamčík [151].

Since every acyclic edge-coloring is proper, so $\chi'_a(G) \geq \chi'(G) \geq \Delta$ for any graph G . On the other hand, in 2001, Alon et al. [19] posed the following conjecture:

Conjecture 12 *For any graph G , $\chi'_a(G) \leq \Delta + 2$.*

This conjecture would be tight, if true, because there exist graphs G which need at least $\Delta + 2$ colors to form an acyclic edge-coloring. However, the only known so far such graphs are subgraphs of K_{2n} before 2001. Basing on this fact, Alon et al. [19] proposed another conjecture:

Conjecture 13 *If G is a Δ -regular graph, then $\chi'_a(G) = \Delta + 1$ unless $G = K_{2n}$.*

Using probabilistic method, Alon et al.[17] proved that $\chi'_a(G) \leq 64\Delta$ for any graph G . Molloy and Reed [273] improved this bound to that $\chi'_a(G) \leq 16\Delta$, which is the better known upper bound for $\chi'_a(G)$ in terms of Δ . By adding girth restriction, Muthu et al. [285, 286] proved that $\chi'_a(G) \leq 4.52\Delta$ if G is a graph with girth at least 220 and that if G has girth at least 9, then $\chi'_a(G) \leq 6\Delta$, whose proofs were based on probabilistic arguments as well as the following:

Theorem 56 *There are absolute constants $c_1, c_2 > 0$ such that, for any graph G with $g \geq c_1 \log \Delta$, $\chi'_a(G) \leq \Delta + 1 + \lceil c_2(\frac{\Delta \log \Delta}{g}) \rceil$.*

Though the best known upper bound for general case is far from the conjectured $\Delta + 2$, Conjecture 12 has been shown to be true for some special classes of graphs.

It is easy to inspect that $\chi'_a(G) \leq 3$ if $\Delta = 2$. Suppose that G is a subcubic graph, that is, $\Delta \leq 3$. Then the linear graph $L(G)$ of G is of maximum degree at most 4, thus is cyclically 5-colorable [90]. Since $\chi'_a(G) = \chi_a(L(G))$, then $\chi'_a(G) \leq 5 = \Delta + 2$. So Conjecture 12 is true for all subcubic graphs. Skurattankulchai [321] provided a polynomial-time algorithm to color a subcubic graph using five colors.

Theorem 57 *Every subcubic graph G has $\chi'_a(G) \leq 5$, and the edges of G can be acyclically colored using five colors in $O(n)$ time.*

Fiamčík [152], and independently Basavaraju and Chandran [35], showed the following result:

Theorem 58 *Every graph G with $\Delta = 3$ is acyclically edge 4-colorable unless either $G = K_4$ or $G = K_{3,3}$.*

Theorem 59 *If G is a non-regular connected graph with $\Delta = 3$, then $\chi'_a(G) \leq 4$.*

Alon et al. showed in [19] that Conjecture 12 holds for almost all Δ -regular graphs. This has been improved by Něsetřil and Wormald [292] by showing that $\chi'_a(G) \leq \Delta + 1$ for a random Δ -regular graph G . Moreover, if the girth of a graph G is sufficiently large, say $g(G) \geq c\Delta \log \Delta$, then $\chi'_a(G) \leq \Delta + 2$ [19]. More recently, Basavaraju and Chandran [37] proved that Conjecture 12 also holds for complete bipartite graphs $K_{p,p}$, where p is an old prime. More specifically, they proved the following theorems:

Theorem 60 $\chi'_a(K_{p,p}) \leq p + 2$, when p is an odd prime.

Theorem 61 *For a prime $p > 2$, if G is a graph obtained by removing just one edge from $K_{p,p}$, then $\chi'_a(G) = p + 1$.*

Notice that determining $\chi'_a(G)$ is a hard problem from both theoretical and algorithmic points of view. Even for the simple and highly structured classes, for instance complete graphs, the value of $\chi'_a(G)$ is still not determined exactly. It has also been shown by Alon and Zaks [21] that determining whether $\chi'_a(G) \leq 3$ is NP-complete for an arbitrary graph G . Meanwhile, the same authors proved the following:

Theorem 62 *The edges of a graph G can be colored acyclically in polynomial time using $\Delta + 2$ colors, provided that $g(G) \geq cd^3$, where c is an appropriate absolute constant.*

The rest part of this section is concerned with the acyclic edge-coloring of some special graphs, including planar graphs and 2-degenerate graphs.

3.3.1 Planar Graphs

The acyclic edge-coloring of planar graphs has been deeply studied in recent years. In 2008, Fiedorowicz et al. [154] gave a general upper bound $2\Delta + 29$ for the class of planar graphs. This result was gradually improved to $\max\{2\Delta - 2, \Delta + 22\}$ by Hou et al. [202] and then to $\Delta + 25$ by Cohen et al. [115]. Today, the better known upper bound for the class of planar graphs is $\Delta + 12$, due to Basavaraju and Chandran [39].

In 2008, Fiedorowicz et al. [154] considered triangle-free planar graphs by showing the following bound:

Theorem 63 *Every planar graph G without triangles has $\chi'_a(G) \leq \Delta + 6$.*

The upper bound $\Delta + 6$ has been reduced to $\Delta + 5$ by Dong and Xu [131] and then to $\Delta + 3$ by Basavaraju and Chandran [40]. More recently, Shu and Wang [318] obtained a better bound:

Theorem 64 *Every planar graph G without triangles has $\chi'_a(G) \leq \Delta + 2$.*

The value $\Delta + 2$ is the best known upper bound for the class of triangle-free planar graphs. A natural and interesting problem arises to consider the acyclic chromatic index of planar graphs with girth 5. In 2009, Hou et al. [202], and independently Borowiecki and Fiedorowicz [80], proved that if G is a planar graph of girth at least 5, then $\chi'_a(G) \leq \Delta + 2$. Obviously, this result is implied in **Theorem 64**. At the nearly same time, Yu et al. [390] improved this result by restricting the value of maximum degree:

Theorem 65 *If G is a planar graph with girth $g \geq 5$ and $\Delta \geq 11$, then $\chi'_a(G) \leq \Delta + 1$.*

Other sufficient conditions for planar graphs without some specific cycles to be acyclically edge $(\Delta + 1)$ -colorable or $(\Delta + 2)$ -colorable have been presented by some authors. At first, Sun and Wu [323] showed the following:

Theorem 66 *Every planar graph G has $\chi'_a(G) \leq \Delta + 2$ if one of the following conditions holds:*

1. *G contains no i -cycles for all $4 \leq i \leq 8$.*
2. *G contains no 4- and 5-cycles and no intersecting triangles.*

Next, Borowiecki and Fiedorowicz [80] obtained following result, which can be regarded, to some extent, as an improvement to **Theorem 66**.

Theorem 67 *If G is a planar graph without 4-, 6-, 8-, and 9-cycles, then $\chi'_a(G) \leq \Delta + 2$.*

In his Ph.D. Dissertation, Hou [201] also discussed the upper bound $\Delta + 2$ on the acyclic chromatic index of planar graphs without cycles of special lengths. He proved the following result:

Theorem 68 *If G is a planar graph without 4- and 5-cycles, or without 4- and 6-cycles, then $\chi'_a(G) \leq \Delta + 2$.*

Clearly, **Theorem 68** improved greatly **Theorem 66**, which requires only the lack of cycles of two lengths. More naturally, one needs to seek which planar graphs can be acyclically edge colored using $\Delta + 1$ colors. Gao and Yu [158] first obtained the following result:

Theorem 69 *A planar graph G has $\chi'_a(G) \leq \Delta + 1$, if one of the following conditions holds:*

1. $\Delta \geq 10$ and no cycles of lengths 4–11.
2. $\Delta \geq 9$ and no cycles of lengths 4–9.

In the study of planar graphs with acyclic chromatic index attaining lower bound Δ , Cohen et al. [115] made the following conjecture:

Conjecture 14 *There exists an integer Δ_0 such that every planar graph G with maximum degree $\Delta \geq \Delta_0$ has $\chi'_a(G) = \Delta$.*

Indeed, Cohen et al. [115] confirmed **Conjecture 14** for outerplanar graphs with $\Delta_0 = 9$ and for planar graphs G with $\Delta_0 = 19$ and $g(G) \geq 5$. To obtain this, they proved a stronger result by considering maximum average degree.

The *maximum average degree* $\text{mad}(G)$ of a graph G is defined by

$$\text{mad}(G) = \max_{H \subseteq G} \{2|E(H)|/|V(H)|\}.$$

The following is a folklore fact:

Proposition 2 *Let G be a planar graph of girth g . Then*

$$\text{mad}(G) < \frac{2g}{g-2}.$$

The maximum average degree of graphs is an important measure to determine the sparseness of an arbitrary graph (not necessarily planar). On the other hand, it is known that the maximum average degree of a graph can be computed in polynomial time by using the Matroid Partitioning Algorithm due to Edmonds [138].

Theorem 70 *If G is a planar graph with $\Delta \geq 19$ and $\text{mad}(G) < \frac{10}{3}$, then $\chi'_a(G) \leq \Delta$.*

Actually, Cohen et al. [115] established a more general result as follows:

Theorem 71 For any $\epsilon > 0$, there exists an integer Δ_ϵ such that if $\Delta \geq \Delta_\epsilon$ and $\text{mad}(G) \leq 4 - \epsilon$, then $\chi'_a(G) = \Delta$.

In view of the previous arguments, two parameters, that is, girth g and maximum degree Δ , play important roles in deciding an acyclically edge Δ -colorable planar graphs. Different combinations of these two parameters will yield different results on this topic. In 2009, Hou et al. [202] and Yu et al. [390] studied this problem and showed the following:

Theorem 72 Let G be a planar graph with $\Delta \geq 3$ and girth $g \geq 16$. Then $\chi'_a(G) = \Delta$.

Theorem 73 Let G be a planar graph with girth g . Then $\chi'_a(G) = \Delta$ if there is a pair $(k, m) \in \{(4, 12), (5, 10), (6, 8), (12, 7)\}$ such that G satisfies $\Delta \geq k$ and $g \geq m$.

Later, Dong and Xu [131], Wang et al. [317, 365], and Hudák et al. [206] obtained several similar results, respectively. Their results are summarized as follows:

Theorem 74 Let G be a planar graph with girth g . Then $\chi'_a(G) = \Delta$ if there is a pair $(k, m) \in \{(3, 14), (4, 10), (5, 9), (6, 8), (8, 7)\}$ such that G satisfies $\Delta \geq k$ and $g \geq m$.

Theorem 75 Let G be a planar graph with girth g . Then $\chi'_a(G) = \Delta$ if there is a pair $(k, m) \in \{(3, 11), (4, 8), (5, 7), (8, 6)\}$ such that G satisfies $\Delta \geq k$ and $g \geq m$.

Theorem 76 Let G be a planar graph with girth $g \geq 5$ and $\Delta \geq 12$. Then $\chi'_a(G) = \Delta$.

Theorem 77 Let G be a planar graph with girth g . Then $\chi'_a(G) = \Delta$ if there is a pair $(k, m) \in \{(3, 12), (4, 8), (5, 7), (6, 6), (10, 5)\}$ such that G satisfies $\Delta \geq k$ and $g \geq m$.

3.3.2 2-Degenerate Graphs

Recall that a graph G is k -degenerate if any induced subgraph H of G has a vertex of degree at most k in H . For example, planar graphs are 5-degenerate and forests are 1-degenerate. The class of 2-degenerate graphs includes series-parallel graphs, partial 2-trees, outerplanar graphs, non-regular subcubic graphs, planar graphs with girth, at least 6 and circle graphs with girth at least 5 as subclasses.

The earliest result on the acyclic edge-coloring of 2-degenerate graphs was obtained by Card and Roditty [94] who proved that $\chi'_a(G) \leq \Delta + k - 1$, where k is the maximum edge connectivity, defined by $k = \max_{u,v \in V(G)} \{\lambda(u, v)\}$, where $\lambda(u, v)$ is the edge connectivity of a pair of vertices u, v . Note that here k can be as large as Δ .

An *outerplanar graph* is a graph which can be embedded in the plane in such a way that every vertex lies on the boundary of the outer face. Muthu et al. [287] proved that [Conjecture 12](#) is true for outerplanar graphs. In fact, they gave a better bound, $\Delta + 1$, as follows:

Theorem 78 Every outerplanar graph G with n vertices is acyclically edge $(\Delta+1)$ -colorable. Moreover, an acyclic edge $(\Delta+1)$ -coloring can be obtained in $O(n \log \Delta)$ time.

In addition, they posed the following interesting question:

Question 7 Is every 2-degenerate graph acyclically edge $(\Delta+2)$ -colorable?

Let H_{2n} , $n \geq 2$ and denote the graph obtained by adding $n-1$ chords $x_2x_{2n}, x_3x_{2n-1}, \dots, x_nx_{n+2}$ to a $2n$ -cycle $x_1x_2 \dots x_{2n}x_1$. Let Q denote the graph obtained by adding four edges y_2y_7, y_2y_6, y_3y_5 , and y_3y_6 to a 7-cycle $y_1y_2 \dots y_7y_1$.

Hou et al. [203], and independently Wang and Wang [367], determined the acyclic edge chromatic number of outerplanar graphs G with $\Delta \neq 4$.

Theorem 79 Let G be an outerplanar graph with $\Delta \geq 3$. Then

1. $\chi'_a(G) = \Delta$ if $\Delta \geq 5$.
2. If $\Delta = 3$, then $3 \leq \chi'_a(G) \leq 4$; and $\chi'_a(G) = 4$ if and only if G contains a 2-connected block isomorphic to H_{2n} for some $n \geq 2$.

For the $\Delta = 4$ case, Hou et al. [203] also provided a characterization, which says that if G is an outerplanar graph with $\Delta = 4$, then $4 \leq \chi'_a(G) \leq 5$ and $\chi'_a(G) = 5$ if and only if G contains a subgraph isomorphic to the graph Q defined above. However, their characterization is incorrect, as Wang and Wang [367] constructed infinitely many outerplanar graphs G with $\Delta = 4$ and $\chi'_a(G) = 5$, which do not contain any configuration isomorphic to Q .

Recall that a graph G has a graph H as a *minor* if H can be obtained from a subgraph of G by contracting edges, and G is called H -*minor-free* if G does not have H as a minor. It is well-known that a graph G is an outerplanar graph if and only if G is K_4 -minor-free and $K_{2,3}$ -minor-free. A graph G is K_4 -minor-free if and only if each block of G is a series-parallel graph. Thus, the class of K_4 -minor-free graphs is a subclass of planar graphs that includes both outerplanar graphs and series-parallel graphs.

Hou et al. [202] and independently Muthu et al. [288] proved that $\Delta + 1$ colors are sufficient for an acyclic edge-coloring of a series-parallel graph G .

Theorem 80 Every series-parallel graph G is acyclically edge $(\Delta+1)$ -colorable.

Theorem 80 extends the result in [287], since every outerplanar graph is a series-parallel graph but the converse may be not true.

A *2-tree* is a graph obtained from the triangle K_3 , by a sequence of operations of adding a new vertex adjacent to the endpoints of an existing edge in the graph, and a *partial 2-tree* is any subgraph of a 2-tree. It is easy to observe that 2-trees are planar and 2-degenerate. Muthu et al. [288] confirmed Conjecture 12 for 2-trees and partial 2-trees.

Theorem 81 If G is a 2-tree or a partial 2-tree, then $\chi'_a(G) \leq \Delta + 1$.

Recently, Wang and Shu [366] further studied the acyclic chromatic indices of K_4 -minor-free graphs. They proved the following:

Theorem 82 *Let G be a K_4 -minor-free graph with $\Delta = 3$ or $\Delta \geq 5$. Then $\Delta \leq \chi'_a(G) \leq \Delta + 1$; and $\chi'_a(G) = \Delta + 1$ if and only if $\Delta = 3$ and G contains a block isomorphic to H_{2n} for some $n \geq 2$.*

Note that [Theorem 82](#) improves and extends the previous [Theorems 79](#) and [80](#). However, it remains open to determine the acyclic chromatic index of a K_4 -minor-free graph with $\Delta = 4$, even for an outerplanar graph with $\Delta = 4$. Solving this question seems to be very interesting.

As it is pointed out before, another two important subclasses of 2-degenerate graphs are planar graphs of girth 6 and circle graphs of girth 5. Nothing much is known about the acyclic edge chromatic number of circle graphs of girth 5. For planar graphs of girth at least 6, some existing conclusions were independently presented in [80, 202, 390].

More recently, Basavaraju and Chandran [38] answered positively [Question 7](#). In fact, they got a stronger result:

Theorem 83 *Every 2-degenerate graph is acyclically edge $(\Delta + 1)$ -colorable.*

Note that the upper bound $\Delta + 1$ in [Theorem 83](#) is sharp, since there exist infinitely many 2-degenerate graphs which require $\Delta + 1$ colors to admit an acyclic edge-coloring (e.g., odd cycles and non-regular subcubic graphs). Moreover, the constructive proof of [Theorem 83](#) yields actually an efficient polynomial-time algorithm with the complexity $O(\Delta|G|^2)$.

3.3.3 Graphs with a Fixed Maximum Degree

Determining $\chi'_a(G)$ for general graphs is a quite difficult problem, only few partial results have been known. For a graph G with $\Delta = 1$, it is trivial that $\chi'_a(G) = 1$. If G is a graph with $\Delta = 2$, then $\chi'_a(G) = 2$ when G is a linear forest and $\chi'_a(G) = 3$ when G contains a cycle. For the general upper bound, Fiamčík [151] proved the following:

Theorem 84 *Let G be a graph. Then $\chi'_a(G) \leq \Delta(\Delta - 1) + 1$; and $\chi'_a(G) \leq 9$ if $\Delta = 4$.*

By considering the relationship between the number of vertices and edges of a graph G , Guldan [172] obtained some helpful lower bounds:

Theorem 85 *Let k be a positive integer and let G be a graph with n vertices and m edges.*

1. *If $n = 2k$ and $m > (k - 1)(\Delta + 1) + 1$, then $\chi'_a(G) \geq \Delta + 2$.*
2. *If $n = 2k + 1$ and $m > k\Delta$, or if $n = 2k$ and $m > (k - 1)\Delta + 1$, then $\chi'_a(G) \geq \Delta + 1$.*

It follows immediately from [Theorem 85](#) that there exist infinitely many graphs with $\chi'_a(G) \geq \Delta + 2$. This disproves a conjecture introduced by Fiamčík at the

Czechoslovak Conference Graph Theory 1984, which states that if a connected graph G has maximum degree Δ and if $G \notin \{K_{\Delta+1}, K_{\Delta,\Delta}, (K_{\Delta+2} - F_1)\}$, then $\chi'_a(G) \leq \Delta + 1$.

The following useful fact is a direct consequence of [Theorem 85](#):

Corollary 6 *Let G be a Δ -regular graph with $\Delta > 1$. Then $\chi'_a(G) \geq \Delta + 1$.*

Alon et al. [19] suggested a possibility that complete graphs of even order are the only regular graphs which require $\Delta + 2$ colors to be acyclically edge colored. Něsetřil and Wormald [292] supported the statement by showing that the acyclic edge chromatic number of a random d -regular graph is asymptotically almost surely equal to $d + 1$ (when $d \geq 2$). However, Basavaraju et al. [41] showed that this is not true in general case by using a simple counting argument. More specifically, they proved the following three theorems:

Theorem 86 *Let G be a d -regular graph with $2n$ vertices and $d > n$. Then $\chi'_a(G) \geq d + 2$.*

Theorem 87 *For any d and n such that dn is even and $d \geq 5$, $n \geq 2d + 3$, there exists a connected d -regular graph that requires $d + 2$ colors to be acyclically edge colored.*

Theorem 88 $\chi'_a(K_{n,n}) \geq n + 2$, when n is odd.

In 2009, Basavaraju and Chandran [36] nearly settled [Conjecture 12](#) for connected graphs G with $\Delta = 4$ with an additional restriction:

Theorem 89 *Let G be a connected graph with n vertices and m edges. If $\Delta = 4$ and $m \leq 2n - 1$, then $\chi'_a(G) \leq 6$.*

Note that a graph G with order n and maximum degree 4 has at most $2n$ edges. Thus, [Theorem 89](#) implies that, to confirm [Conjecture 12](#) for $\Delta = 4$, it suffices to consider the left case where $m = 2n$.

Fiedorowicz [153] studied the acyclic edge-coloring of graphs with the number of edges linearly bounded by the number of vertices and gave the following theorem.

Theorem 90 *Let $t \geq 2$ be an integer. If G satisfies the condition that $|E(G')| \leq t|V(G')| - 1$ for each subgraph $G' \subseteq G$, then $\chi'_a(G) \leq (t - 1)\Delta + p$, where $p = 2t^3 - 3t + 2$.*

Based on this result, the authors gave a polynomial-time algorithm to compute such a coloring. Note that the class of graphs considered in [Theorem 90](#) is quite large, for example, including all t -degenerate graphs.

3.4 Related Coloring Problems

This section is devoted to introducing some concepts related to acyclic coloring and acyclic edge coloring, including acyclic improper colorings, star coloring, frugal coloring, and linear coloring.

3.4.1 Acyclic Improper Coloring

Boiron et al. [54] extended in a natural way the notion of acyclic coloring to the acyclic improper coloring as follows. An *acyclic t -improper k -coloring*, or simply an acyclic $(k, t)^*$ -coloring, of G is a $(k, t)^*$ -coloring which is acyclic, that is, G contains no bichromatic cycles. In other words, an acyclic t -improper coloring is an acyclic coloring such that each color class induces a graph with maximum degree at most t . The t -improper acyclic chromatic number $\chi_a^t(G)$ is the smallest k for which there exists an acyclic t -improper coloring.

The main motivation in the study of acyclic improper coloring is the link with oriented coloring. It was proved in [54] that every subcubic graph is acyclically $(3, 1)^*$ -colorable and conjectured that every subcubic graph is acyclically $(2, 2)^*$ -colorable. Moreover, they constructed subcubic graphs which are not acyclically $(2, 1)^*$ -colorable. They also proved that every outerplanar graph is acyclically $(2, 5)^*$ -colorable and constructed outerplanar graphs which are not acyclically $(2, 4)^*$ -colorable. Furthermore, they proved that for every $k \geq 0$, there exist planar graphs which are not acyclically $(4, k)^*$ -colorable.

Let $\chi_a^t(d) = \max\{\chi_a^t(G) : \Delta(G) \leq d\}$. Clearly, for any d , $\chi_a^0(d) \geq \chi_a^1(d) \geq \dots \geq \chi_a^d(d) \geq 1$, and it is easily seen that $\chi_a^t(d) = \Omega((d/t)^{4/3}/(\ln d)^{1/3})$.

Esperet and Pinlou [143] first introduced and studied the acyclic improper choosability of graphs. It is natural to define the acyclic improper choosability of a graph. A graph G is *acyclically t -improper L -colorable* if for a given list assignment $L = \{L(v) : v \in V(G)\}$, there exists an acyclic t -improper coloring f such that $f(v) \in L(v)$ for every v . If G is acyclically t -improper L -colorable for any list assignment L with $|L(v)| \geq l$ for every v , then G is called *acyclically t -improper l -choosable* or simply acyclically $(l, t)^*$ -choosable. The acyclic t -improper list chromatic number of G is therefore defined as the smallest integer l such that G is acyclically $(l, t)^*$ -choosable.

In [143], Esperet and Pinlou extended two results in [54] by showing the following:

Theorem 91 *Every subcubic graph is acyclically $(3, 1)^*$ -choosable.*

Theorem 92 *Every outerplanar graph is acyclically $(2, 5)^*$ -choosable.*

Furthermore, in [142, 143], the authors also proved that

Theorem 93 *There exists a constant $\eta > 0$ such that if $t < \eta(\frac{n}{\log n})^{3/4}$, then $\chi_a^t(d) = \Omega\left(\frac{d^{3/4}}{(\log d)^{1/3}}\right)$.*

Recently, Addario-Berry et al. [5] studied how $\chi_a^t(d)$ varies as a function of t and d and gave the following three theorems:

Theorem 94 *If $t \leq d - 10\sqrt{d \ln d}$, then $\chi_a^t(d) = \Omega((d-t)^{4/3}/(\ln d)^{1/3})$.*

In particular, if $t = (1 - \varepsilon)d$ for any fixed constant ε , $0 < \varepsilon < 1$, then they obtained the same asymptotic lower bound as Alon et al. [17].

Theorem 95 $\chi_a^t(d) = O(d \ln d + (d - t)d)$.

Theorem 96 $\chi_a^{d-1}(d) = \Omega(d^{2/3})$.

3.4.2 Star Coloring

While Grünbaum [171] introduced the acyclic coloring notion, he also noted that the condition that the union of any two color classes inducing a forest can be generalized to other bipartite graphs. Among other problems, he suggested requiring that the union of any pair of color classes induces a star forest, namely, a proper coloring avoiding 2-colored paths with four vertices. Precisely, a proper coloring of the vertices of a graph G is called a *star coloring* if the union of any two color classes induces a star forest. In other words, no path on four vertices is 2-colored. The *star chromatic number* of G , denoted by $\chi_s(G)$, is the smallest integer k for which G admits a star coloring with k colors.

Grünbaum noted (without proof) that bounding the acyclic chromatic number bounds the star chromatic number. Here the result is stated, a proof of which was given by Fertin et al. [149].

Theorem 97 If $\chi_a(G) = k$, then $\chi_s(G) \leq k \cdot 2^{k-1}$.

Both acyclic and star colorings have applications in the field of combinatorial scientific computing, where they model two different schemes for the evaluation of sparse Hessian matrices. The general idea behind the use of coloring in computing derivative matrices is the identification of entities that are essentially independent and thus may be computed concurrently; see [161] for a survey.

Let \mathcal{P} denote the family of planar graphs. By the Borodin's acyclically 5-colorable theorem and Theorem 97, it is easy to obtain that $\chi_s(\mathcal{P}) \leq 80$. In 2003, Nešetřil and Ossona de Mendez [291] made a big step by showing that $\chi_s(\mathcal{P}) \leq 30$. This result also implies that every triangle-free planar graph can be star colored using 18 colors, whereas Kierstead, Kündgen, and Timmons [226] gave an example of a bipartite planar graph that requires 8 colors to star color. One year later, Albertson et al. [13] further reduced the upper bound 30 to 20 and gave a lower bound by showing an example of a planar graph H using at least 10 colors to star color. It therefore follows that $10 \leq \chi_s(\mathcal{P}) \leq 20$. Moreover, they made an improvement to Theorem 97 as follows:

Theorem 98 If $\chi_a(G) = k$, then $\chi_s(G) \leq k(2k - 1)$.

For graphs with smaller maximum average degree, Jensen and Toft [213] showed that there is a polynomial-time algorithm for determining the maximum average degree of a given graph G . Moreover, as stated before, there exists a close relation between the maximum average degree and girth of a graph G .

In [85], Bu et al. proved the following result:

Theorem 99 Let G be a graph with girth g :

1. If $\text{mad}(G) < \frac{26}{11}$, then $\chi_s(G) \leq 4$.
2. If $\text{mad}(G) < \frac{18}{7}$ and $g \geq 6$, then $\chi_s(G) \leq 5$.
3. If $\text{mad}(G) < \frac{8}{3}$ and $g \geq 6$, then $\chi_s(G) \leq 6$.

From [Proposition 2](#) and [Theorem 99](#), it is immediate to derive that for a planar graph G with girth g , $\chi_s(G) \leq 4$ if $g \geq 13$, $\chi_s(G) \leq 5$ if $g \geq 9$, and $\chi_s(G) \leq 6$ if $g \geq 8$.

Other star coloring results related to planar graphs were provided in Timmons Master's Thesis [[334](#)].

A graph G is *star L -colorable* if for a given list assignment L , there is a star coloring c such that $c(v) \in L(v)$. If G is star L -colorable for any list assignment L with $|L(v)| \geq k$ for all $v \in V(G)$, then G is star k -choosable. The *star list chromatic number*, denoted by $\chi_s^l(G)$, of G is the smallest integer k such that G is star k -choosable.

The star list coloring of graphs has been recently investigated by many authors. Kierstead et al. [[226](#)] showed that bipartite planar graphs are star 14-choosable. In [[241](#)], Kündgen and Timmons proved a theorem about the dependence between the maximum average degree of graphs and their star list chromatic numbers. Their main result is the following:

Theorem 100 *Let G be a graph:*

1. *If $\text{mad}(G) < \frac{8}{3}$, then $\chi_s^l(G) \leq 6$.*
2. *If $\text{mad}(G) < \frac{14}{5}$, then $\chi_s^l(G) \leq 7$.*
3. *If G is planar and with girth at least 6, then $\chi_s^l(G) \leq 8$.*

It should be noticed that the conclusion (1) in [Theorem 100](#) is stronger than the third conclusion in [Theorem 99](#). It can be deduced from [Proposition 2](#) and (1) and (2) in [Theorem 100](#) that $\chi_s^l(G) \leq 6$ if $g \geq 8$, and $\chi_s^l(G) \leq 7$ if $g \geq 7$, where G is a planar graph with girth g .

By the definition, every star coloring is an acyclic coloring but star coloring a graph typically requires more colors than acyclic coloring the same graph. Moreover, determining the minimum (list) chromatic number of many families of graphs is proved to be a challenging problem. This is indeed the case for families as simple as subcubic graphs.

In 2001, Fertin et al. [[149](#)] gave the exact value of the star chromatic number of different families of graphs such as trees, cycles, complete bipartite graphs, outerplanar graphs, and two-dimensional grids. In the same paper, they also gave bounds for the star chromatic number of other families of graphs, such as hypercubes, tori, d -dimensional grids, graphs with bounded treewidth, and planar graphs. One interesting result may be that every subcubic graph is star 9-colorable, while there exists a subcubic graph, that is, the Wagner graph (see [Fig. 3](#)), has star chromatic number at least 6. Recently, Chen et al. [[112](#)] showed that 6 colors are enough to star color any subcubic graphs. Moreover, Albertson et al. [[13](#)] proved that every subcubic graph is star 7-choosable.

[Table 1](#) describes the currently best known bounds for the star chromatic number of planar graphs with girth g . The best known bound is given along with the corresponding reference.

Table 1 Best known bounds on star chromatic number of planar graphs

Girth g	Best known bounds	
	Lower bound	Upper bound
3	10 [13]	20 [13]
4	8 [226]	18 [291]
5	6 [334]	16 [13]
6	5 [334]	8 [241]
7	5 [335]	7 [334]
8	4 [13]	6 [334] [85]
9–13	4 [13]	5 [335]
14 ⁺	4 [13]	4 [335]

By Table 1, planar graphs with girth 4 are star 18-colorable. Recently, Kierstead et al. [226] showed that bipartite planar graphs are star 14-choosable. Since the girth of bipartite planar graphs is at least 4, it seems to be interesting to study the following problem.

Problem 2 *Can the upper bound 18 on star chromatic number of planar graphs of girth at least 4 be improved to 14?*

Besides, Table 1 also shows that planar graphs of girth at least 14 can be star colored with 4 colors and there is a planar graph with girth 7 that requires 5 colors to star color. Finally, this section is ended with the following problem:

Problem 3 *What is the smallest integer k such that planar graphs of girth at least k is star 4-colorable?*

3.4.3 Linear Coloring

A coloring (not necessarily proper) of G is t -frugal if no color appears more than t times in any neighborhood of any vertex. The t -frugal chromatic number $\varphi^t(G)$ denotes the least number of colors needed in a t -frugal coloring that is not necessarily proper. For $t \geq 1$, the superscript t will denote that the coloring considered is t -frugal. That is, $\chi^t(G)$ will denote the least number of colors used in a proper t -frugal coloring. The notion of frugal coloring was introduced in 1997 by Hind et al. [190]. They investigated proper t -frugal colorings as a way to improve bounds related to the Total Coloring Conjecture (cf. [191]). For the graphs of bounded maximum degree, the authors in [190] studied proper t -frugal colorings, and Yuster [391] studied acyclic proper 2-frugal colorings. Recently, Kang and Müller [220] expanded this study and set up some relations among parameters $\varphi^t(G)$, $\chi^t(G)$, $\chi_a^t(G)$, and $\chi_s^t(G)$.

A related concept about t -frugal coloring of graphs is the linear coloring. A proper vertex coloring of a graph G is linear if the graph induced by the vertices of any two color classes is the union of vertex-disjoint paths. The linear chromatic number $lc(G)$ of the graph G is the smallest number of colors in a linear coloring

of G . Thus, a linear coloring is just a 3-frugal coloring and is also a special case of acyclic coloring of G .

If G is linearly L -colorable for any list assignment L satisfying $|L(v)| \geq k$ for any $v \in V(G)$, then G is said to be *linearly k -choosable*. The smallest integer k such that G is linearly k -choosable is called the *linear choice number*, denoted by $\Lambda^l(G)$. By the definition, it is obvious that $lc(G) \leq \Lambda^l(G)$ for any graph G .

Yuster [391] first introduced and investigated the linear coloring of graphs. With a probabilistic method, he proved that $lc(G) = O(\Delta^{\frac{3}{2}})$ for a general graph G with maximum degree Δ and constructed graphs G such that $lc(G) = \Omega(\Delta^{\frac{3}{2}})$.

In 2005, Esperet et al. [141] generalized the linear coloring of graphs to a list-coloring version. They investigated linear choosability for some classical families of graphs such as trees, grids, bipartite complete graphs, planar graphs, outerplanar graphs, graphs with maximum degree 3 or 4, and graphs with given maximum average degree. In particular, the following result is implied in their paper:

Theorem 101 *Let G be a planar graph with girth g :*

1. *If $\Delta \geq 12$, then $\Lambda^l(G) \leq 2\Delta + 26$.*
2. *If $g \geq 16$ and $\Delta \geq 3$, then $\Lambda^l(G) = \lceil \frac{\Delta}{2} \rceil + 1$.*
3. *If $g \geq 10$, then $\Lambda^l(G) \leq \lceil \frac{\Delta}{2} \rceil + 2$.*
4. *If $g \geq 8$, then $\Lambda^l(G) \leq \lceil \frac{\Delta}{2} \rceil + 3$.*

It is easy to see by the definition of linear coloring that $lc(G) \geq \lceil \frac{\Delta}{2} \rceil + 1$ for any graph G . A natural question is which graphs G can attain the lower bound $\lceil \frac{\Delta}{2} \rceil + 1$? Raspaud and Wang [299] proved that planar graphs with high girth and large maximum degree possess such a property. More precisely, they proved the following two theorems:

Theorem 102 *Every planar graph G has $lc(G) = \lceil \frac{\Delta}{2} \rceil + 1$ if there is a pair $(k, g) \in \{(13, 7), (7, 9), (5, 11), (3, 13)\}$ such that G satisfies $\Delta \geq k$ and G has girth at least g .*

Note that the condition that $\Delta \geq 3$ in **Theorem 102** is essential, since every cycle C of length at least 3 satisfies $lc(G) = 3 > 2 = \lceil \frac{\Delta}{2} \rceil + 1$.

Theorem 103 *Let G be a planar graph with girth g :*

1. *If $g \geq 6$, then $lc(G) \leq \lceil \frac{\Delta}{2} \rceil + 4$.*
2. *If $g \geq 5$, then $lc(G) \leq \lceil \frac{\Delta}{2} \rceil + 14$.*

More recently, **Theorem 102** was extended by Wang and Li [357] by showing the following result.

Theorem 104 *Every graph G embeddable in a surface of nonnegative characteristic has $lc(G) = \lceil \frac{\Delta}{2} \rceil + 1$ if there is a pair $(k, g) \in \{(13, 7), (9, 8), (5, 10), (3, 13)\}$ such that G satisfies $\Delta \geq k$ and G has girth at least g .*

Dong, Xu, and Zhang [132] improved partially the results in **Theorem 103** by showing:

Theorem 105 Let G be a planar graph with girth g :

1. If $g \geq 8$, then $lc(G) \leq \lceil \frac{\Delta}{2} \rceil + 2$.
2. If $g \geq 6$, then $lc(G) \leq \lceil \frac{\Delta}{2} \rceil + 3$.
3. If $g \geq 5$, then $lc(G) \leq \lceil \frac{\Delta}{2} \rceil + 10$.

The latest results on linear chromatic number were established by Li et al. [247].

Theorem 106 Let G be a graph:

1. $lc(G) \leq \frac{1}{2}(\Delta^2 + \Delta)$.
2. If $\Delta \leq 4$, then $lc(G) \leq 8$.
3. If $\Delta \leq 5$, then $lc(G) \leq 14$.
4. If G is a planar graph with $\Delta \geq 52$, then $lc(G) \leq \lfloor 0.9\Delta \rfloor + 5$.

3.4.4 Generalized Acyclic Colorings

A generalization of the acyclic edge chromatic number was introduced by Gerke et al. in [163].

Let $r \geq 3$ be a positive integer. Given a graph G , let $\chi'_{a:r}(G)$ be the minimum number of colors required to color the edges of the graph such that every k -cycle has at least $\min\{k, r\}$ colors, for all $k \geq 3$. So $\chi'_a(G) = \chi'_{a:3}(G)$. The r -acyclic edge chromatic number $\chi'_{a:r}(G)$ is the minimum number of colors required to color the edges of the graph G such that every cycle C of G has at least $\min\{|C|, r\}$ colors.

Replacing the word *edges* with *vertices* gives the definition of the r -acyclic chromatic number $\chi_{a:r}(G)$ of G . A proper vertex (respectively, edge) coloring is r -acyclic if each k -cycle has at least $\min\{k, r\}$ colors, for $k \geq 3$. Obviously, a proper r -acyclic coloring of the line graph $L(G)$ of a graph G gives a proper r -acyclic edge coloring of G . Hence, $\chi'_{a:r}(G) \leq \chi_{a:r}(L(G))$.

Note that the complete bipartite graph $K_{d,d}$ satisfies $\chi_{a:4}(K_{d,d}) = d^2$, since every edge must receive a distinct color to avoid a 4-cycle that is colored with less than four colors. This is an example of a class of graphs where the 4-acyclic edge chromatic number of any member is quadratic in its maximum degree. For the case $r \geq 6$, Greenhill and Pikhurko [167] considered the generalized acyclic chromatic number and generalized acyclic edge chromatic number of graphs with maximum degree d and constructed Δ -regular graphs G with $\chi'_{a:r}(G) \geq c_r \Delta^{\lfloor r/2 \rfloor}$, where c_r depends on r but is a constant with respect to Δ . They also proved upper bounds on $\chi'_{a:r}(G)$ of graphs with order $O(\Delta)^{\lfloor r/2 \rfloor}$. Exactly, they proved the following theorem by using the Local Lemma while considering the Hamming cube graphs. The upper bounds and the lower bounds were given in [167].

Before stating the following theorem, some notation is first introduced. Let d be a positive integer. Let $\chi_{a:r}(\Delta)$ and $\chi'_{a:r}(\Delta)$, respectively, be the maximum of $\chi_{a:r}(G)$ and $\chi'_{a:r}(G)$, over all graphs G with maximum degree Δ . The following theorem was obtained in [167].

Theorem 107 Let $r \geq 4$ be fixed. There exist positive constants c, C, c', C' such that $c\Delta^{\lfloor r/2 \rfloor} \leq \chi_{a:r}(\Delta) \leq C\Delta^{\lfloor r/2 \rfloor}$, $c'\Delta^{\lfloor r/2 \rfloor} \leq \chi'_{a:r}(\Delta) \leq C'\Delta^{\lfloor r/2 \rfloor}$ for $\Delta \geq 3$.

In addition, the authors in [167] showed that some well-known algebraic constructions produce families of graphs which, unlike the Hamming cubes, have girth at least r but still provide fairly good lower bounds for the r -acyclic chromatic numbers when $r = 6, 8, 12$.

Theorem 108 Suppose that $d = q + 1$ where q is a prime or prime power. Then there is a graph G which is d -regular, has girth 6, and satisfies $\chi_{a:6}(G) = 2(d^2 - d + 1)$, $\chi'_{a:6}(G) = d(d^2 - d + 1)$.

Theorem 109 Suppose that $d = q + 1$ where q is a prime or prime power. Then there is a graph G which is d -regular, has girth 6, and satisfies $\chi_{a:8}(G) = 2d(d^2 - 2d + 2)$, $\chi'_{a:8}(G) = d^2(d^2 - 2d + 2)$.

Theorem 110 Suppose that $d = q + 1$ where q is a prime or prime power. Then there is a graph G which is d -regular, has girth 12, and satisfies $\chi_{a:12}(G) = 2d(d^4 - 4d^3 + 7d^2 - 6d + 3)$, $\chi'_{a:12}(G) = d^2(d^4 - 4d^3 + 7d^2 - 6d + 3)$.

In [163], it was shown that typical Δ -regular graphs have much smaller r -acyclic edge chromatic number. More precisely, it was shown that a random Δ -regular graph on n vertices has, with probability tending to 1 as n tends to infinity, an r -acyclic edge chromatic number at most $(r - 2)\Delta$.

A property holds *asymptotically almost surely* (a.a.s.) if the probability that it holds tends to 1 as n tends to infinity.

Theorem 111 ([163]) Let $\Delta \geq 2$ and $r \geq 4$ be fixed. The r -acyclic edge chromatic number of a uniformly chosen Δ -regular graph on n vertices is a.a.s. at most $(r - 2)\Delta$.

Therefore, a typical regular graph has an r -acyclic edge chromatic number that is linear in its maximum degree. A natural question is thus to ask which structures force a class of graphs to have an r -acyclic edge chromatic number that is quadratic in Δ . In 2006, Gerke and Raemy [164] showed that such a class has to contain graphs with small girth. More specifically, they showed the following theorem:

Theorem 112 Let $r \geq 4$ be an integer. For any graph G with maximum degree Δ and girth $g \geq 3(r - 1)\Delta$, it holds that $\chi'_{a:r}(G) \leq 6(r - 1)\Delta$.

Theorem 112 showed that for the class of graphs with large girth, the r -acyclic edge chromatic number is linear in Δ if r is fixed. The upper bound is at most a factor 12 away from the optimal bound as it is known [163] that every d -regular graph with girth $r \geq 3$ satisfies $\chi'_{a:r}(G) > (r - 1)d/2$.

4 Vertex-Distinguishing Coloring

This section is concerned with vertex-distinguish coloring problems. To start with this, a new concept is needed, namely, edge-weighting. Let G be a graph. A k -edge weighting of G is a mapping $\phi : E(G) \rightarrow \{1, 2, \dots, k\}$. Let $\phi(e)$

denote the weight of edge e . Usually, it is needed to seek a much smaller size of $\{1, 2, \dots, k\}$ such that there exists a mapping ϕ satisfying several given constraints. Given a graph G and an edge-weighting ϕ of G , for $v \in V(G)$, let $S_\phi(v) = \{\phi(e) | v \in e\}$ be the set of edge-weights appearing on edges incident to v under the edge-weighting ϕ .

Based on the Ph.D. dissertation [293], the class of edge-weighting problems can be roughly split into two parts. The one is the *proper edge-weightings* (also named as edge-coloring), that is, edge weightings of G where any two adjacent edges must be mapped to different weights by ϕ . The other is the *improper edge-weightings* of G , that is, edge-weightings of G where two adjacent edges may be mapped to the same weight by ϕ .

4.1 Proper Edge-Weighting

Firstly, proper edge weighting (namely, edge-coloring) is considered. It is evident that Δ is the lower bound for all the considered edge-coloring problems. Moreover, if G has two adjacent vertices of maximum degree, then $\Delta + 1$ is the corresponding lower bound.

4.1.1 Vertex-Distinguishing Edge-Colorings

An edge-coloring ϕ of G is called *vertex-distinguishing* (or *vde-coloring* for short), if any two vertices u, v have different weight sets, i.e., $S_\phi(u) \neq S_\phi(v)$. A vde-coloring is also called a *strong edge coloring*, or *point-distinguishing edge-coloring*. The *vertex-distinguishing chromatic index* of G , denoted by $\chi'_{vd}(G)$ (or $vd(G)$), is the smallest integer k such that there is a k -vde-coloring of G . This graph parameter is introduced by Burris and Schelp [88, 89] and, independently (as *observability* of a graph), by Černý et al. [96], and Horňák and Soták [195].

If G has an isolated edge uv , then $S(u) = S(v)$ always and G cannot have a vde-coloring. Similarly, if G has two isolated vertices u, v , then $S(u) = S(v) = \emptyset$. However, every graph without isolated edges and with at most one isolated vertex must have a vde-coloring: simply assign different colors to all edges of G . Such graphs are called as *nice graphs*.

In [88], the author conjectured two different upper bounds. The first one has been confirmed by Bazgan et al. [42].

Theorem 113 *If G is a nice graph on n vertices, then $\chi'_{vd}(G) \leq n + 1$.*

The sharpness of Theorem 113 can be confirmed by considering the complete graph on n vertices with n even.

Given a graph G , let n_d denote the number of vertices of degree d . It is easy to see that if there exists a k -vde-coloring of G , then $\binom{k}{d} \geq n_d$ for all $1 \leq d \leq \Delta$. The second conjecture of Burris and Schelp [88, 89] remains open, which is analogous to the Vizing's Theorem on edge coloring:

Conjecture 15 If G is a nice graph and k is the minimum integer such that $\binom{k}{d} \geq n_d$ for all $\delta \leq d \leq \Delta$, then $k \leq \chi'_{\text{vd}}(G) \leq k + 1$.

In the same papers [88, 89], Burris and Schelp gave an upper bound of $\chi'_{\text{vd}}(G)$ for a graph G .

Theorem 114 For a graph G , $m_1 \leq \chi'_{\text{vd}}(G) \leq (\Delta + 1)\lfloor 2m_2 + 5 \rfloor$, where

$$m_1 = \max_{1 \leq k \leq \Delta} \left\{ (k!n_k)^{1/k} + \frac{k-1}{2} \right\}, \text{ and } m_2 = \max_{1 \leq k \leq \Delta} n_k^{1/k}.$$

Corollary 7 For an r -regular graph G of order n , $\chi'_{\text{vd}}(G) \leq (r+1)\lfloor 2n^{1/r} + 5 \rfloor$.

Recently, there has been significant progress on this conjecture. Balister [28] considered the vde-coloring of random graphs by giving a strong bound below:

Theorem 115 If G is a random graph on n vertices with edge probability $p = p(n)$, and if $\frac{pn}{\log n}, \frac{(1-p)n}{\log n} \rightarrow \infty$ as $n \rightarrow \infty$, then the probability that $\chi'_{\text{vd}}(G) = \Delta$ goes to 1 as $n \rightarrow \infty$.

Balister et al. [31] proved that [Conjecture 15](#) is true for graphs with large maximum degree.

Theorem 116 If G is a graph with n vertices, $\Delta \geq \sqrt{2n} + 4$, $\delta \geq 5$, and k is the smallest positive integer such that $n_d \leq \binom{k}{d}$ for all $\delta \leq d \leq \Delta$, then $k \leq \chi'_{\text{vd}}(G) \leq k + 1$.

Balister et al. [29] confirmed [Conjecture 15](#) if G consists of just paths or of just cycles. Specially, they proved the following result.

- Theorem 117**
1. Let G be a vertex-disjoint union of cycles, and let $n_2 = |G| \leq \binom{k}{2}$, with k as small as possible. Then $\chi'_{\text{vd}}(G) = k$ or $k + 1$.
 2. Let G be a vertex-disjoint union of paths of length at least 2. Let $n_1 \leq k$ and $n_2 \leq \binom{k}{2}$, with k as small as possible. Then $\chi'_{\text{vd}}(G) = k$ or $k + 1$.
 3. Let G be any nice graph with $\Delta = 2$. Let $n_1 \leq k$ and $n_2 \leq \binom{k}{2}$, with k as small as possible. Then $k \leq \chi'_{\text{vd}}(G) \leq k + 5$.

[Theorem 117](#) implies that [Conjecture 15](#) holds for 2-regular graphs. Since the conjecture holds for graphs with large maximum degree [31], it is natural to ask whether the conjecture holds for small maximum degree, for example, 3-regular graphs. Many people tried to think about the bounds of $\chi'_{\text{vd}}(G)$ for some regular graphs G , such as Fibonacci and Lucas cubes [124]; Q_n [197]; nG , where G is a 3-regular graph with 1-factor on at most 12 vertices or $G \in \{K_{4,4}, K_{5,5}, K_{6,6}, K_{7,7}, K_6\}$ [307]; ladders and pK_4 [325]; and extended Fibonacci cubes [380].

The following result has been testified for d -regular graphs with small components by Balister et al. [32].

Theorem 118 Let $d \geq 3$ and assume that G is a d -regular graph which contains $d - 2$ disjoint 1-factors. Let $G = \bigcup_{i=1}^s G_i$, where G_1, G_2, \dots, G_s are components of G . If $|G| \leq \binom{k}{d}$ and $|G_i| \leq \frac{3(k-1)}{4(d-1)}$ for all i , then $\chi'_{\text{vd}}(G) \leq k + 1$.

Balister, Riordan, and Schelp [32] defined a few parameters for nice graphs. Here, \oplus is the symmetric difference operator, which produces the set of items which appear in exactly an odd number of its operands. Suppose that G is a nice graph. Let $k(G)$ be the minimum integer k such that $\binom{k}{j} \geq n_j$ for all j with $\delta \leq j \leq \Delta$. Recall for $v \in V(G)$, $S(v)$ denotes the set of colors used to color the edges incident to v . If a vde-coloring with k colors exists for G , then each color meets an even number of vertices. Thus, $\bigoplus_v S(v) = \emptyset$. Let $k'(G)$ be the minimum k such that there exist distinct sets $S(v) \subseteq \{1, 2, \dots, k\}$ with $|S(v)| = d(v)$ for all $v \in V(G)$, such that $\bigoplus_v S(v) = \emptyset$. Therefore, $k'(G) \geq k(G)$. Let $k''(G)$ be the smallest k such that for any set of vertices $X \subseteq V(G)$, there exist distinct sets $S(v) \subseteq \{1, 2, \dots, k\}$, $v \in X$, such that $|S(v)| = d(v)$ and $|\bigoplus_{v \in X} S(v)| \leq |E(X, X^c)|$, where $E(X, X^c)$ is the set of edges between X and $X^c = V(G) \setminus X$. Thus, $\chi'_{\text{vd}}(G) \geq k''(G) \geq k'(G) \geq k(G)$. Also, in [32], it is shown that $k''(G) \leq k(G) + 1$. Hence, they presented the following conjecture.

Conjecture 16 For all nice graphs G , $\chi'_{\text{vd}}(G) = k''(G)$.

Observe that this conjecture is consistent with the inequalities mentioned above. Also, this conjecture implies clearly Conjecture 15.

