Preface

Many practical applications that include machines, people, or different resources that are indivisible, give rise to optimization models with discrete decision variables. On the other hand, nonconvexities (e.g., complementarity) in optimization models can be formulated using discrete variables.

In past years, we witnessed several developments in combinatorial optimization. These developments came along with progress in related fields such as complexity theory, approximation algorithms, as well as with advances in software and hardware technology.

The first edition of the *Handbook of Combinatorial Optimization* received a warm welcome from the scientific community. We are happy to introduce the second edition of the *Handbook of Combinatorial Optimization*. Some material in the first edition has been revised and several new chapters have been added.

We are grateful to all authors and referees for their valuable time. Moreover, we thank the publisher and the production team for helping with editing the handbook. We hope that this book will continue to be a helpful tool for individuals working in the field of combinatorial optimization.

Acknowledgements. We would like to acknowledge the help of our students during the years of editing the handbook. We have also been partially supported by Air Force, NSF, and DTRA grants.

Abstract

This chapter studies approximability and inapproximability for a class of important domination problems in different network topologies. In addition to the well-known *connected dominating set*, *total dominating set*, more general forms

of the problems, in which each node is required to be dominated by more than one of its neighbors, are also considered. An example is the *positive influence dominating set* (PIDS) problem, originated from the context of influence propagation in social networks. The PIDS problem seeks for a minimal set of nodes P such that all other nodes in the network have at least a fraction $\rho > 0$ of their neighbors in P . Furthermore, domination problems can be hybridized to form new problems such as T-PIDS and C-PIDS, the *total* version and the *connected* version of PIDS. The goal of the chapter is to narrow the gaps between the approximability and inapproximability of those domination problems. Going beyond the classic $O(\log n)$ results, the chapter presents the explicit constants in the approximation factors to obtain tighter approximation bounds. While the first part of the chapter focuses on the general topology, the second part presents improved approximation results in different network topologies including power-law networks, social networks, and treelike networks.

1 Introduction

The dominating set problem in graph asks for a minimum size subset of vertices in which each vertex is either in the dominating set or adjacent to some vertex in the dominating set. It is one of the most widely studied topics in graph theory. In a survey by Hanes et al. [1], over 1,200 papers on the subject were listed in the bibliography. Domination problems have found many practical applications in building routing virtual backbones, power management, topology control, broadcast scheduling in sensor networks, and many others [2–9]. Recently, a variation of dominating set, called *positive influence dominating set* (PIDS), has been applied to identify influential users in social networks for viral marketing [10–12].

The approximability of the dominating set problem is the same with that of the *set cover* problem [13]. The work of Slavik [14] states that both problems can be approximated within a factor $\ln n - \ln \ln n + \theta(1)$, where n is the number of vertices in the dominating set instance (or the number of elements in the set cover instance). The lower bound on the approximability is given by Feige [13] in which set cover cannot be approximated within a factor $(1 - o(1)) \ln n$, unless NP has slightly superpolynomial time algorithms.¹ Hence, the approximation factor for the DS problem is tight up to a small sub-logarithm factor. However, this is not true for many variants of the DS problem, in which the gaps between lower bounds and upper bounds on the approximability are rather large.

In many domination problems, only the asymptotic approximation factor $O(\log n)$ is given without stating the explicit constant in the factor. In the case of the PIDS problem, the best hardness result is only APX-hard [11], while the best approximation factor is $O(\log n)$ [16]. This chapter is an effort to narrow down the approximability gaps for variants of the DS problem in some important graph classes, revealing the hidden constant in the approximation factors. In addition,

¹Under the typical assumption that $P \neq NP$, the best known inapproximability result is $c \cdot \ln n$ [15] for some constant $c > 0$.

inapproximability of numerous domination problems can be achieved under the same framework in which parameters in the Feige's construction for set cover [13] are fine-tuned. For special graph classes, better approximation factors can be obtained by exploiting the graph topologies. A common theme in this chapter is that approximability results are first proved for the PIDS problem, and then necessary modification to achieve the same results for other variants is presented.