It is not even known whether there exists an absolute constant c such that $\chi'_{\text{vd}}(G) \leq k(G) + c$, when G is a nice graph. Yet, for graphs with large minimum degree, Bazgan, Harkat-Benhamdine, Li, and Woźniak [43] obtained the following result.

Theorem 119 Let G be a nice graph of order $n \geq 3$. If $\delta > \frac{n}{3}$, then $\chi'_{\text{vd}}(G) \leq \Delta + 5$.

For an integer k with $k \leq \alpha(G)$, where $\alpha(G)$ stands for the independence number of G , $\sigma_k(G)$ is defined by

$$\sigma_k(G) = \min \left\{ \sum_{i=1}^k d(v_i) \mid \{v_1, v_2, \dots, v_k\} \text{ is an independent set of } G \right\}.$$

If $\alpha(G) = 1$, then G is complete and the exact value of $\chi'_{\text{vd}}(G)$ is computed in [89], that is, $\chi'_{\text{vd}}(K_n) = n$ if n is odd and $\chi'_{\text{vd}}(G) = n + 1$ if n is even for $n \geq 4$. For $\alpha(G) \geq 2$, Liu and Liu [254] presented the following result.

Theorem 120 Let G be a connected graph of order $n \geq 3$. If $\sigma_2(G) \geq \frac{2n}{3}$, then $\chi'_{\text{vd}}(G) \leq \Delta + 5$.

It is easy to see that if $\delta > \frac{n}{3}$, then $\sigma_2(G) \geq \frac{2n}{3}$. Thus, Theorem 120 generalizes Theorem 119.

4.1.2 Adjacent Vertex-Distinguishing Edge-Coloring

Instead of requiring that any two vertices have different weight sets, it can be required that only adjacent vertices have different weight sets. An edge-coloring satisfying this condition is *adjacent vertex-distinguishing* (also called an *adjacent strong edge-coloring*, *1-strong edge-coloring*, or *neighbor-distinguishing edge-coloring* and denoted as *avde-coloring* for short). A k -*avde-coloring* is an avde-coloring using k colors. The smallest integer k such that there is a k -*avde-coloring* of G is called the *adjacent vertex-distinguishing chromatic index* of G , denoted by $\chi'_{\text{avd}}(G)$.

Obviously, when G contains an isolated edge, there is no any k -*avde-coloring* of G for any $k \geq 1$. Thus, only simple graphs without isolated edges are considered in the rest of this section.

This graph parameter was introduced by Zhang et al. [396]. They completely determined the adjacent vertex-distinguishing chromatic indices for paths, cycles, complete graphs, and complete bipartite graphs. In light of these examples, they proposed the following conjecture.

Conjecture 17 *If G is a connected graph and $G \neq C_5$, then $\chi'_{\text{avd}}(G) \leq \Delta + 2$.*

Note that $\chi'_a(C_5) = 5 = \Delta + 3$. It is unknown if C_5 is the unique exception graph. The conjecture has been confirmed by Balister et al. [30] for bipartite graphs and for graphs of maximum degree 3. They also gave a general upper bound on $\chi'_{\text{avd}}(G)$, depending on the maximum degree Δ and chromatic number $\chi(G)$:

Theorem 121 *If G is a graph, then $\chi'_{\text{avd}}(G) \leq \Delta + O(\log \chi(G))$.*

Akbari et al. [10] obtained an upper bound of $\chi'_{\text{avd}}(G)$, which was improved by Dai and Bu [123] by one.

Theorem 122 ([10]) *For any graph G , $\chi'_{\text{avd}}(G) \leq 3\Delta$.*

Theorem 123 ([123]) *For any graph G , $\chi'_{\text{avd}}(G) \leq 3\Delta - 1$.*

Later, Ghandehari and Hatami [165] improved these bounds by restricting the maximum degree of the graph:

Theorem 124 *If G is a graph with $\Delta \geq 10^6$, then $\chi'_{\text{avd}}(G) \leq \Delta + 27\sqrt{\Delta \ln \Delta}$.*

Hatami [179] gave an asymptotically stronger upper bound on $\chi'_{\text{avd}}(G)$ by using a random edge-weighting technique.

Theorem 125 *If G is a graph with $\Delta > 10^{20}$, then $\chi'_{\text{avd}}(G) \leq \Delta + 300$.*

Despite the large maximum degree requirement, this result is of importance as it shows that a simple additive constant is enough for an upper bound on $\chi'_{\text{avd}}(G)$.

For graphs with small maximum average degree, Wang and Wang [371] verified Conjecture 17:

Theorem 126 Let G be a graph:

1. If $\text{mad}(G) < 3$ and $\Delta \geq 3$, then $\chi'_{\text{avd}}(G) \leq \Delta + 2$.
2. If $\text{mad}(G) < \frac{5}{2}$ and $\Delta \geq 4$, or $\text{mad}(G) < \frac{7}{3}$ and $\Delta = 3$, then $\chi'_{\text{avd}}(G) \leq \Delta + 1$.
3. If $\text{mad}(G) < \frac{5}{2}$ and $\Delta \geq 5$, then $\chi'_{\text{avd}}(G) = \Delta + 1$ if and only if G contains adjacent vertices of maximum degree.

Recall that if G is a planar graph with girth g , then $\text{mad}(G) \leq \frac{2g}{g-2}$. This fact together with [Theorem 126](#) leads to the following corollary:

Corollary 8 Let G be a planar graph with girth g :

1. If $g \geq 6$ and $\Delta \geq 3$, then $\chi'_{\text{avd}}(G) \leq \Delta + 2$.
2. If $g \geq 10$ and $\Delta \geq 4$, or $g \geq 4$ and $\Delta = 3$, then $\chi'_{\text{avd}}(G) \leq \Delta + 1$.
3. If $g \geq 10$ and $\Delta \geq 5$, then $\chi'_{\text{avd}}(G) = \Delta + 1$ if and only if G contains adjacent vertices of maximum degree.

It should be pointed out that Bu et al. [86] also proved that [Conjecture 17](#) holds for planar graphs of girth at least six, that is, if G is a planar graph with girth $g \geq 6$, then $\chi'_{\text{avd}}(G) \leq \Delta + 2$.

Liu and Liu [255] considered the adjacent vertex-distinguishing chromatic index for graphs with dominating subgraphs. A subgraph H of a graph G is called a *dominating subgraph* of G if $V(G) - V(H)$ is an independent set.

The following three theorems appeared in [255]:

Theorem 127 If G is a Hamiltonian graph with $\chi(G) \leq 3$, then $\chi'_{\text{avd}}(G) \leq \Delta + 3$.

Theorem 128 If G is a graph with $\chi(G) \leq 3$ and G has a Hamiltonian path, then $\chi'_{\text{avd}}(G) \leq \Delta + 4$.

Theorem 129 If a graph G has a dominating cycle or a dominating path H such that $\chi(G[V(H)]) \leq 3$, then $\chi'_{\text{avd}}(G) \leq \Delta + 5$.

For regular graphs, Greenhill and Rucinski [168] used a probabilistic method to obtain the following better bound:

Theorem 130 Let $r \geq 4$. Then a random r -regular graph G a.a.s. has $\chi'_{\text{avd}}(G) \leq \lceil 3r/2 \rceil$.

When $r = 4$, it can be deduced from the above theorem that almost always all 4-regular graphs satisfy [Conjecture 17](#).

Edwards et al. [139] proved that $\chi'_{\text{avd}}(G) \leq \Delta + 1$ if G is bipartite, planar, and $\Delta \geq 12$. Chen and Guo [103] completely determined the adjacent vertex-distinguishing chromatic index of hypercubes. In precise, they showed that if Q_d is a hypercube of dimension $d \geq 3$, then $\chi'_{\text{avd}}(Q_d) = d + 1$. Liu et al. [256] proved that if G is a 2-connected outerplanar graph with $\Delta \geq 5$, then $\Delta \leq \chi'_{\text{avd}}(G) \leq \Delta + 1$, and $\chi'_{\text{avd}}(G) = \Delta + 1$ if and only if G contains adjacent vertices of maximum degree. Wang and Wang [372] extended this result to the following:

Theorem 131 Let G be a K_4 -minor-free graph with $\Delta \geq 4$. Then the following statements hold:

1. $\Delta \leq \chi'_a(G) \leq \Delta + 1$.
2. If $\Delta \geq 5$, then $\chi'_a(G) = \Delta + 1$ if and only if G contains adjacent vertices of maximum degree.

It is somewhat surprising that there exists an interesting relationship between $\chi'_{\text{avd}}(G)$ and $\chi''(G)$, the total chromatic number of a graph G . Zhang et al. [397] proposed the following conjectures:

Conjecture 18 For a graph G with no K_2 or C_5 component, $\chi'_{\text{avd}}(G) \leq \chi''(G)$.

Conjecture 19 For an r -regular graph G with no C_5 component ($r \geq 2$), $\chi'_{\text{avd}}(G) = \chi''(G)$.

In [397], Conjecture 19 was shown to be true for many classes of graphs, such as graphs with $\chi''(G) = \Delta + 1$; 2-regular, 3-regular, and $(|G| - 2)$ -regular graphs; bipartite regular graphs; balanced complete multipartite graphs; hypercubes; and joins of two matchings or cycles.

4.1.3 r -Strong Chromatic Index

Akbari et al. [10] introduced another graph parameter, called as r -strong edge coloring. A proper edge coloring of a graph G is called an r -strong edge-coloring if for any two distinct vertices $u, v \in V(G)$ with the distance $d(u, v) \leq r$, $S(u) \neq S(v)$. The r -strong chromatic index $\chi'_{si}(G, r)$ is the minimum number of colors required for an r -strong edge-coloring of the graph G . Thus, $\chi'_{si}(G, 1) = \chi'_{\text{avd}}(G)$, and for any connected graph G with n vertices, $\chi'_{si}(G, n) = \chi'_{\text{vd}}(G)$.

Akbari et al. [10] generalized a result in [396] about the parameter $\chi'_{\text{avd}}(T)$, where T is a tree as follows:

Theorem 132 Let T be a tree with at least three vertices:

1. $\chi'_{si}(T, 2) \leq \Delta + 1$. Furthermore, if for any two vertices u and v of maximum degree, $d(u, v) \geq 3$, then $\chi'_{si}(T, 2) = \Delta$.
2. If $\Delta \geq 3$, then $\chi'_{si}(T, 3) \leq 2\Delta - 1$.
3. For any integers $k \geq 4$ and $\Delta \geq 1$, there exists a tree T with maximum degree Δ such that $\chi'_{si}(T, k) \geq \Delta(\Delta - 1)^{\lfloor k/2 \rfloor - 1}$.

Ghandehari and Hatami [165] presented an upper bound of $\chi'_{si}(G, k)$ for regular graphs:

Theorem 133 For each r -regular graph G with $r > 100$, $\chi'_{si}(G, k) \leq r + (k + 2) \log_2 r$.

As a direct corollary of Theorem 133, the following holds:

Corollary 9 For an r -regular graph G with $r > 100$, $\chi'_{\text{avd}}(G) \leq r + 3 \log_2 r$.

4.2 Non-proper Edge-Weighting

In this section, non-proper edge-weighting is concerned. Unlike the case of proper edge-weighting, there is no lower bounds compared to $\chi'(G)$.

4.2.1 Point-Distinguishing Chromatic Index

Similar to the vertex-distinguishing edge-coloring problem, an edge-weighting (not needed to be proper) such that all vertices have different weight sets is considered here. This graph parameter is introduced by Harary and Plantholt [177] (as *point-distinguishing chromatic index*) and is denoted by $\chi_0(G)$. Note that if a graph G has at least two isolated vertices or an isolated edge, then point-distinguishing chromatic index cannot be defined very well. This means that once G admits the point-distinguishing chromatic index, then G must be a nice graph.

Harary and Plantholt [177] determined the value of this parameter for paths, cycles, complete graphs, and hypercubes. Furthermore, they presented a lower bound for complete bipartite graphs. Even for complete bipartite graphs, it seems that the problem of determining $\chi_0(K_{m,n})$ is not easy. In fact, it was shown in [177] that $\chi_0(K_{m,n}) \geq \lceil \log_2(m+n) \rceil$ and $\chi_0(K_{m,n}) \leq \lceil \log_2 n \rceil + 2$ if $\lceil \log_2 n \rceil + 1 \leq m \leq n$.

Zagaglia Salvi [393] proved that the sequence $\{\chi_0(K_{n,n})\}_{n=2}^{\infty}$ is non-decreasing with jumps of value 1. As a consequence, there is an increasing sequence $\{n_k\}_{k=2}^{\infty}$ of integers in which $n_2 = 1$ and for any $k \geq 3$, $\chi_0(K_{n,n}) = k$ if and only if $n_{k-1} + 1 \leq n \leq n_k$. Only few exact values of n_k are known, namely, $n_3 = 2$, $n_4 = 5$, $n_5 = 11$, $n_6 = 22$ [392], and $n_7 = 46$ [196]. According to Zagaglia Salvi [393], $n_{k+1} \geq 2n_k$ and so $\{\frac{n_k}{2^{k-1}}\}$ is convergent and $\frac{46}{64} \leq \lim \frac{n_k}{2^{k-1}} \leq 1$. Horňák and Soták [198] succeeded in showing that $\lim \frac{n_k}{2^{k-1}} \geq 3 - \sqrt{5}$.

Horňák and Zagaglia Salvi [200] asked the following question.

Problem 4 Is it true that $\lim \frac{n_k}{2^{k-1}} < 1$?

They also determined $\chi_0(K_{m,n})$ for all n sufficiently large with respect to m in [200]. Let k, l, m, n be integers with $2 \leq m \leq n$, $l = \lceil \log_2 m \rceil$, $k \geq \min\{l+1, 3\}$.

$$d_m^{(k)} = \begin{cases} 2m, & \text{if } k \leq m; \\ 2m-1, & \text{if } k = m+1; \\ m, & \text{if } k \geq m+2. \end{cases}$$

$$b_m^{(k)} = \sum_{i=0}^m \binom{k}{i} - d_m^{(k)},$$

$$I_m^{(k)} = 7[b_m^{(k-1)} + 1, b_m^{(k)}],$$

$$L_m^{(k)} = [b_m^{(k-1)} + 1, 2^{k-1} - m - l - 1],$$

$$R_m^{(k)} = [2^{(k-1)} - m - l, b_m^{(k)}],$$

where $[p, q]$ denotes the interval of all integers z with $p \leq z \leq q$ for fixed integers p, q .

The following several results and one problem appeared in [200]:

Theorem 134 If $n \in I_m^{(k)}$, then $\chi_0(K_{m,n}) \leq k$.

Theorem 135 $\chi_0(K_{m,n}) \geq k + 1$ follows from either of the following conditions:

1. $k \leq m + 1$ and $n \geq 2^k - m - l$.
2. $k \geq m + 2$ and $n \geq b_m^{(k)} + l$.

Theorem 136 The equality $\chi_0(K_{m,n}) = k \Leftrightarrow n \in I_m^{(k)}$ follows from any of the following conditions:

1. $k \leq 2l + 2$.
2. $m \in \{2, 3\}$.

Corollary 10 If $m \geq 7$ and $n \in [2 \cdot 4^l - 2m + 1, 2^{m+1} - 2m]$, then $\chi_0(K_{m,n}) = \lceil \log_2(n + 2m) \rceil$.

Theorem 137 The equality $\chi_0(K_{m,n}) = k$ follows from any of the following conditions:

1. $k \in [l + 2, 2l + 1]$ and $n \in R_m^{(k)}$.
2. $k = l + 1$ and $n \in I_m^{(k)}$.

Theorem 138 Suppose that $m \in [4, 10]$ and $n \in L_m^{(k)}$. Then $\chi_0(K_{m,n}) = k - 1$ if and only if $(k, m, n) = (6, 10, 13)$.

Problem 5 Decide whether there is a triple of integers (k, m, n) such that $m \geq 11$, $k \in [l + 3, 2l + 1]$, $n \in L_m^{(k)}$, and $\chi_0(K_{m,n}) = k - 1$.

4.2.2 General Neighbor-Distinguishing Index

Also, a generalized version of adjacent vertex-distinguishing edge-coloring may be considered, in which edge weighting may be not proper. The corresponding invariant is the *general neighbor-distinguishing index* of a graph G , denoted by $\text{gndi}(G)$. This graph parameter was first introduced and investigated by Győri et al. [174]. Clearly, G is a nice graph when considering this parameter.

First, four authors in [174] established an interesting relationship between $\text{gndi}(G)$ and $\chi(G)$:

Theorem 139 For any graph G , the following statements are equivalent:

1. $\text{gndi}(G) = 2$.
2. G is bipartite and there is a bipartition $\{X_1 \cup X_2, Y\}$ of $V(G)$ such that $X_1 \cap X_2 = \emptyset$ and any vertex of Y has at least one neighbor in both X_1 and X_2 .

Theorem 140 If G is a connected bipartite graph with $|E(G)| \geq 2$, then $\text{gndi}(G) \leq 3$.

Theorem 141 $\text{gndi}(G) \leq 2\lceil \log_2 \chi(G) \rceil + 1$ for any nice graph G .

Thus, when $\chi(G) \leq 2$, a good characterization on $\text{gndi}(G)$ has been established. If $\chi(G) \geq 3$, Horňák and Soták [199] improved the above bound:

Theorem 142 *If G is a connected graph with $\chi(G) \geq 3$, then $\lceil \log_2 \chi(G) \rceil + 1 \leq \text{gndi}(G) \leq \lfloor \log_2 \chi(G) \rfloor + 2$.*

Therefore, when $\log_2 \chi(G)$ is not an integer, then $\text{gndi}(G) = \lceil \log_2 \chi(G) \rceil + 1$. A natural question is as follows: what about the case where $\log_2 \chi(G)$ is an integer? This problem is recently solved by Győri and Palmer [175]:

Theorem 143 *If G is a connected graph with $\chi(G) \geq 3$, then $\text{gndi}G = \lceil \log_2 \chi(G) \rceil + 1$.*

4.2.3 Irregularity Strength

Instead of distinguishing the color set, the problem of distinguishing the total sum of weights can be considered. Chartrand et al. [100] defined the *irregularity strength* of a graph G , denoted by $s(G)$, to be the smallest integer k such that there is a k -edge-weighting ϕ of G and for any two vertices u, v ,

$$\sum_{e \ni u} \phi(e) \neq \sum_{e \ni v} \phi(e).$$

It is easy to see that for every nice graph G , there exists an irregular strength. If G is not a nice graph, set $s(G) = \infty$.

Most of the upper bounds which have been determined for special classes of graphs are based on the minimum and maximum degree. The proofs rely on two techniques, either using the congruence method to find special spanning graphs and then determining a labeling of this spanning graph explicitly or through employing the probabilistic method.

In [100], it was shown that for any graph G with $n \geq 3$ vertices, $s(G) \leq 2n - 3$. This bound was later improved by Nierhoff [290] by refining the idea of Aigner and Triesch [8] to $s(G) \leq n - 1$ for any graph G with $n \geq 4$ vertices.

For regular graphs, stronger upper bounds on $s(G)$ are known. Faudree and Lehel [145] showed that if G is d -regular ($d \geq 2$), then $\lceil \frac{n+d-1}{d} \rceil \leq s(G) \leq \lceil \frac{n}{2} \rceil + 9$. They also proposed the following conjecture.

Conjecture 20 *If G is a d -regular graph with $d \geq 2$, then $s(G) \leq \lceil \frac{n}{d} \rceil + c$ for some constant c .*

The question was motivated by the following facts:

- (i) For every d -regular graph of order n , $s(G) \geq \lceil (n-1)/d \rceil + 1$ (see [100]).
- (ii) In all those cases where the irregularity strength of a regular graph is known, its value is very close to $\lceil (n-1)/d \rceil + 1$. For example, Amar [23] proved that if G is an $(n-3)$ - or $(n-4)$ -regular graph of order n , then $s(G)$ is 3 (except if $G = K_{3,3}$). In light of this result, Amar [23] proposed the following conjecture:

Conjecture 21 *The irregular strength of an r -regular graph of order $n \leq 2r$ is 3, except if G is $K_{l,l}$ with l odd.*

Frieze, Gould, Karoński, and Pfender [157] used a probabilistic analysis to show that for a graph G with minimum degree δ and maximum degree Δ , $s(G) \leq c_1 n / \delta$ if $\Delta \leq n^{1/2}$ and $s(G) \leq c_2 (\log n) n / \delta$ if $\Delta > n^{1/2}$, where c_1 and c_2 are explicit constants. For regular graphs, they obtained the following results in the same paper.

Theorem 144 *Let G be a d -regular graph of order n with no isolated vertices or edges:*

1. *If $d \leq \lfloor (n / \ln n)^{1/4} \rfloor$, then $s(G) \leq 10n/d + 1$.*
2. *If $\lfloor (n / \ln n)^{1/4} \rfloor + 1 \leq d \leq \lfloor n^{1/2} \rfloor$, then $s(G) \leq 48n/d + 1$.*
3. *If $d \geq \lfloor n^{1/2} \rfloor + 1$, then $s(G) \leq 240(\log n)n/d + 1$.*

Cuckler and Lazebnik [122] further obtained the following result:

Theorem 145 *Let G be a graph of order n :*

1. *If $\delta \geq 10n^{3/4} \log^{1/4} n$, then $s(G) \leq 48(n/\delta) + 6$.*
2. *If G is d -regular with $d \geq 10^{4/3} n^{2/3} \log^{1/3} n$, then $s(G) \leq 48(n/d) + 6$.*

However, these results do not confirm even a weaker form of [Conjecture 20](#), namely, $s(G) \leq c_1 n / d + c_2$ holds for all d -regular graphs of order n , with c_1 and c_2 being absolute positive constants. A big step toward this direction has been achieved by Przybyło, who shows that actually constants c_1 and c_2 exist, both for regular graphs in [295] and general graphs in [296].

Theorem 146 *Let G be a d -regular graph of order n with no isolated vertices or edges. Then $s(G) < 16n/d + 6$.*

Theorem 147 *Let G be a graph of order n with no isolated vertices or edges. Then $s(G) < 112n/\delta + 28$.*

Recently, Kalkowski et al. [218] obtained a much better upper bound.

Theorem 148 *Let G be a graph of order n and of minimum degree δ . Then $s(G) \leq 6\lceil n/\delta \rceil$.*

Recall that n_i figures the number of vertices of degree i in a graph G . Then a simple counting argument shows that

$$s(G) \geq \beta(G) = \max_k \left\lceil \frac{1}{k} \sum_{i=1}^k n_i \right\rceil.$$

Lehel [245] felt that $\beta(G)$ with addition of an absolute constant was enough for $s(G)$. Namely,

Conjecture 22 *If G is a connected graph, then $s(G) \leq \beta(G) + c$ for some absolute constant c .*

Note that if G is r -regular with $r \geq 2$, then $\beta(G) = \lceil n/r \rceil$. Therefore, [Conjecture 20](#) is a special case of [Conjecture 22](#).

Baril et al. [33] studied the irregularity strength of circulant graphs of degree 4. Let $C_n(1, k)$ denote the circulant graph which consists of a cycle of length n plus chords joining vertices at distance k on the cycle.

Theorem 149 *For $n \geq 4k + 1$ and $k \geq 2$,*

$$s(C_n(1, k)) = \left\lceil \frac{n+3}{4} \right\rceil.$$

For grids, Dinitz et al. [127] proved that for every positive integer d , $s(X_{m,m}) = \beta(X_{m,n})$ or $\beta(X_{m,n}) + 1$ for all but a finite number of $m \times n$ grids $X_{m,n}$ where $n-m = d$. This finite number was computed in [127] to at most $d+13$. Togni [336] proved that the irregularity strength of the toroidal grid $C_m \times C_n$ is $\lfloor (mn+3)/4 \rfloor$.

Amar and Tongi [24] showed that $s(T) = \beta(T) = n_1$ for all trees T with $n_2 = 0$ and $n_1 \geq 3$. For general trees, it is not even the case that $s(T)$ is within an additive constant of n_1 . Bohman and Kravitz [52] presented an infinite sequence of trees with irregularity strength converging to $\frac{11-\sqrt{5}}{8}n_1 > n_1 > \frac{n_1+n_2}{2}$. Ferrara et al. [146] presented an iterative algorithm to show that $s(T) = \beta(T)$ for another class of trees, but this time, $n_1 < n_2$, that is, $s(T) = \lceil \frac{n_1+n_2}{2} \rceil$.

If the point-distinguishing chromatic index problem is modified so that for any two vertices $u, v \in V(G)$, the multiset of all edge weights appearing on edges incident to u is different from the multiset of all edge weights appearing on edges incident to v (where the multiplicity of an element is exactly how many times that edge weight appears on edges incident to the corresponding vertex). For a given graph G , the smallest k such that a mapping satisfying these conditions exists is denoted by $c(G)$. It is easy to see that $c(G) \leq s(G)$. Aigner, Triesch, and Tuza introduced this problem in [9]. They proved the following result for regular graphs:

Theorem 150 *If G is a regular graph, then there exist constants c_1, c_2 , such that $c_1 n^{1/r} \leq c(G) \leq c_2 n^{1/r}$.*

For other known results of parameter $s(G)$, see a nice survey paper of Lehel [245].

4.2.4 On 1, 2, 3-Conjecture

Motivated by the results on irregularity strength, Karoński et al. [221] studied the improper edge-weighting problem where it is only required that for adjacent vertices u, v ,

$$\sum_{e \ni u} \phi(e) \neq \sum_{e \ni v} \phi(e).$$

The smallest integer k such that there is a mapping ϕ satisfying the above condition is denoted by $\mu(G)$ and is called the *vertex-coloring k -edge-weighting*. Notice that $\mu(G) \leq s(G)$ for every nontrivial graph G . Karoński et al. [221] proved that $\mu(G) \leq 3$ for graphs G without an edge component and having chromatic

number $\chi(G) \leq 3$ and conjectured that $\mu(G) \leq 3$ for all graphs G without an edge component. This is sometimes referred to as 1,2,3-conjecture.

Conjecture 23 *If G is a graph without isolated edges, then $\mu(G) \leq 3$.*

Conjecture 23 has been attacked primarily in two ways. The first is to show it being true for smaller classes of graphs and the second is to find general upper bound on $\mu(G)$. Karoński et al. [221] first proved that for all graphs G without an edge component, $\mu(G) \leq 213$. Addario-Berry et al. [3] improved this upper bound to 30, which was improved later by Addario-Berry et al. [4] to 16 and by Wang and Yu [376] to 13. More recently, Kalkowski et al. [217] improved the bound to 5, based on a method developed in [216].

Note that 2 is not sufficient as seen for instance in complete graphs. Even if it is still far from providing a positive answer to the conjecture, actually $\mu(G) \leq 2$ for many graphs. In fact, Addario-Berry et al. [4] showed that $\mu(G) \leq 2$ for almost all graphs.

Theorem 151 *Let G be a random graph chosen from $G_{n,p}$ for constant $0 < p < 1$. Then there exists, a.a.s., a vertex-coloring 2-edge-weighting for G . In fact, there exists a 2-edge-weighting such that the colors of two adjacent vertices are distinct mod $2\chi(G)$.*

In [99], Chang et al. gave some sufficient conditions for bipartite graphs with $\mu(G) \leq 2$.

Theorem 152 *Every connected bipartite graph $G = (A, B; E)$ without isolated edges admits $\mu(G) \leq 2$ if one of following conditions holds:*

1. $|A|$ or $|B|$ is even.
2. $\delta(G) = 1$.
3. $\lfloor d(u)/2 \rfloor + 1 \neq d(v)$ for any edge of G .

Also, they proposed the following problem.

Problem 6 *Characterize 2-colorable graphs G (i.e., bipartite graphs) with $\mu(G) = 2$.*

Lu et al. [260] continued to consider this problem. They also obtained several sufficient conditions for graphs with $\mu(G) \leq 2$. In particular, they showed that 3-connected bipartite graphs admit $\mu(G) \leq 2$, and every r -regular nice bipartite graph ($r \geq 3$) has $\mu(G) \leq 2$. There exist infinitely many bipartite graphs (e.g., generalized θ -graphs) which are 2-connected and have a vertex-coloring 3-edge-weighting but not a vertex-coloring 2-edge-weighting.

Bartnicki et al. [34] considered the choosability version of edge weighting. A graph is said to be k -edge-weight choosable if the following holds: for any list assignment L which assigns to each edge e a set $L(e)$ of k real numbers, G has a proper edge-weighting f such that $f(e) \in L(e)$ for each edge e . They conjectured

that every graph without isolated edges is 3-edge weight choosable and verified the conjecture for complete graphs, complete bipartite graphs, and some other graphs.

Similar to the problem posed in [8], it can be considered a multiset version of vertex coloring k -edge-weighting. In this case, for any edge $uv \in E(G)$, the multiset of weights on edges incident to u is different from the multiset of weights on edges incident to v . A k -edge-weighting satisfying the above condition is called as *vertex-coloring k -edge partition*.

Karoński et al. [221] proved that if $\chi(G) \leq 3$, then three colors are enough for a graph. Formally, they proved the following result.

Theorem 153 *Let G be a connected graph with at least three vertices. If $\chi(G) \leq 3$, then G permits a vertex-coloring 3-edge partition.*

Addario-Berry et al. [2] proved the following two theorems concerning this version of edge-weighting.

Theorem 154 *If G is a graph without isolated edges, then G permits a vertex-coloring 4-edge partition.*

Theorem 155 *If G is a graph without isolated edges and with minimum degree 1,000, then G permits a vertex-coloring 3-edge partition.*

Recently, Bian et al. [49] improved their results.

Theorem 156 *If G is a graph without isolated edges and with minimum degree 188, then G permits a vertex-coloring 3-edge partition.*

It is unknown if there exists a graph G permits a vertex-coloring 4-edge partition. If such a graph exists, then by [49], $\chi(G) \geq 4$ and $\delta(G) < 188$.

4.3 Some Related Topics

All of the previous vertex-distinguishing edge-weighting problems can be generalized to the vertex-distinguishing total-weighting problems. Given a graph G , a k -*total-weighting* is a mapping $\phi : V(G) \cup E(G) \rightarrow \{1, 2, \dots, k\}$. Given a graph G and a total-weighting ϕ of G , for $v \in V(G)$, let $S_\phi(v) = \{\phi(e) | v \in e\} \cup \{\phi(v)\}$ be the set of weights appearing on the vertex v and the edges incident to v under the total-weighting ϕ . A k -total-weighting is *proper*, if $\phi(e) \neq \phi(f)$ for any pair of adjacent edges e, f ; $\phi(v) \neq \phi(e)$ for any vertex v and incident edge e ; and $\phi(u) \neq \phi(v)$ for any two adjacent vertices u, v .

4.3.1 Adjacent Vertex-Distinguishing Total Coloring

In [395], Zhang et al. defined the *adjacent vertex-distinguishing total chromatic number* of a graph G , denoted by $\chi''_{\text{avd}}(G)$, which is the smallest integer k such that there exists a proper total k -coloring ϕ of G such that for any edge $uv \in E(G)$, $S_\phi(u) \neq S_\phi(v)$. The authors [395] determined the adjacent vertex-distinguishing total chromatic numbers for some special classes of graphs including cycles and complete graphs. Based on these results, they made the following conjecture:

Conjecture 24 *If G is a connected graph with $n \geq 2$ vertices, $\chi''_{\text{avd}}(G) \leq \Delta + 3$.*

If Conjecture 24 is true, then the upper bound $\Delta + 3$ is tight, for instance, a complete graph on odd order can attain this bound. Chen [102] further constructed a class of graphs, that is, the joint graphs $sP_3 \vee K_t$, attaining the upper bound. Chen [102], and independently Wang [347], confirmed Conjecture 24 for graphs G with $\Delta \leq 3$. Hulgan [207] presented a more concise proof for this result and proposed the following question:

Question 8 *For a graph G with $\Delta = 3$, is the bound $\chi''_{\text{avd}}(G) \leq 6$ sharp?*

The following result follows immediately from the definitions of parameters under consideration.

Proposition 3 *For any graph G , $\chi''_{\text{avd}}(G) \leq \chi(G) + \chi'(G)$.*

By Proposition 3, Conjecture 24 holds for all bipartite graphs. For planar graphs, by the Four-Color Theorem and the Vizing's Theorem on edge coloring, $\chi''_{\text{avd}}(G) \leq \Delta + 5$. Moreover, if G is of Class 1, that is, $\chi'(G) = \Delta$, then $\chi''_{\text{avd}}(G) \leq \Delta + 4$.

Coker and Johannson [116] used a probabilistic method to give an upper bound for $\chi''_{\text{avd}}(G)$.

Theorem 157 *There exists a constant $c > 0$ such that for every graph G , $\chi''_{\text{avd}}(G) \leq \Delta + c$.*

For graphs of larger maximum degree, Liu et al. [252] showed the following result.

Theorem 158 *If G is a graph with Δ sufficiently large and $\delta \geq 32\sqrt{\Delta \ln \Delta}$, then $\chi''_{\text{avd}}(G) \leq \Delta + 10^{26} + 2\sqrt{\Delta \ln \Delta}$.*

For graphs with the smaller maximum average degree, Wang and Wang [370] verified Conjecture 24. More precisely, the following theorem and corollary were showed:

Theorem 159 *Let G be a graph:*

1. *If $\text{mad}(G) < 3$ and $\Delta \geq 5$, then $\Delta + 1 \leq \chi''_{\text{avd}}(G) \leq \Delta + 2$; and $\chi''_{\text{avd}}(G) = \Delta + 2$ if and only if G contains adjacent vertices of maximum degree.*
2. *If $\text{mad}(G) < 3$ and $\Delta = 4$, then $\chi''_{\text{avd}}(G) \leq 6$.*
3. *If $\text{mad}(G) < \frac{8}{3}$ and $\Delta = 3$, then $\chi''_{\text{avd}}(G) \leq 5$.*

As an immediate consequence of [Theorem 159](#), the following corollary holds:

Corollary 11 *Let G be a planar graph with girth g :*

1. *If $g \geq 6$ and $\Delta \geq 5$, then $\Delta + 1 \leq \chi''_{\text{avd}}(G) \leq \Delta + 2$; and $\chi''_{\text{avd}}(G) = \Delta + 2$ if and only if G contains adjacent vertices of maximum degree.*
2. *If $g \geq 6$ and $\Delta = 4$, then $\chi''_{\text{avd}}(G) \leq 6$.*
3. *If $g \geq 8$ and $\Delta = 3$, then $\chi''_{\text{avd}}(G) \leq 5$.*

Wang and Wang [373] also completely characterized the adjacent vertex-distinguishing total chromatic number of outerplanar graphs by showing the following:

Theorem 160 *Let G be an outerplanar graph with $\Delta \geq 3$. Then $\Delta + 1 \leq \chi''_{\text{avd}}(G) \leq \Delta + 2$; and $\chi''_{\text{avd}}(G) = \Delta + 2$ if and only if G contains adjacent vertices of maximum degree.*

In [368], [Theorem 160](#) was generalized to the following form:

Theorem 161 *Let G be a K_4 -minor-free graph with $\Delta \geq 3$. Then $\Delta + 1 \leq \chi''_{\text{avd}}(G) \leq \Delta + 2$; and $\chi''_{\text{avd}}(G) = \Delta + 2$ if and only if G contains adjacent vertices of maximum degree.*

When studying the adjacent vertex-distinguishing edge-coloring of hypercubes, Chen and Guo [103] considered also the adjacent vertex-distinguishing total coloring of this kind of graphs. Their result is stated below:

Theorem 162 *If Q_d is a hypercube of dimension $d \geq 2$, then $\chi''_{\text{avd}}(Q_d) = d + 2$.*

4.3.2 Total Vertex Irregularity Strength

Przybyło and Woźniak [297] introduced an improper k -total-weighting question in the light of the problem posed by Karoński et al. [221]. A k -total-weighting of a graph G is called *neighbor-distinguishing* (or *vertex-coloring*, see [4]) if for every edge uv ,

$$\phi(u) + \sum_{e \ni u} \phi(e) \neq \phi(v) + \sum_{e \ni v} \phi(e).$$

If it exists, then G permits a neighbor-distinguishing k -total-weighting. The smallest integer k for which G permits a neighbor-distinguishing k -total-weighting is called *total vertex irregularity strength*, denoted by $\tau(G)$.

Note that if a graph permits a vertex-coloring k -edge-weighting, then it also permits a neighbor-distinguishing k -total-weighting (it is enough to put ones at all vertices). Thus $\tau(G) \leq 5$ for all graphs. Przybyło and Woźniak [297] made the following conjecture.

Conjecture 25 *Every simple graph permits a neighbor-distinguishing 2-total-weighting.*

In [297], the authors gave a positive answer to [Conjecture 25](#) whenever G is 3-colorable, complete, or 4-regular. They also presented upper bounds 11 or

$\lfloor \frac{\chi(G)}{2} \rfloor + 1$ for $\tau(G)$. Przybyło [294] showed that $\tau(G) \leq 7$ for all regular graphs. Later, a big breakthrough is due to Kalkowski [216], who proved that $\tau(G) \leq 3$ for all graphs. Anholcer et al. [26] presented an upper bound of $\tau(G) \leq 3\lceil n/\delta \rceil + 1$ for each graph G of order n and with $\delta > 0$.

The values of $\tau(G)$ for some special graphs are computed. Kristiana and Slamin [239] computed $\tau(G)$ for wheels W_n , fans F_n , suns S_n , and friendship graphs f_n , namely, $\tau(W_n) = \lceil \frac{n+3}{4} \rceil$ for $n \geq 3$, $\tau(F_n) = \lceil \frac{n+2}{4} \rceil$ for $n > 3$, $\tau(S_n) = \lceil \frac{n+1}{2} \rceil$ for $n \geq 3$, and $\tau(f_n) = \lceil \frac{2n+2}{3} \rceil$ for all n .

The choosability version of total weighting was studied in [383] and in [298]. For positive integers k, k' , a (k, k') -total list assignment is a mapping L which assigns to each vertex v a set $L(v)$ of k real numbers as permissible weights and assigns to each edge e a set $L(e)$ of k' real numbers as permissible weights. A graph is called (k, k') -totally weight choosable if for any (k, k') -total list assignment L , G has a proper total-weighting f such that $f(y) \in L(y)$ for all $y \in V(G) \cup E(G)$. It was known in [383] that a graph is $(k, 1)$ -totally weight choosable if and only if it is k -choosable. The following conjectures were proposed in [383] by Wong and Zhu.

Conjecture 26 *Every graph is $(2, 2)$ -totally weight choosable.*

Conjecture 27 *Every graph with no isolated edges is $(1, 3)$ -totally weight choosable.*

However, it is unknown if there are constants k, k' such that every graph is (k, k') -totally weight choosable. It was shown in [383] that complete graphs, trees, cycles, and generalized θ -graphs are $(2, 2)$ -totally weight choosable, $K_{2,n}$ are $(1, 2)$ -totally weight choosable, and $K_{3,n}$ are $(2, 2)$ -totally weight choosable. Wong et al. [382] introduced a method, the max-min weighting method, for finding proper L -total weightings of graphs. Using this method, they proved that $K_{n,m,1,1,\dots,1}$ are $(2, 2)$ -totally weight choosable, and complete bipartite graphs other than K_2 are $(1, 2)$ -totally weight choosable.

5 $L(p, q)$ -Labeling of Graphs

Motivated by the frequency channel assignment problem, Griggs and Yeh [169] introduced the $L(2, 1)$ -labeling of graphs. This notion was subsequently generalized to the $L(p, q)$ -labeling problem of graphs. Let p and q be two nonnegative integers. An $L(p, q)$ -labeling of a graph G is a function f from its vertex set $V(G)$ to the label set $\{0, 1, \dots, k\}$ such that $|f(x) - f(y)| \geq p$ if x and y are adjacent and $|f(x) - f(y)| \geq q$ if x and y are at distance 2. The $L(p, q)$ -labeling number $\lambda_{p,q}(G)$ of G is the smallest integer k such that G has an $L(p, q)$ -labeling f with $\max\{f(v) | v \in V(G)\} = k$.

The $L(p, q)$ -labeling of graphs has been studied rather extensively in recent years [98, 219, 276, 313, 348]. In particular, the case $(p, q) = (p, 1)$ with $p \in \{0, 1, 2\}$ has received much more attention.

5.1 $L(2, 1)$ -Labeling

In 1991, Roberts [304] proposed a variation of the frequency assignment problem in which *close* transmitters must receive different frequencies and *very close* transmitters must receive frequencies that are at least two units apart. To translate the problem into the language of graph theory, the transmitters are represented by the vertices of a graph; two vertices are *very close* if they are adjacent and *close* if they are at distance 2 in the graph. This is indeed the case $L(2, 1)$ -labeling problem of graphs. Along this direction, Griggs and Yeh [169] investigated the $L(2, 1)$ -labeling problem. For a latest survey on this field, see [388].

There are a considerable number of papers studying $L(2, 1)$ -labelings (see [97, 98, 169, 214, 308]). Most of the papers considered the values of $\lambda_{2,1}(G)$ on particular classes of graphs G ; however, Griggs and Yeh [169] provided an upper bound $\Delta^2 + 2\Delta$ for general graphs with maximum degree Δ . Later, Chang and Kuo [98] improved it to $\Delta^2 + \Delta$. Recently, Král and Škrekovski [237] reduced the bound to $\Delta^2 + \Delta - 1$.

In general, Griggs and Yeh [169] suggested the following conjecture:

Conjecture 28 ($L(2, 1)$ -Labeling Conjecture) *For any graph G with $\Delta \geq 2$, $\lambda_{2,1}(G) \leq \Delta^2$.*

It is obvious that [Conjecture 28](#) cannot hold for $\Delta = 1$, as $\Delta(K_2) = 1$ but $\lambda_{2,1}(K_2) = 2$. However, if G is a diameter 2 graph, then $\lambda_{2,1}(G) \leq \Delta^2$. Besides, the upper bound is attainable by Moore graphs (diameter 2 graph with order $\Delta^2 + 1$). Moreover, in [169], the authors proved that determining $\lambda_{2,1}(G)$ of any graph G is NP-complete, and Bodlaender et al. [51] showed that the problem of finding the minimum number $\lambda_{2,1}$ for planar graphs, bipartite graphs, chordal graphs, and split graphs is also NP-complete. Fiala and Kratochvíl [150] even proved that for every integer $p \geq 3$, it is still NP-complete to decide whether a p -regular graph admits an $L(2, 1)$ -labeling of span (at most) $p + 2$.

For general graphs, in [166], Gonçalves constructed a labelling algorithm to get a little bit better upper bound:

Theorem 163 *For any graph G with $\Delta \geq 2$, $\lambda_{2,1}(G) \leq \Delta^2 + \Delta - 2$.*

Recently, Havet et al. [182] showed that [Conjecture 28](#) is true for any graph G with sufficiently large Δ , for example, $\Delta \geq 10^{69}$. This is the first paper addressing the solution of [Conjecture 28](#) for general graphs, although it does not completely solve it. More generally, they showed the following:

Theorem 164 For any positive integer d , there exists a constant Δ_d such that every graph with $\Delta \geq \Delta_d$ has an $L(d, 1)$ -labeling with span at most $\Delta^2 + 1$.

This yields that, for each positive integer d , there is an integer C_d such that every graph has an $L(d, 1)$ -labeling with span at most $\Delta^2 + C_d$.

In the following, it is concerned with the $L(2, 1)$ -labeling of some special graphs such as planar graphs, outerplanar graphs, K_4 -minor-free graphs, trees, and chordal graphs. Some recent results will be displayed.

5.1.1 Planar Graphs

For planar graphs, Bella et al. [47] showed that [Conjecture 28](#) holds for all planar graphs G with $\Delta \geq 4$. Kang [219] showed for every subcubic Hamiltonian graph G , $\lambda_{2,1}(G) \leq 9$, that is, [Conjecture 28](#) holds for this type of graphs. Heuvel and McGuinness [189] proved that $\lambda_{p,q}(G) \leq (4q - 2)\Delta + 10p + 38q - 23$ for every planar graph G . It implies that $\lambda_{2,1}(G) \leq 2\Delta + 35$ for a planar graph G . Molloy and Salavatipour [276] improved this result to $\lambda_{p,q}(G) \leq q\lceil\frac{5}{3}\Delta\rceil + 18p + 77q - 18$ for every planar graph G . It implies that $\lambda_{2,1}(G) \leq \lceil\frac{5}{3}\Delta\rceil + 95$ for a planar graph G . By considering planar graphs without short cycles, Wang and Cai [351] showed that every planar graph G without 4-cycles has $\lambda_{p,q}(G) \leq \min\{(8q - 4)\Delta + 8p - 6q - 1, (2q - 1)\Delta + 10p + 84q - 47\}$. It means that $\lambda_{2,1}(G) \leq \min\{4\Delta + 9, \Delta + 57\}$ for such a planar graph G .

5.1.2 Outerplanar Graphs

For any outerplanar graph G , Bodlaender et al. [50] observed that at most $\Delta + 9$ colors are sufficient to give an $L(2, 1)$ -labeling for outerplanar graph and they suspected this bound is not tight. Later, Calamoneri and Petreschi [93] proved that $\lambda_{2,1}(G) \leq \max\{10, \Delta + 2\}$ for any outerplanar graph G and $\lambda_{2,1}(G) \leq 8$ if $\Delta = 3$. Their results imply that $\lambda_{2,1}(G) \leq \Delta + 6$ for every outerplanar graph G and $\lambda_{2,1}(G) \leq \Delta + 2$ if $\Delta \geq 8$. By investigating the circular distance two labeling of graphs, Liu and Zhu [253] also proved independently that $\lambda_{2,1}(G) \leq \Delta + 6$ for an outerplanar graph G and $\lambda_{2,1}(G) \leq \Delta + 2$ if $\Delta \geq 15$. Wang and Luo [363] improved these results by showing the following: (1) $\lambda_{2,1}(G) \leq \Delta + 5$ for any outerplanar graph G and (2) $\lambda_{2,1}(G) \leq 7$ for an outerplanar graph G with $\Delta = 3$.

In [50], the authors conjectured that every outerplanar graph G has $\lambda_{2,1}(G) \leq \Delta + 2$. Calamoneri and Petreschi [93] disproved this conjecture by constructing an outerplanar graph G with $\Delta = 3$ and $\lambda_{2,1}(G) = 6$ and further conjectured that every outerplanar graph G with $\Delta \geq 4$ has $\lambda_{2,1}(G) \leq \Delta + 2$. Unfortunately, Wang and Luo [363] constructed another example of outerplanar graph G with $\Delta = 4$ and $\lambda_{2,1}(G) = 7$ to disprove their new conjecture. However, it is yet unknown if every outerplanar graph G with $\Delta \in \{5, 6, 7\}$ has $\lambda_{2,1}(G) \leq \Delta + 2$.

5.1.3 K_4 -Minor Free Graphs

Wang and Wang [369] first studied the $L(p, q)$ -labeling of K_4 -minor-free graphs. Their result is as follows:

Theorem 165 Let G be a K_4 -minor-free graph. If $p + q \geq 3$, then $\lambda_{p,q}(G) \leq 2(2p - 1) + (2q - 1)\lfloor \frac{3\Delta}{2} \rfloor - 2$.

Corollary 12 If G is a K_4 -minor-free graph, then $\lambda_{2,1}(G) \leq \lfloor \frac{3\Delta}{2} \rfloor + 4$.

It should be pointed out that [Theorem 165](#) is a generalization of results in [251]. [Corollary 12](#) implies that [Conjecture 28](#) holds for all K_4 -minor-free graphs. More recently, Král and Nejedly [236] showed that there exists Δ_0 such that for every K_4 -minor-free graph G with $\Delta \geq \Delta_0$, $\lambda_{p,q}(G) \leq q\lfloor \frac{3\Delta}{2} \rfloor$, which is best possible.

5.1.4 Trees and Chordal Graphs

Griggs and Yeh [169] proved that every tree T satisfies $\Delta + 1 \leq \lambda_{2,1}(T) \leq \Delta + 2$. Chang and Kuo [98] presented a polynomial algorithm for determining the precise value of $\lambda_{2,1}(T)$ for any tree T . Wang [348] provided a sufficient condition for a tree T to have $\lambda_{2,1}(T) = \Delta + 1$. More precisely, he showed the following:

Theorem 166 If a tree T contains no two vertices of maximum degree at distance either 1, 2, or 4, then $\lambda_{2,1}(T) = \Delta + 1$.

[Theorem 166](#) is the best possible in the sense that for each $\Delta \geq 3$, there exists a tree T of maximum degree Δ such that $\lambda_{2,1}(T) = \Delta + 2$ and the distance between any two vertices of maximum degree is at least 4. Such examples of trees were constructed in [348].

To attack [Conjecture 28](#), Sakai [308] considered the class of chordal graphs. She showed that $\lambda_{2,1}(G) \leq (\Delta + 3)^2/4$ for any chordal graph G . For a unit interval graph G , which is a very special chordal graph, she also proved that $2\chi(G) - 2 \leq \lambda_{2,1}(G) \leq 2\chi(G)$. In [235], Král showed that $\lambda_{2,1}(G) \leq \frac{\Delta^{3/2}}{\sqrt{6}} + O(\Delta)$ if G is a chordal graph. Besides, he conjectured the following:

Conjecture 29 For a chordal graph G , $\lambda_{2,1}(G) \leq \frac{2\Delta^{3/2}}{3\sqrt{3}} + O(\Delta) - 1$.

For a detailed survey on $L(2, 1)$ -labeling problem of graphs, see [92].

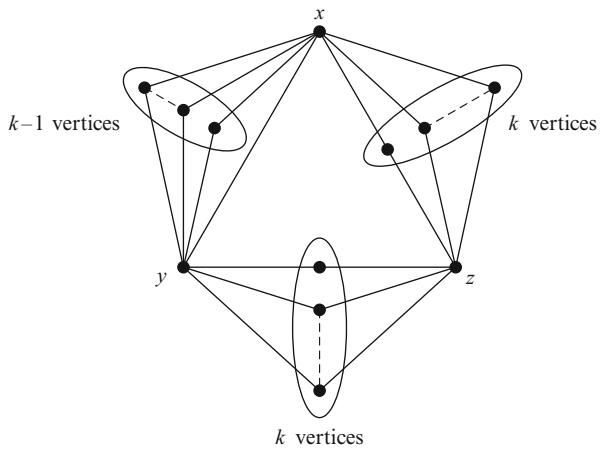

5.2 Coloring the Square of Graphs

The *square* G^2 of a graph G is the graph defined on the vertex set $V(G)$ such that two vertices u and v are adjacent in G^2 if and only if $1 \leq d(u, v) \leq 2$ in G . A mapping ϕ is a k -coloring of G^2 if and only if $\phi(u) \neq \phi(v)$ whenever $1 \leq d(u, v) \leq 2$ in G .