Organization. The chapter continues with a brief summary on variants of the DS problem and their current approximability states. After that, the approximability of the considered domination problems in general graphs is presented. The rest of the chapter studies the domination problems in special graph classes including power-law graphs (social networks), dense graphs, and trees. Finally, a scalable algorithm for multiple-hop PIDS problem is introduced. Experiments on real-world social networks are presented to demonstrate the application of the dominating problem in finding influential users in social networks.

2 Dominating Set Variants and Generalizations

The most famous variant of the DS problem is the *connected dominating set* problem. The problem seeks for a minimum size DS which induces a connected subgraph. The problem has the same inapproximability $(1 - o(1)) \ln n$ of the DS problem. Guha and Khuller [17] give an $H(\Delta) + 2 = \ln n + O(1)$ approximation algorithm for finding minimum CDS, where $H(n) = 1 + 1/2 + \dots + 1/n$ is the harmonic function.

Another well-studied variant of DS is *total dominating set*. The total dominating set has an addition condition on the subgraph induced by the dominating set that the subgraph has no isolated vertices. The problem has the same hardness of the DS problem and can be approximated within a factor $\ln n + O(1)$ [18].

In addition to the well-known *connected dominating set* and *total dominating set*, more generalization forms of the problems, in which each nodes is required to be dominated by more than one of its neighbors, are also considered. The *t-tuple* DS problem seeks for a subset $S \subset V$ in graph $G = (V, E)$ so that each vertex is either in S or adjacent to at least t vertices in S . The problem admits a hardness of approximation factor $(1 - \varepsilon) \ln n$ and an $\ln(\Delta + 1) + 1$ approximation [19–21]. A generalization of the *t-tuple* DS problem is the k -connected *t-tuple* dominating set problem [22] in which the subgraph is induced by the *t-tuple* DS. There is a $6 + \ln 5/2(k-1) + 5/k$ approximation algorithm for the problem on UDG. No hardness results other than NP-completeness for the problem were presented in literature.

2.1 Positive Influence Dominating Set

The positive influence dominating set problem emerges in the context of social networks, in which a set of influential users are sought for to propagate the influence to other users. Regularly, individuals tend to be influenced by the opinions/behaviors

of their relatives, friends, and colleagues. For example, children whose parents smoked are twice as likely to begin smoking between 13 and 21 [23], and peer pressure accounts for 65 % reasons for binge drinking, a major health issue, by children and adolescents [24]. Moreover, the tendency of a user to adopt a behavior increases together with the number of his neighbors that follow that behavior.

The motivation behind the PIDS problem is to exploit the relationships and influences among individuals in social networks might offer considerable benefit to both the economy and society. As an example, positive impacts of intervention and education programs on a properly selected set of initial individuals can diffuse widely into society via various social contacts: face to face, phone calls, email, social networks, and so on.

Formally, let $G = (V, E)$ be a graph that represents the social network and an influence factor $0 < \rho < 1$, in the PIDS problem one wishes to find a minimum set of vertices P , so that every other vertices in G has at least a fraction ρ of their neighbors in P . Denote by $N(v)$ the set of neighbors of a vertex $v \in V$ and $d(v) = |N(v)|$ the degree of v . The problem is defined in graph theory language as follows.

POSITIVE INFLUENCE DOMINATING SET (PIDS)

Input: An undirected graph $G = (V, E)$ with influence factor $0 < \rho < 1$.

Problem: Find a subset $P \subset V$ such that $\forall u \in V \setminus P : |N(u) \cap P| \geq \rho d(u)$.

Vertices in P are said to dominate or influence their neighbors in $V \setminus P$. The constant ρ is called the *influence factor*, since it determines for each vertex the minimum number of neighbors to include in the PIDS. The studied problem in [10–12] is a special case of the above problem with $\rho = 1/2$.

It is rather difficult to show the inapproximability for the PIDS problem. The best hardness result is only APX-hard [11], i.e., there is a certain constant $\varepsilon > 0$ that approximating the problem within a factor $1 + \varepsilon$ is NP-hard. This lower bound on the approximability is far from the typical lower bounds $O(\ln n)$ in many domination problems. In contrast to t -tuple DS and any DS problems with fixed domination requirements, adding edges to a PIDS instance during a reduction will change the domination requirements. The “dynamic” threshold $\rho d(v)$, rather than one fixed t , makes the PIDS problem resist to proof approaches for known domination problems.

The literature on identifying influential users begins with Domingos and Richardson [25] who were the first to study the propagation of influence in networks. Kempe et al. [26, 27] formulated the influence maximization problem as an optimization problem. Later, Leskovec et al. [28] study the influence propagation in a different perspective in which they aim to find a set of nodes in networks to detect the spread of virus as soon as possible.

Similarly, the *connected* and *total* versions of the PIDS problem can be defined as follows.

TOTAL POSITIVE INFLUENCE DOMINATING SET (T-PIDS)

Input: An undirected graph $G = (V, E)$ with influence factor $0 < \rho < 1$.

Problem: Find a subset $P_T \subset V$ such that $\forall u \in V : |N(u) \cap P_T| \geq \rho d(u)$.

CONNECTED POSITIVE INFLUENCE DOMINATING SET (C-PIDS)

Input: An undirected connected graph $G = (V, E)$ with influence factor $0 < \rho < 1$.

Problem: Find a subset $P_C \subset V$ such that $\forall u \in V \setminus P_C : |N(u) \cap P_C| \geq \rho d(u)$ and P_C induces a *connected* subgraph of G .

Similarly, *total connected positive influence dominating set* (TC-PIDS) problem asks for a connected and total PIDS P_{TC} of G .

2.2 Multiple-Hop PIDS Problem

The PIDS problem can be extended to allow multiple-hop influence. The multiple-hop PIDS problem [29] seeks for a minimal cost seeding, measured as the number of nodes, to massively and quickly spread the influence to the whole network (or a large segment of the network). The influence is limited to the nodes that are within d hops from the seeding for some constant $d \geq 1$. In other words, the influence is expected to spread to the whole networks within d propagation rounds.

Locally Bounded Diffusion Model. Let $R_0 \subset V$ be the subset of vertices selected to initiate the influence propagation, called the *seeding*. Also a vertex $v \in R_0$ is said to be a seed. The propagation process happens in round, with all vertices in R_0 are influenced (thus active in adopting the behavior) at round $t = 0$. At a particular round $t \geq 0$, each vertex is either active (adopted the behavior) or inactive, and each vertex's tendency to become active increases when more of its neighbors become active. If an inactive vertex u has more than $\lceil \rho d(u) \rceil$ active neighbors at round t , then it becomes active at round $t + 1$. The process goes on for a maximum number of d rounds, and a vertex once becomes active will remain active until the end. An initial set R_0 of vertices is a *d -seeding* if R_0 can make all vertices in the networks active within at most d rounds.

The influence factor $0 < \rho < 1$ decides how widely and quickly the influence propagates through the network. Influence factor ρ reflects real-world factors such as how easy to share the content with others or some intrinsic benefit for those who initially adopt the behavior. In case $\rho = 1/2$, the model is also known as the *majority* model that has many application in distributed computing, voting system [30], etc.

Problem Definition. The multiple-hop PIDS problem is defined as follows: *Given an undirected graph $G = (V, E)$ modeling a social network and an influence factor $0 < \rho < 1$, find in V a minimum size d -seeding, i.e., a subset of vertices, that can activate all vertices in the network within at most d rounds.*

Influence propagation with a limited number of hops (multiple-hop PIDS) as well as a special case of T-PIDS, when $\rho = 1/2$, were first considered in Wang et al. [10] in which they iteratively find dominating sets until forming a T-PIDS. Feng et al. [16] showed NP-completeness for the PIDS problem, when $\rho = 1/2$.

The APX-hardness and an $O(\log n)$ approximation algorithm for T-PIDS problem were introduced in [11]. Under the condition that the geometric representation of a unit disk graph is given and the maximum degree is bounded by a constant, Zhang et al. [31] devised a polynomial time approximation scheme (PTAS) for the t -latency bounded information propagation.