Since G^2 contains a clique of order at least $\Delta(G) + 1$, $\chi(G^2) \geq \Delta(G) + 1$ for any graph G . If G is a tree, then $\chi(G^2) = \Delta(G) + 1$. On the other hand, $\Delta(G^2) \leq \Delta^2(G)$. Hence, $\chi(G^2) \leq \Delta^2(G) + 1$ for any graph G . The 5-cycle and Petersen graph G satisfy $\chi(G^2) = \Delta^2(G) + 1$. By the definition of $L(p, q)$ -labeling, $\lambda_{1,1}(G) = \chi(G^2) - 1$.

In 1977, Wegner [378] first investigated the chromatic number of the square of a planar graph. He proved that $\chi(G^2) \leq 8$ for every planar graph G with $\Delta = 3$ and

Fig. 3 A planar graph with $\Delta = 2k$ that needs at least $3k + 1 = \frac{3}{2}\Delta + 1$ colors

conjectured that the upper bound could be reduced to 7, which has been confirmed by Thomassen [332]. Moreover, Montassier and Raspaud [281] proved that 7 colors are necessary by giving an example. For planar graphs of maximum degree $\Delta \geq 4$, Wegner [378] proposed the following conjecture.

Conjecture 30 *Let G be a planar graph with maximum degree Δ . Then*

$$\chi(G^2) \leq \begin{cases} \Delta + 5, & \text{if } 4 \leq \Delta \leq 7; \\ \lfloor \frac{3}{2}\Delta \rfloor + 1, & \text{if } \Delta \geq 8. \end{cases}$$

Wegner also gave some bounds for the case $\Delta \leq 7$ and constructed planar graphs to attain the conjectured bounds. For $\Delta \geq 8$ even, these examples are sketched below. The graph in Fig. 3 has maximum degree $2k$, and yet all vertices except z are adjacent in its square. Hence, to color these $3k + 1$ vertices, at least $3k + 1 = \frac{3}{2}\Delta + 1$ colors is required.

Many upper bounds on $\chi(G^2)$ for planar graphs in terms of Δ have been obtained in the past 15 years. In [6], Agnarsson and Halldorsson showed the following:

Theorem 167 *For every planar graph G with maximum degree $\Delta \geq 749$, $\chi(G^2) \leq \lfloor \frac{9}{5}\Delta \rfloor + 2$.*

A similar result was obtained by Borodin et al. [60].

Theorem 168 *For every planar graph G with maximum degree $\Delta \geq 47$, $\chi(G^2) \leq \lceil \frac{9}{5}\Delta \rceil + 1$.*

Nearly at the same time, Heuvel and McGuinness [189] gave a general upper bound without maximum degree restriction.

Theorem 169 For every planar graph G with maximum degree Δ , $\chi(G^2) \leq 2\Delta + 25$.

The currently best known upper bound on this parameter for planar graphs was obtained by Molloy and Salavatipour [276].

Theorem 170 For every planar graph G with maximum degree Δ , $\chi(G^2) \leq \lceil \frac{5}{3}\Delta \rceil + 78$.

Also, Molloy and Salavatipour [276] showed that if G is a planar graph with maximum degree $\Delta \geq 241$, then $\chi(G^2) \leq \lceil \frac{5}{3}\Delta \rceil + 25$. Lih, Wang, and Zhu [251] studied the coloring of the squares of K_4 -minor-free graphs. More precisely, they proved the following:

Theorem 171 Let G be a K_4 -minor-free graph with maximum degree Δ . Then

$$\chi(G^2) \leq \begin{cases} \Delta + 3, & \text{if } 2 \leq \Delta \leq 3; \\ \lfloor \frac{3}{2}\Delta \rfloor + 1, & \text{if } \Delta \geq 4. \end{cases}$$

The upper bound in [Theorem 171](#) is tight. For $\Delta = 2$, it is easy to obtain that $\Delta(C_5) = 2$ and $\chi(C_5^2) = 5$. For $\Delta = 3$, let G be the graph consisting of three internally disjoint paths joining two vertices x and y , where two of the paths are of length 2 and the third one is of length 3. Then $\Delta = 3$ and $\chi(G^2) = \chi(K_6) = 6$. For $\Delta = 2k \geq 4$, let G_{2k} be the graph consisting of k internally disjoint paths joining x and y , k internally disjoint paths joining x and z , and k internally disjoint paths joining y and z . All these paths are of length 2, except one path joining x and y is of length 1, and one path joining x and z is of length 1. Then $\Delta(G_{2k}) = 2k$ and $\chi(G_{2k}^2) = \chi(K_{3k+1}) = 3k + 1$. For $\Delta = 2k + 1 \geq 5$, let G_{2k+1} be obtained from G_{2k} by adding a new path of length 2 joining y and z . Then $\Delta(G_{2k+1}) = 2k + 1$ and $\chi(G_{2k+1}^2) = \chi(G_{3k+2}) = 3k + 2$.

In 2001, Kostochka and Woodall [234] investigated the list coloring of square of graphs and raised the following conjecture:

Conjecture 31 For every graph G , $\chi(G^2) = \chi^l(G^2)$.

If true, this conjecture (together with Thomassen's result [332]) implies that every planar graph G with $\Delta = 3$ satisfies $\chi^l(G^2) \leq 7$. Recently, Cranston and Kim [119] proved that every connected graph (not necessarily planar) with $\Delta = 3$ other than the Petersen graph satisfies $\chi^l(G^2) \leq 8$ (and this is best possible by the Wagner graph).

In addition, Cranston and Kim [119] showed that if G is a planar graph with $\Delta = 3$ and girth $g \geq 7$, then $\chi^l(G^2) \leq 7$. Dvořák, Škrekovski, and Tancer showed that if G is a planar graph with $\Delta = 3$ and $g \geq 10$, then $\chi^l(G^2) \leq 6$, which has been improved to $g \geq 9$ in [119].

For planar graphs G with $\Delta \geq 8$, [Conjecture 31](#) leads directly to the following conjecture:

Conjecture 32 For every planar graph G with $\Delta \geq 8$, $\chi^l(G^2) \leq \lfloor \frac{3\Delta}{2} \rfloor + 1$.

Havet et al. [181] announced the following theorem.

Theorem 172 The square of every planar graph G of maximum degree Δ has list chromatic number at most $(1 + o(1))\frac{3}{2}\Delta$. Moreover, given lists of this size, there is a proper coloring in which the colors on every pair of adjacent vertices of G differ by at least $\Delta^{\frac{1}{4}}$.

The $o(1)$ term here is as $\Delta \rightarrow \infty$. The first-order term $\frac{3}{2}\Delta$ is essentially best possible; see the example described above. On the other hand, the term $\Delta^{\frac{1}{4}}$ is probably far from best possible; it was chosen to keep the proof simple.

In what follows, it is going to study the coloring of squares of some special graphs such as hypercubes, outerplanar graphs, chordal graphs, and planar graphs with high girth.

5.2.1 Planar Graphs with High Girth

By investigating the $L(p, q)$ -labeling of planar graphs, Wang and Lih [360] obtained a general result of planar graphs with high girth.

Theorem 173 Let G be a planar graph with maximum degree Δ and girth g . Then

$$\lambda_{p,q}(G) \leq \begin{cases} (2q - 1)\Delta + 4p + 4q - 4, & \text{if } g \geq 7; \\ (2q - 1)\Delta + 6p + 12q - 9, & \text{if } g \geq 6; \\ (2q - 1)\Delta + 6p + 24q - 15, & \text{if } g \geq 5. \end{cases}$$

As it is mentioned at the beginning of this section, every proper coloring of the square of a graph is exactly an $L(1, 1)$ -labeling of the graph. So [Theorem 173](#) implies the following:

Corollary 13 Let G be a planar graph with maximum degree Δ and girth g . Then

$$\chi(G^2) \leq \begin{cases} \Delta + 5, & \text{if } g \geq 7; \\ \Delta + 10, & \text{if } g \geq 6; \\ \Delta + 16, & \text{if } g \geq 5. \end{cases}$$

$$\lambda_{2,1}(G) \leq \begin{cases} \Delta + 8, & \text{if } g \geq 7; \\ \Delta + 15, & \text{if } g \geq 6; \\ \Delta + 21, & \text{if } g \geq 5. \end{cases}$$

Note that $\lfloor \frac{3\Delta}{2} \rfloor + 1 \geq \Delta + 5$ when $\Delta \geq 8$, $\lfloor \frac{3\Delta}{2} \rfloor + 1 \geq \Delta + 10$ when $\Delta \geq 18$, and $\lfloor \frac{3\Delta}{2} \rfloor + 1 \geq \Delta + 16$ when $\Delta \geq 30$. Thus, the following result is an immediate consequence of [Corollary 13](#).

Corollary 14 [Conjecture 30](#) holds for planar graphs G with $g \geq 7$, or $g = 6$ and $\Delta \geq 18$, or $g = 5$ and $\Delta \geq 30$.

Borodin et al. [63] proved that if G is a planar graph with maximum degree Δ and girth at least 7, then $\chi(G^2) = \Delta + 1$ whenever $\Delta \geq 30$. On the other hand, there are planar graphs G with girth at most 6, arbitrarily large maximum degree Δ , and $\chi(G^2) > \Delta + 1$. Recently, Dvořák et al. [134] discussed the coloring of the square of a planar graph with girth 6. Their result is as follows:

Theorem 174 *Let G be a planar graph with maximum degree $\Delta \geq 8821$ and girth $g \geq 6$. Then $\chi(G^2) \leq \Delta + 2$.*

This result has been improved and extended by Borodin and Ivanova [69, 70].

Theorem 175 ([69]) *Let G be a planar graph with maximum degree $\Delta \geq 18$ and girth $g \geq 6$. Then $\chi(G^2) \leq \Delta + 2$.*

Theorem 176 ([70]) *Let G be a planar graph with maximum degree $\Delta \geq 36$ and girth $g \geq 6$. Then $\chi^l(G^2) \leq \Delta + 2$.*

Borodin et al. [73] gave a sufficient condition for planar graphs with given maximum degree and girth with respect to the list coloring.

Theorem 177 *For every planar graph G with maximum degree Δ and girth g , $\chi^l(G^2) = \Delta + 1$ in each of the following cases:*

- (1) $\Delta = 3$ and $g \geq 24$.
- (2) $\Delta = 4$ and $g \geq 15$.
- (3) $\Delta = 5$ and $g \geq 13$.
- (4) $\Delta = 6$ and $g \geq 12$.
- (5) $\Delta \geq 7$ and $g \geq 11$.
- (6) $\Delta \geq 9$ and $g = 10$.
- (7) $\Delta \geq 15$ and $g = 8$.
- (8) $\Delta \geq 30$ and $g = 7$.

5.2.2 Outerplanar Graphs

For the class of outerplanar graphs, Lih and Wang [250] proved the following result:

Theorem 178 *Let G be an outerplanar graph with maximum degree Δ . Then*

1. $\chi(G^2) \leq \Delta + 2$ if $\Delta \geq 3$.
2. $\chi(G^2) = \Delta + 1$ if $\Delta \geq 7$.

An alternative proof of Theorem 178 was given in [361]. Moreover, Calamoneri and Petreschi [93] also obtained the same result through an algorithmic aspect.

Wang and Luo [363] extended the result of Theorem 178 to the case $\Delta = 6$. That is, they proved the following:

Theorem 179 *If G is an outerplanar graph with $\Delta = 6$, then $\chi(G^2) = 7$.*

Theorem 179 was independently obtained by Agnarsson and Halldórsson [7]. Moreover, it was shown in [7] that there exist infinitely many biconnected outerplanar graphs G with maximum degree $\Delta = 5$ and $\chi(G^2) = 7 = \Delta + 2$. This shows that Theorems 178 and 179 are the best possible with respect to the requirement of maximum degree.

An outerplanar graph G is said to be *maximal* if $G + xy$ is not outerplanar for any two nonadjacent vertices x and y . Let Q denote a maximal outerplanar graph obtained by adding three chords y_1y_3, y_3y_5, y_5y_1 to a 6-cycle $y_1y_2 \dots y_6y_1$.

Luo [262] characterized completely the chromatic number of the square of a maximal outerplanar graph. More precisely, she showed the following:

Theorem 180 *Let G be a maximal outerplanar graph with maximum degree Δ . Then $\Delta + 1 \leq \chi(G^2) \leq \Delta + 2$; and $\chi(G^2) = \Delta + 2$ if and only if G is isomorphic to Q .*

5.2.3 Other Graphs

The coloring of the square of hypercube Q_d has been studied by Wan in [346]. Such coloring problem is known to be related to the conflict-free channel set assignment for the hypercube cluster interconnection topology. According to the definition of hypercube, the vertices with at most one coordinate equal to form a clique of size $d + 1$ in Q_d^2 ; hence, $\chi(Q_d^2) \geq d + 2$. An independent set in Q_d^2 is precisely an error-correcting code. So, a proper coloring of this graph may be viewed as a covering of the hypercube with codes. Wan [346] constructed a coloring of Q_d^2 using $2^{\lfloor \log_2 d \rfloor + 1}$ colors. Furthermore, he conjectured that this is optimal. Note that Q_d^2 contains a subgraph isomorphic to Q_{d-1}^2 . Thus, it suffices to prove the conjecture when d is a power of 2. The cases $d = 1, 2, 4$ are rather easy to verify. However, this conjecture is false, since it was proved by Royle that $13 \leq \chi(Q_8^2) \leq 14$, see [212].

For a chordal graph G with maximum degree Δ , Král [235] showed that the k th power G^k of G is $O(\sqrt{k}\Delta^{(k+1)/2})$ -degenerate for even values of k and $O(\Delta^{(k+1)/2})$ -degenerate for odd values. In particular, this bounds the chromatic number $\chi(G^k)$ of the k th power of G . The bound proven for odd values of k is the best possible. More generally, the author in [235] showed that $\lambda_{p,q}(G) \leq \lfloor \frac{(\Delta+1)^{3/2}}{\sqrt{6}} \rfloor (2q - 1) + \Delta(2p - 1)$, which implies that $\chi(G^2) \leq \lfloor \frac{(\Delta+1)^{3/2}}{\sqrt{6}} \rfloor + \Delta + 1$. On the other hand, a construction of such graphs with $\lambda_{p,q}(G) \geq \Omega(\Delta^{3/2}q + \Delta p)$ was found.

5.3 Backbone Coloring

Let G be a graph and H a spanning subgraph of G . For an integer $\lambda \geq 2$, a λ -backbone- k -coloring of (G, H) is a mapping $f: V(G) \rightarrow \{1, 2, \dots, k\}$ such that $|f(u) - f(v)| \geq \lambda$ if $uv \in E(H)$ and $|f(u) - f(v)| \geq 1$ if $uv \in E(G) \setminus E(H)$. The λ -backbone chromatic number, denoted by $\chi_\lambda(G, H)$ or $\text{BBC}_\lambda(G, H)$, of (G, H) is the smallest integer k such that (G, H) has a λ -backbone- k -coloring. In particular, when $\lambda = 2$, it is called, for short, the *backbone coloring* and the *backbone chromatic number*, denoted by $\chi_b(G, H)$ or $\text{BBC}(G, H)$.

The backbone coloring of graphs was introduced in 2003 by Broersma et al. [81] and later was investigated by some authors; see [82, 83, 270, 271, 350].

The following result is an easy, useful observation:

Theorem 181 If H is a spanning subgraph of G , then $\chi_b(G, H) \leq 2\chi(G) - 1$.

Some better upper bounds for $\chi_b(G, H)$ can be derived from [Theorem 181](#):

- (i) If G is a planar graph, then $\chi(G) \leq 4$ by the Four-Color Theorem, and hence, $\chi_b(G, H) \leq 7$.
- (ii) If G is a bipartite graph, then $\chi(G) \leq 2$, and hence, $\chi_b(G, H) \leq 3$.
- (iii) If G is a triangle-free planar graph, then $\chi(G) \leq 3$ by [170], and hence, $\chi_b(G, H) \leq 5$.
- (iv) If G is a k -degenerate graph, then $\chi(G) \leq k+1$, and thus, $\chi_b(G, H) \leq 2k+1$.

In particular, if G is a K_4 -minor-free graph (especially, outerplanar graph and series-parallel graph), then G is 2-degenerate, and therefore, $\chi_b(G, H) \leq 5$.

It is easy to verify that if G is a connected non-bipartite graph and H is a connected spanning subgraph of G , then $\chi_b(G, H) \geq 4$. Moreover, if G is a connected graph with at least two vertices and H is a connected spanning subgraph of G , then $\chi_b(G, H) = 3$ if and only if G is a bipartite graph.

Now, consider the relation between the backbone chromatic number and ordinary chromatic number of a graph. How far away from $\chi(G)$ to $\chi_\lambda(G, H)$ in the worst case? To answer this question, some symbols are needed. Suppose that k is a positive integer. Set

$$T_\lambda(k) = \max\{\chi_\lambda(G, T) : G \text{ is a graph with a spanning tree } T, \text{ and } \chi(G) = k\}.$$

$$P_\lambda(k) = \max\{\chi_\lambda(G, P) : G \text{ is a graph with a Hamiltonian path } P, \text{ and } \chi(G) = k\}.$$

$$M_\lambda(k) = \max\{\chi_\lambda(G, M) : G \text{ is a graph with a perfect matching } M, \text{ and } \chi(G) = k\}.$$

$$S_\lambda(k) = \max\{\chi_\lambda(G, S) : G \text{ is a graph with disjoint spanning stars } S, \text{ and } \chi(G) = k\}.$$

If $\lambda = 2$, simply write $T(k)$ for $T_2(k)$, $P(k)$ for $P_2(k)$, $M(k)$ for $M_2(k)$, and $S(k)$ for $S_2(k)$.

Broersma et al. [81, 82] determined the exact values of the first three parameters $T(k)$, $P(k)$, and $M(k)$. More precisely, their results are described in [Theorems 182–184](#).

Theorem 182 $T(k) = 2k - 1$ for all $k \geq 1$.

Theorem 183 For $k \geq 1$, $P(k)$ takes the following values:

- (a) If $1 \leq k \leq 4$, then $P(k) = 2k - 1$.
- (b) $P(5) = 8$ and $P(6) = 10$.
- (c) If $k \geq 7$ and $k = 4t$, then $P(4t) = 6t$.
- (d) If $k \geq 7$ and $k = 4t + 1$, then $P(4t + 1) = 6t + 1$.
- (e) If $k \geq 7$ and $k = 4t + 2$, then $P(4t + 2) = 6t + 3$.
- (f) If $k \geq 7$ and $k = 4t + 3$, then $P(4t + 3) = 6t + 5$.

Theorem 184 For $k \geq 1$, $M(k)$ takes the following values:

- (a) $M(4) = 6$.
- (b) If $k = 3t$, then $M(3t) = 4t$.

- (c) If $k = 4$ and $k = 3t + 1$, then $M(3t + 1) = 4t + 1$.
 (d) If $k = 3t + 2$, then $M(3t + 2) = 4t + 3$.

For a general problem, that is, λ may be equal to or greater than 2, Broersma et al. [83] established the following two results:

Theorem 185 For $\lambda \geq 2$, $M_\lambda(k)$ takes the following values:

$$M_\lambda(k) = \begin{cases} \lambda + k - 1, & \text{if } 2 \leq k \leq \lambda; \\ 2k - 2, & \text{if } \lambda + 1 \leq k \leq 2\lambda; \\ 2k - 3, & \text{if } k = 2\lambda + 1; \\ 2t\lambda, & \text{if } k = t(\lambda + 1) \text{ with } t \geq 2; \\ 2t\lambda + 2c - 1, & \text{if } k = t(\lambda + 1) + c \text{ with } t \geq 2 \text{ and } 1 \leq c \leq \frac{\lambda+3}{2}; \\ 2t\lambda + 2c - 2, & \text{if } k = t(\lambda + 1) + c \text{ with } t \geq 2 \text{ and } \frac{\lambda+3}{2} \leq c \leq \lambda. \end{cases}$$

Theorem 186 For $\lambda \geq 2$, $S_\lambda(k)$ takes the following values:

- (a) $S_\lambda(2) = \lambda + 1$, $S_2(3) = 5$, and $S_2(4) = 6$.
 (b) If $3 \leq k \leq 2\lambda - 3$, then $S_\lambda(k) = \lceil \frac{3k}{2} \rceil + \lambda - 2$.
 (c) If $2\lambda - 2 \leq k \leq 2\lambda - 1$ with $\lambda \geq 3$, then $S_\lambda(k) = k + 2\lambda - 2$.
 (d) If $k = 2\lambda$ with $\lambda \geq 3$, then $S_\lambda(k) = 2k - 1$.
 (e) If $k \geq 2\lambda + 1$, then $S_\lambda(k) = 2k - \lceil \frac{k}{\lambda} \rceil$.

Concerning the computational complexity of backbone coloring, Broersma et al. [81, 83] gave the following two theorems:

Theorem 187 (a) The following problem is polynomially solvable for any $l \leq 4$: Given a graph G and a spanning tree T , decide whether $\chi_b(G, T) \leq l$.
 (b) The following problem is NP-complete for all $l \geq 5$: Given a graph G and a Hamiltonian path P , decide whether $\chi_b(G, T) \leq l$.

Theorem 188 (a) The following problem is polynomially solvable for any $l \leq \lambda + 1$: Given a graph G and a star backbone S , decide whether $\chi_\lambda(G, S) \leq l$.
 (b) The following problem is NP-complete for all $l \geq \lambda + 2$: Given a graph G and a star backbone S , decide whether $\chi_\lambda(G, S) \leq l$.

5.3.1 Split Graphs

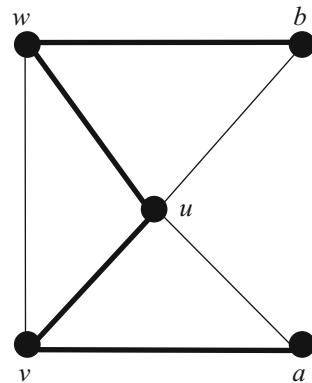

A *split graph* is a graph whose vertex set can be partitioned into a clique and an independent set, with possibly edges in between. Recall that the *size* of a largest clique in G is denoted by $\omega(G)$. It is known that a split graph G is perfect, and hence, $\chi(G) = \omega(G)$. In [81], the authors proved the following:

Theorem 189 Let G be a split graph:

- (a) For every spanning tree T in G , $\chi_b(G, T) \leq \chi(G) + 2$.
 (b) If $\omega(G) \neq 3$, then for every Hamiltonian path P in G , $\chi_b(G, P) \leq \chi(G) + 1$.

Furthermore, they showed that both bounds in **Theorem 189** are tight. Explain here why for split graphs with clique number 3 the statement in **Theorem 189** does

Fig. 4 A split graph G with a Hamiltonian path P such that $\omega(G) = 3$ and $\chi_b(G, P) = 5$

not work. Consider the split graph G on five vertices from Fig. 4. Vertices v, u, w form a clique, vertex a is adjacent to v, u , and vertex b is adjacent to u, w . The clique number (and hence the chromatic number) of this graph is equal to 3. Let $P = avuwba$ be a Hamiltonian path. Then $\chi_b(G, P) > \chi(G) + 1 = 4$. Assume to the contrary that (G, P) has a backbone coloring with colors 1, 2, 3, and 4. It is easy to see that u cannot be colored with color 2 or 3; otherwise, v and w are forced to be colored with the same color, an obvious contradiction. Now suppose that u is colored with color 1 (the case when u is colored with color 4 is similar). Then one of its neighbors in P must have color 3 and the other one color 4. Without loss of generality, assume that v has color 3. Vertex a is adjacent in P to v , so the colors 2, 3, and 4 are forbidden for a and the only valid color for a is 1. But a is adjacent in G to u which has color 1 as well. This contradiction completes the proof of the claim.

In 2006, Salman [309] investigated the λ -backbone colorings of split graphs with a spanning tree. He obtained the following three theorems, where all the upper bounds are tight.

Theorem 190 *Let $\lambda \geq 2$ and let G be a split graph. For every tree backbone T of G ,*

$$\chi_\lambda(G, T) \leq \begin{cases} 1, & \text{if } \chi(G) = 1; \\ 1 + \lambda, & \text{if } \chi(G) = 2; \\ \chi(G) + \lambda, & \text{if } \chi(G) \geq 3. \end{cases}$$

Theorem 191 *Let $\lambda \geq 2$ and let G be a split graph with $\chi(G) = k \geq 2$. For every matching backbone M of G ,*

$$\chi_\lambda(G, M) \leq \begin{cases} \lambda + 1, & \text{if } k = 2; \\ k + 1, & \text{if } k \geq 4 \text{ and } \lambda \leq \min\{\frac{k}{2}, \frac{k+5}{3}\}; \\ k + 2, & \text{if } k = 9 \text{ or } k \geq 11 \text{ and } \frac{k+6}{3} \leq \lambda \leq \lceil \frac{k}{2} \rceil; \\ \lceil \frac{k}{2} \rceil + \lambda, & \text{if } k = 3, 5, 7 \text{ and } \lambda \geq \lceil \frac{k}{2} \rceil; \\ \lceil \frac{k}{2} \rceil + \lambda + 1, & \text{if } k = 4, 6 \text{ or } k \geq 8 \text{ and } \lambda \geq \lceil \frac{k}{2} \rceil + 1. \end{cases}$$

Theorem 192 Let $\lambda \geq 2$ and let G be a split graph with $\chi(G) = k \geq 2$. For every star backbone S of G ,

$$\chi_\lambda(G, S) \leq \begin{cases} k + \lambda, & \text{if either } k = 3 \text{ and } \lambda \geq 2 \text{ or } k \geq 4 \text{ and } \lambda = 2; \\ k + \lambda + 1, & \text{otherwise.} \end{cases}$$

5.3.2 Halin Graphs

Suppose that T is a tree with no vertex of degree 2 and at least one vertex of degree 3 or more. A *Halin graph* is a plane graph $G = T \cup C$, where C is a cycle connecting the leaves, the vertices of degree 1, of T in the cyclic order determined by the drawing of T . Vertices of C are called *outer vertices* of G , and vertices in $V(G) \setminus V(C)$ are called *inner vertices* of G . A Halin graph G is called a *wheel* if G contains only one inner vertex. When $\Delta = 3$, G is 3-regular. In particular, K_4 is a 3-regular Halin graph. It is easy to see that every Halin graph is 3-connected.

It is easy to show that for a Halin graph G , $\chi(G) = 4$ if G is a wheel of order even and $\chi(G) = 3$ otherwise. Wang et al. [350] discussed the backbone coloring of Halin graphs and got the following result.

Theorem 193 Let $G = T \cup C$ be a Halin graph with $X \cup Y$ as a bipartition of T . Then

1. $4 \leq \chi_b(G, T) \leq 5$.
2. $\chi_b(G, T) = 5$ if and only if $|M(T)|$ is odd, and $M(T) \subseteq X$ or $M(T) \subseteq Y$, where $M(T)$ denotes the set of all leaves of T .

An *almost binary tree* is a tree T with $\Delta = 3$ and $|T| \geq 4$ that contains no 2 vertices. Let Γ denote the set of almost binary trees T with the properties: (1) $|M(T)|$ is odd and (2) $M(T) \subseteq X$ or $M(T) \subseteq Y$, where $X \cup Y$ is a bipartition of T .

Let A denote the graph obtained from a path $uxrys$ by gluing a leaf v at x and a leaf t at y . The vertex r is called the *root* of A . Given an almost binary tree T with a leaf z , A is *attached* to T at z if z is identical to the root r of A . And A is an *end subgraph* of T if $A \subseteq T$ and u, v, s, t are leaves of T and r, x, y are of degree 3 in T . Removing an end subgraph A from T means that six vertices x, y, u, v, s, t are removed from T .

Let Λ' denote the set of graphs G_0, G_1, G_2, \dots , where $G_0 = K_{1,3}$, and G_i is obtained by consecutively attaching two copies of A to the graph G_{i-1} for $i = 1, 2, \dots$

In [350], the authors first showed the equality that $\Lambda' = \Lambda$ and afterward gave the following interesting characterization:

Theorem 194 Let $G = T \cup C$ be a 3-regular Halin graph. Then $4 \leq \chi_b(G, T) \leq 5$; and $\chi_b(G, T) = 5$ if and only if $T \in \Lambda'$, that is, T can be obtained by consecutively attaching $2k$, $k \geq 0$, copies of the graph A to the graph $K_{1,3}$.

Notice that the backbone spanning tree T taken in Theorems 193 and 194 is just the tree in the definition of Halin graph $G = C \cup T$. What happens when picking

up other spanning tree as backbone in a Halin graph? The authors in [350] posed the following problem:

Problem 7 *Given a spanning tree T^* , different from T , in a Halin graph $G = T \cup C$, determine $\chi_b(G, T^*)$.*

It seems very difficult to settle [Problem 7](#). The following is a partial solution by considering a class of special spanning trees [350].

For a Halin graph $G = T \cup C$, take $e' = u'v' \in E(T)$ with $u' \in M(T)$ and $e'' = x''y'' \in E(C)$. So, $x'', y'' \in M(T)$. Let $T' = T - M(T)$. Define a spanning tree T^* of G as follows:

$$T^* = T' \cup (C \setminus \{e''\}) \cup \{e'\}.$$

Theorem 195 *Let $G = T \cup C$ be a Halin graph. Let T^* be a spanning tree of G defined as above. If G satisfies one of the following conditions, then $\chi_b(G, T^*) = 4$:*

1. $|M(T)|$ is even.
2. e' is adjacent to e'' in G .

5.3.3 Other Related Results

In [81], the authors asked the following: Is there a constant c such that $\chi_b(G, T) \leq \chi(G) + c$ for every triangle-free graph G with T as a backbone tree? Miškuf et al. [270] answered negatively this question. More precisely, they proved the following:

Theorem 196 *For every $n \in N$, there exist a (finite) triangle-free graph R_n and its spanning tree T_n such that $\chi_b(R_n, T_n) = 2\chi(R_n) - 1 = 2n - 1$.*

Wang et al. [350] considered the backbone coloring of graphs with small maximum average degree. Their result is stated as follows:

Theorem 197 *If G is a connected graph with $\text{mad}(G) < \frac{5}{2}$, then there exists a spanning tree T of G such that $\chi_b(G, T) \leq 4$.*

Corollary 15 *If G is a connected non-bipartite graph with $\text{mad}(G) < \frac{5}{2}$, then there is a spanning tree T such that $\chi_b(G, T) = 4$.*

Note that every planar graph G with girth $g \geq 10$ satisfies $\text{mad}(G) < \frac{5}{2}$ by [Proposition 2](#). This fact, together with [Corollary 15](#), gives the following fact:

Corollary 16 *If G is a connected non-bipartite planar graph with girth at least 10, then there is a spanning tree T such that $\chi_b(G, T) = 4$.*

Let μ denote the smallest integer k such that for every non-bipartite planar graph G with girth at least k , there exists a spanning tree T of G such that $\chi_b(G, T) = 4$. By virtue of [Corollary 16](#), $\mu \leq 10$. What is the exact value of μ ? Bu and Zhang [87] partially answered this question:

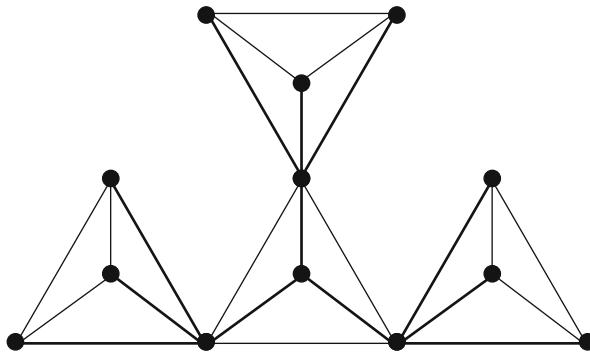

Fig. 5 A planar graph G^* with a spanning tree T^* such that $\chi_b(G^*, T^*) = 6$

Theorem 198 *If G is a connected non-bipartite planar graph without 4-cycles, then there exists a spanning tree T of G such that $\chi_b(G, T) = 4$.*

The following result was given in [350]:

Theorem 199 *There exist infinitely many graphs G with $\Delta \leq 3$ that contain a Hamiltonian path P such that $\chi_b(G, P) = 5$.*

5.3.4 Some Open Problems

The Four-Color Theorem implies that $\chi_b(G, T) \leq 7$ for any planar graph G with an arbitrary spanning tree T . However, this bound 7 is probably not best possible. Can it be improved to 6? The planar graph G^* in Fig. 5, see [82], demonstrates that this bound cannot be improved to 5. Note that the graph G^* consists of four copies of K_4 , each having a $K_{1,3}$ as a spanning tree. In any backbone coloring of such a K_4 with only five colors, its central vertex must receive color 1 or 5. With this observation, it is easy to see that $\chi_b(G^*, T^*) \geq 6$.

Problem 8 *Is $\chi_b(G, T) \leq 6$ for any planar graph G with a spanning tree T ?*

How about the Hamiltonian path case? In this case, it is natural to ask whether the bound 7 is best possible. It can be shown that one cannot improve this bound to 5. Let G_2 be the planar graph from Fig. 6 in which the Hamiltonian path P is indicated by the bold edges. To prove that $\chi_b(G_2, P) \geq 6$, the following claim is needed. Let G_1 be the subgraph of G_2 with the indicated Hamiltonian path P_1 as shown in Fig. 6.

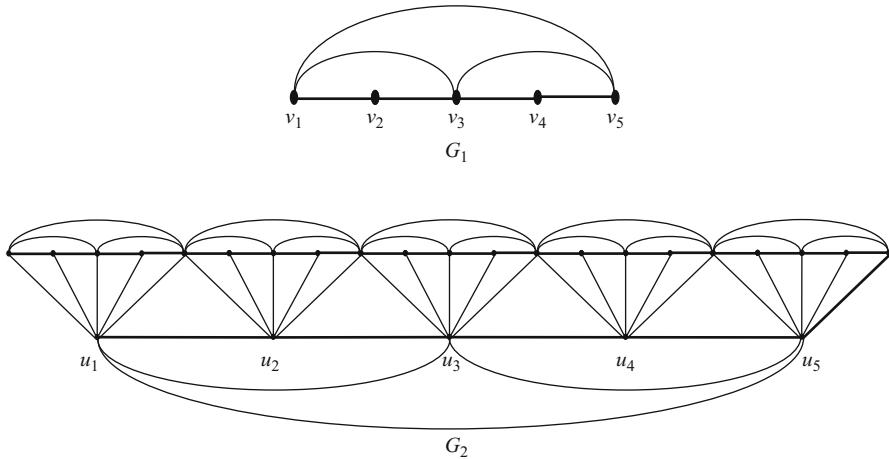

Fig. 6 A planar graph \$G_2\$ with a Hamiltonian path \$P\$ such that \$\chi_b(G_2, P) = 6\$

Claim 1 In any backbone coloring of \$G_1\$ with colors \$\{1, 2, 3, 4, 5\}\$, at least one vertex has color 3.

Proof Suppose that there exists a backbone coloring \$c\$ for \$(G_1, P_1)\$ with colors 1, 2, 4, and 5. By symmetry, assume that \$c(v_1) \in \{1, 2\}\$. Then, it is obvious that \$c(v_2) \in \{4, 5\}\$, \$c(v_3) \in \{1, 2\}\$, and \$c(v_4) \in \{4, 5\}\$. Hence, it follows that \$c(v_4), c(v_5) \in \{4, 5\}\$, contradicting the fact that \$v_1, v_3\$, and \$v_5\$ induce a \$K_3\$ in \$G_1\$. \$\square\$

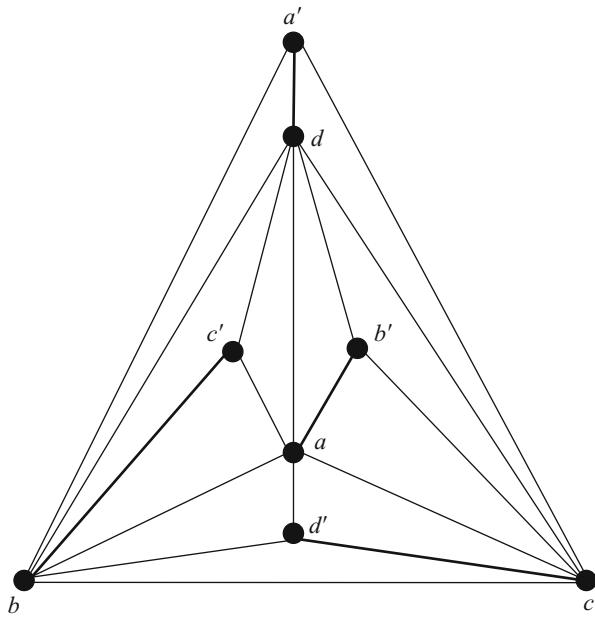

Now suppose that there exists a backbone coloring for \$(G_2, P)\$ with colors \$\{1, 2, 3, 4, 5\}\$. Then **Claim 1** implies that there is a vertex with color 3 among the neighbors of \$u_1\$, hence, \$u_1\$ cannot receive color 3. Similarly, **Claim 1** implies that \$u_2, u_3, u_4\$, and \$u_5\$ cannot receive color 3. But the graph induced by \$\{u_1, u_2, u_3, u_4, u_5\}\$ is isomorphic to \$G_1\$, contradicting **Claim 1**.

Problem 9 Is \$\chi_b(G, P) \leq 6\$ for any planar graph \$G\$ with a Hamiltonian path \$P\$?

What about the perfect matching case? It was shown in [50] that \$\chi_b(G, M) \leq 6\$ for any planar graph \$G\$ with a perfect matching \$M\$. This bound 6 seems to be not best possible. In order to show that this bound cannot be reduced to 4, the authors in [50] constructed an example of planar graph \$G_3\$, as shown in Fig. 7, with an indicated perfect matching \$M = \{ab', bc', cd', da'\}\$. The detailed argument is here omitted.

Problem 10 Is \$\chi_b(G, M) \leq 5\$ for any planar graph \$G\$ with a perfect matching \$M\$?

Fig. 7 A graph G_3 with a perfect matching M such that $\chi_b(G_3, M) = 5$

5.4 Injective Coloring

The injective coloring of a graph was first introduced by Hahn et al. in [188]. A vertex coloring of a graph G is called *injective* if any two vertices having a common neighbor get different colors. Let $\chi_i(G)$ be the minimum number of colors in injective colorings of G . The injective coloring is originated in complexity theory and is used in coding theory [188]. Note that an injective coloring is not necessarily a proper coloring and vice versa.

It is easy to see that if G is a triangle-free graph, then the injective coloring is just the $L(0, 1)$ -labeling of the graph G .

The *common neighbor graph* G_{cn} of a graph G is the graph defined by $V(G_{\text{cn}}) = V(G)$ and

$$E(G_{\text{cn}}) = \{uv \mid \text{there is a path of length 2 in } G \text{ joining } u \text{ and } v\}.$$

By the definition of $L(p, q)$ -labeling, the following relations among several parameters, that is, $\chi_i(G)$, $\chi(G^2)$, and $\chi(G_{\text{cn}})$, can be easily deduced:

- (i) $\chi_i(G) = \chi(G_{\text{cn}})$.
- (ii) If G is a triangle-free graph, then $\lambda_{0,1}(G) = \chi_i(G) - 1$.
- (iii) $\Delta \leq \chi_i(G) \leq \chi(G^2) \leq |G|$.

Let H denote the *prism*, which is a graph obtained by joining three chords u_1u_5, u_2u_4, u_3u_6 to a 6-cycle $u_1u_2 \dots u_6u_1$. It is easy to inspect that H^2 is K_6 , and H_{cn} is $K_6 - M$, where M is a perfect matching of H .

By (iii), $\chi_i(H) \geq \Delta = 3$. On the other hand, an injective 3-coloring c is easily constructed as follows: $c(u_1) = c(u_2) = 1$, $c(u_3) = c(u_6) = 2$, and $c(u_4) = c(u_5) = 3$. Thus, $\chi_i(H) = 3$. Moreover, it is easy to derive that $\chi_i(H) = \chi(H_{\text{cn}}) = 3 < 6 = \chi(H^2)$. This example shows that there exists a graph G such that $\chi(G^2) = 2\chi_i(G)$. In fact, it was proved in [227] that $\chi(G^2) \leq 2\chi_i(G)$ for any graph G .

The authors in [188] considered the injective chromatic number of some special graphs such as complete graphs, paths, cycles, and stars. Moreover, they gave the following results:

Proposition 4 *Let G be a graph with maximum degree Δ :*

1. *If G is d -regular and if $\chi_i(G) = d$, then d divides $|G|$.*
2. *If G is connected and not K_2 , then $\chi(G) \leq \chi_i(G)$.*
3. *If G has the diameter 2 and the independence number α , then $\chi_i(G) \geq \alpha$.*
4. $\chi_i(G) \leq \Delta(\Delta - 1) + 1$.

Theorem 200 *Let Q_n be the hypercube of dimension n :*

1. $\chi_i(Q_n) = n$ if and only if n is a power of 2.
2. $\chi_i(Q_n) \leq 2n - 2$.
3. $\chi_i(Q_{2n+1}) \leq 2\chi_i(Q_{n+1})$.
4. $\chi_i(Q_{2^m-j}) = 2^m$ for $0 \leq j \leq 3$.

The algorithmic aspect of the injective coloring for some special graphs was also considered in [188]:

Theorem 201 *It is NP-complete for a given split (and hence chordal) graph G and an integer k , to decide whether the injective chromatic number of G is at most k .*

Theorem 202 *It is NP-complete to decide, for a given split (and hence chordal) graph G , whether $\chi_i(G) = \chi(G^2) - 1$.*

Theorem 203 *The injective chromatic number of a power chordal graph can be computed in polynomial time.*

Bu et al. [84] studied the injective chromatic number of planar graphs having large maximum degree and girth.

Theorem 204 *Let G be a planar graph with maximum degree Δ and girth g :*

1. $\chi_i(G) = \Delta$ if either $g \geq 20$ and $\Delta \geq 3$ or $g \geq 7$ and $\Delta \geq 71$.
2. $\chi_i(G) \leq \Delta + 1$ if $g \geq 11$.
3. $\chi_i(G) \leq \Delta + 2$ if $g \geq 8$.

Lužar et al. [264] improved some results in [84] by showing the following:

Theorem 205 *Let G be a planar graph with maximum degree Δ and girth g :*

1. $\chi_i(G) \leq \Delta$ if $g \geq 19$ and $\Delta \geq 3$.
2. $\chi_i(G) \leq \Delta + 1$ if $g \geq 10$.
3. $\chi_i(G) \leq \Delta + 4$ if $g \geq 5$ and $\Delta \geq 3$.

Instead of studying planar graphs with high girth, Doyon et al. [133] considered the injective chromatic number of graphs with small maximum average degree. Their result is the following theorem:

Theorem 206 *Let G be a graph with maximum degree Δ :*

1. *If $\text{mad}(G) < \frac{14}{5}$, then $\chi_i(G) \leq \Delta + 3$.*
2. *If $\text{mad}(G) < 3$, then $\chi_i(G) \leq \Delta + 4$.*
3. *If $\text{mad}(G) < \frac{10}{3}$, then $\chi_i(G) \leq \Delta + 8$.*

Again, applying the relation $\text{mad}(G) < \frac{2g}{g-2}$ for a planar graph G with girth g , the following results hold: If G is a planar graph, then $\chi_i(G) \leq \Delta + 3$ if $g \geq 7$, $\chi_i(G) \leq \Delta + 4$ if $g \geq 6$, and $\chi_i(G) \leq \Delta + 8$ if $g \geq 5$.

In [120, 121], Cranston et al. improved the upper bounds given in [133, 264] in certain cases. More specifically, they studied sufficient conditions to imply $\chi_i(G) = \Delta$ and $\chi_i(G) \leq \Delta + 1$.

Theorem 207 ([121]) *Let G be a graph with maximum degree Δ :*

1. *If $\text{mad}(G) < \frac{14}{5}$ and $\Delta \geq 4$, then $\chi_i(G) \leq \Delta + 2$.*
2. *If $\text{mad}(G) < \frac{36}{13}$ and $\Delta = 3$, then $\chi_i(G) \leq 5$.*

Furthermore, an example to show that the maximum average degree in the second conclusion of **Theorem 207** is sharp was constructed in [121].

Chen et al. [104] obtained some upper bounds of the injective chromatic numbers for some graphs, that is, planar graphs, K_4 -minor-free graphs, etc. The following three theorems were established in [104].

Theorem 208 *Let G be a K_4 -minor-free graph with $\Delta \geq 1$. Then $\chi_i(G) \leq \lceil \frac{3}{2}\Delta \rceil$.*

Theorem 208 is best possible in the sense that there exist K_4 -minor-free graphs G such that $\chi_i(G) = \lceil \frac{3}{2}\Delta \rceil$, where Δ is even. Such an example was constructed in [104]. However, it is unknown if, for each given odd integer $k \geq 3$, there exists a K_4 -minor-free graph G with $\Delta = k$ and $\chi_i(G) = \frac{3k+1}{2}$.

Theorem 209 *If G is a planar graph with $\Delta \geq 3$, then $\chi_i(G) \leq \Delta^2 - \Delta$.*

It follows from **Theorem 209** that every planar graph G with $\Delta \leq 3$ has $\chi_i(G) \leq 6$. Some examples of planar subcubic graphs G with $\chi_i(G) = 5$ have been constructed by different authors (in private communications). **Figure 8** is such a planar cubic graph example, which has ten vertices.

Theorem 210 *Let G be a connected graph with $\Delta \geq 3$. Then $\chi_i(G) = \Delta^2 - \Delta + 1$ if and only if $G_{\text{cn}} = 2K_{\Delta(\Delta-1)+1}$.*

By **Theorem 210**, the following consequences hold automatically:

- (i) *If G is a graph with $\Delta \leq 4$, then $\chi_i(G) \leq 13$. Moreover, $\chi_i(G) = 13$ if and only if $G_{\text{cn}} = 2K_{13}$.*
- (ii) *If G is a graph with $\Delta \leq 3$, then $\chi_i(G) \leq 7$. Moreover, $\chi_i(G) = 7$ if and only if G is isomorphic to the Heawood graph.*

Fig. 8 A planar graph G with $\Delta = 3$ and $\chi_i(G) = 5$

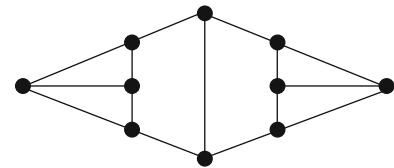

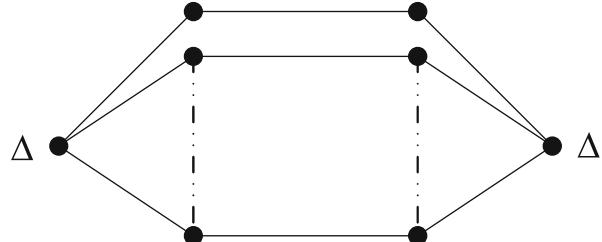

Fig. 9 Graph G' with $g(G') = 6$ and $\chi_i(G') = \Delta + 1$ for $\Delta \geq 2$

In the end of the paper [265], the authors put forward the challenging problem:

Conjecture 33 *Let G be a planar graph with maximum degree Δ . Then*

- (a) $\chi_i(G) \leq 5$, if $\Delta = 3$.
- (b) $\chi_i(G) \leq \Delta + 5$, if $4 \leq \Delta \leq 7$.
- (c) $\chi_i(G) \leq \lfloor \frac{3}{2}\Delta \rfloor + 1$, if $\Delta \geq 8$.

In 2011, Borodin and Ivanova [72] first investigated the list injective colorings of planar graphs. A graph G is said to be *injectively k -choosable* if any list L of size k allows an injective coloring φ such that $\varphi(v) \in L(v)$ whenever $v \in V(G)$. The *injective choice number* of G , denoted by $\chi_i^l(G)$, is the least integer k such that G is injectively k -choosable. Clearly, $\chi_i^l(G) \geq \chi_i(G) \geq \Delta$ for every graph G .

Theorem 211 ([72]) *If G is a planar graph with maximum degree Δ and girth g , then $\chi_i^l(G) = \chi_i(G) = \Delta$ in each of the following cases:*

1. $\Delta \geq 16$ and $g = 7$.
2. $\Delta \geq 10$ and $8 \leq g \leq 9$.
3. $\Delta \geq 6$ and $10 \leq g \leq 11$.
4. $\Delta = 5$ and $g \geq 12$.

Observe that a cycle C_{4n-1} has $\chi_i(C_{4n-1}) = \Delta(C_{4n-1}) + 1 = 3$, whereas the graph G' in Fig. 9 has girth $g = 6$ and $\chi_i(G) = \Delta + 1$ for arbitrarily large Δ . It means that the assumption on $g = 7$ of Theorem 211 (1) is tight.

Theorem 212 ([72]) *Every planar graph G with $\Delta \geq 24$ and $g \geq 6$ has $\chi_i^l(G) \leq \Delta + 1$.*

Furthermore, Borodin and Ivanova [72] posed the following problem.

Problem 11 *Find a precise upper bound for the injective choice number of planar graphs with given girth and maximum degree.*

5.5 $(d, 1)$ -Total Coloring

This section is devoted to the $(d, 1)$ -total coloring problem of graphs. Recall that a *total k -coloring* of a graph G is a coloring of $V(G) \cup E(G)$ using k colors such that no two adjacent or incident elements in $V(G) \cup E(G)$ receive the same color. The *total chromatic number* $\chi''(G)$ of G is the smallest integer k such that G has a total k -coloring. By the definition, $\chi''(G) \geq \Delta + 1$ for any graph G .

Behzad [46] and Vizing [340] posed independently the famous conjecture, named as the Total Coloring Conjecture:

Conjecture 34 (Total Coloring Conjecture) *For any simple graph G , $\chi''(G) \leq \Delta + 2$.*

Conjecture 34 remains still open. For the case $\Delta = 3$, it was verified by Rosenfeld [306] and independently by Vijayaditya [338]. Later, Kostochka [230–232] gradually settled the case $4 \leq \Delta \leq 5$. For planar graphs G , Conjecture 34 was confirmed by Borodin [56] for $\Delta \geq 9$, then by Yap [387] for $\Delta = 8$, and later by Sanders and Zhao for $\Delta = 7$ [311]. However, it remains open for planar graphs with $\Delta = 6$.

Recently, the total coloring of planar graphs with certain restrictions, that is, without some special short cycles or with given maximum degree, attracts much attention and has been deeply investigated in literatures [77, 204, 315, 316, 349, 374].