2.3 Generalized Dominating Set Problems

Another way to generalize the PIDS problem is to replace the domination requirement $\rho d(v)$ for vertex v with a function $r_v(x)$ of $d(v)$, called the *threshold function*. This yields the so-called generalized DS problem.

GENERALIZED DOMINATING SET (GDS)

Input: An undirected graph $G = (V, E)$ and a family of functions $r_v(x)$ for $v \in V$.

Problem: Find a subset $P \subset V$ such that $\forall v \in V \setminus P : |N(v) \cap P| \geq r_v(d(v))$.

Different family of $\{r_v(x)\}_{v \in V}$ corresponds to different domination problems, for example, $r_v(x) = 1$ gives the usual dominating set; $r_v(x) = \rho x$ gives the PIDS problem; $r_v(x) = t$, where t is a positive constant, gives the t -TUPLE DOMINATING SET problem [20, 21]; and $r_v(x) = c_v$, where c_v are positive constants, gives the FIXED THRESHOLD DOMINATING SET (FTDS) problem. Moreover, for scale-free networks that degree sequences follow power-law distribution, the threshold functions can take any of the form \sqrt{x} or $\log x$, etc.

Notice that using a function $r_v(x)$ instead of a simple constant c_v for vertex v (the case of FTDS) allows the domination requirement of v to be adjusted accordingly when the network evolves or is augmented. It is important to treat GDS as a family of problems but not a single problem. Different families of threshold functions might lead to very different approximation algorithm and inapproximability results. For example, setting $r_v(x) = x$ yields the MINIMUM VERTEX COVER that has simple two-approximation algorithm and $2 - \varepsilon$ lower bound under the unique game conjecture [32], while most domination problems achieve only $O(\log n)$ approximation algorithms.

In the same way that T-PIDS, C-PIDS, and TC-PIDS are formulated, the following problems are defined by considering the generalized threshold function:

- TOTAL GENERALIZED DOMINATING SET (T-GDS).
- CONNECTED GENERALIZED DOMINATING SET (C-GDS).
- k -CONNECTED GENERALIZED DOMINATING SET (k C-GDS), in which the subgraph induced by the dominating set is k -vertex connected, i.e., there are at least k -vertex-disjoint paths between any vertices in the dominating set, where k is an integral constant. C-GDS is a special case of k C-GDS with $k = 1$.
- TOTAL CONNECTED GENERALIZED DOMINATING SET (TC-GDS).
- k -CONNECTED TOTAL GENERALIZED DOMINATING SET (k CT-GDS).

Threshold Function. Not all threshold functions yield meaningful domination problems. For example, if $r_v(x) > x$, then there is no way to satisfy the requirement $|N(v) \cap P| > r_v(d(v)) > d(v)$. Only *monotone increasing threshold function* $r_v(x)$ that satisfies the following conditions is considered in the rest of the chapter:

1. $0 < r_v(x) < x \quad \forall x > 0$.
2. $0 \leq r_v(x) - r_v(x-1) \leq 1 \quad \forall x > 0$.
3. $\lim_{x \rightarrow \infty} \frac{r_v(x)}{x} < 1$.

The first condition makes the problem “nontrivial” to solve (to be precise, it makes the problem hard to approximate within $O(\log n)$). The second and third conditions guarantee the growing rate of the function to be linear or sublinear.

3 Approximability of Domination Problems in General Graphs

This section presents inapproximability results (lower bound) for domination problems in families GDS, T-GDS, kC -GDS, and TC-GDS followed by approximation algorithms (upper bound). All the results also hold for PIDS, C-PIDS, and T-PIDS, as they are the special cases of the generalized dominating set problems considered in this section.

3.1 Hardness of Approximation

First, the hardness $\ln \Delta - O(\ln \ln \Delta)$ is proved by studying the problems in B -bounded graphs (Sect. 3.1.2). Then the proofs are extended to obtain the hardness $(1/2 - \varepsilon) \ln n$ in Sect. 3.1.3. Finally, the hardness result for multiple-hop PIDS is derived through a reduction from the one-hop PIDS problem.