Whittlesey et al. [381] investigated the $L(2, 1)$ -labeling of incidence graphs. The *incidence graph*, denoted by G_I , of a graph G is the graph obtained from G by replacing each edge by a path of length 2. The $L(2, 1)$ -labeling of the incidence graph of G is equivalent to an assignment of integers to each element of $V(G) \cup E(G)$ such that adjacent vertices have different labels, adjacent edges have different labels, and incident vertex and edge have the difference of labels by at least 2.

Let d be a positive integer and G be a simple graph. A $(d, 1)$ -*total labeling* of G is an integer-valued function f defined on the set $V(G) \cup E(G)$ such that

$$|f(x) - f(y)| \geq \begin{cases} 1, & \text{if verticse } x \text{ and } y \text{ are adjacent in } G; \\ 1, & \text{if edges } x \text{ and } y \text{ are adjacent in } G; \\ d, & \text{if vertex } x \text{ and edge } y \text{ are incident.} \end{cases}$$

Notice that $|f(x) - f(y)|$ for adjacent elements x and y may be required to be greater than or equal to p , instead of 1, in the above, defining inequality for some given positive integer p to obtain a more general notion of (d, p) -total labeling. A $(d, 1)$ -*total labeling* taking values in the set $\{0, 1, \dots, k\}$ is called a $(d, 1)$ - k -*total labeling*. The *span* of a $(d, 1)$ -total labeling is the maximum difference between two labels. The minimum span, that is, the minimum k , among all $(d, 1)$ - k -*total labelings* of G , denoted by $\lambda_d^T(G)$, is called the $(d, 1)$ -*total number* of G .

It is easy to observe that a $(1, 1)$ -total labeling is a total coloring of G and that $\lambda_1^T(G) = \chi''(G) - 1$. Moreover, $\lambda_d^T(G) = \lambda_{d,1}(G_I)$, where G_I is the incidence graph of G .

The concept of $(d, 1)$ -total labeling was firstly introduced and investigated by Havet and Yu [184, 185]. They proposed the following conjecture:

Conjecture 35 (($d, 1$)-Total Labeling Conjecture) *For any graph G and any integer $d \geq 1$, $\lambda_d^T(G) \leq \min\{\Delta + 2d - 1, 2\Delta + d - 1\}$.*

Notice that when $d = 1$, Conjecture 35 is equivalent to Conjecture 34. By generalizing a result of [191], Havet and Yu in [185] showed that $\lambda_d^T(G) \leq 2\Delta - 2\log(\Delta + 2) + 2\log(16d - 8) + d - 1$ for any graph G . Moreover, Havet and Thomassé [183] showed that determining $(d, 1)$ -total number of graphs is very difficult, even for bipartite graphs. For instance, if $\Delta \geq 2d \geq 4$, or if $2d - 1 \geq \Delta \geq d + 2 \geq 5$, then the Δ -bipartite $(d, 1)$ -total labeling problem is NP-complete; if $d \geq 3$, then the $(d + 1)$ -bipartite $(d, 1)$ -total labeling problem is NP-complete.

5.5.1 General Bounds

Observing the label of a vertex with maximum degree and its incident edges, it is easy to see that $\lambda_d^T(G) \geq \Delta + d - 1$. This lower bound may be increased in some cases. In [185], the authors proved that if G is Δ -regular, or if $d \geq \Delta$, then $\lambda_d^T(G) \geq \Delta + d$. For upper bound, the following obvious fact was indicated in [185]:

Proposition 5 *Let G be a graph. Then*

1. $\lambda_d^T(G) \leq \chi(G) + \chi'(G) + d - 2$.
2. $\lambda_d^T(G) \leq 2\Delta + d - 1$.

Since $\chi'(G) = \Delta$ for a bipartite graph G (see [228]), it follows from Proposition 5(1) that every bipartite graph G satisfies $\Delta + d - 1 \leq \lambda_d^T(G) \leq \Delta + d$. In particular, if $d = 2$, then $\Delta + 1 \leq \lambda_d^T(G) \leq \Delta + 2$.

In [267], McDiarmid and Reed proved that if G is a graph with n vertices and k is an integer such that $k! > n$, then $\chi''(G) \leq \chi'(G) + k + 1$. A slight modification of the proof can be applied to the following extension [185]:

Theorem 213 *If G is a graph with n vertices and k is an integer with $\frac{k!}{(2p-1)^k} > n$, then $\lambda_d^T(G) \leq \chi'(G) + k + 3d - 3$. Hence, as $n \rightarrow \infty$, $\lambda_d^T(G) \leq \chi'(G) + O\left(\frac{\log n}{\log(\log n)}\right)$.*

It was proved in [191] that if Δ is large enough, then $\chi''(G) \leq \Delta + O(\log^{10} \Delta)$. This result was also extended to the $(d, 1)$ -total labeling situation [185]:

Theorem 214 *There exists a Δ_0 such that for each graph G with $\Delta \geq \Delta_0$, $\lambda_d^T(G) \leq \Delta + 2\log^{10} \Delta + 3d - 2$.*

Molloy and Reed [274] affirmed that there is a constant c so that the total chromatic number of a graph G is at most $\Delta + c$ as long as Δ is sufficiently large, where $c \leq 10^{26}$. It is possible that a similar proof leads to an analogous theorem for $(d, 1)$ -total labeling but with a larger constant.

The following bound, which slightly improves the known upper bound $2\Delta + d - 1$, also appeared in [185].

Theorem 215 *For any graph G and an integer $d \geq 1$, $\lambda_d^T(G) \leq 2\Delta - 2\log(\Delta + 2) + 2\log(16d - 8) + d - 1$.*

Employing a probabilistic discussion, Havet and Yu [185] showed the following result:

Theorem 216 *If G is a graph with n vertices and k is an integer with $\frac{k!}{(2d-1)^k} > n$, then $\lambda_d^T(G) \leq \chi' + k + 3d - 3$.*

It was shown in [185] that $\lambda_2^T(G) \leq 2\Delta$ for any graph G with $\Delta \geq 2$, and $\lambda_2^T(G) \leq 2\Delta - 1$ if $\Delta \geq 5$ is odd. This implies that $\lambda_2^T(G) \leq 6$ if $\Delta \leq 3$. Also it was conjectured [185] that $\lambda_2^T(G) \leq 5$ if G is a graph with $\Delta \leq 3$ and $G \neq K_4$. Moreover, it was affirmed that $\lambda_3^T(G) \leq 7$ if $\Delta \leq 3$.

Lih et al. [248] also discussed the general upper bounds of $(d, 1)$ -total number of graphs. They gave the following two results and one problem:

Theorem 217 *For any graph G with the list chromatic index k , $\lambda_d^T(G) \leq k + 4d - 3$.*

Theorem 218 *For any graph G , $\lambda_d^T(G) \leq \lfloor \frac{3}{2}\Delta \rfloor + 4d - 3$.*

Conjecture 36 *Let G be a graph with $\chi(G) > \max\{2, d\}$. Then $\lambda_d^T(G) \leq \chi(G) + \chi'(G) + d - 3$.*

5.5.2 Special Graphs

The $(d, 1)$ -total labeling for some kind of special graphs have been studied, for example, complete graphs [185], complete bipartite graphs [248], planar graphs [44], graphs with a given maximum average degree [280], trees for $d = 2$ [205, 352], and outerplanar graphs for $d = 2$ [110].

Complete graphs In their papers, Havet and Yu [185, 186] occupied nearly five pages to study the $(d, 1)$ -total labeling of the complete graphs K_n , according to the various values of n and d . In particular, they determined completely the exact value of $\lambda_2^T(K_n)$ for any $n \geq 1$. Here, only several main results are listed on this topic. For more details, readers may refer to [185].

Theorem 219 *Let $n, d \geq 1$ be integers:*

1. *If $d \geq n$, then $\lambda_d^T(K_n) = 2n + d - 3$.*
2. *If $d \leq n - 1$, then $\lambda_d^T(K_n) \leq n + 2d - 2$.*
3. *If $n \geq d$, then $\lambda_d^T(K_n) \geq n + 2d - 3$.*

4. If n is odd, then $\lambda_d^T(K_n) \leq n + 2d - 3$.
5. If n is even and $n > 6d^2 - 10d + 4$, then $\lambda_d^T(K_n) = n + 2d - 2$.
6. If $n \geq 4$ is even and $d \geq n - 3$, then $\lambda_d^T(K_n) \leq n + 2p - 3$.

Lih et al. [248] studied the $(d, 1)$ -total number of complete bipartite graphs $K_{m,n}$. In particular, they achieved the exact values of $\lambda_d^T(K_{m,n})$ for $d = 1, 2, 3$. Three main results are stated as follows:

Theorem 220 *If $m < n + d$, then $\lambda_d^T(K_{m,n}) = m + d$.*

Theorem 221 *Let $1 \leq n \leq m$. Then*

$$\lambda_2^T(K_{m,n}) = \begin{cases} m + 2, & \text{if } m \leq n + 1, \text{ or } m = n + 2 \text{ and } n \geq 3; \\ m + 1, & \text{otherwise.} \end{cases}$$

Theorem 222 *Let $1 \leq n \leq m$. Then*

$$\lambda_3^T(K_{m,n}) = \begin{cases} m + 3, & \text{if } m \leq n + 2, \text{ or } m = n + 3 \text{ and } n \geq 4, \\ & \quad \text{or } m = n + 4 \text{ and } n = 5, 9, 10, 13, 14, 15; \\ m + 2, & \text{otherwise.} \end{cases}$$

Planar graphs Suppose that G is a planar graph with maximum degree Δ . By the Four-Color Theorem, $\chi(G) \leq 4$. By the Vizing's Theorem [339], $\chi'(G) \leq \Delta + 1$. Thus, by Proposition 5(1), it is immediate to conclude that $\lambda_d^T(G) \leq \Delta + d + 3$. Further, if $\Delta \geq 7$, then $\chi'(G) = \Delta$ by [312] or [394], and therefore, $\lambda_d^T(G) \leq \Delta + d + 2$. If G is triangle-free and $\Delta \geq 5$, then $\chi(G) \leq 3$ [170] and $\chi'(G) = \Delta$ [246]; therefore, $\lambda_d^T(G) \leq \Delta + d + 1$.

In [44], Bazzaro et al. proved that $\lambda_d^T(G) \leq \Delta + 2d - 2$ for a planar graph G with high girth and large maximum degree Δ . Precisely, their main result is stated below:

Theorem 223 *Let G be a planar graph with maximum degree Δ and girth g . Then $\lambda_d^T(G) \leq \Delta + 2d - 2$ with $d \geq 2$ in each of the following cases:*

1. $\Delta \geq 2d + 1$ and $g \geq 11$.
2. $\Delta \geq 2d + 2$ and $g \geq 6$.
3. $\Delta \geq 2d + 3$ and $g \geq 5$.
4. $\Delta \geq 8d + 2$.

As pointed out above, the case $d = 1$ corresponds just to the total coloring of graphs. So, Theorem 223 extends actually the partial results obtained by Borodin et al. [77] regarding the total coloring of planar graphs with large girth. It should be emphasized that Bazzaro et al. [44] constructed a planar graph G which needs at least $\Delta + 2d - 1$ colors for a $(d, 1)$ -total labeling when $d = 2$. Furthermore, they posed the following risky conjecture:

Conjecture 37 *For any triangle-free planar graph G with $\Delta \geq 3$, $\lambda_d^T(G) \leq \Delta + d$.*

In [280], Montassier and Raspaud proved the following:

Theorem 224 *Let G be a graph with maximum degree Δ . Then $\lambda_d^T(G) \leq \Delta + 2d - 2$ with $d \geq 2$ in each of the following cases:*

1. $\Delta \geq 2d + 1$ and $\text{mad}(G) < \frac{5}{2}$.
2. $\Delta \geq 2d + 2$ and $\text{mad}(G) < 3$.
3. $\Delta \geq 2d + 3$ and $\text{mad}(G) < \frac{10}{3}$.

Moreover, Montassier and Raspaud [280] gave examples to show that **Theorem 224** is optimal for $d = 2$.

Let G be an outerplanar graph with $\Delta \geq 3$. It is known that $\chi(G) \leq 3$ and $\chi'(G) = \Delta$. Thus, it follows from [Proposition 5\(1\)](#) that $\lambda_d^T(G) \leq \Delta + d + 1$. In particular, when $d = 2$, then $\lambda_d^T(G) \leq \Delta + 3$. The upper bound $\Delta + 3$ is not the best possible. In 2007, Chen and Wang [110] obtained the following result:

Theorem 225 *Let G be an outerplanar graph:*

1. *If $\Delta \geq 5$, then $\lambda_2^T(G) \leq \Delta + 2$.*
2. *If G is 2-connected and $\Delta = 3$, then $\lambda_2^T(G) \leq 5$.*
3. *If $\Delta = 4$ and G does not contain intersecting triangles, then $\lambda_2^T(G) \leq 6$.*

Recently, Hasunumaa et al. [178] improved the results (2) and (3) of **Theorem 225**. That is, they showed that every outerplanar graph G with $3 \leq \Delta \leq 4$ also satisfies $\lambda_2^T(G) \leq \Delta + 2$.

Other graphs For a tree T , it is easy to prove that $\Delta + 1 \leq \lambda_2^T(T) \leq \Delta + 2$. In [352], Wang and Chen gave a complete characterization for a tree T with $\Delta = 3$ to have $\lambda_2^T(T) = 4$ or $\lambda_2^T(T) = 5$.

Suppose that T is a tree. A path $P_{k+2} = x_0x_1 \dots x_kx_{k+1}$ of length $k + 1$ of T is called a *k-chain* if $d(x_0) > 2$, $d(x_{k+1}) > 2$, and $d(x_i) = 2$ for all $i = 1, 2, \dots, k$. Note that a 0-chain is exactly an edge of T with two ends of degree more than 2. Let $V_i(T)$ denote the set of vertices of degree i in T .

Assume that $\Delta(T) = 3$. A subtree T^* of T is called *bad* if it satisfies the following conditions (1)–(4):

1. $V_3(T^*) \neq \emptyset$.
2. $V_1(T^*) \cup V_3(T^*) \subseteq V_3(T)$ and $V_2(T^*) \subseteq V_2(T)$.
3. Every vertex $x \in V_1(T^*)$ is connected to some vertex $y \in V_3(T^*)$ by a 1-chain.
4. Every two closest vertices $x, y \in V_3(T^*)$ are connected by a 2-chain or 1-chain.

A tree T is called *good* if it contains neither bad subtrees nor 3 vertices adjacent to two other 3 vertices.

Theorem 226 ([352]) *If T is a tree with $\Delta = 3$, then $\lambda_2^T(T) = 4$ if and only if T is good.*

Wang and Chen [352] also proposed the following interesting problem:

Problem 12 *Give a complete classification for trees T with $\Delta \geq 4$ according to their (2, 1)-total numbers.*

It seems hard to settle the above problem. Huang et al. [205] gave a partial solution.

For a tree T , let $D_\Delta(T)$ denote the set of integers k for which there exist two distinct vertices of maximum degree of distance at k in T . Based on this definition, the authors in [205] established the following sufficient condition:

Theorem 227 *Let T be a tree with $\Delta \geq 4$. If $1 \notin D_\Delta(T)$ or $2 \notin D_\Delta(T)$, then $\lambda_2^T(T) = \Delta + 1$.*

This result is best possible in the sense that for any fixed integer $k \geq 3$, there exist infinitely many trees T with $\Delta \geq 4$ and $k \notin D_\Delta(T)$ such that $\lambda_2^T(T) = \Delta + 2$.

Chen and Wang [109] determined completely the $(2, 1)$ -total number of the Cartesian product of cycles or paths.

Theorem 228 *If $m, n \geq 3$, then $\lambda_2^T(C_m \times C_n) = 6$.*

Theorem 229 *Let $m \geq n \geq 2$. Then*

$$\lambda_2^T(P_m \times P_n) = \begin{cases} 4, & \text{if } m = 2 \text{ and } n = 2, 3; \\ 5, & \text{if } m = 2 \text{ and } n \geq 4, \text{ or } m = 3 \text{ and } 3 \leq n \leq 6, \text{ or } m = n = 4; \\ 6, & \text{otherwise.} \end{cases}$$

Recall that the join $G \vee H$ of two vertex-disjoint graphs G and H is the graph obtained by joining each vertex of G to each vertex of H .

Wang et al. [356] provided a complete characterization for the $(2, 1)$ -total number of the join of cycles or paths.

Theorem 230 *Let $n \geq m \geq 3$. Then*

$$\lambda_2^T(C_m \vee C_n) = \begin{cases} n + 3, & \text{if either } n \geq m + 2 \text{ and } m \text{ is even,} \\ & \quad \text{or } n = m + 1 \text{ and } m \equiv 2, 4 \pmod{12}; \\ n + 4, & \text{otherwise.} \end{cases}$$

Theorem 231 *Let $n \geq m \geq 1$. Then*

$$\lambda_2^T(P_m \vee P_n) = \begin{cases} n + 1, & \text{if } m = 1 \text{ and } n \geq 4; \\ n + 2, & \text{if } m = 1 \text{ and } 1 \leq n \leq 3, \text{ or } m = 2 \text{ and } n \geq 4; \\ n + 3, & \text{if } m = 2 \text{ and } n = 3, \text{ or } m \geq 3 \text{ and } n \geq m + 1; \\ n + 4, & \text{if } m = n \geq 2. \end{cases}$$

6 Conclusion

Graph coloring is an important branch in graph theory. From the viewpoint of historical development, graph theory came first from the graph coloring problems, for example, the Four-Coloring Conjecture. Since the famous Four-Coloring Conjecture

was proposed, many variants, generalizations, techniques, and applications on graph coloring problem have emerged. There have existed a large amount of literature regarding this area.

In this chapter, some subjects of graph coloring problems are selected to investigate, including classical chromatic number, choice number, acyclic chromatic number, acyclic chromatic index, vertex-distinguishing edge-weighting (especially, adjacent vertex-distinguishing edge coloring and total coloring), and $L(p, q)$ -labeling problems. So far there have been many well-known conjectures and open problems on these selected topics, such as Hajós Conjecture, Hadwiger Conjecture, Steinberg's Conjecture, Acyclic Edge-Coloring Conjecture, Griggs and Yeh's Conjecture, Wegner's Conjecture, and Havet and Yu's Conjecture. Some main results and progresses on each of these problems are surveyed, without proofs provided. Of course, methods and tools to solve the related problems are rarely mentioned, because of the limited pages. For the interested reader, they can refer to a mass of literatures listed below.

Acknowledgements The authors deeply thank their postgraduate students M. Chen, D. Huang, Q. Shu, S. Zhang, W. Gao, and Y. Wang for their careful search for a number of literatures and patience inspection for this manuscript.

Abstract

During the last two decades, online and semi-online scheduling problems have received considerable research interest. This chapter provides definitions of several online paradigms, including online over list, online over time, and semi-online. This chapter presents details of the basic online algorithms and referencing other significant results.

1 Introduction

1.1 Scheduling

Scheduling is the earliest studied branch in combinatorial optimization and also one of the problems with the most fruitful results achieved. Early scheduling problems are motivated from manufacturing systems. Later, more and more scheduling problems are formalized in the areas of information science, supply chain management, public management, and so on. In the following, we summarize the basic concepts and notations which will be used later. For more detailed introduction on scheduling theory, please refer to [21, 36, 117, 143].

Scheduling problems can be generally described as follows. There is a sequence \mathcal{J} of n jobs J_1, J_2, \dots, J_n , which need to be processed on a set \mathcal{M} of m machines M_1, M_2, \dots, M_m . A *schedule* is an assignment for each job to one or more time intervals of one or more machines. Schedules that satisfy various requirements of the problem are called *feasible*. Scheduling problems are specified by the machine environment, the job characteristics, and an optimality criterion.

There are two basic types of machine systems: single-stage system and multi-stage system. In a single-stage system, each job requires one operation, while in multiple-stage system the jobs may require several operations at different stages. There are also two classical single-stage systems: single machine and parallel machines. In a single machine system, job J_j must be processed on the unique machine M_1 with a *processing time* p_j , $j = 1, 2, \dots, n$. In a parallel machines system, each job can be processed by *one* of the m machines. The time needed for job J_j to be processed on M_i is p_{ji} , $j = 1, \dots, n$, $i = 1, \dots, m$. If $p_{ji} = p_j$ for any $i = 1, \dots, m$ and $j = 1, \dots, n$, then the machine system is called *identical*. If there exist s_i , $i = 1, \dots, m$ such that $\frac{p_{j_1}}{p_{j_2}} = \frac{s_{i_2}}{s_{i_1}}$ for any $j = 1, \dots, n$, then the machine system is called *uniform*, and s_i is called the *speed* of M_i , $i = 1, \dots, m$. W.l.o.g., we assume $s_1 \geq s_2 \geq \dots \geq s_m = 1$ and let $p_j = p_{jm}$, which is the

normalized *processing time* of job J_j . In the case of two uniform machines, it is of more convenience for discussion to replace the speed parameters s_1 and $s_2 (= 1)$ by the *speed ratio* $s = \frac{s_1}{s_2}$, and both are equivalent. Parallel machines system that does not fall into above categories is called *unrelated*. In a multi-stage system, each operation of a job has a separate processing time, and different operations of the same job cannot be scheduled at the same time. The multi-stage system is usually distinguished into *open shop*, when different operations of the same job may be scheduled in any order; *flow shop*, if the order of the operations is fixed and same for all the jobs; and *job shop*, if the order of the operations is fixed and possibly different for each job.

Apart from the processing time of the jobs, the processing mode can also be classified into the job characteristics. Some scheduling models allow *preemption* of jobs, that is, the processing of a job may be interrupted and resumed later on possibly a different machine. If each job can be arbitrarily split between the machines and parts of the same job can run on different machines in parallel, this model is called *fractional assignment*. There is another possibility allowing jobs to *restart*, which means that a processing job can be stopped and restarted later to finish the full processing time.

Given a schedule σ , let $C_j(\sigma)$ (or C_j if there is no confusing) be the completion time of J_j , $j = 1, 2, \dots, n$. Some commonly used objective functions include:

The makespan: $\max_{1 \leq j \leq n} C_j(\sigma)$.

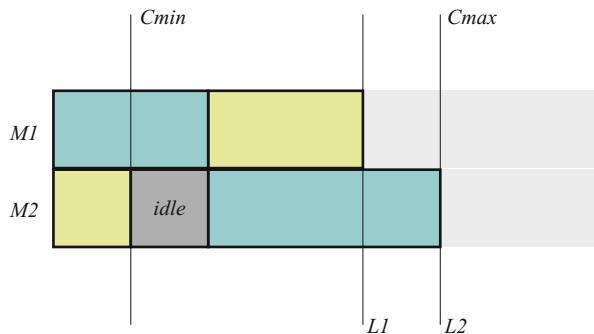

The total completion time: $\sum_{j=1}^n C_j(\sigma)$,

The total weighted completion time: $\sum_{j=1}^n w_j C_j(\sigma)$, where w_j is the weight of J_j . All these objectives are for minimization problems. There is another criteria which maximizes the continuous period of time when all machines are busy. Such criteria have applications in the sequencing of maintenance actions for modular gas turbine aircraft engines [49] and fairly allocation of indivisible goods [15]. Problems with this objective are often called *machine covering*.

The period when one machine is not assigned to any job during the scheduling process is called *idle* time. For most non-preemptive problems, there is no benefit to introduce idle times. But idle time is of great help if preemption is allowed, especially for uniform machines scheduling. Let L_i be the completion time of machine M_i in schedule σ . The makespan of σ equals to $\max_{i=1, \dots, m} L_i$. However, $\min_{i=1, \dots, m} L_i$ is not always identical with the objective value of the machine covering problem if idle times exist (Fig. 1).

In general, scheduling problems are specified in terms of a three-field notation [88]. Here, we adopt the notation from it. In this chapter, we will use $1, P, Q, R$ to denote single, identical, uniform, unrelated machine system and F, O, J to denote flow shop, open shop, and job shop system. Problems allowing preemption, fractional assignment, and restart will be denoted by *pmtn*, *frac*, and *res*, respectively. The objectives of minimizing makespan, minimizing the total completion time, and minimizing the total weighted completion time will be shortly denoted by C_{\max} , $\sum C_j$, and $\sum w_j C_j$, respectively. The objective of machine covering is denoted C_{\min} .

Fig. 1 Machine completion times and objective value of a schedule

1.2 Online Problems and Competitive Analysis

Online problems began to draw attention in the middle period of the eighties of the twentieth century. The basic character of online models is “lack of information,” while the previously studied problems having the access to full information are called *offline*. For more detailed introduction of online theories and variants, please refer to [20, 75].

For scheduling problems, there are a variety of online models, among which the following two are the most common.

Online over list: Jobs are ordered in a list and arrived one by one (at time 0). The information of a job is known to the scheduler only when all the jobs before it have been assigned. And the assignment of jobs is irrevocable.

Online over time: Each job has a *release time* after which the information of the job is known and can be processed. The release time of J_j is denoted by r_j , $j = 1, 2, \dots, n$.

Since almost all problems considered in this chapter are online, we will ignore *online over list* in the second field of the three-field notation. On the other hand, r_j will be included in the second field of the three-field notation for the online over time model.

The *competitive analysis* is the most common method in analysis of online algorithms, which is formally introduced by Sleator and Tarjan [161]. The performance of an online algorithm is measured by its *competitive ratio*, which has some similarity as *worst-case ratio* for offline problems. For a job sequence \mathcal{J} and an online algorithm A , if A produces a schedule with objective value $C^A(\mathcal{J})$ for the minimization (or maximization) problem and the optimal offline objective value is $C^*(\mathcal{J})$, then the competitive ratio of A is defined as

$$r_A = \inf_{\mathcal{J}} \{r \mid C^A(\mathcal{J}) \leq rC^*(\mathcal{J})\} \quad (\text{or } r_A = \inf_{\mathcal{J}} \{r \mid C^*(\mathcal{J}) \leq rC^A(\mathcal{J})\}).$$

If there is an online algorithm A for the problem with a competitive ratio r , then A is called an r -*competitive* algorithm. On the contrary, if no online algorithm has

a competitive ratio smaller than ρ , then the problem must have a *lower bound* ρ . Therefore, an online algorithm is called *optimal* or *best possible* for the problem if its competitive ratio just matches the lower bound. Here, optimal does not mean that it always produces an optimal schedule. It only indicates the fact that no online algorithm can be better. An online algorithm is stated to possess competitive ratio 1 if it always produces an optimal schedule, but such algorithm seldom exists. In this chapter, we use *optimal bound* to denote the competitive ratio of the optimal algorithm of the problem for simplicity. Symmetrically, a problem has *upper bound* r if there exists an online algorithm for the problem with competitive ratio r .

A *randomized algorithm* is one which somehow bases its decision making on the outcome of random coin flips. For a randomized algorithm, the objective value $C^A(\mathcal{J})$ is a random variable. Thus, the competitive ratio of a randomized algorithm (for a minimization problem) is defined as

$$r_A = \inf_{\mathcal{J}} \{r \mid E(C^A)(\mathcal{J}) \leq r C^*(\mathcal{J})\},$$

where the expectation is taken over the random choices of the algorithm. In addition, concepts of randomized upper and lower bound can also be defined accordingly. Algorithms which do not use randomization are called *deterministic algorithm*. Since deterministic algorithm can be viewed as a special randomized algorithm, the randomized lower bound cannot be larger than deterministic lower bound. In this chapter, without special mention, all algorithms (competitive ratio, lower bound) are deterministic. For a general introduction on randomized algorithms, please refer to [134].

1.3 Structure and Notation

Online scheduling boasts of extensive results; thus, it is impossible to cover all the problems in one chapter, and only part of paradigms together with the according main results is included. There have been two excellent surveys [144, 156] concerning online scheduling, and some paradigms discussed elaborately there will be omitted. We will mainly introduce paradigms approaching classical scheduling problems and withal active in recent research. There are several interesting and important problems not covered due to limited space and number of references, and we will sketch some of them in the following. Firstly, scheduling problems with deadline constraints, including interval scheduling, are not included in this chapter. Secondly, it does not cover problems concerning other objective functions, for example, the (weighted) total flow time and the L_p norm of machine completion times, together with objectives deriving from bicriteria situations, for example, scheduling with rejection and scheduling with machine cost. Thirdly, performance measures other than competitive analysis, including resource argumentation, will not be contained in this chapter. Finally, we skip problems which have specific

applications, such as scheduling problems in power management, broadcasting, and supply chain management.

The chapter is organized as follows. In Sect. 2, we survey main results for the online over list model. Section 3 is devoted to semi-online variants of online over list model. In Sect. 4, we introduce online and semi-online problems of the online over time model. Other variants of online scheduling are contained in Sect. 5.

The following notations as well as those defined above will be used frequently in the remainder of this chapter. For any $i = 1, \dots, m$, let $S_i = \sum_{l=1}^i s_l$ be the total speeds of the first i machines in uniform machine system, and we simplify S_m as S . For any $j = 1, \dots, n$, let \mathcal{J}_j be the subset of \mathcal{J} containing the first j jobs and P_j be the total processing times of the first j jobs. We simplify P_n as P . Let $p_{(j)}$ be the processing time of the job which has the j th largest processing time, that is, $p_{(1)} \geq p_{(2)} \geq \dots \geq p_{(n)}$. For any $i = 1, \dots, m$ and $j = 1, \dots, n$, let L_i^j be the completion time of machine M_i after the job J_j is assigned. L_i^j is also called the *load* of M_i if no idle time exists. Clearly, L_i^n equals to L_i .

2 Online Over List

This section summarizes main results for online over list model on parallel machines. In this paradigm, the makespan, which is the most common objective function with no doubt, will be considered throughout this section except the last subsection.

2.1 Non-preemptive Scheduling

2.1.1 Identical Machines

$Pm||C_{max}$ is the most studied and historical problem for online scheduling. In his epoch making paper, Graham [86] designed the first approximation algorithm in combinatorial optimization called *List Scheduling* (*LS* for short). *LS* uses greedy idea and has a very simple structure. It always assigns the current job to the machine where it can be started to process the earliest, that is, the machine with the smallest current load, ties are broken arbitrary. Such principle of assigning jobs is sometimes called *LS rule* in the literature. Graham proved the following result.

Theorem 1 ([86]) *The competitive ratio of LS for $Pm||C_{max}$ is $2 - \frac{1}{m}$.*

Proof (Sketch) Without loss of generalization, the last job J_n determines the makespan. Let s_n be the start time of J_n . By *LS* rule, no machine will idle during $[0, s_n]$. Hence, $s_n \leq \frac{P-p_n}{m}$. Clearly,

$$C^* \geq \frac{P}{m} \tag{1}$$

and

$$C^* \geq \max_{1 \leq j \leq n} p_j. \quad (2)$$

Hence,

$$C^{LS} = s_n + p_n \leq \frac{P - p_n}{m} + p_n = \frac{P}{m} + \frac{m-1}{m} p_n \leq C^* + \frac{m-1}{m} C^* = \left(2 - \frac{1}{m}\right) C^*. \quad \square$$

LS is a typical online algorithm. When assigning a new job, it does not use any information of jobs that have not arrived yet. Not only the rule of *LS* but also the ideas behind the proof are frequently used in design and analysis of other online algorithms. Twenty years have passed since the appearance of *LS*, and online problems are drawing more and more attentions. Feige et al. [74] proved that *LS* is the optimal algorithm for $Pm||C_{max}$ when $m = 2, 3$. It should be emphasized that no other algorithm has been proved to be optimal for any $m \geq 4$ up till now.

Though *LS* is irreplaceable in online scheduling, it is gradually recognized that *LS* cannot be the optimal algorithm for $Pm||C_{max}$ when $m \geq 4$. Hence, algorithms and lower bounds have been refined bit by bit, and brief results and history are summarized in Table 1. In these new algorithms, jobs are not always assigned to the least loaded machine. Sometimes, the current job may be assigned to the second smallest or the machine whose load lies approximately in middle of all machines. Almost all these algorithms contain some parameters which have been carefully selected, and the analysis of the algorithm is much more involved. The instances used to prove the lower bound are likewise very sophisticated. The current best lower bound is obtained even by exhaustive search using computers.

It seems that improvement of the algorithm could be carried on since there is still a gap 0.066 between the current best upper and lower bounds. However, there is a turning point when Albers [2] proposed her important results. When proving the competitive ratio of an online algorithm, it is in fact that some *lower bounds* instead of the exact value of the optimum itself are used. For example, lower bounds

Table 1 Improvement of lower and upper bounds of $Pm||C_{max}$

Reference	Competitive ratio	Reference	Lower bound
Graham [86]	$2 - \frac{1}{m}$	Falgle et al. [74]	$\frac{1+\sqrt{2}}{2}(m \geq 4)$
Galambos and Woeginger [82]	$2 - \frac{1}{m} - \epsilon_m^a$	Bartal et al. [17]	$1.837(m \geq 3454)$
Bartal et al. [18]	$2 - \frac{1}{70} \approx 1.986^b$	Albers [1]	$1.852(m \geq 80)$

^bThe first algorithm with competitive ratio strictly less than 2 for any m

^cThe best current known algorithm

^dThe best current known lower bound

(1) and (2) are used in the proof of [Theorem 1](#). Another useful lower bound on the optimum is

$$C^* \geq 2p_{(m+1)}. \quad (3)$$

Theorem 2 ([2]) *If only using (1), (2) and (3) as lower bounds on the optimum, it is impossible to prove an online algorithm A has a competitive ratio less than 1.919.*

Note that the competitive ratio of the algorithm could be smaller than 1.919, but it cannot be proved using existing techniques. The bound 1.919 in [Theorem 2](#) is very close to the current best upper bound 1.9201. Hence, it seems more urgent to find new lower bounds on the optimum than to designing more delicate algorithms. Though [Theorem 2](#) does not give new lower bounds, it does point out the direction of future research. Such ideas can be adopted to other hard online scheduling problems as well.

When the number of machines is small, better lower bounds and algorithms can be obtained. For example, Chen et al. [31] presented an algorithm with competitive ratio at most

$$\max \left\{ \frac{4m^2 - 3m}{2m^2 - 2}, \frac{2(m-1)^2 + \sqrt{1 + 2m(m-1)} - 1}{(m-1)^2 + \sqrt{1 + 2m(m-1)} - 1} \right\}$$

for $Pm||C_{max}$, $m \geq 4$. Rudin III and Chandrasekaran [147] proved the lower bound of $P4||C_{max}$ is at least $\sqrt{3}$, which is in line with the conjecture that the optimal bound of $P4||C_{max}$ is $\sqrt{3}$. Numerical bounds are summarized in [Table 2](#).

2.1.2 Uniform and Unrelated Machines

The competitive analysis for $Qm||C_{max}$ is even more difficult than that for $Pm||C_{max}$. Both the competitive ratios of online algorithms and lower bounds of the problems are functions of machine speeds s_i , $i = 1, \dots, m$. This might be the reason why optimal or tight bounds can only be obtained for small values of m . For larger m or arbitrary number of machines, it is of more significance and practical that either to consider some special combinations of s_i or to obtain *overall* upper and lower bounds, that is, the maximal value among all possible choice of s_i , $i = 1, \dots, m$ for both.

Since the machines have different speeds, the machine where a job can be started to process the earliest may not be the machine where it can be completed the earliest. Therefore, it is necessary to distinguish two variants of LS , namely, LSc and LSs . LSc and LSs assign the arriving job to the machine which the job can be completed or started the earliest, respectively. It is evident to see that for $Qm||C_{max}$, LSc is better than LSs .

The competitive ratio of LSc for $Qm||C_{max}$ is at most

$$\min_{1 \leq k \leq m} \left\{ \frac{\sum_{i=1}^m s_i + (k-1)s_1}{\sum_{i=1}^k s_i} \right\}$$

Table 2 Current best upper and lower bounds for online over list model on identical machines

m	Non-preemptive			Preemptive		
	Deterministic	Upper bounds	Lower bounds	Randomized	Upper bounds	Optimal bounds
2	$\frac{3}{2} = 1.5000$ [74]	$\frac{3}{2} = 1.5000$ [86]	$\frac{4}{3} \approx 1.3333$ [18]	$\frac{4}{3} \approx 1.3333$ [18]	$\frac{4}{3} \approx 1.3333$ [18]	$\frac{4}{3} \approx 1.3333$ [33]
3	$\frac{5}{3} \approx 1.6667$ [74]	$\frac{5}{3} = 1.5000$ [86]	$> \frac{27}{19}$ [174]	1.53727 [153]	$\frac{27}{19} \approx 1.42105$ [33]	
4	$\sqrt{3} \approx 1.732$ [147]	$\frac{26}{15} \approx 1.7333$ [31]	$\frac{256}{175} \approx 1.46286$ [32, 155]	1.65669 [153]	$\frac{256}{175} \approx 1.46286$ [33]	
5	1.74625 [31]	$\frac{85}{48} \approx 1.77083$ [31]	$\frac{3.125}{2.101} \approx 1.48739$ [32, 155]	1.73376 [151]	$\frac{3.125}{2.101} \approx 1.48739$ [33]	
6	1.77301 [31]	$\frac{9}{5} = 1.8000$ [31]	$\frac{46.656}{31.031} \approx 1.50353$ [32, 155]	1.78295 [151]	$\frac{46.656}{31.031} \approx 1.50353$ [33]	
7	1.79103 [31]	$\frac{175}{96} \approx 1.82292$ [31]	$\frac{823.543}{543.607} \approx 1.51496$ [32, 155]	1.81681 [151]	$\frac{823.543}{543.607} \approx 1.51496$ [33]	
∞	1.85358 [85]	1.9201 [77]	$\frac{e-1}{e} \approx 1.582$ [32, 155]	1.916 [2]	$\frac{e-1}{e} \approx 1.582$ [33]	

[90]. The overall competitive ratio is at most

$$\begin{cases} \frac{1+\sqrt{5}}{2}, & m = 2, \\ \frac{2+\sqrt{2m-2}}{2}, & m \geq 3, \end{cases}$$

and the bound is tight in the overall sense when $m \leq 6$ [44]. For large m , the bound $O(\log m)$ obtained by using an alternative method different from those in Theorem 1 is better [10]. Specifically, for $m = 2$, the bound is

$$\begin{cases} \frac{2s+1}{s+1}, & 1 \leq s \leq \frac{1+\sqrt{5}}{2}, \\ \frac{s+1}{s}, & s > \frac{1+\sqrt{5}}{2}, \end{cases}$$

and LSc is the optimal algorithm [72]. For $m = 3$, the bound is

$$\begin{cases} \frac{s_1 + s_2 + s_3}{s_1}, & s_1^2 \geq s_2^2 + s_1s_2 + s_2s_3, \\ \frac{2s_1 + s_2 + s_3}{s_1}, & s_1^2 < s_2^2 + s_1s_2 + s_2s_3 \text{ and } s_1^2 + s_1s_2 \geq s_3^2 + s_1s_3 + 2s_2s_3, \\ \frac{3s_1 + s_2 + s_3}{s_1 + s_2 + s_3}, & s_1^2 + s_1s_2 < s_3^2 + s_1s_3 + 2s_2s_3, \end{cases}$$

and it is tight for any combinations of machine speeds [90]. However, it has been shown that LSc is optimal only for the case when $s_1 = s_2 = 1 \geq (\sqrt{2} - 1)s_3$ and $s_1^2 \geq s_2^2 + s_1s_2 + s_2$ [90, 136], and there does exist another online algorithm which beats LSc when $\frac{1+\sqrt{97}}{8} < \frac{s_1}{s_2} = \frac{s_1}{s_3} < 2$ [90]. It implies that the optimality of LS for $P3||C_{max}$ cannot be generalized to the problem with different machine speeds.

Since the competitive ratio of LSc tends to infinite when m becomes very large [44], it is natural to raise the question that whether an algorithm with finite competitive ratio exists. The first such algorithm with competitive ratio 8 was obtained by using a so-called *doubling strategy* [10]. Their results were later improved by Berman [19], where a new algorithm with overall competitive ratio $3 + \sqrt{8} \approx 5.828$ and a overall lower bound 2.4380 are given. The lower bound was recently improved to θ by Ebenlendr and Sgall [60], where $\theta \approx 2.564$ is the solution of the equation $\int_0^1 \frac{\ln \theta}{\ln(1-\theta-x)} dx = -1$.

For the most studied special case of $s_1 > s_2 = s_3 = \dots = s_m = 1$, the overall competitive ratio of LSc for $Qm||C_{max}$ is at most $\frac{3m-1}{m+1}$, where the maximum value achieves at $s_1 = 2$ [44]. The bound matches the overall lower bound 2 when $m = 3$ [118]. For $m \geq 4$, Li and Shi [118] designed a new algorithm which has a smaller competitive ratio around $s_1 = 2$. Thus, the overall competitive ratio can be decrease to 2.8795. Cheng et al. [42] further raised an algorithm which has a competitive ratio of 2.45 if the speed of the fastest machine is restricted to $1 \leq s_1 \leq 2$.

For $Rm||C_{max}$, Aspnes et al. [10] proved that the competitive ratio of LSc is at most m , and thus, LSc is optimal when $m = 2$. They also designed a new algorithm

with competitive ratio $O(\log m)$. Since the lower bound of the problem is at least $\lceil \log_2(m+1) \rceil$ [13], their algorithm is optimal up to a constant factor.

2.2 Preemptive Scheduling

Results of preemptive online scheduling are more complete than those of non-preemptive problems. The main reason may be that the optimal offline makespan can be obtained in polynomial time. The following lemma plays an important role in designing online algorithms for $Pm|pmtn|C_{max}$ and $Qm|pmtn|C_{max}$.

Lemma 1 ([84, 101]) *For $Qm|pmtn|C_{max}$,*

$$C^* = \min \left\{ \frac{\sum_{j=1}^n p_j}{\sum_{i=1}^m s_i}, \max_{1 \leq l \leq m-1} \frac{\sum_{i=1}^l p(i)}{\sum_{i=1}^l s_i} \right\}.$$

Chen et al. [33] designed an optimal algorithm *preemptive* for $Pm|pmtn|C_{max}$. Let $\Gamma_m = \frac{m^m}{m^m - (m-1)^m}$. Note that $\lim_{m \rightarrow \infty} \Gamma_m = \frac{e-1}{e} \approx 1.582$. Recall that for any j , $C^*(\mathcal{J}_j)$ can be calculated by Lemma 1.

Algorithm Preemptive

Let the current job be J_j . Reindex the machines such that $L_1^{j-1} \leq L_2^{j-1} \leq \dots \leq L_m^{j-1}$. If $L_m^{j-1} + p_j \leq \Gamma_m C^*(\mathcal{J}_j)$, then assign J_j to M_m . Otherwise, let $l = \min\{i | L_i^{j-1} + p_j \geq \Gamma_m C^*(\mathcal{J}_j)\}$. Assign part of J_j of processing time $\Gamma_m C^*(\mathcal{J}_j) - L_l^{j-1}$ to M_l and the remaining part of J_j of processing time $L_l^{j-1} + p_j - \Gamma_m C^*(\mathcal{J}_j)$ to M_{l-1} .

Theorem 3 ([33]) *The competitive ratio of Preemptive for $Pm|Pmtn|C_{max}$ is Γ_m .*

Proof (Sketch) Prove by induction that for any j , the following two inequalities hold

$$\begin{aligned} L_m^j &\leq \Gamma_m C^*(\mathcal{J}_j), \\ \sum_{i=1}^k L_i^j &\leq \frac{(\frac{m}{m-1})^k - 1}{(\frac{m}{m-1})^m - 1} P_j, k = 1, \dots, m. \end{aligned}$$

Then, it can be confirmed that the schedule produced by *Preemptive* is feasible, and the competitive ratio holds. \square

Several attempts have been made to modify and generalize *Preemptive* to handle uniform machines, which resulted in an optimal algorithm for $Q2|pmtn|C_{max}$ with competitive ratio $\frac{s^2+2s+1}{s^2+s+1}$ [72, 180] and an optimal algorithm for $Qm|pmtn|C_{max}$ with nondecreasing speed ratios, that is, $\frac{s_{i-1}}{s_i} \leq \frac{s_i}{s_{i+1}}$, $2 \leq i \leq m-1$ [64]. But it seems difficult to make further generalizations using similar ideas.

Recently, Ebenlendr et al. [62] introduced a novel technique which leads to an optimal algorithm of $Qm|pmtn|C_{max}$ for any combinations of machine speeds. The competitive ratio $\Gamma(s_1, \dots, s_m)$ of the algorithm is the optimal value of the following linear programming with decision variables $q_1, \dots, q_m, O_1, \dots, O_m$ and parameters s_1, \dots, s_m .

$$\begin{aligned} & \max q_1 + q_2 + \dots + q_m \\ & \text{s.t. } q_1 + \dots + q_k \leq (s_1 + s_2 + \dots + s_m)O_k, \quad k = 1, \dots, m, \\ & \quad q_j + q_{j+1} + \dots + q_k \leq (s_1 + s_2 + \dots + s_{k-j+1})O_k, \quad 2 \leq j \leq k \leq m, \\ & \quad 1 = s_1O_m + s_2O_{m-1} + \dots + s_mO_1, \\ & \quad q_j \leq q_{j+1}, \quad j = 2, \dots, m-1, \\ & \quad q_1 \geq 0, q_2 \geq 0. \end{aligned} \quad (4)$$

However, it can only be proved that the algorithm is optimal for any m and any combinations of machine speeds, but the concrete expression of the optimal bound $\Gamma(s_1, \dots, s_m)$ is not known yet, even the overall bounds are hard to get. The currently known best lower and upper bound for arbitrary m is 2.054 (achieves at $m = 100$ and is obtained by numerical calculation) and $e \approx 2.718$, respectively [62]. When the number of machines is small or some assumptions are made on the values of s_i , (4) can be solved theoretically [62]. For example, the optimal bounds for $Q3|pmtn|C_{max}$ are

$$\Gamma(s_1, s_2, s_3) = \begin{cases} \left(\frac{s_1}{S} + (1 - \frac{s_1}{S})\frac{s_2}{S} + (1 - \frac{s_1}{S})^2\frac{s_3}{S}\right)^{-1}, & \text{if } \frac{s_1}{s_2} \leq \frac{s_2}{s_3} + 1; \\ \frac{s_2^2}{s_1^2 + s_2^2 + s_3^2 + s_1s_2 + s_1s_3 + s_2s_3}, & \text{if } \frac{s_1}{s_2} \geq \frac{s_2}{s_3} + 1. \end{cases}$$

Another question requiring answer is that whether the optimal bounds will increase if idle time is prohibited. Note that algorithms in [33, 64, 72, 180] all do not introduce idle time, but no algorithm which allows idle time can have a smaller competitive ratio under certain machine environment mentioned there. However, the algorithm given in [62] does use idle time. It is not known yet that whether an algorithm which does not use idle time will necessarily have a strict larger competitive ratio than $\Gamma(s_1, \dots, s_m)$ for general $Qm|pmtn|C_{max}$.

2.3 Randomized Algorithm

As far as ever known results are concerned, for case on parallel machine scheduling problem with objective to minimize makespan, any lower bound for deterministic preemptive online algorithm (allowing idle time) is also a lower bound for randomized preemptive or non-preemptive online algorithms. For example, the randomized lower bound for $Pm||C_{max}$ and $Qm||C_{max}$ is $\frac{(m-1)^m}{m^m - (m-1)^m}$ [32, 155] and $\Gamma(s_1, \dots, s_m)$ [62], respectively. But the converse is not true. Tichý [174] showed that there does not exist a randomized algorithm for $P3||C_{max}$ with competitive

ratio $\frac{27}{19}$. However, his proof does not yield a new randomized lower bound with a strict larger value.

The first randomized algorithm for parallel machine scheduling is due to [18], where an optimal randomized algorithm for $P2||C_{max}$ is given. The algorithm was restated in a simpler version in [155] as follows.

Algorithm Random

1. If possible, assign the current job J_j randomly so that afterwards the expected makespan equals $\frac{2}{3}P_j$.
2. Otherwise, assign job J_j always on the less loaded machine.

Theorem 4 ([18, 155]) *The competitive ratio of Random for $P2||C_{max}$ is $\frac{4}{3}$.*

Proof (Sketch) Prove by induction that for any j , the following two invariants hold

$$\begin{aligned} E(C^{\text{Random}}(\mathcal{J}_j)) &\geq \frac{2}{3}P_j, \\ \text{If } E(C^{\text{Random}}(\mathcal{J}_j)) > \frac{2}{3}P_j, \text{ then } \max_{1 \leq l \leq j} p_l &\geq \frac{3}{4}E(C^{\text{Random}}(\mathcal{J}_j)). \end{aligned} \quad (5)$$

Clearly, (5) is also valid for $j = n$. Then, by (1) and (2), the theorem is thus proved. \square

Design effective randomized algorithm for $Pm||C_{max}$ is rather a challenging work. When the number of machines is small, the competitive ratios of algorithms proposed by Seiden [151, 153] can be less than the best known deterministic algorithms (See Table 2). For arbitrary m , Albers [2] designed a randomized algorithm with competitive ratio 1.916, which is a combination of two deterministic algorithms with equal probability, and it is better than any known deterministic algorithm.

There is even less study on randomized algorithm for uniform machines. For $Q2||C_{max}$, Epstein et al. [72] showed that randomization does not help when $s \geq 2$. They also presented numerical randomized lower bounds for $1 \leq s \leq 2$ by solving linear programmings and a smaller analytical randomized lower bound $\frac{(s+1)^2(s+2)}{3s^2+5s+1}$ for $1 \leq s \leq \sqrt{2}$. Three randomized algorithms are proposed, and thus, an overall upper bound 1.52778 can be achieved, but the gap between the lower and upper bounds for any $s \geq 1$ is still relatively large. For $Q3||C_{max}$ with restricted machine speeds $s_1 = s_2 \geq s_3 = 1$, Musitelli and Nicoletti [136] presented a randomized algorithm with competitive ratio

$$\begin{cases} \frac{4s_2 + 2}{3s_2}, & 1 \leq s_2 < \frac{\sqrt{10}+2}{3}, \\ \frac{6s_2 + 2}{3s_2 + 2}, & s_2 \geq \frac{\sqrt{10}+2}{3}. \end{cases}$$

It is only a little smaller than the competitive ratio of LSc , and no randomized lower bound has been reported.

2.4 Other Objectives

2.4.1 Total Completion Time

The property of the objective of minimizing the total completion time is different from that of minimizing makespan. The objective value of the schedule will be affected by not only the set of jobs assigned to each machine but also the process sequence of it. As a result, there exists no algorithm with constant competitive ratio, even for the single machine case.

Theorem 5 ([76]) *For every function $f : N \rightarrow R^+$ that fulfills conditions:*

1. $f(n)$ is nondecreasing,
2. $\sum_{n=1}^{\infty} \frac{1}{nf(n)}$ converges,

there exists an online algorithm for $1||\sum C_j$ with competitive ratio at most $O(f(n))$, where n is the number of jobs. On the other hand, let $g : N \rightarrow R^+$ be a function that fulfills condition:

1. $g(n)$ is nondecreasing,
2. $\sum_{n=1}^{\infty} \frac{1}{ng(n)}$ diverges,
3. $g(n) = O(\log^2 n)$,
4. $g\left(\frac{n}{\log^2 n}\right) = \Omega(g(n))$,

then there does not exist an online algorithm for $1||\sum C_j$ with competitive ratio $o(f(n))$.

By selecting specific functions which satisfy the respective conditions, it can be found that the gap between the lower and upper bounds is rather small.

Corollary 1 ([76]) *For every $\epsilon > 0$, there exists an online algorithm with competitive ratio at most $(\log n)^{1+\epsilon}$, but no online algorithm with competitive ratio $\log n$ can exist.*

2.4.2 Machine Covering

The online version of non-preemptive machine covering problem is relatively easy. It should be mentioned that for machine covering problems, LSS is better than LSc in most cases. Woeginger [181] and Epstein [66] proved that LSS is the optimal algorithm for $Pm||C_{min}$ and $Q2||C_{min}$, respectively. In fact, their analysis can be generalized to $Qm||C_{min}$. LSS remains the optimal algorithm with competitive ratio $\sum_{i=1}^m s_i$. Azar and Epstein [12] designed a randomized algorithm for $Pm||C_{min}$ with an overall competitive ratio $O(\sqrt{m} \log m)$ and proved an overall randomized lower bound $\frac{\sqrt{m}}{4}$.

Surprisingly, machine covering problem becomes much more difficult if preemption is allowed, even though the optimal offline objective value

$$\min_{0 \leq j \leq m-1} \frac{\sum_{l=j+1}^n p(l)}{\sum_{l=j+1}^m s_l}$$

for $Qm|pmtn|C_{min}$ can be calculated similarly as $Qm|pmtn|C_{max}$ [108]. Jiang et al. [108] proved that $\sum_{i=1}^m \frac{1}{i}$ is a lower bound of $Pm|pmtn|C_{min}$ and m is an overall lower bound of $Qm|pmtn|C_{min}$, but no algorithm with matched competitive ratio has been given. For $Q2|pmtn|C_{min}$, they designed an optimal algorithm with competitive ratio $\frac{2s+1}{s+1}$. However, their algorithm may introduce idle time, even when it assigns the first job. If idle time is not allowed, then no deterministic algorithm can have a smaller competitive ratio than

$$\begin{cases} \frac{2s+1}{s+1}, & 1 \leq s < \frac{1+\sqrt{5}}{2}, \\ s, & s \geq \frac{1+\sqrt{5}}{2}. \end{cases}$$

A corresponding algorithm prohibiting idle time with matched competitive ratio was also given in [108]. Therefore, whether idle time is allowed or not does affect the optimal bounds for machine covering problems. It should be noted that different from algorithms allowing idle time, for non-idle time situation, there is no evidence yet that the lower bound also holds for randomized algorithm. Such phenomenon also appears in similar situations in the following.

3 Semi-online Scheduling

3.1 Motivation and Taxonomy

There are two basic characteristics for the online over list model. The first is that jobs arrive one by one and it is required to assign each job without any knowledge of the jobs that arrive later. The second is that the assignment of the job should be determined immediately upon its arrival and cannot be changed later. The reason of the first characteristic is “lack of information,” while the essence of the second is “restriction of scheduling.” There are often voices of criticism on the model for the sake of both theoretical study and practical application. In practice, most problems are not pure offline or online but somehow in between. Theoretically, the competitive ratio of an online algorithm tends to be over large in contract with the actual performance, since offline algorithms are more powerful than online algorithms. Moreover, the lower bound of the problem can also be ineffective, namely, too large, as the adversary can arbitrarily determine the instances without any restriction.

The reasons aforementioned bring semi-online scheduling about an active research area. Semi-online can be looked upon as relaxation of online or an intermediate state of offline and online. The primary significance of study on semi-online settings is as follows. First and foremost, without reasonable understanding of semi-online problems, there will be no more than online algorithm to implement faced with semi-online cases, which will give rise to inevitable loss definitely, just as *LS* algorithm performs not satisfactorily on offline problems. Furthermore, deep

study on semi-online problems will lead to initiative search for crucial factors in algorithm design and improving, which will certainly save the cost and energy on many pointless factors. In theory, research on semi-online scheduling is of help to clarify influence of various restrictions of both information accessed to and algorithm design, and to reveal some deep and dominant properties. For example, it is interesting to consider the question that whether it is possible or under what kind of circumstance that an *online approximation scheme*, that is, a class of semi-online algorithms with competitive ratio arbitrarily close to 1 can exist. In contrast to *PTAS* of offline problems, whose time complexity increases as the worst-case ratio of the algorithm decreases, more partial information or more freedom of scheduling is required in online cases when pursuing a better competitive ratio. In fact, one such approximation scheme has already been obtained [160]. Last but not least, it will be meaningful for algorithm design and analysis on online problems when researching on semi-online models, as will see later.

Though semi-online model can be viewed as an intermediate state between online and offline, its properties and research approach are almost the same as the online model. Competitive analysis is still the primary technique adopted, and lower bound of the problem, together with competitive ratio of the algorithm, can be defined accordingly.

The value of a semi-online model, denoted by Π_s , is evaluated by comparing its upper (or lower) bound with that of a corresponding online model reacting to the same machine environment and objective function, which is represented by Π_o . The semi-online model is called *valuable* if there exists an online algorithm for Π_s whose competitive ratio is smaller than the optimal bound (or lower bound) of the Π_o . On the other hand, if the lower bound of Π_s is no smaller than the competitive ratio of an algorithm for Π_o , it is called *valueless*. Of course, a semionline model is valuable or may not be determined by certain machine environment or objective functions. In this section, mainly identical and uniform machines, as well as minimizing makespan and maximizing minimum machine load, are considered. It is also possible to compare variants of semi-online models qualitatively, according to the extent to which the optimal bound of pure online problem can be improved. However, the outcomes may be quite sensitive to the machine environment or objective function.

Various semi-online paradigms have been studied in the literature, which can be divided into several categories. The taxonomy and their notations, which will be included in the middle field of the three-field notation, are summarized in the [Table 3](#). Their specific implications will be introduced in the rest of the subsection.

3.1.1 Basic Semi-online Models of Type I

Basic semi-online models of Type I modify the first assumption of the online over list model, that is, some partial information about the future jobs are known in advance. The following four kinds of partial information are the most heated.

decr [154]: The jobs are arriving in nonincreasing order of their processing times, that is, $p_1 \geq p_2 \geq \dots \geq p_n$.

Table 3 Semi-online models

Basic	Type I	<i>Valuable:</i> sum, opt, max, decr <i>Valueless:</i> num, LB, UB, min, incr, lookahead
	Type II	buffer, parallel, reassignment
Combined	Type I and Type I	UB & LB, UB & sum, LB & max, max & sum, max & opt, decr & sum, decr & opt, end of sequence
	Type I and Type II	sum & buffer, sum & parallel, sum & reassignment
Disturbed	inexact information	inexact sum, inexact opt, inexact max

sum [111]: The total processing time of all jobs $P = \sum_{j=1}^n p_j$ is known before the first job is arrived.

opt [14]: The optimal offline makespan C^* is known before the first job is arrived.

max [111]: The maximal processing time of all jobs $p_{\max} = \max_{j=1,\dots,n} p_j$ is known before the first job is arrived.

The motivation of *decr*, *sum*, and *max* is obvious, whereas it may seem to be strange at first glance that the optimal offline makespan can be known in advance. In fact, it can be interpreted from the realistic scenario of remote file transfer [14]. Besides, online problems with C^* is known in advance have already been studied before semi-online began to draw attention, since the following lemma is useful in competitive analysis of difficult online problems [10].

Lemma 2 *For some scheduling problem of online over list model with objective to minimize makespan, if there exists an algorithm for the opt variant with competitive ratio r, then there exists an algorithm for the pure online model with competitive ratio at most 4r.*

Some variants reacting to other partial knowledge of input are also reasonable, which is quite common in practice. For example,

num: The number of all jobs n is known before the first job is arrived.

incr: The jobs are arriving in nondecreasing order of their processing times, that is, $p_1 \leq p_2 \leq \dots \leq p_n$.

UB(LB): The upper (lower) bound on the processing time of all jobs $p_{UB} \geq \max_{j=1,\dots,n} p_j$ ($p_{LB} \leq \min_{j=1,\dots,n} p_j$) is known before the first job is arrived.

min: The minimal processing time of all jobs $p_{\min} = \min_{j=1,\dots,n} p_j$ is known before the first job is arrived.

However, such paradigms, which seem worthless under certain machine environment and objective functions discussed so far, have not drawn much attention.

Another kind of partial information which is common in practice is called *lookahead* [111]. When assigning the current job, the information of the next k jobs is known, where k is a constant number. Lookahead tends to be of benefit for scheduling according to practical experience, whereas it turns out to be still worthless as far as competitive ratio is concerned.

3.1.2 Basic Semi-online Models of Type II

There are other variants which lie between online and offline. However, they have nothing to do with the partial information of the input but more freedom acquired in scheduling. These variants belong to *Type II* semi-online models. It is a much more potential research area compared with Type I semi-online models, which is fruitful of results.

In the *buffer* [111] paradigm, there is a buffer of size K which can store at most K jobs. The incoming job can either be scheduled immediately or be stored in the buffer, which enables it to be scheduled later. The root cause of the improved performance attributed to buffer lies in the fact that it can reorder the job sequence. Pure online and offline models are equivalent to problems with buffer size 0 and ∞ , respectively. In another related class of models *reassignment* [160, 167], it is allowed to reassign some of the jobs during or after the process. Recall that in the pure online model, no job can be reassigned.

A technique frequently used in designing algorithm for the offline problems is to run several procedures in parallel and then select the best result as output. However, it does not fit pure online setting. Semi-online variant which allows to use such technique is called *parallel*. A real-world system which resembles such situation was claimed to exist in [111]. Kellerer et al. [111] proved that the optimal bound of $P2|parallel(2)|C_{max}$ is $\frac{4}{3}$; here, *parallel(2)* means that two procedures are run in parallel.

3.1.3 Combined Semi-online Models

Since some semi-online variants are indeed of value, it is natural to raise the question whether a more efficient algorithm can be designed for a problem possessing characteristics of several semionline variants in the meantime. A combination is *useful*, if there exists an online algorithm for the combined semi-online problem whose competitive ratio is smaller than the optimal bound (or lower bound) of any one of the basic semi-online model. Otherwise, the combination is *useless*. The combination could be of two basic semi-online variants of Type I, as well as that of Type I and II, respectively. In spite of the fact that combination consisting of more than three variants can certainly be concerned with, such cases are always quite complicated and seldom studied.

3.1.4 Disturbed Semi-online Models

The *disturbed* semi-online models were first studied in [165]. In some cases, it is allowed to use some additional information or slightly more resources than the offline algorithm, whereas the information or resources might be unreliable. For example, it is known in advance that the total processing time lies in the interval $[P_0, \alpha P_0]$, but the exact value of P is still unknown. It can be believed that the value of inexact partial information lies largely on the value of α , which is called

disturbance parameter. For problem with inexact partial information, special stress is laid on determining the value of α which insures the information to be useful and further designing algorithm making use of the beneficial information acquired.

3.2 Results on Basic Semi-online Models of Type I

3.2.1 Identical Machines

It has been widely known for a long time that in combinatorial optimization, the performance of an algorithm can be improved after appropriate preprocessing for the input. Graham [87] proved that the worst-case ratio of algorithm *Longest Processing Time first* (*LPT* for short), where *LS* is implemented after a preprocessing step, namely, reordering the jobs in a nonincreasing sequence of their processing time, is $\frac{4}{3} - \frac{1}{3m}$. However, it is not allowed to reorder the sequence in the pure online setting. But if the jobs are arrived in nonincreasing order of their processing times, the performance of *LS* will be just the same as that of *LPT*. Above situation was reformulated as a semi-online variant by Seiden et al. [154]. They proved that *LS* is the optimal algorithm for $P2|decr|C_{max}$. However, *LS* is no longer optimal when $m \geq 3$, since there exists an algorithm with competitive ratio $\frac{5}{4}$ for $m \geq 4$ and an optimal algorithm with competitive ratio $\frac{1+\sqrt{37}}{6}$ for $m = 3$ [43].

If the total processing time of all jobs P is known in advance, a lower bound $\frac{P}{m}$ on the optimal makespan is readily available, which will be of great help in designing algorithm with a better competitive ratio. Take the optimal algorithm reacting to two machines [111] for example. Jobs are successively assigned to M_1 until there exists a crucial job, such that the load of M_1 would exceed a threshold $\frac{4}{3} \cdot \frac{P}{2}$ if the crucial job is still assigned to M_1 ; here, $\frac{4}{3}$ is the expected competitive ratio of the algorithm. Then, the crucial job is assigned to M_2 , and the remaining jobs will no longer have any negative effect on the competitive ratio. The core idea of the algorithm is to keep one machine lightly loaded so as to serve the long jobs which might present later. The significance of *sum* lies in the fact that it is impossible to determine the threshold without access to P .

For $Pm|sum|C_{max}$, Angelelli et al. [6] proposed an algorithm with competitive ratio $\frac{\sqrt{6}+1}{2} \approx 1.725$ and proved that the lower bound of the problem is 1.565 for sufficiently large m . The lower bound was recently improved to 1.585 by Albers and Hellwig [3]. By more careful classification according to the processing time of the jobs as well as the current load of the machines, Cheng et al. [41] designed an improved algorithm with competitive ratio $\frac{8}{5}$. They also showed that $\frac{3}{2}$ is a lower bound of the problem for any $m \geq 6$. For the case of $m = 3$, the current best lower and upper bounds are $\frac{\sqrt{129}-3}{6} \approx 1.393$ and $\frac{27}{19} \approx 1.421$, respectively [9].

The semi-online variant *opt* is closely associated with the variant *sum*. In fact, many instances used to show the tightness of the competitive ratio of some algorithms satisfy $C^* = \frac{P}{m}$. However, the instance with $C^* > \frac{P}{m}$ does exist. Therefore, it is not easy to answer whether corresponding two problems regarding

sum and *opt* variants have the same optimal bound. Nevertheless, Dósa et al. [54] proved the following result.

Lemma 3 ([54])

- (i) If ρ is a lower bound of $Qm|opt|C_{max}$, then the lower bound of $Qm|sum|C_{max}$ is at least ρ .
- (ii) If there is an algorithm for $Qm|sum|C_{max}$ with competitive ratio r , then there also exists an algorithm for $Qm|sum|C_{opt}$ with competitive ratio at most r .

By Lemma 3, the algorithm for $Pm|sum|C_{max}$ given in [41] can be modified to solve $Pm|opt|C_{max}$ with at most the same competitive ratio $\frac{8}{5}$, which improves the former algorithm for $Pm|opt|C_{max}$ with a competitive ratio of $\frac{13}{8}$ [14]. When the number of machines is small, another algorithm also given in [14] has a smaller competitive ratio of $\frac{5m-1}{3m+1}$. On the other hand, the lower bound of $Pm|sum|C_{max}$ is no longer valid for $Pm|opt|C_{max}$. Though $\frac{4}{3}$ is clearly a lower bound of $Pm|opt|C_{max}$ for any $m \geq 2$ [14], no larger lower bound has been reported for $m \geq 3$.

There are fewer results on the *max* variant. He and Zhang [97] presented an optimal algorithm for $P2|max|C_{max}$ with competitive ratio $\frac{4}{3}$. Note that for the *max* variant, not only the processing times of all jobs are no more than p_{max} , but also at least one job with processing time p_{max} will arrive sooner or later. Hence, the first job with processing time p_{max} , which is denoted as J_{max} , can be shifted to the beginning of the job sequence by assumption. Thus, the optimal algorithm given in [97] can be simplified by using above idea.

Algorithm PLS

1. Let J_{max} be scheduled on M_1 from time 0 to p_{max} .
2. Assign the remaining jobs by *LS* rule.

Theorem 6 *The competitive ratio of PLS is $\frac{4}{3}$ for $P2|max|C_{max}$.*

Proof If $\max\{L_1, L_2\} \leq \frac{2}{3}P$, then $\frac{C^{PLS}}{C^*} \leq \frac{\max\{L_1, L_2\}}{\frac{P}{2}} \leq \frac{4}{3}$ by (1). Otherwise,

$$\begin{aligned} \max\{L_1, L_2\} + (L_1 + L_2) + |L_1 - L_2| &= 3 \max\{L_1, L_2\} > 2P = (L_1 + L_2) \\ &\quad + \max\{L_1, L_2\} + \min\{L_1, L_2\}. \end{aligned} \quad (6)$$

Since the remaining jobs are assigned by *LS* rule, $|L_1 - L_2| \leq p_{max}$. Combining it with (6), $\min\{L_1, L_2\} < |L_1 - L_2| \leq p_{max}$. Recall that J_{max} is assigned to M_1 , $L_1 \geq p_{max}$. Hence, $L_2 < p_{max}$ and thus no job other than J_{max} will be assigned to M_1 , which implies that *PLS* produces an optimal schedule. \square

However, for general m , no algorithm performing better than the best known algorithm for pure online model has been obtained. It is also unknown that whether

Table 4 Results of semi-online variants on arbitrary m identical machines

Variant	Non-preemptive				Preemptive
	Makespan minimization		Machine covering		Makespan minimization
	Lower bound	Upper bound	Lower bound	Upper bound	Optimal bound
<i>decr</i>	$\frac{1+\sqrt{37}}{6}$ [154]	$\frac{5}{4}$ [43]	Open	$\frac{4m-2}{3m-1}$ [47]	$\max_{0 \leq k \leq m} \frac{2m^2+2mk}{2m^2+k^2+k}$ [154]
<i>sum</i>	1.585 [3]	$\frac{8}{5} = 1.6000$ [41]		$m-1$ [22, 166]	1 [98]
<i>opt</i>	$\frac{4}{3} \approx 1.333$ [14]	$\frac{8}{5} = 1.6000$ [41]	$\frac{43}{24} \approx 1.791$ [61]	$\frac{11}{6} \approx 1.834$ [61]	1 [58]
<i>max</i>	Open	Open		$m-1$ [22, 166]	$\max_{0 \leq k \leq m} \frac{2m^2+2mk}{2m^2+k^2+k}$ [154]

the partial information is still valuable for sufficiently large m , since the effect of the information about the single job J_{\max} tend to reduce as m increases.

As far as the problem of machine covering is concerned, the four semi-online variants differ hugely both in property and difficulty. Optimal algorithms for $Pm|sum|C_{\min}$ and $Pm|max|C_{\min}$ can be obtained, both having a competitive ratio $m-1$ for $m \geq 3$ [22, 166]. However, the research on $Pm|opt|C_{\min}$ seems to be much more difficult than that of $Pm|sum|C_{\min}$. Azar and Epstein [12] proposed an algorithm with competitive ratio $2 - \frac{1}{m}$, which is optimal for $m = 2, 3, 4$. A more involved algorithm with competitive ratio $\frac{11}{6} \approx 1.834$ was given in [61]. The current best lower bound is $\frac{7}{4}$ for $m > 4$ [12] and $\frac{43}{24} \approx 1.791$ for sufficiently large m [61]. These bounds are far smaller than those for $Pm|sum|C_{\min}$. For the problem $Pm|decr|C_{\min}$, LS has a competitive ratio of $\frac{4m-2}{3m-1}$ [47] and is optimal for $m = 2, 3$ [96].

Tables 4 and 5 summarize the current best results of different semi-online variants on identical machines for arbitrary m and small number of m , respectively. As is shown in the table, different semi-online variants are diverse in value. In addition, optimal algorithm for two machines has almost all been found, whereas for three or more machines, nearly all problems are waiting to be answered, which is quite thought-provoking.

3.2.2 Two Uniform Machines

Similarly as pure online problems, the upper and lower bounds for most semi-online problems on two uniform machines are piece-wise rational or irrational functions of s . But the number of the pieces could be considerably large, often exceeding 10. There may be large difference among optimal algorithms for the same problem with different value of s , which make the analysis of these problems extremely difficult. Most results are obtained mainly by case by case analysis. Up till now, no universal or revolutionary method has been developed to handle these problems efficiently.

^aMC machine covering, OB optimal bound, LB lower bound, UB upper bound^bFor most semi-online variants, the makespan minimization problem and the machine covering problem on two identical machines are equivalent. The competitive ratios r_1 and r_2 of the same algorithm for corresponding two problems satisfy $r_1 + \frac{1}{r_2} = 2$. Therefore, results about machine covering problems on two identical machines are omitted. However, there does exist semi-online model that above two problems are not equivalent, such as *UB & LB*^cThe lower bound is $\frac{15}{11}$ for any buffer size K [63], and there exists an algorithm with matched competitive ratio which uses a buffer of size 6 [112]^dThe lower bound is $\frac{11}{6}$ for any buffer size K , and the upper bound is $\frac{5}{2}$ for $K \geq 2$ [73]

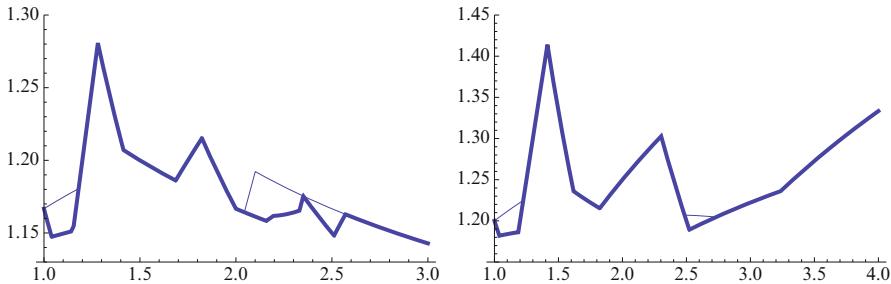

Fig. 2 The optimal bounds (thick) and competitive ratios of LS (dash) for $Q2|decr|C_{max}$ (left) and $Q2|decr|C_{min}$ (right)

Among the four basic semi-online variants of Type I, *decr* is the only one which optimal bounds for all values of $s \geq 1$ are obtained for both minimization and maximization problems. Based on the worst-case ratio of *LPT* for the offline version [133], Epstein and Favrholdt proved that LSc is optimal for the majority value of s . For the remaining two intervals which is close to 1 and nearby 2.5 where LSc is not optimal, they designed three new algorithms and proved their optimality. Symmetrically, for $Q2|decr|C_{min}$, LSs is also optimal except for two similar intervals of s , and new optimal algorithms have been proposed for these intervals [39]. The figures depicting two optimal bounds (as functions of s) bear some similarities (Fig. 2).

The other two problems which optimal algorithms for any $s \geq 1$ have been obtained are $Q2|sum|C_{min}$ and $Q2|opt|C_{min}$. The optimal bound of $Q2|sum|C_{min}$ [163] is

$$\begin{cases} \frac{s+2}{s+1}, & s \in [1, \sqrt{2}], \\ s, & s \in [\sqrt{2}, \frac{1+\sqrt{5}}{2}], \\ \frac{s^2+s+1+\sqrt{5s^4+6s^3+3s^2+2s+1}}{2s(s+1)}, & s \in (\frac{1+\sqrt{5}}{2}, \infty), \end{cases}$$

while the optimal bound of $Q2|opt|C_{min}$ [66] is

$$\begin{cases} \frac{s+2}{s+1}, & s \in [1, \sqrt{2}], \\ s, & s \in [\sqrt{2}, \frac{1+\sqrt{5}}{2}], \\ \frac{2s+1}{s+1}, & s \in (\frac{1+\sqrt{5}}{2}, \infty). \end{cases}$$

Note that the optimal bound of $Q2|sum|C_{min}$ is strict smaller than that of $Q2|opt|C_{min}$ for $s > \frac{1+\sqrt{5}}{2}$. The overall optimal bound of $Q2|sum|C_{min}$ is also strict less than that of $Q2|opt|C_{min}$ (See Fig. 3). These conclusions turn out to be opposite to both the results of Lemma 3 concerning problems with objective to minimize makespan and that of machine covering problems on m identical machines.

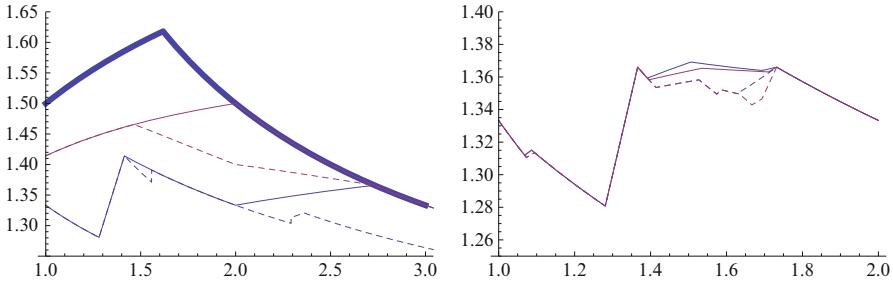

Fig. 3 Left: the optimal bound of $Q2||C_{max}$ (thick) and the upper bounds (solid) and lower bounds (dash) of $Q2|max|C_{max}$ (bottom) and $Q2|eos|C_{max}$ (top). Right: the upper bounds (solid) and lower bounds (dash) of $Q2|sum|C_{max}$ (top) and $Q2|opt|C_{max}$ (bottom)

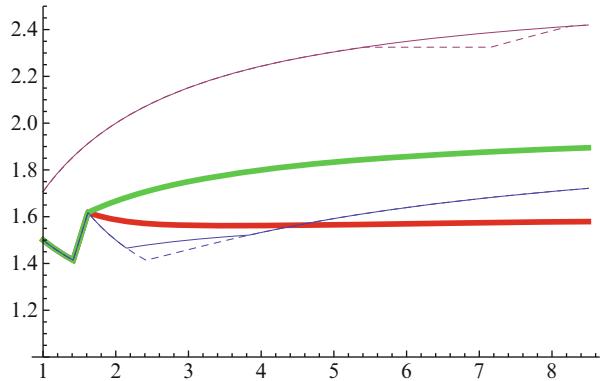

Fig. 4 The optimal bounds (thick) of $Q2|sum|C_{min}$ (bottom) and $Q2|opt|C_{min}$ (top) and the upper bounds (solid) and lower bounds (dash) of $Q2|max|C_{min}$ (bottom) and $Q2|eos|C_{min}$ (top)

For the remaining four problems, there are still gaps between upper and lower bounds for some values of s , though ceaseless efforts have been put into narrowing the gap. The gaps of some problems seem to be small, but it is usually the case that the gap might appear exactly be the place where the analysis becomes toughest. For the sake of conciseness, only best known bounds will be listed in the following. General information of these bounds is summarized in Table 6 (also see Figs. 4 and 3). It can be seen that $Q2|sum|C_{max}$ and $Q2|opt|C_{max}$ are much more complicated than the corresponding machine covering problems. For $Q2|max|C_{max}$, the effect of the information about the single job J_{max} declines when s is sufficiently large. There is a noteworthy fact that for majority makespan minimization problems, the overall bound is achieved at the point where the argument s values exactly the overall bound itself and lies in the interval $[1.2, 1.5]$. For machine covering problems, the overall bounds all achieve at $s = \infty$ except $Q2|sum|C_{max}$.

Table 6 General information and current status of upper and lower bounds on two uniform machines

The lower and upper bounds of $Q2|sum|C_{max}$ [54, 65, 137] are

$$\left\{ \begin{array}{ll} \frac{3s+1}{3s}, & s \in \left[1, \frac{5+\sqrt{205}}{18} \approx 1.0732 \right], \\ \frac{8s+5}{5s+5}, & s \in \left[\frac{5+\sqrt{205}}{18}, \frac{1+\sqrt{31}}{6} \approx 1.0946 \right], \\ \frac{2s+2}{2s+1}, & s \in \left[\frac{1+\sqrt{31}}{6}, \frac{1+\sqrt{17}}{4} \approx 1.280 \right] \\ s, & s \in \left[\frac{1+\sqrt{17}}{4}, \frac{1+\sqrt{3}}{2} \approx 1.36603 \right] \\ \frac{2s+1}{2s}, & s \in \left[\frac{1+\sqrt{3}}{2}, \sqrt{2} \approx 1.41421 \right] \\ \frac{3s+5}{2s+4}, & s \in \left[\sqrt{2}, \frac{\sqrt{21}}{3} \approx 1.52753 \right] \\ \frac{3s+3}{3s+1}, & s \in \left[\frac{\sqrt{21}}{3}, \frac{5+\sqrt{193}}{12} \approx 1.57437 \right] \\ \frac{4s+2}{2s+3}, & s \in \left[\frac{5+\sqrt{193}}{12}, \frac{7+\sqrt{145}}{12} \approx 1.5868 \right] \\ \frac{5s+2}{4s+1}, & s \in \left[\frac{7+\sqrt{145}}{12}, \frac{9+\sqrt{193}}{14} \approx 1.63509 \right] \\ c(s), & s \in \left[\frac{9+\sqrt{193}}{14}, \sqrt{3} \right] \\ \frac{s+2}{s+1}, & s \in [\sqrt{3}, \infty) \end{array} \right.$$

and

$$\left\{ \begin{array}{ll} \frac{3s+1}{3s}, & s \in [1, x_1 \approx 1.071], \\ \frac{7s+6}{4s+6}, & s \in \left[x_1, \frac{1+\sqrt{145}}{12} \approx 1.0868 \right], \\ \frac{2s+2}{2s+1}, & s \in \left[\frac{1+\sqrt{145}}{12}, \frac{1+\sqrt{17}}{4} \approx 1.280 \right] \\ s, & s \in \left[\frac{1+\sqrt{17}}{4}, \frac{1+\sqrt{3}}{2} \approx 1.36603 \right] \\ \frac{2s+1}{2s}, & s \in \left[\frac{1+\sqrt{3}}{2}, x_2 \approx 1.3915 \right] \\ \frac{s+\sqrt{29s^2+59s+30}}{4s+5}, & s \in [x_2, x_3 \approx 1.5062] \\ \frac{\sqrt{36s^4+9s^3-32s^2-2s+9}+6s^2+9s+3}{9s^2+7s}, & s \in [x_3, x_4 \approx 1.6932] \\ \frac{\sqrt{4s^4+8s^3+s^2+4+2s^2+3s+2}}{2s^2+6s}, & s \in [x_4, \sqrt{3}] \\ \frac{s+2}{s+1}, & s \in [\sqrt{3}, \infty), \end{array} \right.$$

respectively, where $c(s) = \frac{\sqrt{s^2x^2 + 4s(s+1-x)} + sx}{2s}$, x is a root of the equation $\frac{\sqrt{s^2x^2 + 4s(s+1-x)} + sx}{2s} = \frac{s(2s+2-x)}{(s+1)(x+2)}$, x_1, x_2, x_3, x_4 are the positive roots of

$$3s^2(9s^2 - s - 5) = (3s+1)(5s+5 - 6s^2),$$

$$\begin{aligned} \frac{2s+1}{2s} &= \frac{s + \sqrt{29s^2 + 59s + 30}}{4s+5}, \\ \frac{s + \sqrt{29s^2 + 59s + 30}}{4s+5} &= \frac{\sqrt{36s^4 + 9s^3 - 32s^2 - 2s + 9} + 6s^2 + 9s + 3}{9s^2 + 7s}, \\ &\quad \frac{\sqrt{36s^4 + 9s^3 - 32s^2 - 2s + 9} + 6s^2 + 9s + 3}{9s^2 + 7s} \\ &= \frac{\sqrt{4s^4 + 8s^3 + s^2 + 4} + 2s^2 + 3s + 2}{2s^2 + 6s}, \end{aligned}$$

respectively.

The lower and upper bounds of $Q2|opt|C_{max}$ [54, 65, 137] are

$$\left\{ \begin{array}{l} \frac{3s+1}{3s}, s \in \left[1, \frac{5+\sqrt{205}}{18} \approx 1.0732 \right], \\ \frac{8s+5}{5s+5}, s \in \left[\frac{5+\sqrt{205}}{18}, \frac{1+\sqrt{31}}{6} \approx 1.0946 \right], \\ \frac{2s+2}{2s+1}, s \in \left[\frac{1+\sqrt{31}}{6}, \frac{1+\sqrt{17}}{4} \approx 1.280 \right] \\ s, \quad s \in \left[\frac{1+\sqrt{17}}{4}, \frac{1+\sqrt{3}}{2} \approx 1.36603 \right] \\ \frac{2s+1}{2s}, s \in \left[\frac{1+\sqrt{3}}{2}, \sqrt{2} \approx 1.41421 \right] \\ \frac{3s+5}{2s+4}, s \in \left[\sqrt{2}, \frac{\sqrt{21}}{3} \approx 1.52753 \right] \\ \frac{3s+3}{3s+1}, s \in \left[\frac{\sqrt{21}}{3}, \frac{5+\sqrt{193}}{12} \approx 1.57437 \right] \\ \frac{4s+2}{2s+3}, s \in \left[\frac{5+\sqrt{193}}{12}, \frac{7+\sqrt{145}}{12} \approx 1.58668 \right] \\ \frac{5s+2}{4s+1}, s \in \left[\frac{7+\sqrt{145}}{12}, \frac{9+\sqrt{193}}{14} \approx 1.63509 \right] \\ \frac{7s+4}{7s}, s \in \left[\frac{9+\sqrt{193}}{14}, \frac{5}{3} \right] \\ \frac{7s+4}{4s+5}, s \in \left[\frac{5}{3}, \frac{5+\sqrt{73}}{8} \approx 1.89300 \right] \\ \frac{s+1}{2}, s \in \left[\frac{5+\sqrt{73}}{8}, \sqrt{3} \right] \\ \frac{s+2}{s+1}, s \in [\sqrt{3}, \infty) \end{array} \right.$$

and

$$\begin{cases} \frac{3s+1}{3s}, & s \in [1, s_8 \approx 1.071], \\ \frac{7s+6}{4s+6}, & s \in \left[s_8, \frac{1+\sqrt{145}}{12} \approx 1.0868 \right], \\ \frac{2s+2}{2s+1}, & s \in \left[\frac{1+\sqrt{145}}{12}, \frac{1+\sqrt{17}}{4} \approx 1.280 \right] \\ s, & s \in \left[\frac{1+\sqrt{17}}{4}, \frac{1+\sqrt{3}}{2} \approx 1.36603 \right] \\ \frac{2s+1}{2s}, & s \in \left[\frac{1+\sqrt{3}}{2}, \frac{1+\sqrt{21}}{4} \approx 1.39562 \right] \\ \frac{6s+6}{4s+5}, & s \in \left[\frac{1+\sqrt{21}}{4}, \frac{1+\sqrt{13}}{3} \approx 1.535187 \right] \\ \frac{12s+10}{9s+7}, & s \in \left[\frac{1+\sqrt{13}}{3}, \frac{5+\sqrt{241}}{12} \approx 1.71035 \right] \\ \frac{2s+3}{s+3}, & s \in \left[\frac{5+\sqrt{241}}{12}, \sqrt{3} \right] \\ \frac{s+2}{s+1}, & s \in [\sqrt{3}, \infty), \end{cases}$$

respectively.

The lower and upper bounds of $Q2|max|C_{max}$ [23, 24, 128] are

$$\begin{cases} \frac{2s+2}{2s+1}, & s \in \left[1, \frac{1+\sqrt{17}}{4} \approx 1.280 \right], \\ s, & s \in \left[\frac{1+\sqrt{17}}{4}, \sqrt{2} \right], \\ \frac{1+\sqrt{4s^2+1}}{2s}, & s \in [\sqrt{2}, x_5 \approx 1.558] \\ \frac{s+2}{s+1}, & s \in [x_5, x_6 \approx 2.292] \\ \frac{(s+1)(9s+5) - \sqrt{(s+1)(-3s^3+7s^2+7s+1)}}{2(s+1)(3s+2)}, & s \in [x_6, x_7 \approx 2.360] \\ \frac{s+\sqrt{s^2+4s}}{2s}, & s \in [x_7, \frac{3+\sqrt{17}}{2} \approx 3.56] \\ \frac{s+1}{s}, & s \in \left[\frac{3+\sqrt{17}}{2}, \infty \right) \end{cases}$$

and

$$\begin{cases} \frac{2s+2}{2s+1}, & s \in \left[1, \frac{1+\sqrt{17}}{4} \approx 1.280\right], \\ s, & s \in \left[\frac{1+\sqrt{17}}{4}, \sqrt{2}\right], \\ \frac{s+2}{s+1}, & s \in [\sqrt{2}, 2] \\ \frac{3s+2}{2s+2}, & s \in [2, 1 + \sqrt{3}] \\ \frac{s+1}{s}, & s \in [1 + \sqrt{3}, \infty), \end{cases}$$

respectively, where x_5, x_6, x_7 are the roots of

$$2s^4 + 2s^3 - 6s^2 - 5s + 3 = 0,$$

$$\begin{aligned} 12s^6 - s^5 - 32s^4 - 12s^3 + 7s^2 + s - 1 &= (6s^4 - 3s^3 - 6s^2 - 3s - 1) \\ &\times \sqrt{(s+1)(-3s^3 + 7s^2 + 7s + 1)}, \\ 8s^3 + 15s^2 + 13s + 4 &= (6s^2 + 9s + 3)\sqrt{s^2 + 4s}, \end{aligned}$$

respectively.

The lower and upper bounds of $Q2|max|C_{min}$ [27, 129] are

$$\begin{cases} \frac{s+2}{s+1}, & s \in [1, \sqrt{2}], \\ s, & s \in \left[\sqrt{2}, \frac{1+\sqrt{5}}{2}\right], \\ \frac{s+1}{s}, & s \in \left[\frac{1+\sqrt{5}}{2}, 1 + \sqrt{2}\right] \\ \frac{s^2 + s + 1 + \sqrt{s^4 - s^2 + 2s + 1}}{s^2 + 2s}, & s \in [1 + \sqrt{2}, \infty) \end{cases}$$

and

$$\begin{cases} \frac{s+2}{s+1}, & s \in [1, \sqrt{2}], \\ s, & s \in \left[\sqrt{2}, \frac{1+\sqrt{5}}{2}\right], \\ \frac{s+1}{s}, & s \in \left[\frac{1+\sqrt{5}}{2}, x_8 \approx 2.148\right] \\ \frac{s+1 + \sqrt{5s^2 + 6s + 1}}{2(s+1)}, & s \in [x_8, x_9 \approx 3.836] \\ \frac{s^2 + s + 1 + \sqrt{s^4 - s^2 + 2s + 1}}{s^2 + 2s}, & s \in [x_9, \infty). \end{cases}$$

respectively, where x_8, x_9 are the positive roots of

$$\frac{s+1}{s} = \frac{s+1+\sqrt{5s^2+6s+1}}{2(s+1)}$$

and

$$\frac{s+1+\sqrt{5s^2+6s+1}}{2(s+1)} = \frac{s^2+s+1+\sqrt{s^4-s^2+2s+1}}{s^2+2s},$$

respectively.

3.2.3 Preemption

In regard to preemptive semi-online scheduling problems, there were some results on optimal algorithms [56, 67, 93, 94]. But breakthrough was not made until Ebenlendr and Sgall introduced the general framework for preemptive online scheduling, through which for the majority of semi-online variants, preemptive scheduling problems with the objective function of makespan can be solved. The optimal algorithm for these semi-online problems is identical with the optimal algorithm for the pure online problem; only the optimal bound needs to be recalculated by using the reformed linear programming (Eq. 4). However, as in the pure online case, there are still two points at issue. The first is that the analytically optimal bounds can hardly be obtained when m is large, even for the identical machines case. The second is that it is necessary for the algorithm to use idle times, and whether it is inevitable still remains unknown.

For $Qm|pmtn, opt|C_{max}$, there exists an algorithm which always produces an optimal schedule [58]. Similar result for two uniform machines was obtained by Epstein [65] before. $Pm|pmtn, sum|C_{max}$ also has an algorithm with competitive ratio 1 [98], but it does not hold for $Qm|pmtn, sum|C_{max}$ [59].

For $Pm|pmtn, decr|C_{max}$, Seiden et al. designed an optimal algorithm with competitive ratio $\max_{0 \leq k \leq m} \frac{2m^2+2mk}{2m^2+k^2+k}$ [154]. The bound tends to $\frac{1+\sqrt{3}}{2}$ when $m \rightarrow \infty$, and the algorithm does not introduce idle times. Interestingly, it is also the optimal algorithm for $Pm|pmtn, max|C_{max}$. However, above two variants do not share optimal algorithm for uniform machines. The optimal bounds for $Q2|pmtn, decr|C_{max}$ [67] and $Q2|pmtn, max|C_{max}$ [94] are

$$\begin{cases} \frac{3s+3}{3s+2}, & 1 \leq s \leq 3, \\ \frac{2s^2+2s}{2s^2+s+1}, & s > 3 \end{cases}$$

and $\frac{2s^2+3s+1}{2s^2+2s+1}$, respectively (Fig. 5). Moreover, no deterministic algorithm that never uses idle time can have the same competitive ratio as those use idle time when $s > 2$ for the former problem and $s > \frac{1+\sqrt{5}}{2}$ for the latter. But the corresponding lower and upper bounds are still unknown. More optimal bounds for different semi-online variants on $m = 2, 3, 4$ uniform machines can be found in [57, 59].

Preemptive machine covering problems are much more complicated than corresponding makespan minimization problems. Due to the particularity of the definition of the objective, whether idle time is allowed should be taken into special consideration. The lower bound of $Pm|pmtn,sum|C_{min}$ is $\frac{2m-3}{m-1}$, and there exists optimal algorithm with matched competitive ratio when $m = 2, 3$ [98]. For $Q2|pmtn,max|C_{min}$, the optimal bound is $\frac{s^2+3s+1}{s^2+2s+1}$ [99]. However, the algorithm may introduce idle time before J_{max} arrives when $s > s' \approx 1.247$. Here, s' is the positive root of $s^3+s^2-2s-1 = 0$. For $Q2|pmtn,decr|C_{min}$, the optimal bound is

$$\begin{cases} \frac{2s+3}{2s+2}, & 1 \leq s \leq 3, \\ \frac{s^2+3s}{s^2+2s+1}, & s > 3. \end{cases}$$

The optimal algorithm also needs to introduce idle time when assigning the first job if $s > \frac{\sqrt{6}}{2}$. Whether there exist algorithms for $Q2|pmtn,sum|C_{min}$ and $Q2|pmtn,opt|C_{min}$ that can always obtain the optimal schedule remains open (Fig. 5).

3.2.4 Other Results

Due to the difficulty in competitive analysis with multiple parameters, there is little study on non-preemptive semi-online problems on more than two uniform machines. Azar and Epstein [11] proposed algorithms with competitive ratio both m for $Qm|opt|C_{min}$ and $Qm|decr|C_{min}$, respectively. These algorithms are optimal in the overall sense.

Even less is known about randomized algorithms for semi-online problems. Seiden et al. [154] proposed a barely random algorithm for $P2|decr|C_{max}$ with competitive ratio $\frac{8}{7}$, and no randomized algorithm can achieve a better competitive ratio.

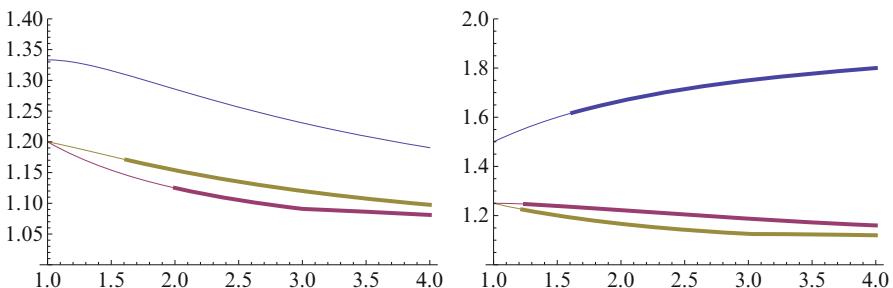

Fig. 5 Left: the optimal bounds of $Q2|pmtn|C_{max}$ (top), $Q2|max, pmtn|C_{max}$ (middle), and $Q2|decr, pmtn|C_{max}$ (bottom). Right: the optimal bounds of $Q2|pmtn|C_{min}$ (top), $Q2|max, pmtn|C_{min}$ (middle), and $Q2|decr, pmtn|C_{min}$ (bottom). Thick segments represent the intervals of s where idle time is necessary

3.3 Results on Basic Semi-online Models of Type II

3.3.1 Buffer

Evidently, it is more likely to design algorithm with a better performance if larger buffer is allowed. However, a buffer of size more than 1 is dispensable for two identical machines. That is to say, the lower bound of the problem with a buffer of size arbitrary large equals to the competitive ratio of an algorithm using a buffer of size only 1, which is $\frac{4}{3}$ [111, 187]. However, such phenomenon does not occur in the case where there are more than two machines or machines have different speeds. Therefore, the algorithm, as well as its corresponding competitive ratios, may be relevant to the size of the buffer. However, it seems impossible and also redundant to obtain optimal algorithms for any values of K . An alternate way is to find an algorithm satisfying *super optimality*. An algorithm with competitive ratio r which uses a buffer of size K is *super optimal* if no algorithm which uses a buffer of size arbitrary large can have a competitive ratio smaller than r , where K is a constant number. Clearly, if two algorithms are both super optimal, then the algorithm which uses a smaller buffer is better. However, research on the problem with a buffer of limited size is also of significance, since in practical application, the buffer size is limited by the cost, space, or other additional restrictions.

Main results on the *buffer* variant on arbitrary number of machines are summarized in Table 7. For $Pm|buffer|C_{max}$ [63], $Pm|pmtn, buffer|C_{max}$ [51], and $Qm|buffer|C_{min}$ [73], super optimal algorithms have been obtained (in the overall sense for the last problem on uniform machines). Note that the super optimal bound for $Pm|pmtn, buffer|C_{max}$ is not an increasing function of m , and the problem cannot be solved by using the general framework included in [59].

For $Q2|buffer|C_{max}$, it is possible to obtain lower and upper bounds as functions of s [52]. A buffer of size 2 is enough to achieve the super optimal bound

$$\begin{cases} \frac{s^2 + 2s + 1}{s^2 + s + 1}, & 1 \leq s \leq \frac{1+\sqrt{5}}{2}, \\ \frac{s^2}{s^2 - s + 1}, & \frac{1+\sqrt{5}}{2} \leq s \leq 2, \\ \frac{s+2}{s+1}, & s \geq 2. \end{cases}$$

Moreover, the optimal algorithm only needs a buffer of size 1 when $s \geq 2$. However, when the buffer size reduces to 1, the optimal bound increases to $\frac{s+2}{s+1}$ for $\sqrt{2} < s < 2$, and there exists an algorithm with competitive ratio $\frac{2(s+1)}{s+2}$ while the lower bound is $\max \left\{ s, \frac{s^2 + 2s + 1}{s^2 + s + 1} \right\}$ $1 \leq s \leq \sqrt{2}$.

Table 7 Main results for the *buffer* variant on arbitrary number of machines

Problem	Buffer size/lower bound		Buffer size	Lower bound	Buffer size/competitive ratio
	Buffer size	Lower bound			
$P_m buffer C_{max}$ [63] (except marked)	Constant	γ_m^a		$\left\lceil \left(1 + \frac{2}{\gamma_m}\right)m \right\rceil + 1^a$	γ_m^a
	$\lfloor \frac{m}{2} \rfloor - 1$	$\frac{3}{2}$		$\frac{3m}{2}$	$\frac{3}{2}$ [112]
	$\lfloor \frac{m}{8} \rfloor - 1 (m \geq 8)$	$1 + \frac{1}{\sqrt{2}}$		m	$1 + \frac{\gamma_m a}{2}$
			$K \in [1, \frac{m+1}{2}]$		$2 - \frac{1}{m-K}$
$Q^m buffer C_{max}$				$m - 1$	$2 + \epsilon (\epsilon > 0)$ [63]
				m	$2 - \frac{1}{m} + \epsilon (\epsilon > 0)$ [112]
$Pm pmtn,$ <i>buffer</i> [51]	m is even	Constant	$\frac{4}{3}$	$\frac{m}{2} - 1$	$\frac{4}{3}$
	m is odd	Constant	$\frac{4m^2}{3m^2+1}$	$\frac{m-1}{2}$	$\frac{4m^2}{3m^2+1}$
			b		
	General m	$\leq \lceil \frac{m-2}{2} \rceil$			
		$1 (m \geq 5)$	$\frac{4m^3-12m^2+4m}{3m^3-11m^2+18m-24}$		
$Pm buffer C_{min}$ [73]	Constant		$\sum_{i=1}^m \frac{1}{i}$	$m - 1$	$1 + \sum_{i=1}^{m-1} \frac{1}{i}$
		$K = f(m) < m$	$\frac{m}{f(m)+1}$		
$Qm buffer C_{min}$ [73]	constant		m	$m + 1$	m
		$m - 2$	∞	$m - 1$	$\frac{2m-1+\sqrt{4m^2-8m+5}}{2}$

^a γ_m is the smallest positive solution of the equation

$$\left\lceil m - \frac{m}{\gamma_m} \right\rceil \frac{\gamma_m}{m} + (\gamma_m - 1) \sum_{i=m-\frac{m}{\gamma_m}}^{m-1} \frac{1}{i} = 1.$$

For any given m , γ_m can be calculated numerically, for example, $\gamma_3 \approx 1.3666$, $\gamma_4 \approx 1.375$. Moreover, $\lim_{m \rightarrow \infty} \gamma_m = \gamma_\infty \approx 1.4659$, where γ_∞ is the smallest solution of equation $\gamma_\infty e^{\gamma_\infty} = -\frac{1}{e^2}$

$$b_{\max K+1 \leq i \leq m+1} \frac{m'}{(i+IK-im-Km)m^{K-i}(m-1)^{-K-i}+(K+m)m^{i-1}}$$

3.3.2 Reassignment

Recall that the online over list model is typically characterized by the disallowance of reassignment. Since semi-online can be viewed as relaxation of online, it is natural to consider the situation where some jobs can be actually reassigned, which is also of realistic interest from an application perspective.

Variants in this category can be classified into two main types: sequential reassignment and final one-off reassignment. For the first type, reassignment can be done when every new job arrives, while for the second one, reassignment can only be done after all jobs have been assigned. For both cases, however, there should be some constraints on the reassignment; otherwise, the problem will reduce to an offline fashion.