The proofs require setting parameters in Feige’s reduction for set cover [13]. The hardness results of set cover cannot be applied in a black-box fashion since it leads to weaker inapproximability $O(\log B)$ and $O(\log n)$ for B -bounded graph and general graph. That is, they cannot provide the explicit constants in the inapproximability factors. The challenge lies on bounding the size of added vertices in our reductions with the size of the optimal set cover. Two important quantities that are not mentioned in the Feige’s reduction are the maximum capacity of a set and the maximum frequency of a point.

The approximation factor and hardness of approximation of domination problems are summarized in Tables 1 and 2. The new results shown in this chapter are the following:

- The proof that domination problems belong to the families GDS, T-GDS, C-GDS, and TC-GDS can be approximated within $\ln \Delta + O(1)$ but cannot be approximated within $(\frac{1}{2} - o(1)) \ln n$, unless $\text{NP} \subset \text{DTIME}(n^{O(\log \log n)})$.
- On B -bounded degree graphs, none of the problems can be approximated within $\ln B - O(\ln \ln B)$, under the standard assumption $P \neq NP$. As a consequence,

Table 1 Hardness of approximation for domination problems in graphs

Problem	Original	T-(*)	$kC\text{-(*)}$	$kCT\text{-(*)}$
t -tuple DS	$(1 - \varepsilon) \ln n$ [20]	$(1 - \varepsilon) \ln n$	$(1 - \varepsilon) \ln n, k = 1$ $k = 1$ [20], $\forall k [\star]$	$(1 - \varepsilon) \ln n, k = 1$ $k = 1$ [20], $\forall k [\star]$
Positive Influence DS	APX-hard, $\rho = \frac{1}{2}$ [12]	–	APX-hard, $k = 1$ [11]	–
	$(1 - \varepsilon) \ln \Delta [\star]$	$(1 - \varepsilon) \ln \Delta [\star]$	$(1 - \varepsilon) \ln \Delta [\star]$	$(1 - \varepsilon) \ln \Delta [\star]$
	$(\frac{1}{2} - \varepsilon) \ln n [\star]$	$(\frac{1}{2} - \varepsilon) \ln n [\star]$	$(\frac{1}{2} - \varepsilon) \ln n [\star]$	$(\frac{1}{2} - \varepsilon) \ln n [\star]$
Fixed Threshold DS	$(1 - \varepsilon) \ln n$	$(1 - \varepsilon) \ln n$	$(1 - \varepsilon) \ln n [\star]$	$(1 - \varepsilon) \ln n [\star]$

Symbol $[\star]$ means results are derived from this chapter. The hardness $(1 - \varepsilon) \ln \Delta$ is proved under the typical assumption $P \neq NP$, while the hardness $(\frac{1}{2} - \varepsilon) \ln n$ is proved with the assumption $NP \not\subseteq DTIME(n^{O(\log \log n)})$

Table 2 Hardness of approximation for domination problems in graph with maximum degree Δ

Problem	Original	T-(*)	$kC\text{-(*)}$	$kCT\text{-(*)}$
Dominating Set	$\ln \Delta - O$ $(\ln \ln \Delta)$ [33]	$\ln \Delta - O$ $(\ln \ln \Delta)$ [33]	$\ln \Delta - O$ $(\ln \ln \Delta)$ $k = 1$ [33], $\forall k [\star]$	$\ln \Delta - O$ $(\ln \ln \Delta)$ $k = 1$ [33], $\forall k [\star]$
t -tuple DS	$\ln \Delta - O$ $(\ln \ln \Delta)[\star]$	$\ln \Delta - O$ $(\ln \ln \Delta)[\star]$	$\ln \Delta - O$ $(\ln \ln \Delta)[\star]$	$\ln \Delta - O$ $(\ln \ln \Delta)[\star]$
Positive Influence DS	$\ln \Delta - O$ $(\ln \ln \Delta)[\star]$	$\ln \Delta - O$ $(\ln \ln \Delta)[\star]$	$\ln \Delta - O$ $(\ln \ln \Delta)[\star]$	$\ln \Delta - O$ $(\ln \ln \Delta)[\star]$
Fixed Threshold DS	$\ln \Delta - O$ $(\ln \ln \Delta)[\star]$	$\ln \Delta - O$