In [160], Sanders et al. considered the *proportional sequential reassignment* model. When a job with processing time p_j arrives, some jobs with total processing time at most δp_j can be reassigned, where δ is the *migration factor*. Obviously, the competitive ratio r of an algorithm will decrease when δ increases. For identical machines with objective to minimize makespan, they designed algorithms for different value of δ . Some combinations of r and δ are $(r, \delta) = (\frac{3}{2}, \frac{4}{3})$, $(r, \delta) = (\frac{3}{2} - \frac{1}{2m}, 2)$, and $(r, \delta) = (\frac{4}{3}, \frac{5}{2})$, respectively. They even obtained a family of online algorithms with competitive ratio $1 + \varepsilon$, where $\varepsilon > 0$ can be arbitrarily close to 0, while δ only depends exponentially on $\frac{1}{\varepsilon}$. However, only for the case of $m = 2$ and $\delta = 1$, an algorithm with competitive ratio $\frac{7}{6}$ has been proved to be optimal. For the machine covering problem, they obtained an algorithm with competitive ratio 2 for $\delta = 1$.

Epstein and Levin [71] studied the above variants in a preemptive setting. Since a job can be split, the scheduler is allowed to reassign only part of the job. As a result, the migration factor does not reckon in the entire processing time but rather only the reassigned fraction of that. They presented a $(r, \delta) = (1, 1 - \frac{1}{m})$ algorithms for m identical machines, and the migration factor cannot be improved. For m uniform machines, a migration factor at least $m - 1$ is needed to obtain an algorithm with competitive ratio 1.

The restriction of reassigned job can be made through numbers of jobs instead of total processing times. That is at most G already assigned jobs can be reassigned when a new job arrives. Such variant can be called as *sequential reassignment with quantitative restriction* and is denoted *reassignSQ*. It is stronger than *buffer* since the former can simulate the latter by the following steps: First, temporarily set the jobs on any one of the machines as if they were stored in a buffer. And then reassign them on the machine as if jobs in the buffer were assigned. Contrariwise, a job can no longer be reassigned unless it is in the buffer. In brief, *reassignSQ* can do what *buffer* can, but not vice versa.

For $Q2|reassignSQ|C_{max}$, Dósa et al. [55] proved that the optimal bound when $G \geq 2$ coincides with the optimal bound of $Q2|buffer|C_{max}$ with buffer size $K \geq 2$. However, when $G = 1$, the lower bound is

$$\begin{cases} \frac{s^2 + 2s + 1}{s^2 + s + 1}, & 1 \leq s \leq \frac{1 + \sqrt{5}}{2}, \\ \frac{s + 1}{2}, & \frac{1 + \sqrt{5}}{2} \leq s \leq \sqrt{3}, \\ \frac{s + 2}{s + 1}, & s \geq \sqrt{3}, \end{cases}$$

while the upper bound is

$$\begin{cases} \frac{s^2 + 2s + 1}{s^2 + s + 1}, & 1 \leq s \leq s'', \\ \frac{s + \sqrt{5s^2 + 8s + 4}}{2(s + 1)}, & s'' \leq s \leq \sqrt{3}, \\ \frac{s + 2}{s + 1}, & s \geq \sqrt{3}, \end{cases}$$

where s'' is the root of equation $s^3 - s - 1 = 0$. The algorithm is not optimal when $s \in [s'', \sqrt{3}]$, and it is not identical with the bound of $Q2|buffer|C_{max}$ with buffer size $K = 1$ (Fig. 6).

Several final one-off reassignment models were first proposed by Tan and Yu [167]. One is that when all jobs have been assigned, at most H arbitrary jobs can be reassigned. The model is denoted as *reassignFA*. Tan and Yu proved that optimal bound for two identical machines with objective to minimize makespan is $\frac{4}{3}$, and the optimal algorithm only needs to reassign at most one job. Albers and Hellwig [4] generalized the model to m identical machines. Interestingly, the competitive ratio γ_m of the given algorithm is the same as that of the optimal algorithm for $Pm|buffer|C_{max}$, and the algorithm only reassigns at most $\left(\lceil \frac{2-\gamma_m}{(\gamma_m-1)^2} \rceil + 4\right)m$ jobs. Moreover, no algorithm can achieve a better competitive ratio if $H = o(n)$. They also obtained algorithms with different value of r and H , such as $(r, H) = (\frac{5}{3}, 4m)$ and $(r, H) = (\frac{7}{4}, \frac{5}{2}m)$. For two uniform machines, the optimal bound of $Q2|reassignFA|C_{max}$ when $H \geq 2$ is again the same as that of $Q2|buffer|C_{max}$ when $K \geq 2$. Also, the optimal algorithm reassigns at most one job when $s > 2$. However, if only one job can be reassigned, the competitive ratio of the best known algorithm is also the same as that of $Q2|buffer|C_{max}$ with buffer size $K = 1$, but it is larger than that of $Q2|reassignSQ|C_{max}$ with $G = 1$ (Fig. 6).

Another final one-off reassignment model is denoted *reassignFE*. After all jobs have been arrived, the *last* job assigned to *each* machine can be reassigned. For two identical machines with objective to minimize makespan, the optimal bound is $\sqrt{2}$ [167]. In fact, in such situation at most one job is needed to be reassigned [132]. Cao and Liu [25] generalized the result to two uniform machines and obtain the optimal bound

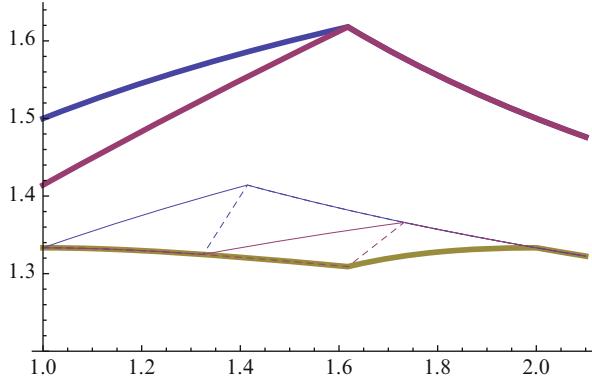

Fig. 6 The optimal bounds (thick) of $Q2||C_{max}$ (top), $Q2|reassignFE|C_{max}$ (middle), and $Q2|buffer|C_{max}$ with $K \geq 2$ (also $Q2|reassignSQ|C_{max}$ with $G \geq 2$ and $Q2|reassignFA|C_{max}$ with $H \geq 2$) (bottom), the upper bounds (solid) and lower bounds (dash) of $Q2|buffer|C_{max}$ with $K = 1$ (also $Q2|reassignFA|C_{max}$ with $H = 1$) (top) and $Q2|reassignSQ|C_{max}$ with $G = 1$ (bottom)

$$\begin{cases} \sqrt{s+1}, & 1 \leq s \leq \frac{1+\sqrt{5}}{2}, \\ \frac{s+1}{s}, & s > \frac{1+\sqrt{5}}{2}. \end{cases}$$

Comparing it with the optimal bound of the pure online problem [72], reassignment is useless when $s > \frac{1+\sqrt{5}}{2}$ (Fig. 6).

3.4 Results on Combined Semi-online Models

3.4.1 UB and LB

Though *UB* and *LB* are both valueless, their combination can be valuable. Such situation is very common in practice, since schedulers tend to estimate the processing time of jobs. However, it would be of little significance if the estimation is too rough to neglect the error. Hence, it is necessary to take influence of a parameter β , defined as $\beta = \frac{UB}{LB} \geq 1$, into consideration when dealing with competitive analysis. Main results of this variant are summarized in Table 8.

Note that *LS* remains optimal for any value of β for $P2|UB\&LB|C_{max}$ and $Pm|UB\&LB|C_{min}$. It is not true for $P3|UB\&LB|C_{max}$, though *LS* is also the optimal algorithm for $P3||C_{max}$. He and Dósa [92] proved the competitive ratio of *LS* is

$$\begin{cases} \frac{2\beta+1}{3}, & \beta \in [1, \frac{3}{2}], \\ \frac{2\beta+3}{\beta+3}, & \beta \in [\frac{3}{2}, \sqrt{3}], \\ \frac{\beta+1}{2}, & \beta \in [\sqrt{3}, 2], \\ 2 - \frac{1}{\beta}, & \beta \in [2, 3], \\ \frac{5}{3}, & \beta \in [3, +\infty), \end{cases}$$

and LS is optimal only when $\beta \in [1, \frac{3}{2}] \cup [\sqrt{3}, 2] \cup [6, +\infty)$. When $\beta \in [2, 6]$, there exists an improved algorithm with competitive ratio

$$\begin{cases} \frac{3}{2}, & \beta \in [2, \frac{5}{2}], \\ \frac{4\beta+2}{2\beta+3}, & \beta \in [\frac{5}{2}, 3], \\ \frac{5}{3} - \frac{1}{18} \min \left\{ \frac{6-\beta}{18}, \frac{3}{103} \right\}, & \beta \in [3, 6]. \end{cases}$$

Nevertheless, the new upper bound matches the lower bound of the problem only when $\beta \in [2, \frac{5}{2}]$. By the definition of the paradigm, the lower bound of the problem is obviously a nondecreasing function of β . For the remaining intervals of β where optimal algorithm has not been obtained, nonconstant lower bound of the problem, equaling to $\frac{7\beta+4+\sqrt{\beta^2+8\beta+4}}{2\beta+2+2\sqrt{\beta^2+8\beta+4}}$, can be found only in the situation where $\beta \in [\frac{5}{2}, 3]$. It is implied again from the results stated above that scheduling for two machines is of enormous difference in essence from that of three machines, while the latter is much more complicated.

A similar model of LB and max is proposed by Cao et al. [26]. It is assumed that $\frac{p_{max}}{\beta} \leq p_j \leq p_{max}$ for any j , and there always exists a job of processing time p_{max} . They proved that the optimal bound of $P2|LB\&max|C_{max}$ is

$$\begin{cases} \frac{\beta+1}{2}, & \beta \in [1, \frac{4}{3}], \\ \frac{4\beta+4}{3\beta+4}, & \beta \in [\frac{4}{3}, \sqrt{2}], \\ \frac{2\beta}{\beta+1}, & \beta \in [\sqrt{2}, 2], \\ \frac{4}{3}, & \beta \in [2, +\infty). \end{cases}$$

It is smaller than that of $P2|LB\&UB|C_{max}$ for some value of β (Fig. 7).

3.4.2 sum/opt and max/UB

Angelelli et al. [7, 8] studied the problem $P2|sum\&UB|C_{max}$. Lower bounds as functions of $\gamma = \frac{2UB}{P}$ and several algorithms are proposed. Optimal bounds are achieved for majority value of γ (see Figs. 4–6 of [8]).

Table 8 Main results for the *UB&LB* variant

Problem	Interval of β where the partial information is valuable and the optimal bound	Interval of β where the partial information is valueless ^a
$P2 UB\&LB C_{max}$ [97]	$\beta \in [1, 2], \frac{1+\beta}{2}$	$\beta \in [2, +\infty]$
$Pm UB\&LB C_{max}, m \geq 3$ [92] ^b	$\beta \in [1, \frac{m}{m-1}], 1 + \frac{(m-1)(r-1)}{m}$	
$Pm UB\&LB C_{min}$ [91]	$\beta \in [1, m], \beta$	$\beta \in [m, +\infty)$
$Pm pmtn, UB\&LB C_{max}$ [94]	^c	$\beta \in [(\frac{m}{m-1})^{m-1}, +\infty)$
$Q2 pmtn, UB\&LB C_{max}$ [56, 93]	$\beta \in [1, 2s],^d$	$\beta \in [2s, +\infty)$
$Q2 pmtn, UB\&LB C_{min}$ [105]	$\beta \in [1, 2s], \frac{2s+2+\beta}{2s+2}$	$\beta \in [2s, +\infty)$

^aValueless implies that the optimal bound is the same as the optimal bound of the corresponding pure online problem

^bOnly partial results about this problem have been obtained

^cOptimal algorithm can be obtained by using the general framework included in [59]. The analytical lower bound for $\beta \in \left[1, \left(\frac{m}{m-1}\right)^{m-1}\right]$ is at least

$$\frac{m \left(\frac{m}{m-1}\right)^k + (m-k-1)\beta}{(2m-k-1) \left(\left(\frac{m}{m-1}\right)^k - 1\right) + (m-k) + \frac{(m-k)(m-k-1)\beta}{2m}},$$

$$\left(\frac{m}{m-1}\right)^k \leq \beta \leq \left(\frac{m}{m-1}\right)^{k+1}, k = 0, 1, \dots, m-2.$$

Whether it is the optimal bounds remains open except for $m = 2, 3$.

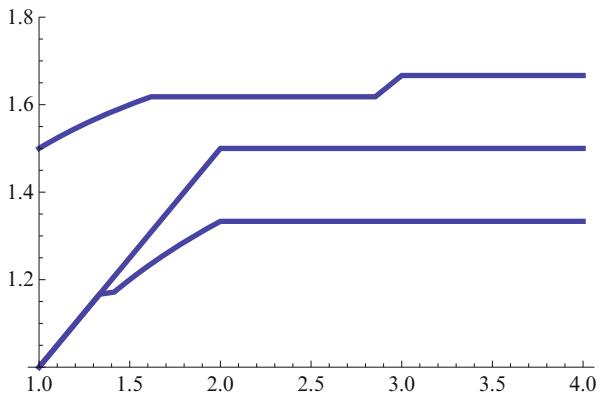

^dThe optimal bound is

$$\begin{cases} \frac{1+s+\frac{\beta}{2}+\frac{\beta s}{2}}{1+s+\frac{\beta s}{2}}, & 1 \leq s \leq 2 \text{ and } \beta \in [1, 2s], s > 2 \text{ and } \beta \in \left[1, \frac{2}{s-1}\right] \cup [2s-2, 2s] \\ \frac{(1+\beta)(1+s)s}{1+s+s^2+s\beta^2}, & s \geq 2 \text{ and } \beta \in \left[\frac{2}{s-1}, s\right] \\ \frac{s^2+s}{s^2+1}, & s \geq 2 \text{ and } \beta \in [s, 2s-2]. \end{cases}$$

If idle time is not allowed, then the (deterministic) lower bound will be larger, but no online algorithm with matched competitive ratio has been obtained [93]

There are other papers considering the combination of *sum(opt)* and *max*. However, only overall bounds (the maximum bound among all combinations of P (or C^*) and p_{max}) are obtained. For example, the optimal bound for $Pm|sum\&max|C_{min}$ [166] is

Fig. 7 The optimal bounds of $P2|\mathcal{M}_j(GoS), LB\&UB|C_{max}$ (top), $P2|LB\&UB|C_{max}$ (middle), and $P2|LB\&max|C_{max}$ (bottom)

$$\begin{cases} \frac{5}{4}, & m = 2, \\ \frac{3}{2}, & m = 3, \\ m - 2, & m \geq 4. \end{cases}$$

For the makespan minimization problem, optimal bounds are obtained only on a small number of machines (See [Table 5](#)). If preemption is allowed, optimal bound of $Q3|pmtn, sum\&max|C_{max}$ for any combinations of P and p_{max} and any values of $s_i, i = 1, 2, 3$, can be obtained by using the general framework included in [\[59\]](#).

3.4.3 End of Sequence

Zhang and Ye [\[190\]](#) proposed an interesting semi-online variant, which was called “end of sequence” (*eos* for short) later [\[70\]](#). It is known that the last job has the largest processing time, and the scheduler will be informed whether the current arrived job is the last one. Such variant can be viewed as a weaker version of the combined semi-online variant *num&incr*. Recall that both *num* and *incr* are valueless if they are considered solely. Thus, it is likely that *eos* is adjacent to the boundary between valuable semi-online variants and valueless ones.

Zhang and Ye [\[190\]](#) proved the optimal bounds of $P2|eos|C_{max}$ and $P3|eos|C_{max}$ are $\sqrt{2}$ and $\frac{3}{2}$, respectively. Note that the lower bound of $P2|eos|C_{max}$ does not hold for $P2|num\&incr|C_{max}$, the optimal bound for the latter problem remains open. Epstein and Ye considered the problems $Q2|eos|C_{max}$ and $Q2|eos|C_{min}$. Optimal algorithms for almost all values of s are given [\[70\]](#) ([Table 6](#), [Figs. 3 and 4](#)).

Table 9 Results for the non-preemptive problems with inexact partial information

Problem	The interval of α where the inexact information is valuable	The interval of α where the obtained algorithm is optimal	The gap between the upper and lower bound	The total length of non-optimal intervals	The interval of α where the inexact information is valueless
$P2 inexact sum C_{max}$	$[1, \frac{3}{2})$	$[\frac{3+\sqrt{21}}{6}, \frac{3}{2})$	≤ 0.0303	≤ 0.2635	$[\frac{3}{2}, \infty)$
$P2 inexact opt C_{max}$	$[1, \frac{3}{2})$	$[\frac{3+\sqrt{21}}{6}, \frac{1+\sqrt{10}}{3}] \cup [\frac{6-\sqrt{10}}{2}, \frac{3}{2})$	≤ 0.0303	≤ 0.2957	$[\frac{3}{2}, \infty)$
$P2 inexact max C_{max}$	$[1, 2)$	$[1, \sqrt{5} - 1]$	≤ 0.0445	≤ 0.7640	$[2, \infty)$

Table 10 Results for the preemptive problems with inexact partial information

Problem	The interval of α where the inexact information is valuable and the optimal bound	The interval of α where the inexact information is valueless
$Q2 pmtn, inexact opt C_{max}$	$\alpha \in \left[\left(\frac{m}{m-1} \right)^k, \left(\frac{m}{m-1} \right)^{k+1} \right],$ $\frac{1}{1 - \left(\frac{m}{m-1} \right)^k + (m-k) + \frac{m-k}{m\alpha}},$ $k = 0, 1, \dots, m-2$	$\left[\left(\frac{m}{m-1} \right)^{m-1}, \infty \right)$
$Pm pmtn, inexact opt C_{max}$	$[1, s+1), \frac{\alpha(s+1)}{\alpha s + 1}$	$[s+1, \infty)$
$Q2 pmtn, inexact max C_{max}$	$[1, s+1), \frac{(s+1)(1+s+\alpha s)}{1+2s+s^2+rs^2}$	$[s+1, \infty)$

3.4.4 Miscellanies

The optimal bounds of $P2|decr\&sum|C_{max}$ and $P2|decr\&opt|C_{max}$ are both $\frac{10}{9}$ [65, 164]. Azar and Epstein [11] designed an algorithm for $Qm|decr\&opt|C_{min}$ with an overall competitive ratio 2, which is optimal in the overall sense.

By using the general framework included in [59], it can be proved that the overall optimal bound of $Qm|pmtn, decr\&sum|C_{max}$ is $\frac{12}{11}$ when $m = 3$ and $\frac{10}{9}$ when $m = 4$. For the problem $Pm|pmtn, decr\&buffer|C_{max}$, Dósa and Epstein [51] proved that a buffer of size $m-1$ is enough for an online algorithm to produce the optimal schedule, and the optimal bounds for any buffer size $K < m-1$ is $\max_{0 \leq \mu \leq m-K-1} \frac{2m(m+\mu)}{2m^2+2K\mu+\mu^2+\mu}$.

Dósa and He [53] studied two problems $P2|sum\&buffer|C_{max}$ and $P2|sum\¶llel(2)|C_{max}$. They designed two optimal algorithms with competitive ratio $\frac{5}{4}$ and $\frac{6}{5}$, respectively. Min et al. [132] studied the problem $P2|sum\&reassignFE|C_{max}$ and proposed an optimal algorithm with competitive ratio $\frac{5}{4}$.

3.5 Results on Disturbed Semi-online Models

In regard to disturbed semi-online model, there are fewer variants brought forward and results achieved. Study on problems with inexact partial information is much more difficult than the problem with exact partial information. One reason is that it is expected to find the upper and lower bound as functions of disturbance parameter α . If preemption is not allowed, only problems on two identical machines have been studied [165]. Related results are summarized in [Table 9](#), and the detailed bounds are omitted here. If preemption is allowed, some research approaches and techniques of previous variants can be generalized to m identical machines or two uniform machines [106]. These results are summarized in [Table 10](#). By using the general framework included in [59], even the optimal bound of $Q3|pmtn, \text{inexact sum}|C_{max}$ for any α and any values of s_i , $i = 1, 2, 3$ can be obtained. However, the known algorithms for the non-preemptive problem are not optimal for all values of α , and also there is no study on the problems of $Pm|pmtn, \text{inexact max}|C_{max}$, $Pm|pmtn, \text{inexact sum}|C_{max}$, $Q2|pmtn, \text{inexact sum}|C_{max}$.

4 Online Over Time

Scheduling jobs that arrive over time is usually called online over time model. A number of researches are done with respect to the minimization problems for the three following classical objective functions: the makespan C_{max} , the total completion time $\sum_{j=1}^n C_j$, and the total weighted completion time $\sum_{j=1}^n w_j C_j$. For these objective functions, and some special cases, deterministic and randomized online algorithms are analyzed deriving different approximation guarantees. Results on online over time model are summarized in [Table 11](#).

4.1 Single Machine Scheduling

4.1.1 Minimize the Total Completion Time

Problems of minimizing the total completion time on a single machine are extensively studied. Phillips et al. [142] presented a 2-competitive algorithm based on the optimal preemptive schedule, which can be found by the *SRPT* (Shortest Remaining Processing Time first) rule in polynomial time [148]. There is another 2-competitive algorithm, namely, delayed SPT ($D - SPT$), provided by Hoogeveen and Vestjens [100].

Algorithm D-SPT

At any time t a machine is idle and a job is available, choose a job with shortest processing time, say J_i . If there are more than one job with the same processing

Table 11 The best known results on over time model

Problem	Jobs	Lower bound	Upper bound	Randomized lower bound	Randomized upper bound
$1 r_j \sum C_j$	None	2	[100]	2	[100, 127, 142]
pmtn	1	[148]	1	[148]	1

$Q2 r_j \sum w_j C_j$	pmtn	1	2	2	[122]

^aThe semi-online problems that release times of all jobs are known in advance

time, choose the one with the smallest release time. If $p_i \leq t$, then process J_i ; otherwise, wait until time p_i or until a new job arrives, whichever happens first.

A very important idea in $D - SPT$ algorithm is to shift the release time of jobs before scheduling, which was adopted by Stougie as well (cited in [176]). Lu et al. [127] generalized this idea and proposed a class of online algorithms that have the same competitive ratio of 2. Note that for this problem, it is shown by Hoogeveen and Vestjens [100] that any online algorithm must have a competitive ratio no smaller than 2, and hence, all above algorithms are best possible.

In online over time problems, it is commonly interesting to know whether or how much the competitive ratio would decrease if restarts are allowed. Vestjens [176] first showed a lower bound for the competitive ratio of any online algorithm. Later, Epstein and van Stee [69] improved the bound from 1.112 to 1.2108. The algorithm provided by van Stee and Poutré [175] indicates that the upper bound of the problem allowing restarts is at most $\frac{3}{2}$.

In contrast with online over list, only a few researches are found involving in semi-online variants, even though there are actually more semi-online models than those in online over list model. Tao et al. [170] investigated the problem with the knowledge of the upper and lower bounds of the processing times, $UB \& LB$. A semi-online algorithm with competitive ratio $\frac{\sqrt{1+\beta(\beta-1)}+\beta-1}{\beta}$, as well as a lower bound

$$\Phi = \min_{s \geq 0} \max \left\{ 1 + s, \max_{k \in \mathbb{Z}^+} \left\{ 1 + \frac{2k(\beta - 1)}{2\beta(k + 1)s + 2\beta + k^2 + 3k} \right\} \right\},$$

is proposed, where $\beta = \frac{UB}{LB} \geq 1$.

4.1.2 Minimize the Total Weighted Completion Time

Indeed, the weighted problem is more general and hence more difficult. Anderson and Potts [5] considered the delayed weighted shortest processing time rule ($D - WSPT$), which is a direct generalization of the $D - SPT$ algorithm. By introducing a new proof technique, they showed that $D - WSPT$ has a competitive ratio of 2 and therefore matches the known lower bound [100]. If restarts are allowed, the lower and upper bounds of this problem are 1.2232 and 2, respectively [5, 69].

If preemption is allowed, unlike the unweighted version, Vestjens [176] showed that any preemptive algorithm must have a competitive ratio no smaller than 1.0333. The lower bound is later improved to 1.0730 by Epstein and van Stee [69]. Several algorithms are proved to be 2-competitive, including $D - WSPT$, $P - WSPT$, and $WSRPT$ [130, 146]. Here, $P - WSPT$ (preemptive $WSPT$) schedules at any time the job with the largest ratio of weight over processing time, while $WSRPT$ (weighted shortest remaining processing time first) schedules at any time the job with the largest ratio of weight over remaining processing time. The instance given by Xiong and Chung [184] recently showed that the competitive ratio of

WSRPT cannot be smaller than 1.215. Though there is a big gap between the lower and upper bounds, developing an online algorithm with a competitive ratio better than 2 is a hard work. Breakthrough on this problem is finally made by Sitters [158]. By using a parameter $c \geq 1$ and applying the $P - WSPT$ rule with a restriction that a job cannot be preempted at time t if it can be completed before time ct , a class of online algorithms, namely, $ONLINE(c)$, are obtained and shown to be c -competitive for any $c \geq \xi$, where $\xi \approx 1.57$ is the real root of $2\xi^3 - 4\xi^2 + 2\xi - 1 = 0$. Hence, there exists a ξ -competitive algorithm for the preemptive problem.

If the release times of all jobs are known in advance, Hall et al. [89] showed that the problem has a lower bound of

$$\Psi = \max_{1 \leq j \leq n} \min_{0 \leq l \leq j-1} \frac{r_{l+1} + r_l + \sqrt{(r_{l+1} - r_l)^2 + 4r_j r_{l+1}}}{2r_{l+1}}$$

where $r_1 \leq r_2 \dots \leq r_n$ are the release times of all jobs. It can be proved that Ψ is in between $\frac{\sqrt{5}+1}{2}$ and 2. An online algorithm with matched competitive ratio is provided as well. Clearly, this variant will never be classified into online over list model. The semi-online problem *UB&LB* is considered by Tao et al. [171], where they presented an optimal algorithm with competitive ratio $1 + \frac{\sqrt{4\beta^2+1}-1}{2\beta}$.

4.1.3 Randomized Algorithm and Lower Bound

Chekuri et al. [29] designed a randomized algorithm to minimize the total completion time with competitive ratio $\frac{e}{e-1}$. Their algorithm is intriguing as it beats the lower bound 2 for deterministic online algorithms [100]. Moreover, it is also optimal since its competitive ratio matches the randomized lower bound given by Stougie and Vestjens [162]. If restarts are permitted, Epstein and van Stee [69] proved that any randomized algorithm must have a competitive ratio at least 1.1068. In the same paper, they also considered problems aiming at minimizing the total weighted completion time, where a lower bound 1.0389 and a lower bound 1.1161 for the preemptive problem and the problem allowing restarts are proposed, respectively. Regarding the upper bounds, Schulz and Skutella [149] provided a $\frac{4}{3}$ -competitive randomized algorithm for the preemptive problem. Goemans et al. [83] presented a randomized algorithm with competitive ratio 1.6853 for the problem allowing restarts.

4.2 Results on Parallel Machine Scheduling

4.2.1 Minimize the Makespan

For the makespan minimization problems, it should be emphasized that Shmoys et al. [157] have described a general method to use offline algorithms to obtain online algorithms for problems of online over time model. However, the method

always produces a competitive ratio at least 2, even if the corresponding offline problem can be solved to optimality. In the same paper [157], Shmoys et al. proved a lower bound of $\frac{10}{9}$ for the problem on m identical machines. Chen and Vestjens [30] improved the lower bound to $1 + \alpha$ for $m \geq 3$ and to $\frac{5-\sqrt{5}}{2}$ for $m = 2$, where $\alpha \approx 0.3473$ is the solution of $\alpha^3 - 3\alpha + 1 = 0$. Moreover, they proposed a simple algorithm, namely, online Longest Processing Time first (online *LPT*).

Algorithm Online *LPT*

At any time a machine becomes idle for processing, schedule an available job with the longest processing time.

The competitive ratio of online *LPT* is shown to be $\frac{3}{2}$. As far as we know, this is the best result on this problem except that in [138], where Noga and Seiden presented an improved algorithm *SLEEP* for $m = 2$. The difference between *SLEEP* and online *LPT* is that it might wait for some time even when there is an idle machine and an available job. The idea makes the algorithm optimal for $m = 2$ and, hence, beat online *LPT*. For further study, one may ask how to extend the algorithm and whether it can beat online *LPT* for a general number of machines. Nevertheless, there are still no such study by now. The randomized lower bounds on makespan minimization problem are studied in [162] and [138], where a lower bound of $4 - 2\sqrt{2}$ for a general number of machines and a lower bound of 1.21207 for $m = 2$ are provided, respectively.

4.2.2 Minimize the Total (Weighted) Completion Time

For the problem of minimizing the total completion time, any deterministic algorithm is at least $\frac{21}{19} \approx 1.105$ -competitive for the preemptive version and is at least 1.309-competitive for the non-preemptive version [176, 184]. Moreover, any randomized algorithm is at least 1.047-competitive for the preemptive version and is at least 1.157-competitive for the non-preemptive version [176].

The simple and well-known *SRPT* algorithm plays a significant rule in preemptive scheduling of minimizing the total completion time. As we have seen before, it produces an optimal schedule for the single machine case [148]. The upper bound of *SRPT* for m identical machines was known to be 2 [142] for a long time until recently, Chung et al. [45] claimed that it is at most 1.86. Shortly after that, Sitters [159] improved it to $\frac{5}{4}$.

For the preemptive problem of minimizing the total weighted completion time, 2-competitive online algorithm is found in [131]. The lower bound of the problem is proved to be $\frac{16-\sqrt{14}}{11} \approx 1.114$ [184]. For the non-preemptive version, a randomized algorithm with competitive ratio 2 as well as a deterministic algorithm with competitive ratio 2.62 are obtained by Schulz and Skutellathe [150] and Correa and Wagner [46], respectively. The best known result for this objective is due to Sitters [159], who gave a deterministic algorithm with competitive ratio of $1.791 + o(m)$ for both versions. Even applying the algorithm to unweighted problem, the competitive ratio remains the same, and the algorithm beats the previously best one with competitive ratio 2 [121]. If the number of

machines is small, randomized algorithms with smaller competitive ratios are found in [46].

With respect to machines with different speeds, Liu and Lu [122] studied the two machine case. They presented a $\frac{\sqrt{5}+3}{2}$ -competitive algorithm for the non-preemptive problem of minimizing the total completion time. If preemption is allowed, they gave an algorithm with competitive ratio of 2 to minimize the total weighted completion time. The non-preemptive algorithm in [122] for two uniform machines was extended to m uniform machines by Liu et al. [124], who established a competitive ratio of $\frac{\sqrt{4m-3}+3}{2}$.

5 Other Variants of Online Scheduling

5.1 Online Shop Scheduling

Researches on online shop scheduling are mainly focused on two or three machines. Chen and Woeginger [34] considered the two-machine open shop scheduling of online over list model. A 1.875-competitive algorithm, as well as a lower bound $\frac{1+\sqrt{5}}{2} \approx 1.618$, was given. By restricting to *permutation algorithms* that always produce schedules with the same job sequence on both machines, the upper and lower bound can be further improved to 1.848 and $\frac{23-2\sqrt{13}}{9} \approx 1.754$ [37], respectively. If preemption is allowed, Chen and Woeginger [34] presented a $\frac{4}{3}$ -competitive algorithm for two machines, and a $\frac{27}{19}$ -competitive algorithm for three machines was provided by Chen et al. [37]. Since the lower bound Γ_m of $Pm|pmtn|C_{max}$ is also a lower bound of $Om|pmtn|C_{max}$ [155], both algorithms are optimal. For two-machine flow shop and job shop problems, optimal algorithms were proven to have a competitive ratio of 2 by Chen and Woeginger [34].

If jobs arrive over time, Chen et al. [35] considered the two-machine open shop scheduling and proved that greedy-like algorithm has a competitive ratio $\frac{3}{2}$ and is optimal for non-preemptive version. Another algorithm, namely, SLICE, was shown to have a competitive ratio of $\frac{5}{4}$ and best possible for preemptive version. Liu et al. [125] further extended SLICE to the semi-online problem *UB & LB*. They proved the corresponding algorithm is $\frac{5\beta-1}{4\beta}$ -competitive and matches the lower bound of the considered problem with $\beta = \frac{UB}{LB}$. Stougie and Vestjens [162] proved that 1.25 is a randomized lower bound of $O2|r_j|C_{max}$.

Recently, Zhang and Velde [188, 189] investigated problems with time lags, where the time lag of a job is defined as the maximum allowable delay between the completion time of the first and the start time of the second operation of the job. For these problems, it might benefit from allowing a machine to be idle while an operation is available for assignment. Such algorithms are called delay algorithms. The greedy-like algorithm has a competitive ratio 2 for two-machine open shop, job shop, and flow shop problems [188, 189]. However, the lower bound of delay algorithms is only proved to be $\sqrt{2}$ for open shop [189] and $\frac{1+\sqrt{5}}{2}$ for job shop or

flow shop [188]. It is hopeful that a delay algorithm might beat the greedy algorithm in this model. Nevertheless, it is still an open question so far.

5.2 Batch Scheduling

In this problem, jobs arrive over time and can be processed together by a batch processing machine which can handle up to B jobs simultaneously. All jobs in a batch start and complete at the same time. The processing time of a batch is given by the longest processing time of any job in the batch. There are two models considered in the literature: the unbounded model where $B = \infty$ and the bounded model where B is bounded. For both models, problems of minimizing makespan on single or parallel identical machines are widely studied.

5.2.1 Unbounded and Bounded Model on a Single Machine

Suppose that there is a single batch processing machine, Deng et al. [48] and Zhang et al. [191] independently provided an optimal online algorithm (denoted as H^∞) with competitive ratio $\frac{\sqrt{5}+1}{2}$.

Algorithm H^∞

0. Set $t = 0$.
1. Let $U(t)$ be the set of all unscheduled jobs available at time t and J_k be the job with the longest processing time in $U(t)$, compute $\alpha_k = \frac{\sqrt{5}+1}{2}r_k + \frac{\sqrt{5}-1}{2}p_k$ and $s = \max\{t, \alpha_k\}$.
2. In the time interval $[t, s]$, whenever a new job J_h arrives (at time t') with $p_h > p_k$, then reset $k = h$ and reset α_k and s accordingly. Let $U(t') = U(t) \cup \{J_h\}$. Reset $t = t'$.
3. At time s , schedule all jobs in $U(s)$ as a single batch. If some new jobs arrives by $s + p_k$, let $t = s + p_k$; otherwise, wait until a new job arrives and let t be the arrival time of such a job. Go to Step 1.

In fact, the lower bound $\frac{\sqrt{5}+1}{2}$ even holds when $B = 2$, and all jobs have only two distinct arrival times [191]. It seems much more challenging to derive optimal algorithms for the bounded model. When all jobs have exactly two distinct arrival time, Zhang et al. [191] gave an optimal one with competitive ratio $\frac{\sqrt{5}+1}{2}$. When jobs have arbitrary arrival times, Poon and Yu [145] obtained a $\frac{7}{4}$ -competitive algorithm for $B = 2$. For the general B , we note there exist several 2-competitive algorithms. The first one is the greedy-like algorithm GRLPT, which was proposed by Lee and Uzsoy [113], and was shown to be 2-competitive by Liu and Yu [123]. Another two are due to Zhang et al. [191], which can be seen as a generalization of H^∞ . Finally, Poon and Yu [145] claimed all the FBLPT-based (full-batch longest processing time) algorithms, including the above three, can achieve the same competitive ratio of 2.

5.2.2 Unbounded and Bounded Model on Identical Machines

For batch scheduling on m parallel identical machines, researches are mostly focused on the unbounded model. Zhang et al. [191] gave a lower bound $\sqrt[m+2]{2}$ and

an online algorithm $PH(\beta_m)$ with a competitive ratio $1 + \beta_m$, where $0 < \beta_m < 1$ is a solution to the equation $\beta_m = (1 - \beta_m)^{m-1}$. In the same paper, the dense algorithms, which always immediately assign the currently available job to one idle machine as long as there are two or more idle machines, are proposed. Zhang et al. proved that the competitive ratio of any dense algorithm is no smaller than $\sqrt{2}$ and there exists one dense algorithm with competitive ratio $\frac{\sqrt{5}+1}{2}$. In a later paper [192], Zhang et al. gave an optimal algorithm with competitive ratio $1 + \xi_m$ for the special case that all jobs have unit processing time, where ξ_m is the positive solution of the equation $(1 + \xi_m)^{m+1} = \xi_m + 2$.

When jobs have arbitrary processing times, the optimal algorithm for two-machine case has a competitive ratio of $\sqrt{2}$ [139, 173]. The optimal algorithm for the general case is due to Liu et al. [126] and Tian et al. [172] independently, who both proved the competitive ratio to be $1 + \frac{\sqrt{m^2+4-m}}{2}$. In addition, Tian et al. [172] provided a dense algorithm with competitive ratio $\frac{3}{2}$ and showed it is best possible.

For the bounded model, Zhang et al. [192] observed that the optimal algorithm is $\frac{\sqrt{5}+1}{2}$ -competitive if all jobs have equal processing times. Apart from this, neither algorithm results nor lower bounds are found in the literature.

5.2.3 Other Variants

There are some other discussions with respect to the online batch scheduling problems. One interesting variant is allowing to restart a batch, which means a running batch may be interrupted, losing all the work done on it, and the jobs in the interrupted batch are released and become independently unscheduled. Allowing restarts reduces the impact of a wrong decision. For the unbounded model on single machine, Fu et al. [78] showed the competitive ratio of any online algorithm is no less than $\frac{5-\sqrt{5}}{2}$ and gave a $\frac{3}{2}$ -competitive algorithm. Shortly after that, Yuan et al. [185] gave a $\frac{5-\sqrt{5}}{2}$ -competitive algorithm for the problem, and thus it is optimal. Fu et al. [79] studied the same problem with an additional assumption that any job cannot be restarted twice. Optimal algorithm with competitive ratio $\frac{3}{2}$ is obtained. In another paper [81], Fu et al. extended the result to identical machines, where a lower bound of 1.298, as well as a $\frac{1+\sqrt{3}}{2}$ -competitive online algorithm, was given.

Nong et al. [140] introduced *job families* to the batch scheduling problem, which means jobs from different families cannot be processed in the same batch. Online algorithms with competitive ratio 2 are presented for both bounded and unbounded models on single machine. Besides, they showed that the algorithm is best possible for the unbounded model in the sense that jobs consist of an infinite number of families. For the bounded model, there is no online algorithm with competitive ratio smaller than $\max\{\frac{2B}{B+1}, \frac{1+\sqrt{5}}{2}\}$. Fu et al. [80] revisited the unbounded model and gave a best possible algorithm with competitive ratio $\frac{\sqrt{17}+3}{4}$ for the special case of two families of jobs.

Yuan et al. [186] and Li et al. [119] studied a lookahead semi-online model. Yuan et al. [186] considered the unbounded problem on a single batch machine.

With the information of the next longest job at any time t , they presented a best possible online algorithm with competitive ratio $\frac{5-\sqrt{5}}{2}$. If jobs are of unit length and an online algorithm can foresee all the jobs that will arrive in the time segment $(t, t + \beta]$ at any time t , Li et al. [119] presented a best possible online algorithm for the unbounded problem on m parallel-batch machines.

Chen et al. [38] considered a batch scheduling problem on single machine to minimize the total weighted completion times of jobs. They developed a linear time online algorithm with competitive ratio of $\frac{10}{3}$ for the unbounded model and an efficient algorithm with competitive ratio $4 + \epsilon$ for any $\epsilon > 0$ for the bounded model. Also, they observed that there exists a 2.89-competitive and a $(2.89 + \epsilon)$ -competitive randomized algorithm for unbounded and bounded models, respectively.

5.3 Online Scheduling with Machine Eligibility

Online scheduling with machine eligibility constraints has received much attention in recent years. Unlike the classical parallel machine scheduling, job J_j cannot be processed on any one among the machine set \mathcal{M} in this model. Instead, it has a specific set $\mathcal{M}_j \subseteq \mathcal{M}$ that can be assigned to. Set \mathcal{M}_j is so-called the *eligible processing set* of job J_j . Depending on the structure of \mathcal{M}_j , $j = 1, \dots, n$, there are five classes of eligibility constraints that have been studied extensively [116]:

1. Arbitrary eligible processing sets
2. Tree-hierarchical processing sets
3. Grade of Service (GoS) processing sets
4. Interval processing sets
5. Nested processing sets.

With tree-hierarchical processing sets, each machine is represented by a node, and the nodes are connected in the form of a rooted tree. Any job assignable to a node is also assignable to the node's ancestors in the tree. The GoS processing set structure can be seen as a special case of the tree-hierarchical processing set structure where the rooted tree actually forms a chain. Problems with a GoS processing set are also called *online hierarchical scheduling* in the literature. With regard to interval processing sets, job J_j is associated with two integers a_j and $b_j \geq a_j$ such that $\mathcal{M}_j = \{M_{a_j}, M_{a_j+1}, \dots, M_{b_j}\}$. A special case of interval processing set structure is a nested processing set structure, where, for any pair of jobs J_j and J_k , we either have $\mathcal{M}_j \subseteq \mathcal{M}_k$ or $\mathcal{M}_k \subseteq \mathcal{M}_j$ or $\mathcal{M}_j \cap \mathcal{M}_k = \emptyset$. Clearly, the GoS processing set structure is also a special case of nested processing set structure.

Problems with one of the above classes of eligibility constraints will be denoted as “ \mathcal{M}_j ,” “ $\mathcal{M}_j(\text{tree})$,” “ $\mathcal{M}_j(\text{GoS})$,” “ $\mathcal{M}_j(\text{interval})$ ” and “ $\mathcal{M}_j(\text{nested})$ ” in the middle field of the three-field notation, respectively. It is clear that $P||C_{max}$ ($Q||C_{max}$) is a special case of $P|\mathcal{M}_j|C_{max}$ ($Q|\mathcal{M}_j|C_{max}$) with $\mathcal{M}_j = \mathcal{M}$ for all J_j , while $R|\mathcal{M}_j|C_{max}$ is a special case of $R||C_{max}$. However, in the rest of this subsection, we will mostly consider the identical machine environment, unless stated otherwise.

5.3.1 Online Over List

For arbitrary eligibility, Azar et al. [13] contributed the first result. They consider a greedy algorithm, namely, AW , as follows: When a job arrives the algorithm assigns it to an eligible machine that has the smallest current load among all eligible machines. The competitive ratio of AW is shown to be at most $\lceil \log_2 m \rceil + 1$, and the lower bound is proved to be at least $\lceil \log_2(m + 1) \rceil$. Hwang et al. [102] improved the analysis of AW and obtained a slightly smaller competitive ratio of $\log_2 m + 1$. The best known upper and lower bounds for this problem are found by Lim et al. [120] recently. They showed that AW has a competitive ratio no greater than $EU_m = \lfloor \log_2 m \rfloor + \frac{m}{2^{\lfloor \log_2 m \rfloor}}$, and the lower bound of the problem is EL_m , where $EL_1 = 1$ and

$$EL_m = EL_{\theta_m} + \frac{1}{\lfloor \frac{\theta_m}{m-\theta_m} \rfloor}, \theta_m = \operatorname{argmax}_{\lfloor \frac{m}{2} \rfloor \leq i \leq m-1} \left\{ EL_i + \frac{1}{\lfloor \frac{i}{m-i} \rfloor} \right\}.$$

The gap between the two bounds does not exceed 0.1967 and AW is optimal when the number of machines can be written as a sum of two powers of 2. Lee et al. [114] proved the optimal bound of $Q2|\mathcal{M}_j|C_{max}$ is $1 + \min\{s, \frac{1}{s}\}$. Note that for $Q2|\mathcal{M}_j|C_{max}$, the index of M_1 and M_2 cannot be reordered, and thus the speed ratio s can be an arbitrary positive number.

Bar-Noy et al. [16] analyzed online scheduling problem subject to tree-hierarchical eligibility. A 5-competitive online algorithm is proposed. Furthermore, if jobs are of unit size, then the competitive ratio can be improved to 4. Randomized algorithms are also proposed, where the competitive ratios are shown to be $e + 1$ and e , respectively. A lower bound of $1 + \frac{1}{2} \lceil \log_2 m \rceil$ for $Pm|\mathcal{M}_j(\text{nested})|C_{max}$ was given in [120].

There is a large number of researches discussing problems with a GoS eligibility, since it is very natural and has application in the service industry [103]. In [16], Bar-Noy et al. gave an algorithm with competitive ratio $e + 1$ for the general problem $P|\mathcal{M}_j(\text{GoS})|C_{max}$ and showed that it is e -competitive if either jobs have unit size or can be fractionally processed. Moreover, they proved a lower bound of e for the fractional assignment case. However, the lower bound is valid only in the case when the number of machines tends to infinity. If the number of machines is fixed, Tan and Zhang [169] proposed an improved algorithm with competitive ratio GU_m and lower bound GL_m for the fractional assignment case; both are based on the solutions of mathematical programming. The algorithm can be modified to solve the general problem $Pm|\mathcal{M}_j(\text{GoS})|C_{max}$ by using the same technique included in [16]. When the number of machines is small, algorithms for the general problem can be further improved. For $m = 5$ and 4, Tan and Zhang [169] proposed two algorithms with competitive ratios of 2.610 and $\frac{7}{3}$, respectively. Lim et al. [120] improved the two results to 2.501 and 2.294. For $m = 3$, Zhang et al. [193] showed that there exists an optimal algorithm with competitive ratio 2. For $m = 2$, Park et al. [141] and Jiang et al. [109] independently proposed an optimal algorithm with competitive ratio $\frac{5}{3}$. If machines have different speeds, the optimal

bound

$$h_1(s) = \begin{cases} \min\{1 + s, \frac{2+2s+s^2}{1+s+s^2}\}, & 0 < s \leq 1, \\ \min\{\frac{1+s}{s}, \frac{1+3s+s^2}{1+s+s^2}\}, & 1 \leq s < \infty, \end{cases}$$

of $Q2|\mathcal{M}_j(GoS)|C_{max}$ was given by Tan and Zhang [169] (Fig. 8).

If preemption is allowed, Jiang et al. [109] designed a $\frac{3}{2}$ -competitive algorithm for the problem $P2|\mathcal{M}_j(GoS), pmtn|C_{max}$ and showed that it is optimal if idle time is not allowed. For general m , Dósa and Epstein [50] proved that $\frac{2m}{m+1}$ is a lower bound even if idle time is allowed. An algorithm for three machines with matched competitive ratio was also given. In the same paper, they also studied the problem $Q2|\mathcal{M}_j(GoS), pmtn|C_{max}$. An online algorithm with competitive ratio

$$h_2(s) = \max \left\{ \frac{(1+s)^2}{1+s+s^2}, \frac{s(1+s)^2}{1+s^2+s^3} \right\}$$

is proposed and is shown to be optimal. Both algorithms need to introduce idle time. For $Q2|\mathcal{M}_j(GoS), \text{frac}|C_{max}$, Chassid and Epstein [28] designed an optimal algorithm with competitive ratio $\frac{(1+s)^2}{1+s+s^2}$ (Fig. 8).

For semi-online scheduling, Park et al. [141] studied the problem on two machines with the knowledge of the total processing time of jobs, where an optimal algorithm with competitive ratio $\frac{3}{2}$ is presented. Wu et al. [183] considered two semi-online problems on two machines. The first one is known the optimal makespan, for which they showed an optimal algorithm with competitive ratio $\frac{3}{2}$. The second is known the maximum processing time, for which an algorithm with competitive ratio $\frac{\sqrt{5}+1}{2}$, as well as a matched lower bound, is given. Liu et al. [125] considered the semi-online problem on two machines where upper and lower bounds on the processing time of jobs are known in advance. An online algorithm, as well as a lower bound of the problem, was presented. Optimal bound of the problem

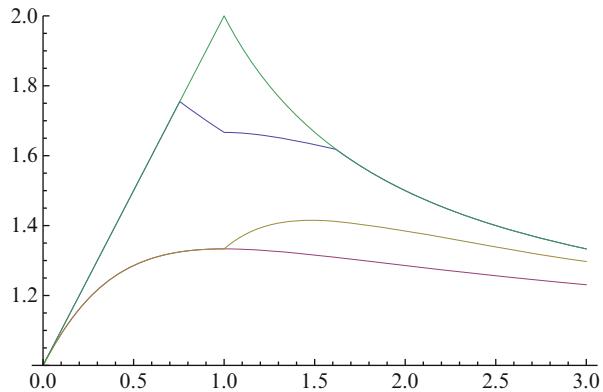

$$h_3(\beta) = \begin{cases} \frac{2\beta+1}{\beta+1}, & 1 \leq \beta < \frac{\sqrt{5}-1}{2}, \\ \frac{\sqrt{5}+1}{2}, & \frac{\sqrt{5}+1}{2} \leq \beta < \frac{3\sqrt{5}-1}{2}, \\ \frac{\beta+2}{\beta^3}, & \frac{3\sqrt{5}-1}{2} \leq \beta < 3, \\ \frac{5}{3}, & r \geq 3, \end{cases}$$

is given by Jiang and Zhang [107], where $\beta = \frac{UB}{LB}$ (Fig. 7).

There are several researches considering problems with two GoS levels (denoted as $2GoS$). In this problem, jobs that can be processed on first k machines are called high level and the other jobs which can run on all m machines are called low level. Jiang [104] first showed that the AW algorithm is at least $(4 - \frac{1}{m})$ -competitive and then provided an online algorithm with a competitive ratio of $\frac{12+4\sqrt{2}}{7} \approx 2.522$. Later, Zhang et al. [194] improved the result to $1 + \frac{m^2-m}{m^2-km+k^2} < \frac{7}{3}$.

For machine covering problems, Chassid and Epstein [28] proved that no algorithm can have a constant competitive ratio even for the most special

Fig. 8 The optimal bounds of $Q2|\mathcal{M}_j|C_{max}$, $Q2|\mathcal{M}_j(GoS)|C_{max}$, $Q2|\mathcal{M}_j(GoS), pmtn|C_{max}$, and $Q2|\mathcal{M}_j(GoS)$, $frac|C_{max}$ (from top to bottom)

problem $Q2|\mathcal{M}_j(GoS)|C_{min}$. For problems $Q2|\mathcal{M}_j(GoS)$, $frac|C_{min}$ and $Q2|\mathcal{M}_j(GoS)$, $sum|C_{min}$, they gave optimal bounds of $\frac{2s+1}{s+1}$ and $\max\{1, s\} + \frac{1}{s}$, respectively. Main results on online over list scheduling with machine eligibility are summarized in Tables 12–14.

5.3.2 Online Over Time

In contrast with problems of online over list, there are very few results concerning problems of online over time. Lee et al. [115, 116] considered the problems allowing restart or preemption of jobs. Various lower bounds, as well as a full study on two machines, are given. They also observed that the general method introduced by Shmoys et al. [157] that uses offline algorithms to obtain online algorithms for problems with job release times can work for scheduling with machine eligibility as well [116], although it produces algorithms with competitive ratio at least 2. All related results are summarized in Table 15.

Wang et al. [178] introduced another interesting problem with respect to scheduling with GoS eligibility, which is so-called *online service scheduling*. The problem arises from the service industry where customers (jobs) are classified as either “ordinary” or “special.” Ordinary customers can be served on any service facility (machines), while special customers can be served only on a flexible service facility. The difference between their model and the problem with two GoS levels is that customers arrive over time and the order of the assignment should be consistent with the order of arrival time of jobs in the same class. For several service policies used in practice, Wang et al. [178] and Wang and Xing [177] analyzed and compared their performance in the sense of competitive ratios.

6 Conclusion

This chapter surveyed different paradigms of online scheduling, including online over list and online over time, and gave a relatively complete picture to the semi-online scheduling problem. Most of detailed algorithms and proofs are not given in

Table 12 Results of online over list scheduling with machine eligibility on two identical and uniform machines

Problems	Optimal bounds	Problems	Optimal bounds
$P2 \mathcal{M}_j C_{max}$	2 [13]	$Q2 \mathcal{M}_j C_{max}$	$1 + \min\{s, \frac{1}{s}\}$ [114]

Abstract

In wireless networks, we need to allocate spectrum efficiently. One challenge is that the spectrum usage requests often come in an online fashion. The second challenge is that the secondary users in a cognitive radio network are often selfish and prefer to maximize their own benefits. In this chapter, we review results in the literature that address these two challenges, namely, (1) *TOFU*, semi-truthful online frequency allocation method for wireless networks when primary users can sublease the spectrums to secondary users, and (2) *SALSA*, an online truthful mechanism when the distributions of user arrivals are known.

In *TOFU* protocol [36], secondary users are required to submit the spectrum bid α time slots before its usage. Upon receiving an online spectrum request, the protocol will decide whether to grant its exclusive usage or not, within at least γ time slots of requests' arrival. It is assumed that existing spectrum usage can be preempted with some compensation. For various possible known information, authors in [36] analytically proved that the competitive ratios of their methods are within small constant factors of the optimum online method. Furthermore, in their mechanisms, no selfish users will gain benefits by bidding lower than its willing payment. The extensive simulation results show that they perform almost optimum: their methods get a total profit that is more than 95 % of the offline optimum when γ is about the duration of spectrum usage Δ .

In [39], Xu, Wang, and Li proposed *SALSA*, strategyproof online spectrum admission for wireless networks. They assume that the requests arrival follows the Poisson distribution. Preempting existing spectrum usage is *not* allowed. They proposed two protocols that have guaranteed performances for two different scenarios: (1) *random-arrival case*: the bid values and requested time durations follow some distributions that can be learned, or (2) *semi-arbitrary-arrival case*: the bid values could be arbitrary, but the request arrival sequence is random. They analytically proved that their protocols are strategyproof and are both approximately social efficient and revenue efficient. Their extensive simulation results show that they perform almost optimum. Their method for semi-arbitrary-arrival model achieves social efficiency and revenue efficiency almost 20–30 % of the optimum, while it has been proven that no mechanism can achieve social efficiency ratio better than $1/e \simeq 37\%$. Their protocol for the random-arrival case even achieves social efficiency and revenue efficiency 2–6 times the expected performances by the celebrated VCG mechanism.

1 Introduction

The current fixed spectrum allocation scheme leads to significant spectrum *white spaces*. Several new spectrum management models [28] have been proposed to improve the spectrum usage. One promising technology is the opportunistic spectrum usage. Subleasing is widely regarded as another potential way to share

spectrum, if we ensure that primary users' spectrum usage is not interfered with. Assume that there is a set of n secondary nodes V that will share a spectrum channel. Each secondary user v_i may wish to pay (by leasing) for the usage of the available spectrum.

Previous studies on spectrum assignment (e.g., [25, 38, 42, 43]) often assume that the information of all spectrum requests is known before allocation is made. However, the spectrum usage requests often arrive online and the central authority (typically a primary user) needs to *quickly* decide whether the requests are granted or not. Here, assume that upon receiving an online spectrum request, the protocol needs to decide whether to grant its exclusive usage or not, within at least γ time slots. The rejection typically could not be revoked. Two different approaches of granting the request could be used: *preemptive* and *non-preemptive*. If the requests are non-preemptive, then the central authority could not stop the current running request(s) to satisfy this new request. In the first part of the chapter (Sect. 3), we review the results with preemptive requests where the central authority could potentially terminate the current running request(s) to satisfy this new request to potentially make more profits. Assume that requests terminated cannot be restarted or resumed later (so it is also called “abortion”). Terminating a running request e_i , the central authority has to pay a penalty that is $\beta > 0$ times of the amount paid for the remaining unserved time slots. In the second part of the chapter (Sect. 4), we assume that the central authority could not preempt existing requests to satisfy new requests.

Without any known constraint on requests, it was shown in [35–37] that the competitive ratio of *any* online spectrum allocation method can be arbitrarily bad when preemption is not allowed. This is because any online method has to accept the first coming request (it is possible that no other requests come), therefore miss the following conflicting requests with an arbitrarily large value. In the first part of this chapter, we review the results in [36] on the case when the maximum time requirement is Δ time slots. Always assume that every request arrives at the beginning of a time slot and the number of time slots requested is an integer $t \in [1, \Delta]$. To the best of our knowledge, [35–37] are the first to study online spectrum allocation with cancelation and preemption penalty.

Assume that a sequence of spectrum requests arrives online: the i th request e_i arrives at time a_i , requesting the usage of the spectrum channel for a duration t_i (starting at time s_i), with a bid b_i . The central authority needs to design an online method which, upon receiving the i th bidding request, decides before time $s_i - \alpha + \gamma$ whether the request will be granted or not, and if it is granted, how much will be charged. Here, γ is called *delay factor*. If allowed, terminating a running request e_i , the central authority has to pay some penalty, denoted as $\mu(b_i, \ell_i, t_i) = \beta \frac{\ell_i}{t_i} b_i$, to the user who initiated the request e_i , where $\beta \geq 0$ is a constant. In other words, the penalty is proportional to the amount $\frac{\ell_i}{t_i} b_i$ paid by the requestor for the service of remaining ℓ_i unserved time slots.

The main contributions of the protocol *TOFU* by Xu and Li [36] are as follows. They design several efficient online spectrum allocation methods, called *TOFU*, that

perform almost optimum in all cases. When $0 \leq \beta < 1$, their protocol has a constant competitive ratio depending on β . When $\beta > 1$, they show that the competitive ratio of any online method is at most $O(\frac{\gamma+1}{\Delta})$. They then show that their protocol TOFU achieves the bound $\Omega(\frac{\gamma+1}{\Delta})$. When $\beta = 1$, they show that the competitive ratio of any online algorithm is at most $O((\frac{\gamma+1}{\Delta})^{1/2})$. They then show that their online method TOFU has competitive ratios that match the bounds asymptotically, i.e., $\Theta((\frac{\gamma+1}{\Delta})^{1/2})$. Their extensive simulations show that their methods have competitive ratios almost 95 % in most cases, even compared with the optimum offline spectrum allocation method that knows all future inputs. They also extend their protocol to a more general case in which the secondary users are distributed arbitrarily and the required service regions are heterogeneous disks. They show that the same asymptotic lower bounds and upper bounds apply to this general model.

They also design efficient auction mechanism for spectrum allocation when secondary users are selfish. In such a mechanism, each user will be charged an amount, say \mathbf{p}_i , if its request \mathbf{e}_i is granted. They show that in their online mechanism, to maximize its profit, no secondary user will bid lower than its actual valuation. However, a user may have a chance to improve its profit by bidding higher than its actual valuation. They call this property as *semi-truthful*. Recall that a protocol is called *truthful* in the literature if no user can lie about its bid to improve its profit. Their methods still achieve similar results when the requested region of each user is a sectoral cell.

The main contributions of the *SALSA* protocol [39] are as follows. For both requests arrival models, they designed an admission and charging protocol, called *SALSA* (for strategyproof online spectrum admission), such that the expected social efficiency and revenue are within small constant factors of that of the optimum *offline* method in which all information is known in advance. They also proved that their protocol is strategyproof, which implies that any secondary user cannot improve its profit by lying on his request (bid value and time requirement). They also extended their results to a more general model in which secondary users are distributed in a domain arbitrarily and the conflict graph formed by secondary users is growth-bounded. They showed that their results still hold for this general model.

Their extensive simulations show that their methods perform almost optimum, even compared with the optimum *offline* methods that know all bids in advance. For example, for semi-arbitrary-arrival model, their protocol gets a total profit that is almost 20–30 % of the optimum, while it has been proven in [7] that no mechanism can achieve social efficiency ratio better than $1/e$ in the worst case. The spectrum utilization is also around 20–40 % for this model. For the random-arrival model, their protocol achieves social efficiency and revenue efficiency that is 2–6 times of that by the celebrated VCG mechanism. The spectrum efficiency is around 90 % even for slightly loaded systems.

The rest of the chapter is organized as follows. In Sect. 2, we define in detail the problems to be studied.

Section 3 reviews the *TOFU* protocol when the central authority only knows the time ratio Δ . Specifically, in Sect. 3.1, we review upper bounds on the competitive

ratios of any online allocation methods. Then, we review their solutions in Sect. 3.2 and their analytical proof on the performance bounds of their methods. Their methods for networks with general conflict graphs are discussed in Sect. 3.3. We review their mechanisms to deal with selfish users in Sect. 3.4. We summarize their simulation studies in Sect. 3.5.

Section 4 reviews the protocol SALSA when the central authority knows some distribution information about the future requests. Specifically, in Sect. 4.1, the SALSA protocol with semi-arbitrary-arrival is presented, and Sect. 4.2 presents the SALSA protocol for the case with random-arrival. Section 4.3 reviews the SALSA protocols to networks with growth-bounded conflict graphs. The simulation results are reported in Sect. 4.4.

The related work is reviewed in Sect. 5. We conclude the chapter in Sect. 6.

2 System Model, Problem Formulation

2.1 Network and System Models

Consider a wireless network consisting of some primary users $\mathcal{U} = \{u_1, u_2, \dots, u_p\}$ who hold the right of some spectrum channels for subleasing. There is a central authority who decides the spectrum assignment on behalf of these primary users. In other words, here assume that each primary user will trust the central authority and is satisfied with what he/she will get from the auction based on the mechanism designed. If each primary user has an asking price for its spectrums, we need to design mechanisms (such as double auction in which buyers enter competitive bidders and sellers enter competitive offers simultaneously) that also take into account the selfish behavior of primary users. Note that Wang et al. [31] proposed some truthful double-auction mechanisms with known distributions on bids. The wireless network also consists of some secondary users $\mathcal{V} = \{v_1, v_2, \dots, v_n\}$. Those secondary users may lease the spectrum usage in some region for a time period at any time. In this chapter, assume a simple scenario where there is only one channel available. It is interesting to design allocation and auction schemes when multiple channels are available and a secondary user may request for a number of channels at same time.

Secondary users may reside at different geometry locations. Here, assume that each request is associated with a disk region. Whether a secondary user's request of channels conflicts with the request of another secondary user depends on their locations, in addition to the required time period. This location-dependent conflict will be modeled by a conflict graph $H = (\mathcal{V}, E)$, where two nodes v_i and v_j form an edge (v_i, v_j) in H if and only if they cannot use same channel simultaneously. We will first study the networks with a complete conflict graph and then extend the methods to cases when requested disks are of arbitrary sizes. We will show that the methods have asymptotically optimum performance guarantees in both cases.

2.2 Problem Formulation

Assume that secondary users $\mathcal{V} = \{v_1, v_2, \dots, v_n\}$ will ask for spectrum usage on the fly. A user could ask for spectrum usage at different time slots. Let $\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_i, \dots$ be the sequence of all requests. Each request $\mathbf{e}_i = (v, b_i, a_i, s_i, t_i)$ is claimed by a secondary user v at time a_i , who bids b_i for the usage of the channel from time s_i to time $s_i + t_i$. Here, we omit the region requirement since this chapter will first address networks with complete conflict graph. For most discussions, we will omit the user v when it is clear from the context. In other words, $\mathbf{e}_i = (b_i, a_i, s_i, t_i)$ denotes the i th request. Obviously, $a_i \leq s_i$ for all requests, which means only spectrum usage in future can be requested. Assume time is slotted and time requirement t_i must be an integer. Assume that every user will ask for the spectrum usage for at most Δ time slots ($t_i \leq \Delta$ for all i). They call Δ the *time bound*.

Since the objective for spectrum auction/lease is to improve spectrum utilization and improve the revenue from the spectrum auction/lease, the central authority (i.e., spectrum auctioneer) can post a requirement that all requests must be submitted in advance of a certain time slots. In this chapter, assume that for every request \mathbf{e}_i , $s_i - a_i \geq \alpha$ for a value α given by the auctioneer. Hereafter, call α the *advance factor*. Each request is claimed at least α time slots before its required usage. Intuitively, a larger advance factor α will give more advantage to the central authority. Later, we will show that the asymptotic performances of the methods do not depend on α as long as $\alpha \geq \gamma$, the delay factor.

The advance factor puts some constraints on the secondary users on when they should submit their bids. To be fair, the system will also put some condition on the central authority about when the central authority should make a decision on each request. In this work, it is always required that the central authority should make a decision on a request within γ time slots of its arrival time. Call γ *delay factor* in the spectrum allocation problem. Obviously, they need $\gamma \leq \alpha$ to make the system meaningful. When $\gamma = 0$, central authority has to make decision *immediately* on request \mathbf{e}_i at time a_i . When $\gamma = \alpha$, central authority could make decision as late as possible. If a request has been rejected, it will never be reconsidered and accepted later. [Figure 1](#) illustrates the model of advance and delay factor. For each request, its arrival time a_i must be before time t_1 in the figure, and central authority must make a decision before time t_2 in the figure.

Since central authority is not able to estimate accurate price for spectrum usage, the model lets the central authority accept a reservation in advance and lets the secondary user get a reasonable guarantee. Crucially, to improve the spectrum usage and revenue, let the central authority terminate a reserved/running request at a later time for new request with higher priority at any time. Cancelation and preemption is necessary to take advantage of a spike in demand and rising prices for spectrum channels and not be forced to sell the spectrum below the market because of an a priori contract. When current spectrum usage is terminated, penalty should be paid to compensate the preemption. Here, assume that the penalty $\mu(b, \ell, t)$ is a linear function of the unfinished time $\ell \leq t$ of that request $\mathbf{e}(v, b, a, s, t)$, i.e., $\mu(b, \ell, t) = \beta \frac{\ell}{t} b$ for a constant $\beta \geq 0$. Notice that the cancelation is modeled as $\ell = t$ since the spectrum usage was not started at all. [Figure 2](#) illustrates the unfinished time ℓ

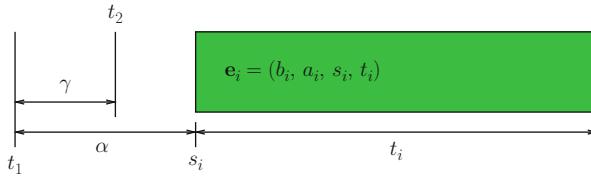

Fig. 1 Advance factor α and delay factor γ

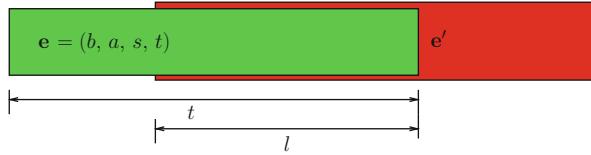

Fig. 2 Unfinished time ℓ when \mathbf{e} is preempted by \mathbf{e}'

Table 1 Symbols used in this chapter

Symb.	Meaning	Symb.	Meaning
\mathbf{e}_i	Request	b_i	Bid value
a_i	Arrival time	s_i	Start time
t_i	Required service time	ℓ_i	Unfinished service time
Δ	Time bound	α	Advance factor
γ	Delay factor	β	Penalty factor

when a request \mathbf{e} is preempted by another request \mathbf{e}' . Here, the constant $\beta \geq 0$ is the *penalty factor*. **Table 1** summarizes the symbols used in this chapter.

As stated before, all requests arrive on the fly, thus any information about the future, e.g., the distribution of future bids, the arrival times, the start times, and the required time durations, are all unknown. The objective of the spectrum allocation is to find an allocation which maximizes the total net profit, i.e., the total payment collected minus the total penalties caused by preemption and cancelation.

To evaluate the performance of an online algorithm, it is usually compared with an optimal *offline* algorithm. The following lemma indicates the hardness of the offline version of the problem.

Lemma 1 *Even knowing all requests, it is NP-hard to find an optimal spectrum allocation that maximizes the total bids of admitted requests.*

Proof Observe that the maximum weighted independent set (MWIS) problem in geometry graph is a special case of the spectrum allocation problem: assume that all spectrum requests are for the same time duration, the graph for MWIS problem is the conflict graph H , and the weight of a node is the bid value of the spectrum request by this node. Recall that MWIS in geometry graph itself is an NP-complete problem [24]. Thus, the lemma follows. \square

For all online spectrum allocation problems studied here, online algorithms with constant competitive ratios will be designed if advance factor is chosen carefully.

The performance of an online algorithm \mathcal{A} for spectrum allocation is measured by its *competitive ratio* $\varrho(\mathcal{A}) = \min_{\mathcal{I}} \frac{\mathcal{A}(\mathcal{I})}{\text{OPT}(\mathcal{I})}$, where \mathcal{I} is *any* possible sequence of requests arrival, $\mathcal{A}(\mathcal{I})$ is the profit produced by *online algorithm* \mathcal{A} on input \mathcal{I} , and $\text{OPT}(\mathcal{I})$ is the profit produced by optimum *offline algorithm* OPT on input \mathcal{I} when the sequence \mathcal{I} is known in advance by OPT. In this work, when we study the competitive ratio, we assume all users are truthful. Given a sequence of spectrum requests, at any time instant t , an online spectrum allocation method only knows all spectrum requests that arrived from time $t - \gamma$ to time slot t . On the other hand, for the same sequence of spectrum requests, although the optimum offline method also has to make decision for a request within γ time slots of its arrival, it does know *all future* requests it will get, thus makes a smarter decision.

As we will see later that the performances of methods and the lower bounds on the performance of any online algorithm vary when the penalty factor β , the advance factor α , and the delay factor γ are different, for certain parameters β , α , and γ , call it (β, α, γ) problem in this chapter.

2.3 Requests Arrival Following a Distribution

In this chapter, two different scenarios will be reviewed. The first scenario assumes that the mechanism designer does not know any distribution information about requests, except the delay factor γ , the penalty factor β , the advance factor α , and the time ratio Δ . [Section 3](#) will focus on this scenario. The second scenario assumes that the mechanism designer does know some distribution information about the arrived requests, such as the expected bid values by all requests. [Section 4](#) will focus on the second scenario.

In the second scenario, it is assumed that the true bid values b_i and time requirement t_i are always independent variables. This assumption is reasonable in practice since b_i is the amount a user is willing to pay for a unit of time. Also assume that arrival time a_i is *memoryless*, i.e., the distribution of arrival time is Poissonian. The arrival rate λ is not necessarily known in advance.

In this chapter, two different cases, random-arrival case, and semi-arbitrary-arrival case, will be studied. The simplest case is *random-arrival* case, in which the true bid values b_i and required time slots t_i are sampled *i.i.d.* from some *stationary* distributions that are not necessarily known to the central authority in advance. For example, true bid values b_i of all requests could be randomly and independently drawn from a normal distribution with mean μ and variance σ , and the values of μ and σ could be known or unknown to the central authority in advance. Or the central authority may also know that the arrival of requests follows the Poisson process with a rate λ , although the value of λ may be unknown to the central authority in advance.

Although motivated by this *i.i.d.* model, it may be more robust to work in *semi-arbitrary-arrival model*. This model also implies some fundamental limits to this online spectrum allocation problem. Assume that bid values b_i , and required time durations t_i are generated by an adversary who wants to beat these protocols. Let n

be the number of requests that will be posted. The adversary generates a (potentially random) set $\mathcal{A} = \{a_1, a_2, \dots, a_n\}$ of arrival times that are produced from Poisson distribution with unknown rate and a set $\mathcal{T} = \{t_1, t_2, \dots, t_n\}$ of required time durations that are produced from an unknown distribution. And the adversary could generate an arbitrary set $\mathcal{B} = \{b_1, b_2, \dots, b_n\}$ which is not necessarily sampled from any stationary distributions. After these three sets are generated, the bid values, arrival times, and required time durations are matched together using a *random permutation*, which is *not* controlled by the adversary. Call this the *random ordering hypothesis*. The hypothesis is reasonable since we concern the *expected* performance of these mechanisms. When this matching is also controlled by the adversary, we can present examples of requests such that, for *any* online spectrum allocation and auction method, the expected social efficiency or revenue could be arbitrarily bad comparing with that of *offline* methods.

The protocols need to compute how much each request needs to pay. When a request is accepted, the secondary user who issued the request will be granted the usage of channel, and will need to pay some monetary value for this. We will design mechanisms to compute the payment by secondary users. Let \mathbf{v}_i be the true valuation of the spectrum usage requested by \mathbf{e}_i and \mathbf{p}_i be the payment that request \mathbf{e}_i should pay. Then, the final profit (or the utility) of request \mathbf{e}_i is $\mathcal{U}(i) = x_i \cdot \mathbf{v}_i - \mathbf{p}_i$. When \mathbf{e}_i is admitted, $x_i = 1$; otherwise, $x_i = 0$. Notice that $b_i t_i = \mathbf{v}_i$ when secondary user issued request \mathbf{e}_i truthfully.

In the online auction, the secondary users seek to place requests to maximize their individual utility in equilibrium. As a standard approach, in this chapter, we will only focus on direct revelation mechanisms in which secondary users directly submit their bid values and time requirement (although not necessarily truthfully). We assume that each secondary user cannot announce an earlier arrival time than its true arrival. At every time t , given the set of submitted requests θ that are not processed yet, the central authority decides an allocation $x_i(\theta, t) \in \{0, 1\}$ and a payment $\mathbf{p}_i(\theta, t)$ for request \mathbf{e}_i . We place the following natural conditions on the allocation and payments: allocations cannot be revoked, so $x_i(\theta, t)$ is a nondecreasing function of t . The allocation and payments must be online computable, in that they can only depend on information available at time t . We are interested in mechanisms with dominant-strategy equilibrium, such that every secondary user has a single optimal strategy regardless of the strategies of others. This is a particularly robust solution concept. Notice that a secondary user may lie lower or lie higher its bid value b_i (compared with its true bid value b'_i) and can only lie its time requirement t_i to a larger value.

Definition 1 A mechanism is value-strategyproof and time-strategyproof if a secondary user's dominant strategy is to report its true bid value (called *value-SP*) and true time requirement (called *time-SP*).

Competitive ratio is always used to evaluate the performance of an online algorithm. Most of the previous work focused on the worst-case competitive ratio of the online algorithm; however, the probability that the worst case will happen is very small in practice. Thus, we study the expected competitive ratio instead, which

could better reflect the practical performance of an online algorithm. The *average competitive ratio* of an online algorithm is defined as the ratio between its average performance and the average performance of the optimal *offline* algorithm for *all* possible inputs. We focus on the *average competitive ratio* since it is easy to prove that without any known constraint, the worst-case competitive ratio of any online method can be arbitrarily bad.

To evaluate the performance of an online mechanism, we usually compare it with *offline Vickrey* mechanism which will maximize the total social efficiency (but not necessarily strategyproof in the online model). Notice that *offline* mechanism knows all future inputs before it makes decisions, which surely improves the performance significantly. The performance of an online mechanism \mathcal{M} is measured by its *social efficiency* $\text{Eff}_s(\mathcal{M})$ and *revenue efficiency* $\text{Eff}_r(\mathcal{M})$. The *social efficiency* of mechanism \mathcal{M} is defined as the total true valuations of all winners, i.e., $\text{Eff}_s(\mathcal{M}) = \sum_i x_i v_i$. For a mechanism \mathcal{M} , let \mathbf{p}_i be the payment collected from secondary request \mathbf{e}_i . And the *revenue efficiency* of mechanism \mathcal{M} is simply $\text{Eff}_r(\mathcal{M}) = \sum_i \mathbf{p}_i$. The benchmark mechanisms that we adopt for the purpose of competitive analysis are the offline Vickrey mechanisms, denoted as *Vick*. Notice that for offline Vickrey mechanism, it will always select a set of winners that maximize the social efficiency.

Definition 2 The *social efficiency competitiveness* of an admission mechanism \mathcal{M} is defined as the ratio of the total valuations of winners under mechanism \mathcal{M} over the total valuations of winners under *offline Vickrey* mechanism. In other words, $\text{Eff}_s(\mathcal{M}, \text{Vick}) = \text{Eff}_s(\mathcal{M})/\text{Eff}_s(\text{Vick})$. Similarly, the *revenue efficiency competitiveness* of mechanism \mathcal{M} is defined as the ratio of the total payments of winners under mechanism \mathcal{M} over the total payments of winners under *offline Vickrey* mechanism. In other words, $\text{Eff}_r(\mathcal{M}, \text{Vick}) = \text{Eff}_r(\mathcal{M})/\text{Eff}_r(\text{Vick})$. We say that mechanism \mathcal{M} is $\frac{1}{\text{Eff}_s(\mathcal{M}, \text{Vick})}$ -competitive for social efficiency and $\frac{1}{\text{Eff}_r(\mathcal{M}, \text{Vick})}$ -competitive for revenue efficiency.

The objective is to design *online strategyproof spectrum admission mechanisms* in different cases which maximize the *expected* social efficiency and revenue efficiency. The expectations are computed over *all* possible permutations of bid values b_i and *all* possible permutations of time requirements.

3 Spectrum Allocation and Mechanism Design with Known Δ , β and γ Only

3.1 Upper Bounds on All Online Methods

In this section, we present upper bounds on the competitive ratios of online allocation methods in cases depending on whether β is less than 1, equal to 1, or larger than 1. These bounds will be proved to be almost tight later.

3.1.1 Upper Bound for $(\beta < 1, \gamma, \alpha)$ Problem

We first show upper bounds on the competitive ratios when $\beta < 1$. Note that in this case, we assume that every preempted job must be executed for at least one time slot.

The main approach of the proofs in this section is *adversary argument*: an adversary carefully constructs sequences of requests to make the performance of online algorithms as bad as possible. The trick is that the adversary can choose the future requests based on the current decision of online algorithms. Then, no matter what decision is made, certain performance cannot be achieved.

Theorem 1 *Let $\theta = \frac{1}{c\beta}$. No online algorithm has a competitive ratio $> \theta$ for $(\beta < 1, \gamma, \alpha)$ problem when $\gamma \leq \frac{\beta}{(c+1)(2+\beta)}\Delta$ for $c > 1/\beta$.*

3.1.2 Upper Bound for $(\beta = 1, \gamma, \alpha)$ Problem

When the penalty factor $\beta = 1$, there are two different cases: $\gamma = o(\Delta)$ or $\gamma = \Omega(\Delta)$.

- (1) When $\gamma = o(\Delta)$, i.e., $\lim \frac{\gamma}{\Delta} = 0$, we first show that no online algorithm can achieve competitive ratio more than $\sqrt[3]{2(\gamma+1)}\Delta^{-\frac{1}{3}}$ for $(1, \alpha, \gamma)$ problem. Then, we improve this bound to $\sqrt{2(\gamma+1)}\Delta^{-\frac{1}{2}}$.
- (2) When $\gamma = \Omega(\Delta)$, we show that $(1, \alpha, \gamma)$ problem cannot have a competitive ratio $1 - \epsilon$ for an arbitrary $\epsilon > 0$.

Theorem 2 ([37]) *No online algorithm has a competitive ratio $> \sqrt[3]{2(\gamma+1)}\Delta^{-\frac{1}{3}}$ for $(\beta = 1, \gamma, \alpha)$ problem when $\gamma = o(\Delta)$.*

Theorem 3 ([37]) *No online algorithm has competitive ratio $> \frac{1}{c}$ for $(\beta = 1, \gamma, \alpha)$ problem, where $\sqrt{2(\gamma+1)}\Delta^{-\frac{1}{2}} < \frac{1}{c} \leq \sqrt[3]{2(\gamma+1)}\Delta^{-\frac{1}{3}}$ for $(\beta = 1, \gamma, \alpha)$ problem when $\gamma = o(\Delta)$.*

Theorem 4 ([37]) *No online algorithm has a competitive ratio $\geq 1 - \epsilon$ for an arbitrary small $\epsilon > 0$, for $(\beta = 1, \gamma, \alpha)$ problem when $\gamma = \Omega(\Delta)$.*

3.1.3 Upper Bound for $(\beta > 1, \gamma, \alpha)$ Problem

For $(\beta > 1, \gamma, \alpha)$ problem, we show that upper bound of competitive ratios is $O(\frac{\gamma+1}{\Delta})$ when $\gamma = o(\Delta)$.

Theorem 5 ([37]) *No online algorithm has competitive ratio more than $\frac{2\beta}{(\beta-1)^2}\frac{\gamma+1}{\Delta}$ for $(\beta > 1, \gamma, \alpha)$ problem, when $\gamma = o(\Delta)$.*

A surprising result from the analysis in this section is that the performance upper bounds do not depend on the *advance factor* α . In other words, no matter how many time slots the secondary users claim their requests in advance, the theoretical upper bounds will not be improved asymptotically if the *delay factor* γ does not change.

3.2 Efficient Online Allocation Methods

In this section, we present several methods for efficient online spectrum allocation. We then analytically study the performances of the methods and prove that they have asymptotically best competitive ratios. All results in this section assume that the conflict graph of the network is a complete graph.

3.2.1 Method \mathcal{K} for $(\beta < 1, \gamma, \alpha)$ Problem

When $\beta < 1$, whenever we admit a request e_i at time t , even we preempt it at next time slot $t + 1$, we still receive a profit $(1 - \beta)b_i$. Thus, we will adopt the following strategy \mathcal{K} : at any time t , let e_i be the request from the set of all currently available requests, denoted as $\mathcal{R}_a(t)$, with the largest bid b_i among all requests whose starting time is $t - \gamma + \alpha$. We admit request e_i at time t . It is easy to prove the following Lemma.

Lemma 2 *Strategy \mathcal{K} is at least $(1 - \beta)$ -competitive.*

3.2.2 Method \mathcal{G} for $(\beta = 1, \gamma, \alpha)$ Problem

We then consider the case $\beta = 1$, i.e., the preemption penalty is exactly the remaining portion of the bid. Since we do not know anything about the future, to maximize the total profits, we shall accept request with large bid or large bid per time slot (called *density*) intuitively. The main difficulty is the trade-off between requests with large bid and requests with large *density*. The results on upper bounds of competitive ratio in Sect. 3.1 illustrate some intuitions. In this and following subsection, we design online algorithms whose competitive ratios match corresponding upper bounds.

Consider current time t , and let $\mathcal{R}_a(t)$ be all spectrum requests submitted before time t , which are not processed. Based on the delay requirement, we know that all requests in $\mathcal{R}_a(t)$ must be submitted during the time slots $[t - \gamma, t]$, and their starting times must be in the time interval $[t - \gamma + \alpha, t + \alpha]$. Among all spectrum requests in $\mathcal{R}_a(t)$, let $\mathcal{R}(t) \subseteq \mathcal{R}_a(t)$ be all spectrum requests whose starting times are in the time interval $[t, t + \gamma]$. Recall that we always have $\gamma \leq \alpha$. The online algorithms will only make decisions at time t using the information about requests $\mathcal{R}(t)$, although it knows a superset of requests $\mathcal{R}_a(t)$. See Fig. 3 for illustration, where $\mathcal{R}_a(t) = \{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3, \mathbf{e}_4, \mathbf{e}_5\}$ and $\mathcal{R}(t) = \{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$. We will show that this method can achieve a competitive ratio that is already asymptotically optimum. In other words, knowing the information α will not enable us to get a method with a better competitive ratio asymptotically.

Candidate Requests Set

For requests $\mathcal{R}(t)$, we will find some subsets, called *candidate requests set*, using dynamic programming to optimize some objective functions. This method will then make decisions on whether to admit these subsets of requests under some conditions involving the currently running spectrum usages.

Fig. 3 All requests $\mathcal{R}_a(t)$ and a subset of requests $\mathcal{R}(t)$ with starting time in $[t, t + \gamma]$ (denoted by green color)

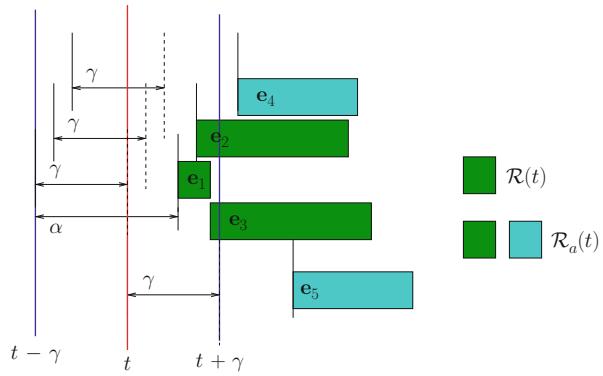

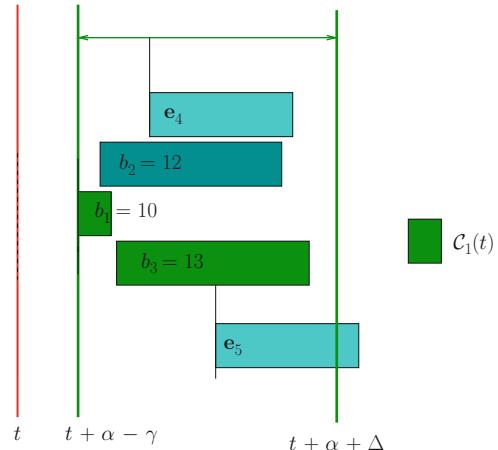

Fig. 4 Strong candidate set $\mathcal{C}_1(t)$ at time t (color green)

Definition 3 Candidate Requests Set:

- (1) A *strong candidate requests set* at time t , denoted as $\mathcal{C}_1(t)$, is a subset of requests from $\mathcal{R}(t)$ that has the largest total bids if $\mathcal{C}_1(t)$ were allowed to run from time $t - \gamma + \alpha$ to time at most $t + \alpha + \Delta$. See [Fig. 4](#) for illustration where $\mathcal{C}_1(t) = \{e_1, e_3\} \subseteq \mathcal{R}(t)$ since the total profit during time interval $[t - \gamma + \alpha, t + \alpha + \Delta]$ is maximized. We abuse the notation little bit here by also letting $\mathcal{C}_1(t)$ denote the profit made by $\mathcal{C}_1(t)$.

Also let $\mathcal{P}(\mathcal{C}_1(t), t')$ denote the profit made from $\mathcal{C}_1(t)$ if $\mathcal{C}_1(t)$ are admitted and then possibly being preempted at a time slot $t' \in [t - \gamma + \alpha, t + \alpha + \Delta]$.

- (2) A *weak candidate requests set* at time t , denoted as $\mathcal{C}_2(t)$, is a subset of requests from $\mathcal{R}(t)$ that has the largest total bids if $\mathcal{C}_2(t)$ were allowed to run during time interval $[t - \gamma + \alpha, t + \alpha]$ (assume they are preempted at time $t + \alpha + 1$). We abuse the notation little bit here by also letting $\mathcal{C}_2(t)$ denote the profit made by $\mathcal{C}_2(t)$.

Algorithm 1 Find $\mathcal{C}_1(t)$ by dynamic programming

Input: $\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_{n(t)}$ such that $s_1 \leq s_2 \leq \dots \leq s_{n(t)}$.

Output: Strong candidate set $\mathcal{C}_1(t)$.

```

1: for  $i = 1$  to  $n(t)$  do
2:   for  $j = 1$  to  $i$  do
3:      $\mathcal{Q}(j, s_i) = \max_{k \in [1, n]} \{\mathcal{Q}(k, s_j) + b_j - \mu(\mathbf{e}_k, s_j)\}$ 
4:    $\mathcal{C}_1(t) = \max_{k \in [1, n]} \{\mathcal{Q}(k, s_{n(t)})\}$ 

```

Briefly speaking, $\mathcal{C}_1(t)$ maximizes the total bids at time t , and $\mathcal{C}_2(t)$ maximizes the total bid per time slot in the predictable future (since the requests are claimed in advance). Observe that the starting times of candidate sets are in the interval $[t, t + \alpha]$. Since $\gamma \leq \alpha$, at time t , we should know all requests whose starting times are from t to $t + \gamma$. So we could find the *candidate requests set* $\mathcal{C}_1(t)$ and $\mathcal{C}_2(t)$ by dynamic programming as following.

Consider requests $\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_n$ in the increasing order of their starting times, i.e., $t - \gamma + \alpha \leq s_1 \leq s_2 \leq \dots \leq s_n \leq t + \alpha$. When we compute the strong candidate set $\mathcal{C}_1(t)$, we will *not* consider any requests that are currently running or have been rejected before. Additionally, for the scheduling of requests in $\mathcal{C}_1(t)$, we may use one request to preempt another request in $\mathcal{C}_1(t)$. Let $\mathcal{Q}(j, s_i)$ denote the maximum possible profit made during time interval $[t, t + \gamma + \Delta]$ from $\mathcal{R}(t)$ when \mathbf{e}_j is the last accepted request before or at time s_i . If the starting time s_j of \mathbf{e}_j satisfies $s_j > s_i$, $\mathcal{Q}(i, s_j) = 0$ since it is not a feasible solution. Then,

$$\mathcal{C}_1(t) = \max_{k \in [1, n]} \mathcal{Q}(k, s_n).$$

For each i and j such that $i \geq j$, we have

$$\mathcal{Q}(j, s_i) = \max_{k \in [1, n]} \{\mathcal{Q}(k, s_j) + b_j - \mu(\mathbf{e}_k, s_j)\}.$$

Here, $\mu(\mathbf{e}_k, s_j)$ is the paid penalty when request \mathbf{e}_k is preempted at time s_j .

Algorithm 1 summarizes the method finding $\mathcal{C}_1(t)$. For each i and j , the algorithm takes $O(n(t))$ time to compute $\mathcal{Q}(j, s_i)$. Therefore, it takes $O(n(t)^3)$ time to find $\mathcal{C}_1(t)$ where $n(t)$ is the total number of spectrum requests in $\mathcal{R}(t)$. The method can be easily extended to find $\mathcal{C}_2(t)$ with same running time.

The Greedy Algorithm \mathcal{G}

We then propose an online algorithm \mathcal{G} . At each time t , the input of our algorithm \mathcal{G} is $\mathcal{R}_a(t)$. Algorithm \mathcal{G} should decide whether a request that arrived at time slot $t - \gamma$ will be accepted or rejected. The basic idea of our method is as follows.

Assume that time 0 is the reference point for time. First, before time γ , we do not need to make decisions on any arrived requests. At time γ , we need to decide whether to accept/reject requests that arrive at time 0. If channel is not occupied, we will simply accept the request from $\mathcal{C}_1(\gamma)$ with the earliest starting time being α , if there is any. We call $\mathcal{C}_1(\gamma)$ as *virtual meta job* requests currently being accepted.

For any time $t > \gamma$, our method will choose either a request from the strong candidate request $\mathcal{C}_1(t)$, or a request from weak candidate request $\mathcal{C}_2(t)$, or continue to run the request (which could be empty) chosen previously. The method deals with three complementary cases about the channel status at time $t - \gamma + \alpha$, separately.

Case 1: Non-occupied Channel If the channel will be *empty* at time $t - \gamma + \alpha$, we find $\mathcal{C}_1(t)$ with the maximum overall profit in $\mathcal{R}(t)$. We accept the request in $\mathcal{C}_1(t)$ with starting time $t - \gamma + \alpha$, and we say that the channel is being used by candidate requests set $\mathcal{C}_1(t)$. In other words, here we treat $\mathcal{C}_1(t)$ as a large *virtual meta* spectrum request. Note that at current time slot t , we only admit the first spectrum request from $\mathcal{C}_1(t)$ while leave the admission decisions on other requests in $\mathcal{C}_1(t)$ *pending*. Whether these pending “admitted” requests will be actually admitted depending on future coming requests, if future coming requests are better, we will preempt this virtual meta request $\mathcal{C}_1(t)$.¹ Thus, those preempted pending admissions from $\mathcal{C}_1(t)$ will not be processed at all.

Case 2: Occupied by Weak Candidate Requests If the channel will be used by a *weak candidate requests set* $\mathcal{C}_2(t)$ at time $t - \gamma + \alpha$ and this candidate requests set $\mathcal{C}_2(t)$ *weakly preempted* (exact definitions will be given later) some other candidate requests set before, all requests from $\mathcal{R}_a(t)$ submitted at time $t - \gamma$ will *not be admitted*.

Case 3: Occupied by Strong Candidate Requests The last case is that the channel will be used by a *strong candidate requests set* $\mathcal{C}_1(t)$ at time $t - \gamma + \alpha$. Assume the request to be run at time $t - \gamma + \alpha$ is \mathbf{e}_j from some virtual candidate requests set $\mathcal{C}_1(t_1)$. There are three possible steps in this case.

- (1) We first find the strong candidate requests set $\mathcal{C}_1(t)$. The first request $\mathbf{e}_i \in \mathcal{C}_1(t)$ such that $s_i = t - \gamma + \alpha$ will be accepted only if

$$\mathcal{C}_1(t) \geq c_1 \cdot \mathcal{C}_1(t_1), \quad (1)$$

where $c_1 > 1$ is a constant parameter. In other words, we use a virtual meta request $\mathcal{C}_1(t)$ to replace another virtual request $\mathcal{C}_1(t_1)$ if the potential profit from new virtual meta request is sufficiently larger. We call it a *strong-preemption*.

- (2) If strong-preemption cannot be applied, we find $\mathcal{C}_2(t)$. The request $\mathbf{e}_i \in \mathcal{C}_2(t)$ such that $s_i = t - \gamma + \alpha$ will be accepted only if

$$\mathcal{C}_2(t) + \mathcal{P}(\mathcal{C}_1(t_1), t - \gamma + \alpha) \geq c_2 \cdot \mathcal{C}(t_1), \quad (2)$$

where $c_2 > 0$ is an adjustable control parameter. In other words, we use a virtual candidate requests set $\mathcal{C}_2(t)$ to replace another virtual candidate requests set $\mathcal{C}_1(t_1)$ if the profit from this new meta request and the profit from the meta request $\mathcal{C}(t_1)$ being preempted at future time $t - \gamma + \alpha$ are at least a constant

¹Preempting $\mathcal{C}_1(t)$ at a time, say t' , will be implemented by preempting the requests from $\mathcal{C}_1(t)$ that are supposed to be running at and after time t' .

Algorithm 2 Online spectrum allocation \mathcal{G}

Input: A constant parameter $c_1 > 1$, an adjustable control parameter $c_2 > 0$, γ , α , Δ , $\mathcal{R}_a(t)$, $\mathcal{R}(t)$, $\mathcal{C}_1(t)$, and $\mathcal{C}_2(t)$.

Current candidate requests set \mathcal{C} from time $t' < t$. Here, $\mathcal{C} = \mathcal{C}_1(t')$ if $\mathcal{C}_1(t')$ strongly preempted others, or $\mathcal{C} = \mathcal{C}_2(t')$ if $\mathcal{C}_2(t')$ strongly preempted others.

Output: Whether requests submitted at time $t - \gamma$ will be admitted and new *current candidate requests set \mathcal{C}* .

```

1: if  $\mathcal{C} = \mathcal{C}_2(t')$  then
2:   if  $t - t' \geq \gamma$  then
3:      $\mathcal{C} = \emptyset$ ;
4:   else
5:     Accept request  $\mathbf{e}_i \in \mathcal{C}_2(t)$  such that  $s_i = t - \gamma + \alpha$ .
6: if  $\mathcal{C} = \mathcal{C}_1(t')$  or  $\emptyset$  then
7:   if  $\mathcal{C}_1(t) \geq c_1 \cdot \mathcal{C}_1(t')$  then
8:      $\mathcal{C} = \mathcal{C}_1(t)$ ;
9:     Accept request  $\mathbf{e}_i \in \mathcal{C}_1(t)$  such that  $s_i = t - \gamma + \alpha$ .
10:  else if  $\mathcal{C}_2(t) + \mathcal{P}(\mathcal{C}_1(t'), t) \geq c_2 \cdot \mathcal{C}_1(t)$  then
11:     $\mathcal{C} = \mathcal{C}_2(t)$ ;
12:    Accept request  $\mathbf{e}_i \in \mathcal{C}_2(t)$  such that  $s_i = t - \gamma + \alpha$ .
13:  else
14:    Accept request  $\mathbf{e}_i \in \mathcal{C}_1(t')$  such that  $s_i = t - \gamma + \alpha$ .

```

c_2 fraction of the profit by keeping running the meta request $\mathcal{C}(t_1)$. We call it a *weak-preemption*. In this subcase, all requests in $\mathcal{C}_2(t)$ will be accepted and the last request will be terminated at time $t + \alpha + 1$ automatically.

- (3) If the weak-preemption cannot be applied also, we accept the request in the previously used candidate requests set $\mathcal{C}(t_1)$, whose starting time is $t - \gamma + \alpha$ (if there is any) or continue the request \mathbf{e}_j that will run through the time slot $t - \gamma + \alpha$.

[Algorithm 2](#) summarizes the online spectrum allocation method \mathcal{G} .

Theoretical Performance Study

We then show that the algorithm \mathcal{G} is asymptotically optimal if we choose constant c_1 and control parameter c_2 carefully. We use $\mathcal{G}(\mathcal{I})$ to denote the profit made on requests sequence \mathcal{I} by the algorithm \mathcal{G} . Also use $\text{OPT}(\mathcal{I})$ to denote the profit made by the optimal offline algorithm. To analyze the performance of the method, we first give a definition *candidate sequence*.

Definition 4 Candidate Sequence: A *candidate sequence* is a sequence of *candidate requests sets* $\mathcal{C}_1(t_1), \mathcal{C}_1(t_{i+1}), \dots, \mathcal{C}_1(t_{j-1}), \mathcal{C}_2(t_j)$ or $\mathcal{C}_1(t_1), \mathcal{C}_1(t_{i+1}), \dots, \mathcal{C}_1(t_{j-1}), \mathcal{C}_1(t_j)$ which satisfies all of following three conditions:

- (1) Strong candidate requests set $\mathcal{C}_1(t_i)$ does not preempt another candidate requests set.
- (2) Strong candidate requests set $\mathcal{C}_1(t_{k+1})$ strongly preempts strong candidate requests set $\mathcal{C}_1(t_k)$, for $k = i, \dots, j - 2$.

- (3) Weak candidate set $\mathcal{C}_2(t_j)$ weakly preempts strong candidate set $\mathcal{C}_1(t_{j-1})$, or a strong candidate set $\mathcal{C}_1(t_j)$ strongly preempts $\mathcal{C}_1(t_{j-1})$ and $\mathcal{C}_1(t_j)$ is not preempted by another requests set.

Here, we use the parameters of the first and last *candidate requests set* to denote a *candidate sequence*, e.g., $\mathcal{S}(t_i, t_j)$. According to the definition, we can decompose the solution of algorithm \mathcal{G} , i.e., $\{\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_m\}$, into multiple *candidate sequences*. Notice that each spectrum request \mathbf{e} will appear in exactly one *candidate sequence*. We use $\mathcal{G}(\mathcal{S}(t_i, t_j))$ to denote the profit made on *candidate sequence* $\mathcal{S}(t_i, t_j)$ by algorithm \mathcal{G} . And we use $\text{OPT}[t_i, t_j]$ to denote the profit made by optimal offline algorithm on the requests whose starting times are in interval $[t_i, t_j]$.

Lemma 3 *For each candidate sequence $\mathcal{S}(s_i, s_j)$ in the solution given by algorithm \mathcal{G} , we have*

$$\mathcal{G}(\mathcal{S}(s_i, s_j)) \geq \min(c_1, c_2) \cdot \mathcal{C}_1(s_{j-1}).$$

Proof By definition of candidate sequences, there are two different cases: (1) $\mathcal{C}_1(s_j)$ strongly preempted $\mathcal{C}_1(s_{j-1})$ or (2) $\mathcal{C}_2(s_j)$ weakly preempted $\mathcal{C}_1(s_{j-1})$.

If request $\mathcal{C}_1(s_j)$ strongly preempted $\mathcal{C}_1(s_{j-1})$, \mathcal{G} makes at least $\mathcal{C}_1(s_j) \geq c_1 \cdot \mathcal{C}_1(s_{j-1})$. If request $\mathcal{C}_2(s_j)$ weakly preempted $\mathcal{C}_1(s_{j-1})$, \mathcal{G} makes at least $\mathcal{P}(\mathcal{C}_1(s_{j-1}), s_j) + \mathcal{C}_2(s_j) \geq c_2 \cdot \mathcal{C}_1(s_{j-1})$. So the lemma holds for either case. \square

Lemma 4 ([37]) *For each candidate sequence $\mathcal{S}(s_i, s_j)$ in the solution given by algorithm \mathcal{G} , for each $i \leq k < j$, we have*

$$\text{OPT}[s_k, s_{k+1}] \leq \left(c_1 + c_2 + \frac{c_2}{\sqrt{(fl+1)/\Delta}} \right) \mathcal{C}_1(s_k).$$

Lemma 5 *For each candidate sequence $\mathcal{S}(s_i, s_j)$ in the solution given by algorithm \mathcal{G} , we have*

$$\text{OPT}[s_i, s_j] \leq \left(c_1 + 1 + \frac{1}{c_1 - 1} \right) \left(c_1 + c_2 + \frac{c_2}{\sqrt{(fl+1)/\Delta}} \right) \mathcal{C}_1(s_{j-1}).$$

Proof Obviously, $\text{OPT}[s_i, s_j] = \sum_{k=i}^{j-1} \text{OPT}[s_k, s_{k+1}]$. From Lemma 4, we have $\text{OPT}[s_k, s_{k+1}] \leq \left(c_1 + c_2 + \frac{c_2}{\sqrt{(fl+1)/\Delta}} \right) \mathcal{C}_1(s_k)$. Thus, $\text{OPT}[s_i, s_j] \leq \left(c_1 + c_2 + \frac{c_2}{\sqrt{(fl+1)/\Delta}} \right) \sum_{k=i}^{j-1} \mathcal{C}_1(s_k)$. Based on the condition of strong-preemption, we have $\mathcal{C}_1(s_k) \geq c_1 \cdot \mathcal{C}_1(s_{k-1})$ for all $i \leq k \leq j$. The lemma then follows. \square

Theorem 6 *Algorithm \mathcal{G} is $\Theta(\sqrt{\gamma+1}\Delta^{-\frac{1}{2}})$ -competitive.*

Proof Given a request sequence \mathcal{I} , we decompose the solution by algorithm \mathcal{G} into multiple *candidate sequence* $\mathcal{S}(t_i, t_j)$. Then, the total profit made by algorithm \mathcal{G} is

$\sum_{\forall S(t_i, t_j)} \mathcal{S}(t_i, t_j)$. On the other hand, the total profit made by the optimal offline algorithm is $\sum_{\forall S(t_i, t_j)} \text{OPT}[t_i, t_j]$. From [Lemmas 3](#) and [5](#), the competitive ratio of algorithm \mathcal{G} is at least

$$\frac{\sum_{\forall S(t_i, t_j)} \mathcal{S}(t_i, t_j)}{\sum_{\forall S(t_i, t_j)} \text{OPT}[t_i, t_j]} \geq \frac{\min(c_1, c_2)}{(c_1 + 1 + \frac{1}{c_1 - 1})(c_1 + c_2 + \frac{c_2}{\sqrt{(\gamma+1)/\Delta}})}.$$

It is easy to show that the right-hand side gets the maximum value $\frac{1}{4(1+\sqrt{\Delta/(\gamma+1)})}$ if $c_1 = 2$ and $c_2 = \frac{2}{1+\sqrt{\Delta/(\gamma+1)}}$. Thus, the competitive ratio is at least $\frac{1}{8} \sqrt{\frac{\gamma+1}{\Delta}}$ when $\gamma \leq \Delta - 1$. \square

Let $n(t)$ be the cardinality of $\mathcal{R}_a(t)$. At time t , [Algorithm 2](#) takes $O(n(t)^3)$ time to find $\mathcal{C}_1(t)$ and $\mathcal{C}_2(t)$, then takes constant time to make decision. The time complexity of [Algorithm 2](#) is $\sum_{\forall t} n(t)^3$. Notice that each request could appear in at most $\Delta + \gamma$ different $\mathcal{R}_a(t)$. Let n be the number of all online requests. We have $\sum_{\forall t} n(t) \leq (\Delta + \gamma)n$ and $n(t) \leq n$ for all t , which implies following theorem.

Theorem 7 *Time complexity of [Algorithm 2](#) is $O((\Delta + \gamma)n^3)$.*

3.2.3 Method \mathcal{H} for $(\beta > 1, \gamma, \alpha)$ Problem

In this subsection, we propose a greedy algorithm \mathcal{H} for $(\beta > 1, \gamma, \alpha)$ problem. At time t , the method \mathcal{H} should decide whether a request whose start time is $t + \alpha - \gamma$ will be accepted.

Then, we show that algorithm \mathcal{H} is asymptotically optimal. The notations are used in previous subsection.

Theorem 8 *Algorithm \mathcal{H} is $\frac{(c-\beta-1)}{c^2} \frac{\gamma+1}{\Delta+\gamma+1}$ -competitive.*

Proof We divide the requests accepted by algorithm \mathcal{H} into multiple *candidate requests sets*. Let us consider the profit made by \mathcal{H} on each *candidate requests set* $\mathcal{C}_1(t)$. For each admitted $\mathcal{C}_1(t)$, we redistribute $(1 + \beta)\mathcal{C}_1(t')$ of the money from $\mathcal{C}_1(t)$ to $\mathcal{C}_1(t')$ if $\mathcal{C}_1(t)$ preempts $\mathcal{C}_1(t')$.

There are three complementary cases here.

Case 1: $\mathcal{C}_1(t)$ does not preempt others and is not preempted. \mathcal{H} makes $\mathcal{C}_1(t)$ profit on $\mathcal{C}_1(t)$. Let $t_s = t + \alpha - \gamma$. For the optimal offline algorithm OPT, if time $t_s + i(\gamma + 1)$ (for some integer $i > 0$) is before the end time of $\mathcal{C}_1(t)$, we have $\text{OPT}[t_s + i(\gamma + 1), t_s + (i + 1)(\gamma + 1)] \leq c \cdot \mathcal{C}_1(t)$. Otherwise, the requests whose starting times are during time interval $[t_s + i(\gamma + 1), t_s + (i + 1)(\gamma + 1)]$ should preempt $\mathcal{C}_1(t)$. We know that the total running time of $\mathcal{C}_1(t)$ is no more than $\Delta + \gamma + 1$. Thus, no more than $c \lceil \frac{\Delta+\gamma+1}{\gamma+1} \rceil \mathcal{C}_1(t)$ profit will be made by OPT during the running time of $\mathcal{C}_1(t)$.

Case 2: $\mathcal{C}_1(t)$ does not preempt others and is preempted in \mathcal{H} . \mathcal{H} makes $\mathcal{C}_1(t)$ profit on $\mathcal{C}_1(t)$ since the *candidate requests* which preempted $\mathcal{C}_1(t)$ will distribute $(1 + \beta)\mathcal{C}_1(t)$ profit to $\mathcal{C}_1(t)$. And at most $\beta\mathcal{C}_1(t)$, profit is paid as penalty.

No more than $c \lceil \frac{\Delta+\gamma+1}{\gamma+1} \rceil \mathcal{C}_1(t)$) profit will be made by OPT during the running time of $\mathcal{C}_1(t)$.

Case 3: $\mathcal{C}_1(t)$ preempts another candidate requests set in \mathcal{H} . \mathcal{H} makes at least $\frac{c-\beta-1}{c} \mathcal{C}_1(t)$ profit from $\mathcal{C}_1(t)$ (after considering redistributing some to the candidate requests set being preempted by $\mathcal{C}_1(t)$) since we distribute $(1 + \beta)\mathcal{C}_1(t') \leq \frac{1+\beta}{c} \mathcal{C}_1(t)$ to the candidate set preempted by $\mathcal{C}_1(t)$. If $\mathcal{C}_1(t)$ is not preempted, we make at least $\frac{c-\beta-1}{c} \mathcal{C}_1(t)$. If $\mathcal{C}_1(t)$ is preempted, we will receive $(1 + \beta)\mathcal{C}_1(t)$ from the future candidate requests set that preempts it. Thus, we always make at least $\mathcal{C}_1(t)$. For OPT, it is easy to show that OPT will make no more than $c \lceil \frac{\Delta+\gamma+1}{\gamma+1} \rceil \mathcal{C}_1(t)$ profit.

Thus, the competitive ratio for each candidate requests set is at least $\frac{(c-\beta-1)}{c^2} \lceil \frac{\gamma+1}{\Delta+\gamma+1} \rceil$. The competitive ratio of \mathcal{H} is at least $\frac{(c-\beta-1)}{c^2} \frac{\gamma+1}{\Delta+\gamma+1}$. We finish the proof. \square

When $\gamma = a\Delta - 1$, it is easy to show that

Theorem 9 *Method \mathcal{H} is at least $\frac{a}{4(1+a)(1+\beta)}$ -competitive (by choosing $c = 2(1 + \beta)$), when $\gamma = a\Delta - 1$.*

3.3 More General Networks

All studies in previous sections assumed that the conflict graph of networks, which models the location-dependent conflict, is a complete graph. In this section, we extend the algorithms for the networks where each request \mathbf{e}_i asks for spectrum usage in a disk-shaped region D_i centered at (x_i, y_i) with a radius r_i . For the performance upper bounds, all Lemmas and Theorems in Sect. 3.1 still hold since complete conflict graph is a special case.

If we can find the strong (weak) candidate sets $\mathcal{C}_1(t)$ ($\mathcal{C}_2(t)$) in polynomial time as we did by using Algorithm 1 in Sect. 3.2.2, then the method \mathcal{G} (or \mathcal{H}) still works since all previous analysis still holds. However, the main difficulty is that, in this case, the central authority may accept multiple requests at same time, which makes it hard to get the strong/weak candidate sets in polynomial time by using dynamic programming. Therefore, we propose to approximate strong/weak candidate sets at each time t in polynomial time by using *shifting strategy* [24] as follows.

We divide the request disks into different levels according to their radii. At same level, the radii of all request disks are within a constant factor λ of each other. Let d be the diameter of smallest request disk; level i includes all request disks whose diameters are within $[d\lambda^{i-1}, d\lambda^i]$.

First, we show that a PTAS can be achieved in *each* level i . In other words, here we approximate the strong/weak candidate sets when only request disks in level i are considered. Let $k > 1$ be an integer. At level i , a (p, q) partition is defined as the region is partitioned by a set of horizontal lines, $y = \dots, -2\lambda^i k + p, -\lambda^i k$

$+p, p, \lambda^i k + p, 2\lambda^i k + p, \dots$, and a set of vertical lines, $x = \dots, -2\lambda^i k + q, -\lambda^i k + q, q, \lambda^i k + q, 2\lambda^i k + q, \dots$. In each partition, the region is partitioned into a number of $\lambda^i k \times \lambda^i k$ squares. We ignore the requests whose disks are hit by any lines of the partition and find the strong/weak candidate sets in each $\lambda^i k \times \lambda^i k$ square. Together with strong/weak candidate sets in all squares, we get strong/weak candidate sets for a partition.

Lemma 6 *Strong/weak candidate sets for each partition can be computed in polynomial time.*

Proof According to area argument, the number of independent requests that can be accepted at same time is no more than $C = 4\lambda^2 k^2 / \pi$ which is a constant. Then, we can find the strong/weak candidate sets in each $\lambda^i k \times \lambda^i k$ square in polynomial time by using dynamic programming as we did in [Algorithm 1](#). Assume $n_{a,b}(t)$ requests located in a $\lambda^i k \times \lambda^i k$ square whose top left corner is $(a \lambda^i k + p, b \lambda^i k + q)$ in a (p, q) partition at time t . The main difference is that we need to define $\mathcal{Q}(e_1, e_2, \dots, e_C, s)$ as the maximum possible profit from $\mathcal{R}(t)$ when e_1, e_2, \dots, e_C are the last independent requests accepted by central authority before or at time s . Then,

$$\mathcal{C}_1(t) = \max \mathcal{Q}(e_1, e_2, \dots, e_C, \max s),$$

where $\max s$ the latest start time among $\mathcal{R}(t)$. Since there are at most $\binom{n_{a,b}(t)}{C+1} = O(n_{a,b}(t)^{C+1})$ different \mathcal{Q} , and each \mathcal{Q} can be computed within $\binom{n_{a,b}(t)}{C} = O(n_{a,b}(t)^C)$ time, the time complexity to compute strong/weak candidate sets in a $k \times k$ square whose left top corner is $(ak + i, bk + j)$ at time t is $O(n_{a,b}(t)^{2C+1})$. Let $n(t)$ denote the total number of requests in $\mathcal{R}(t)$. The time complexity to compute strong/weak candidate sets in all $\lambda^i k \times \lambda^i k$ squares of a partition (p, q) at time t is no more than $O(n(t)^{2C+1})$. \square

In each partition, some requests may be ignored. To achieve a better approximation, we shift the horizontal and vertical lines and compute strong/weak candidate sets for k^2 partitions where $p \in [1, k]$ and $q \in [1, k]$. We set the best strong/weak candidate sets among all partitions as the strong/weak candidate sets of time t . It takes $O(k^2 n(t)^{2C+1})$ time to find strong/weak candidate sets at each time. Then, the total running time is at most $O(k^2 n^{2C+2})$ where n is the number of total requests since we have to compute this at most n times.

On the other hand, the strong/weak candidate sets we find are at least a $1 - \frac{2}{k}$ approximation as following lemma.

Lemma 7 *At least one partition achieves at least $1 - \frac{2}{k}$ approximation.*

Proof We prove the lemma by using strong candidate set. The weak candidate set case follows same proof. Let $\mathcal{C}_1^{i,j}(t)$ denote the total profit made by all requests such that (1) appear in $\mathcal{C}_1(t)$ and (2) not ignored in partition (i, j) . Then,

$$\sum_{\forall i,j} \mathcal{C}_1^{i,j}(t) \geq (k^2 - 2k)\mathcal{C}_1(t)$$

since each request is ignored in at most 2 partitions.

On the other hand, $\mathcal{C}_1^{i,j}(t)$ is smaller than the profit of the strong candidate set for partition (i, j) , which is no larger than the profit of the approximated strong candidate set, called $\mathcal{C}'_1(t)$. In other words,

$$k^2\mathcal{C}'_1(t) \geq \sum_{\forall i,j} \mathcal{C}_1^{i,j}(t) \geq (k^2 - 2k)\mathcal{C}_1(t)$$

which implies $\mathcal{C}'_1(t) \geq (1 - \frac{2}{k})\mathcal{C}_1(t)$ and finishes the proof. \square

According to [Lemmas 6](#) and [7](#), shifting strategy gives a PTAS for *each* level i . The result can be extended when request disks in *all* levels are considered. The main technology is dynamic programming which is discussed in [Sect. 3.2](#) of [24]. We omit the details here.

Since the strong/weak candidate sets can be approximated well, we have the following theorem.

Theorem 10 *The methods $(\mathcal{K}, \mathcal{G}, \mathcal{H})$ will achieve asymptotically optimum competitive ratios in polynomial time for general networks modeled by disk graphs. The competitive ratios will have an additional factor $1 - \epsilon$ for any constant $\epsilon > 0$ comparing with previous analysis, when we set $\epsilon = \frac{2}{k}$.*

3.4 Dealing With Selfish Users

In this section, we show how to design a mechanism based on the allocation algorithm described in [Sect. 3.2](#) when secondary users could be selfish. For the spectrum allocation and auction problem, when each secondary user declares his request, he may lie on the bid and time requirement. We need to design rules such that each secondary user has incentives to declare his request truthfully. Each secondary user i has its own private information \mathbf{t}_i , including b_i , a_i , and t_i . Let $\mathbf{a}_i = (b'_i, a'_i, t'_i)$ be the value user i will report. For each vector of actions $\mathbf{a} = (\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_n)$, a mechanism $M = (\mathcal{A}, P)$ (including allocation algorithm \mathcal{A} and pricing scheme P) computes a spectrum allocation $\mathcal{A}(\mathbf{a}) = (\mathcal{A}_1(\mathbf{a}), \mathcal{A}_2(\mathbf{a}), \dots, \mathcal{A}_n(\mathbf{a}))$ and a payment vector $\mathbf{p}(\mathbf{a}) = (\mathbf{p}_1(\mathbf{a}), \mathbf{p}_2(\mathbf{a}), \dots, \mathbf{p}_n(\mathbf{a}))$. Each user i will be allocated $\mathcal{A}_i(\mathbf{a})$ and be charged $\mathbf{p}_i(\mathbf{a})$.

A mechanism is said to be truthful if it satisfies both incentive compatible (IC) and individual rational (IR) properties. A mechanism is incentive compatible if every user i will maximize its utility by reporting its private type \mathbf{t}_i truthfully. A mechanism is individual rational if the utility of an agent winning the auction is not less than its utility of losing the auction. We assume that no user will delay his/her request and a user will not lie about t_i and s_i . Unfortunately, in this work, we cannot

Algorithm 3 Online spectrum allocation \mathcal{H}

Input: A constant parameter $c > 1 + \beta, \gamma, \alpha, \Delta, \mathcal{R}_a(t), \mathcal{R}(t), \mathcal{C}_1(t)$. Previous *current candidate requests set* $\mathcal{C} = \mathcal{C}_1(t')$ where $t' < t$. Here, $\mathcal{C}_1(t')$ may be empty.

Output: Whether requests submitted at time $t - \gamma$ will be admitted and new *current candidate requests set* \mathcal{C} .

- 1: **if** $\mathcal{C}_1(t) \geq c \cdot \mathcal{C}_1(t')$ **then**
 - 2: $\mathcal{C} = \mathcal{C}_1(t)$;
 - 3: Accept request $\mathbf{e}_i \in \mathcal{C}_1(t)$ such that $a_i = t - \gamma$.
 - 4: **else**
 - 5: Accept request $\mathbf{e}_i \in \mathcal{C}_1(t')$ such that $a_i = t - \gamma$.
-

design an online spectrum allocation mechanism that is always truthful. Instead, we will show that under the mechanism TOFU, regardless of the actions of other users, no user i can improve its profit by reporting a bid b'_i that is smaller than its true bid value b_i . We call this property as *semi-truthful*.

For the spectrum auction problem, the final profit (or the utility) of a user i is 0 if its request is rejected. If its request is admitted, the final profit is

$$\text{utility}(i) = b_i - \mathbf{p}_i + \mu(b'_i, \ell'_i, t_i),$$

where b_i is the actual valuation, \mathbf{p}_i is the real payment, and $\mu(b'_i, \ell'_i, t_i)$ is the potential preemption penalty, where b'_i is the actual bid of user i .

It is a folklore result that the allocation method in a mechanism that can prevent lying must have the monotone property. Here, a spectrum allocation method \mathcal{A} is monotone if a user i is granted the spectrum usage under \mathcal{A} with a bid $\mathbf{e}_i = (b_i, a_i, t_i)$, then the user i will still be granted the spectrum usage under \mathcal{A} if the user increases bid b_i and/or decreases the required time duration t_i . First, the methods ([Algorithms 2](#) and [3](#)) presented in previous section do have the monotone property. In the algorithm, we need to find strong candidate requests set, and weak candidate requests set. Both sets will be found by dynamic programming. It is easy to show that these dynamic programming methods are monotone. Thus, it is possible to design a mechanism using the algorithms (\mathcal{G} and \mathcal{H}) as spectrum allocation methods.

Consider a user i , and assume the bids of all other users remain the same. We first propose the following definition based on the monotone property of the methods.

Definition 5 Let \underline{b}_i be the minimum bid that i has to bid to get admitted when its spectrum request is to be processed at γ time slots later. Let \bar{b}_i be the minimum bid that i has to bid to get admitted and not get preempted later.

Clearly, $\underline{b}_i \leq \bar{b}_i$. For a secondary user whose request is not granted, the value $\underline{b}_i = 0$. The values \underline{b}_i and \bar{b}_i clearly can be computed in polynomial time since the bid values of all other users are known. Here, \underline{b}_i can be computed at the time $a_i + \gamma$. To compute the value \bar{b}_i , we need to know whether request i will be preempted later. Since the latest job that can preempt \mathbf{e}_i must have starting time no later than $s_i + \Delta$,

Algorithm 4 TOFU semi-truthful online spectrum auction

-
- 1: Based on the setting, we use either [Algorithms 2](#) or [3](#) to decide whether a request \mathbf{e}_i will be admitted or not.
 - 2: The mechanism will charge user i a payment

$$\mathbf{p}_i = \underline{b}_i$$

we must process the potential jobs that can preempt \mathbf{e}_i no later than $s_i + \Delta - \alpha + \gamma$. In other words, the value \bar{b}_i can be computed within time $\Delta + \gamma$ after job i arrived. Then, the protocol TOFU works as follows.

Theorem 11 *The mechanism TOFU is semi-truthful, i.e., to maximize its profit, every secondary user will not bid a price lower than its actual value.*

Proof Consider a user i arrived at time t . Let b_i be its private willing bid and b'_i be its actual bid. When i bids some value $b'_i \in (\underline{b}_i, \bar{b}_i)$, i will get preempted with some unserved time ℓ'_i and receive a compensation $\mu(b'_i, \ell'_i, t_i) = \beta \frac{\ell'_i}{t_i} b'_i$.

Case 1: $b'_i \geq \bar{b}_i$. There are three strategies again for i .

- (1) If $b'_i \geq \bar{b}_i$, then user i will be admitted and will not be preempted. It will be charged a payment $\mathbf{p}_i < \bar{b}_i$ and thus will get a profit $b_i - \mathbf{p}_i > 0$.
- (2) If $b'_i < \underline{b}_i$, it will not get admitted and thus get 0 utility.
- (3) If $b'_i \in (\underline{b}_i, \bar{b}_i)$, then i will be admitted and then be preempted with unserved time ℓ'_i . It will get a compensation $\mu(b'_i, \ell'_i, t_i) = \beta \frac{\ell'_i}{t_i} b'_i$. Its utility then is $f \cdot b_i - \mathbf{p}_i + \mu(b'_i, \ell'_i, t_i) = (1 - \beta \frac{\ell'_i}{t_i}) b_i - \mathbf{p}_i + \beta \frac{\ell'_i}{t_i} b'_i = b_i - \mathbf{p}_i - \beta \frac{\ell'_i}{t_i} (b_i - b'_i)$, which is less than the profit $b_i - \mathbf{p}_i$ that it will get when reported b_i since $b'_i < \bar{b}_i \leq b_i$.

Thus, in all subcases, reporting untruthfully will not gain any benefit for i .

Case 2: $b'_i \in (\underline{b}_i, \bar{b}_i)$. There are five strategies for i .

- (1) If $b'_i = b_i$, it will be admitted and then be preempted. Let ℓ_i be the unserved time slots when bidding b_i . Then, its utility is $(1 - \beta \frac{\ell_i}{t_i}) b_i - \mathbf{p}_i + \beta \frac{\ell_i}{t_i} b_i = b_i - \mathbf{p}_i > 0$.
- (2) If $b'_i \geq \bar{b}_i$, then user i will be admitted and will not be preempted. It will be charged a payment $\mathbf{p}_i < \bar{b}_i$ and thus will get a profit $b_i - \mathbf{p}_i > 0$.
- (3) If $b'_i < \underline{b}_i$, it will not get admitted and thus get 0 utility.
- (4) If $b_i < b'_i < \bar{b}_i$, then i will be admitted and then be preempted with a shorter unserved time $\ell'_i \leq \ell_i$, due to the monotone property of the method. It will get a compensation $\mu(b'_i, \ell'_i, t_i) = \beta \frac{\ell'_i}{t_i} b'_i$. Its utility then is $f \cdot b_i - \mathbf{p}_i + \mu(b'_i, \ell'_i, t_i) = (1 - \beta \frac{\ell'_i}{t_i}) b_i - \mathbf{p}_i + \beta \frac{\ell'_i}{t_i} b'_i = b_i - \mathbf{p}_i - \beta \frac{\ell'_i}{t_i} (b_i - b'_i)$, which is larger than the profit $b_i - \mathbf{p}_i$ that it will get when reported b_i since $b'_i > b_i$.
- (5) If $\underline{b}_i < b'_i < b_i$, then i will be admitted and then be preempted with a longer unserved time $\ell'_i \geq \ell_i$. Its utility then is $f \cdot b_i - \mathbf{p}_i + \mu(b'_i, \ell'_i, t_i) = (1 - \beta \frac{\ell'_i}{t_i}) b_i - \mathbf{p}_i + \beta \frac{\ell'_i}{t_i} b'_i = b_i - \mathbf{p}_i - \beta \frac{\ell'_i}{t_i} (b_i - b'_i)$, which is smaller than the profit $b_i - \mathbf{p}_i$ that it will get when reported b_i since $b'_i < b_i$.

Thus, in all subcases, reporting lower will not gain any benefit for i .

Case 3: $b_i \leq \underline{b}_i$. There are several strategies again for i .

- (1) If $b'_i \leq \underline{b}_i$, it will not get admitted and thus has 0 profit.
- (2) If $b'_i \geq \bar{b}_i$, it will be admitted and not be preempted. In this case, its profit is $b_i - \mathbf{p}_i < 0$.
- (3) If $\underline{b}_i < b'_i < \bar{b}_i$, it will be admitted and be preempted with an unserved time ℓ'_i .

In this case, its profit is $b_i - \mathbf{p}_i - \beta \frac{\ell'_i}{t_i} (b_i - b'_i) < 0$ since $b_i < \mathbf{p}_i$ and $b_i < b'_i$. In all subcases, bidding untruthfully is not beneficial to user i . \square

Observe that, in the scheme, the only scenario (case 2.4) that a secondary user can gain benefit is when $b_i \in (\underline{b}_i, \bar{b}_i)$ and it bids a value $b'_i \in (b_i, \bar{b}_i)$. The user i must bid larger than its true valuation b_i , but not larger than \bar{b}_i . Observe that value \bar{b}_i is computed at time $a_i + \gamma + \Delta$ using the requests submitted during time interval $[a_i, a_i + \Delta]$, where user i does not know when it arrives at time a_i . Thus, we have

Theorem 12 *If any user i does not know the requests within Δ time after its arrival, the mechanism TOFU is truthful, i.e., to maximize its profit, every secondary user will bid truthfully even it learned history.*

It is not difficult to construct examples in which a user can gain profit by bidding larger than its true valuation if it can know the bids of other users. It will be an interesting future work to study the total payment of a mechanism compared with the best possible payments collected by a truthful mechanism. Notice that, when we know the distributions of all bids, and there is only one spectrum, and no spatial and temporal reuse, Myerson [26] presented a mechanism that guarantees the payment is optimal. We note that it is very challenging to design a mechanism with a total payment close to optimum for the problem studied here.

3.5 Simulation Studies

We conducted extensive simulations to study the performance of the algorithm \mathcal{G} , specifically, the competitive ratio of the algorithm in practice. We set $c_1 = 2$ and $c_2 = \sqrt{\frac{\gamma+1}{\Delta}}$ for algorithm \mathcal{G} . Suppose the total service time is always 2,000 time slots, which is large enough comparing with time requirements. In the experiment, we first generate n secondary nodes that are randomly placed. We randomly deployed 100 nodes in a 5×5 square area. Assume that all secondary users locate at these positions. The geometry location of a request is exactly the location of secondary user who claimed that request. We assume that any two requests within distance 1 will conflict with each other if they requested the same channel for some time slots. We then generate random requests with random bid values, and time requirement. The bid of each request is uniformly distributed in $[0, 1]$; the time requirement of each request is uniformly distributed in $[1, \Delta]$.

Observe that the average load of a node in the simulation is $\frac{J \cdot D}{T \cdot n}$, where J is total number of requests, D is the average duration of a request (thus, $D = \Delta/2$ in the

setting), T is total duration of scheduling (thus, $T = 2,000$ time slots here), and n is number of secondary users ($n = 100$ here). Observe that the expected number of users in a unit area is $n/5^2 = 4$ in the setting. Thus, varying J and Δ , we tested both lightly loaded system and also highly loaded system.

3.5.1 Competitive Ratio of Algorithm \mathcal{G}

A number of parameters may affect the performances of algorithm \mathcal{G} , e.g., the number of total requests, the *time bound* Δ , and the *delay factor* γ . To study the effect of these parameters, we first fix the *time bound* Δ and study the competitive ratios of \mathcal{G} while the *delay factor* γ varies. Then, we fix the *delay factor* γ and study the competitive ratios of \mathcal{G} while the *time bound* Δ changes. We set three different total numbers of requests in these experiments to study how the degree of competition affects \mathcal{G} 's performance.

In Fig. 5, we plot the competitive ratios of \mathcal{G} in various cases while the *delay factor* γ is fixed (see Fig. 5a–c); we also plot the competitive ratios of algorithm \mathcal{G} in various cases while *time bound* Δ is fixed (see Fig. 5d–f). In most cases, method \mathcal{G} makes a total profit that is more than 95 % of the optimum offline method when $\gamma \simeq \Delta$. Observe that although it is NP-hard to find the optimum offline solution, we implemented a method (omitted here due to space limit) that will find an almost optimum solution (within a factor $1 - \epsilon$ for an arbitrarily small $\epsilon > 0$) when the conflict graph is a disk-intersection graph. The experimental results are much better than the theoretical bound we proved in previous sections.

The competitive ratios decrease when Δ increases. This is exactly what the theoretical analysis implies. When $\gamma < \Delta$, the competitive ratio of \mathcal{G} increases significantly when *dfactor* increases. This implies that increasing the *delay factor* is a good way to achieve better performance if the *delay factor* is relatively small. We also observe that \mathcal{G} almost achieves the optimum offline solution when *delay factor* γ is close to or larger than Δ , which verifies the theoretical bound. Furthermore, the competitive ratio will not improve much when $\gamma > \Delta$. Thus, we recommend to set $\gamma \in [\Delta/2, \Delta]$.

The total number of requests also affects the performance of \mathcal{G} . We observe that the competitive ratios decrease when the total number of requests increases. This is because \mathcal{G} is conservative: the weak preemption in \mathcal{G} just tries to satisfy the theoretical bound, which may lose some profit potentially. Thus, when there are more requests, the optimal offline algorithm will make more profit but the profit made by \mathcal{G} will not increase so much.

3.5.2 Efficiency Ratio of Algorithm \mathcal{G}

Recall that to ensure that secondary users will not bid a price lower than their actual values, we do not charge what they bid. For secondary user whose request is accepted, we charge the minimum bid such that the request will still be accepted. Thus, the actual profit made is not the winners' total bids but the winners' total payments. Clearly, the total payments are no more than the total bids. Here, we define the *efficiency ratio* as the ratio between the profit made by the mechanism and the winners' total bids computed by the method \mathcal{G} . We also study the effect of

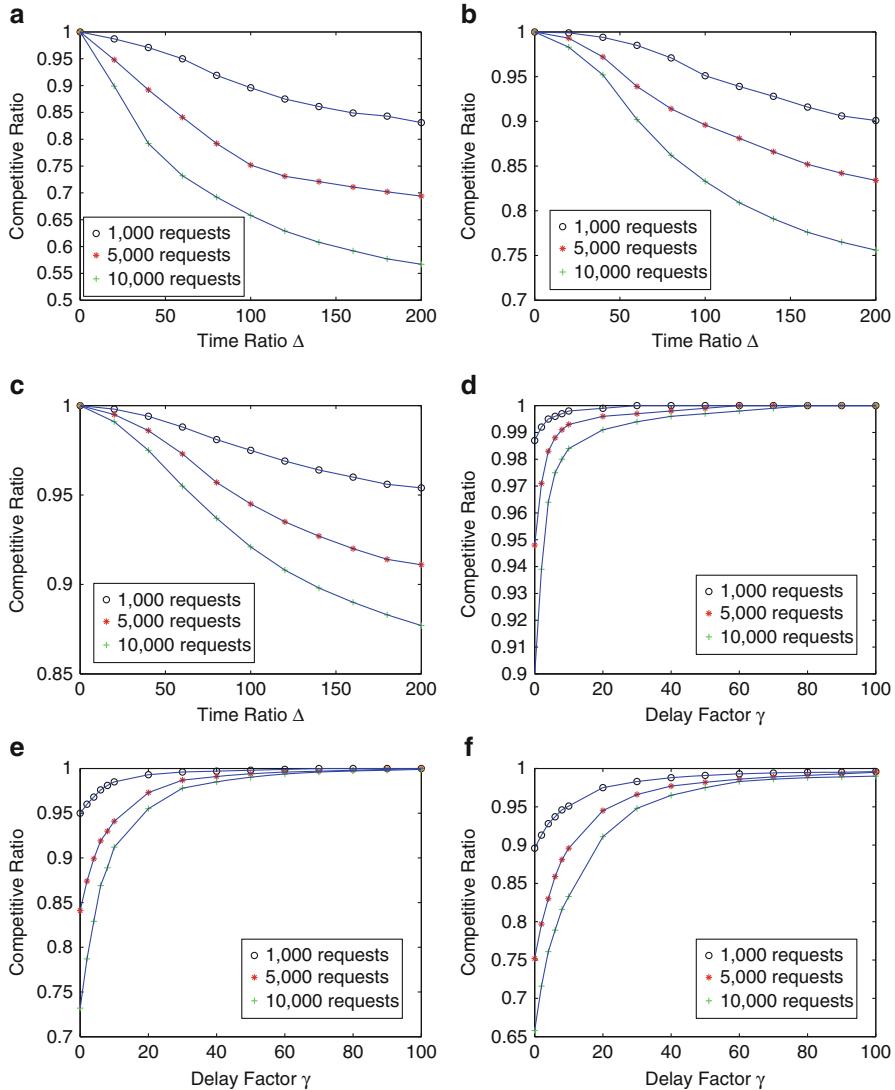

Fig. 5 The competitive ratios of method \mathcal{G} in various cases. **(a)** Delay factor $\gamma = 0$. **(b)** Delay factor $\gamma = 10$. **(c)** Delay factor $\gamma = 20$. **(d)** Time bound $\Delta = 20$. **(e)** Time bound $\Delta = 60$. **(f)** Time bound $\Delta = 100$

some parameters such as the number of total requests, the *time bound* Δ , and the *delay factor* γ .

In Fig. 6, we plot the efficiency ratios of the mechanism in various cases. In (a)–(c), we fix *time bound* Δ and plot the efficiency ratio while *delay factor* γ changes; in (d)–(f), we fix *delay factor* γ and plot the efficiency ratio while time bound Δ changes.

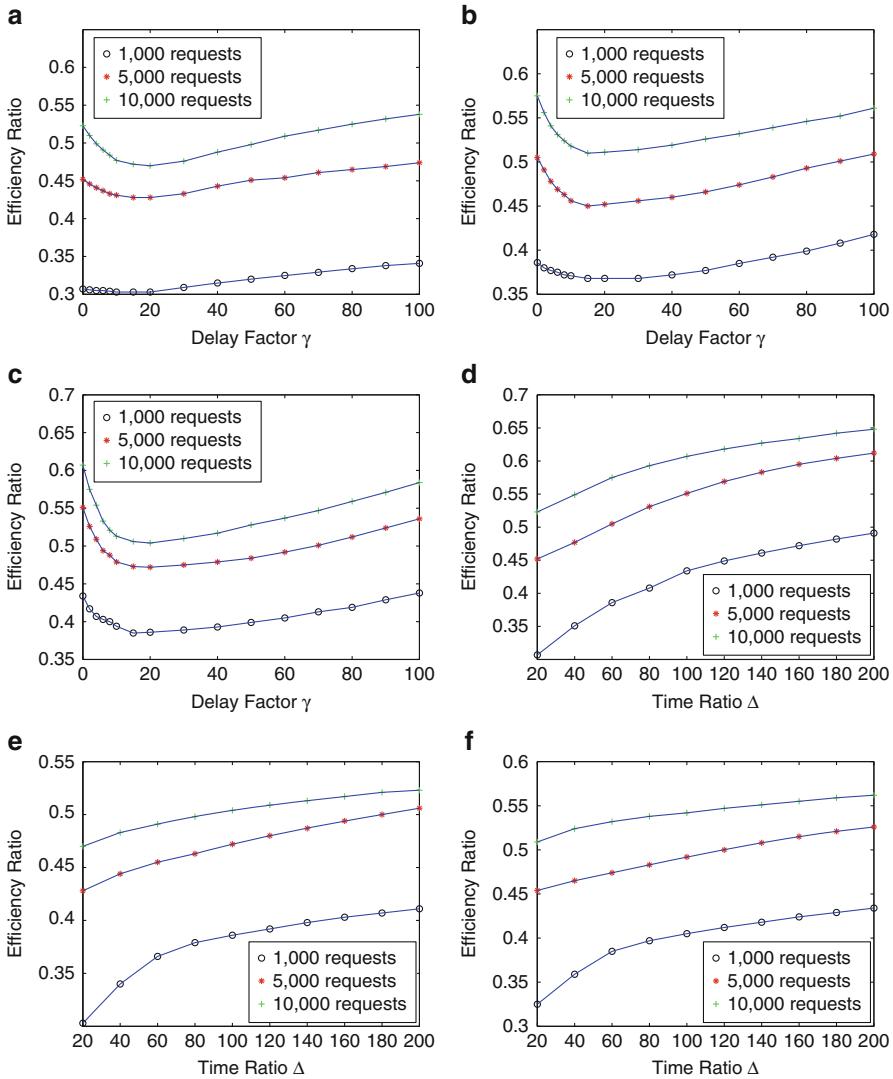

Fig. 6 The efficiency ratios of the mechanism in various cases. **(a)** Time bound $\Delta = 20$. **(b)** Time bound $\Delta = 60$. **(c)** Time bound $\Delta = 100$. **(d)** Delay factor $\gamma = 0$. **(e)** Delay factor $\gamma = 20$. **(f)** Delay factor $\gamma = 60$

We observe that the efficiency ratios increase when the Δ or the number of total requests increases. In this case, a request has more chance to conflict with other requests. Thus, it is easier to find a replacement which increases the minimum value a winner has to bid. We also find that the efficiency ratios first decrease then increase when the *delay factor* γ increases. Comparing with Fig. 5d-f, we know that the

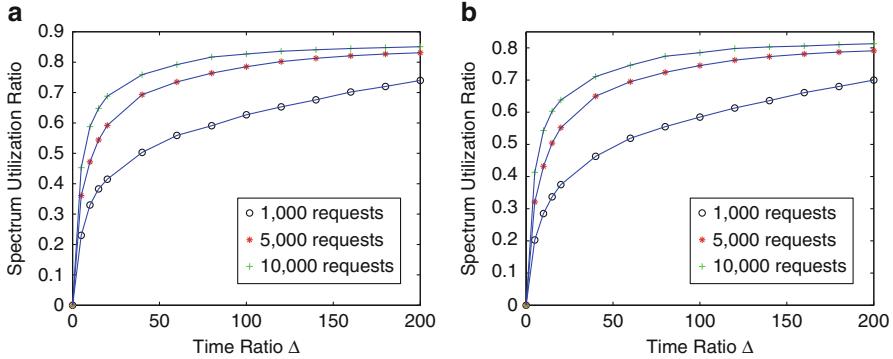

Fig. 7 The spectrum utilization ratios of method \mathcal{G} in various cases. (a) Delay factor $\gamma = 0$. (b) Delay factor $\gamma = 20$

efficiency ratios decrease because the competitive ratios increase dramatically when γ is relatively small. The total payments do not increase as fast as the total bids do. When the *delay factor* γ is larger than Δ , the efficiency ratios increase because the competitive ratios increase slowly.

3.5.3 Spectrum Utilization Ratio of Algorithm \mathcal{G}

We also studied the spectrum utilization of the method. The spectrum utilization in a time interval $[1, T]$ under a spectrum allocation method \mathcal{A} is defined as $\sum_{t=1}^T \ell_{\mathcal{A}}(t) / \sum_{t=1}^T n(t)$, where $\ell_{\mathcal{A}}(t)$ is the number of users who are using the channel (at different locations) at time t without conflict in spectrum allocation produced by \mathcal{A} and $n(t)$ is the maximum number of users who can use the channel concurrently without conflict. Figure 7 reports the results. We find that varying γ does not affect the spectrum utilization that much. Observe that the measurement of spectrum utilization compared to the method with the offline method that can arbitrarily preempt the spectrum usage. When the system is highly loaded, the spectrum utilization of the method is about 80 %, while the spectrum utilization is about 50 % for lightly loaded system.

3.5.4 Compare Algorithm \mathcal{G} with Simple Heuristics

We then compare algorithm \mathcal{G} with two simple greedy algorithms. One greedy algorithm \mathcal{B} always satisfies the virtual spectrum candidate request with the largest $C_1(t)$ value. When request with larger bid is coming, \mathcal{B} will terminate current assignments with smaller value if necessary. Another greedy algorithm \mathcal{D} always satisfies the virtual spectrum candidate request with the largest $C_2(t)$ value. When request with larger bid is coming, \mathcal{D} will terminate current assignments with smaller value if necessary. The competitive ratio of these two simple greedy algorithms could be arbitrarily bad theoretically. We conduct simulations to compare them with algorithm \mathcal{G} which is asymptotically optimal theoretically.

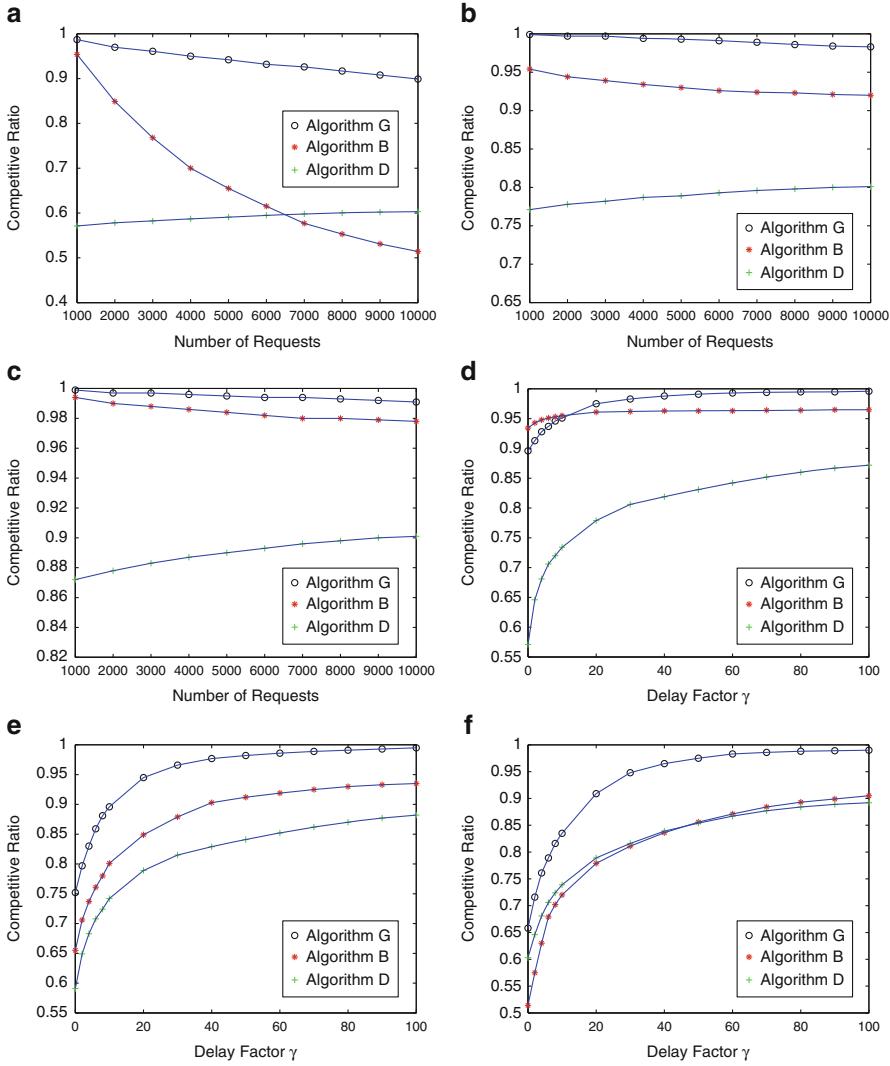

Fig. 8 Compare algorithm \mathcal{G} with two simple greedy algorithms. **(a)** Delay factor $\gamma = 0$. **(b)** Delay factor $\gamma = 10$. **(c)** Delay factor $\gamma = 20$. **(d)** 1,000 requests. **(e)** 5,000 requests. **(f)** 10,000 requests

In Fig. 8, we plot the competitive ratios of algorithm \mathcal{G} , simple greedy algorithm \mathcal{B} and \mathcal{D} to compare their performances. In Fig. 8a–c, we fix time bound $\Delta = 20$ and vary the number of total requests for different delay factors γ . In Fig. 8d–f, we fix time bound $\Delta = 100$ and vary delay factor γ for different number of total requests. We observe that the algorithm \mathcal{G} outperforms these two simple greedy algorithms significantly in most cases.

The effect of number of total requests is also investigated in Fig. 8a–c. We can see that the competitive ratio of algorithm \mathcal{G} is not affected much when the number of total requests increases. On the other hand, the performance of algorithm \mathcal{B} decreases significantly when the number of total requests increases and *delay factor* $\gamma = 0$. The competitive ratio of algorithm \mathcal{D} increases slightly when the number of total requests increases. However, the competitive ratio of algorithm \mathcal{D} is always worse than that of the algorithm \mathcal{G} .

The effect of *delay factor* γ is then investigated in Fig. 8a–c. We can see that the performances of all three algorithms increase significantly when the *delay factor* γ increases. When *delay factor* γ is increasing, the algorithm \mathcal{G} is always the best one whose performance is close to the optimum.

4 Spectrum Allocation and Mechanism Design with Known Distribution on Requests

In this section, we review the results on online spectrum allocation and mechanism design when some additional distribution information about online spectrum requests are known. Two different models will be studied here. The first model assumed that semi-arbitrary-arrival case, while the second model assume a random-arrival case.

4.1 Semi-Arbitrary-Arrival Case

In this section, we consider the semi-arbitrary-arrival case. We first show the lower bounds of competitive ratios under the *random ordering hypothesis*. The lower bound of social efficiency ratio comes from the well-known secretary problem [7] which is a special case in the model. The lower bound of revenue efficiency ratio comes from the result in [16]. Consider the model used in [16] (Sect. 5), in which a single item is being sold and an adversary specifies a set of bids that are randomly matched with arrival and departure intervals. That model is actually a special case of the model when $T = 1$. So its lower bound on the efficiency is also a lower bound in the model. We have following theorems.

Theorem 13 *For the online spectrum admission problem, no online mechanism is e -competitive for social efficiency.*

Theorem 14 *For the online spectrum admission problem, for any constant $\epsilon > 0$, there is no strategyproof online mechanism which is $(3/2 - \epsilon)$ -competitive for revenue efficiency.*

We are now ready to describe the online mechanism for spectrum allocation. The online mechanism \mathcal{M}_1 runs as following. It will divide the overall time times T into two phases. In the first phase (composed of the first δT time slots), it studies some

Algorithm 5 Learning algorithm $\mathcal{M}_1(\mathcal{L})$ for mechanism \mathcal{M}_1

Input: Requests arriving during $[0, \delta T]$.

Output: A parameter $\tau > 0$.

```

1: for  $\tau = 1$  to  $\lfloor \frac{T}{2} \rfloor$  do
2:   if  $\Pr(t_1 \leq t_i \leq 2t_1) \geq \frac{1}{2}$  then
3:     Return parameter  $\tau$ 

```

properties of the distribution of the requested time durations. Then, in the second phase, the mechanism will start to allocate the channel to the coming requests.

In the first phase, the mechanism \mathcal{M}_1 collects the information of coming requests and computes the information $\Pr(t_1 \leq t_i \leq 2t_1)$ for $t_1 \in [1, T/2]$. Here, we use $\Pr(t_1 \leq t_i \leq t_2)$ to denote the estimated probability that the required time duration of a coming request is at least t_1 and at most t_2 . We then learn a parameter τ which will be introduced later by using the *learning Algorithm 5* $\mathcal{M}_1(\mathcal{L})$. Here, $[\tau, 2\tau]$ will be a time interval such that at least a constant proportion of the requests whose requested duration of time slots will be in this interval. During the first δT time slots, we reject all coming requests. Later, we will show that it does not affect the performance significantly.

Notice that the adversary can pick up a common distribution (such as uniform distribution, normal distribution, exponential distribution) as the distribution of required time durations. The learning method ([Algorithm 5](#)) can find a feasible parameter τ without knowing the exact distribution. Notice that here the constant $1/2$ in [Algorithm 5](#) could be replaced by any positive constant $\in (0, 1)$. For example, if the required time durations are uniformly distributed in $[t_1, t_2]$, then $\tau = \frac{t_1+t_2}{2}$ is a feasible solution. If the required time durations are normally distributed with mean μ , then $\tau = \mu$ is a feasible solution. In the rest of chapter, we make the following assumption.

Assumption 1 *Given a distribution on the required time slots, we assume that a feasible value τ can always be found by [Algorithm 5](#).*

Since we only sampled the requests arrived in time $[0, \delta T]$, we first would like to bound the estimation error of these probabilities. Let Err be the maximum error

$$Err = \max_{t_1 \leq T/2} \|\Pr(t_1 \leq t_i \leq 2t_1) - \overline{\Pr}(t_1 \leq t_i \leq 2t_1)\|,$$

where $\overline{\Pr}(t_1 \leq t_i \leq t_2)$ is the actual probability that the required time slots of a coming request are in $[t_1, t_2]$.

Lemma 8 *The estimation error Err is neglectable.*

Proof According to the theory of VC-dimension [30], the bound on the test error of a classification model is

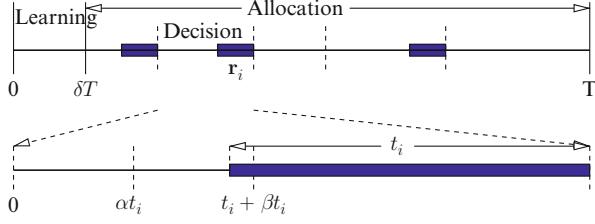

Fig. 9 In mechanism $\mathcal{M}_1(\mathcal{D})$, time is divided into several decision phases. A decision phase may not accept any request. For each decision phase with one accepted request e_i , the requested number of time slots should be $t_i \in [\tau, 2\tau]$

$$\Pr \left(Err \leq \sqrt{\frac{h(\log(2N/h) + 1) - \log(\eta/4)}{N}} \right) \geq 1 - \eta,$$

where $h < N$ is the VC-dimension of the classification model, and N is the size of the training set. The formula is valid when $h < N$. In the case, the VC-dimension is at most $h = \log \frac{T}{2}$ since we only consider the inputs with requested time duration at most $T/2$. Assume the arrival rate is λ , then the size of training set is $N = \delta\lambda T$ with high probability. The bound on the test error is given by $\sqrt{\frac{\log \frac{T}{2} (\log(\delta\lambda T / \log \frac{T}{2}) + 1)}{\delta\lambda T}} = \sqrt{\frac{\log(2\delta\lambda - \log \log \frac{T}{2} + 1) \log \frac{T}{2}}{2\delta\lambda T}}$. Since δ and λ are constants, the error is neglectable when T is large enough. \square

After the first δT time slots, based on the results from learning algorithm, the decision algorithm $\mathcal{M}_1(\mathcal{D})$ of mechanism \mathcal{M}_1 decides which requests will be admitted and how much each admitted request should be charged. The following concept is needed for presenting mechanism \mathcal{M}_1 .

Definition 6 Let $p_{\leq \tau}^{(s)}$ denote the s -th highest bid value (for the usage of per unit time slot) among all requests received during time interval $[0, \tau]$.

The main idea of algorithm $\mathcal{M}_1(\mathcal{D})$ is to divide the time interval $[\delta T, T]$ into multiple non-overlap decision phases. Figure 9 illustrates the protocol. In each decision phase, the decision algorithm waits for some time slots, then tries to admit a request with the highest bid value in this decision phase. The reason why we do so is that the adversary could generate any kind of bid values set. In some cases, to guarantee the performance, we have to admit the highest bid value, e.g., all bid values are 0 except the highest one $\max_i b_i = 1$. By waiting a certain number of time slots, we can ensure that we will see the highest bid with a constant probability. Later, we will prove that the decision algorithm $\mathcal{M}_1(\mathcal{D})$ could admit the request with highest bid value in each decision phase with constant probability. Current decision

Algorithm 6 Decision algorithm $\mathcal{M}_1(\mathcal{D})$ for mechanism \mathcal{M}_1

Input: Parameter τ returned from [Algorithm 5](#), constant parameter $\alpha \leq 1$ and β , requests arrived during $[\delta T, T]$.
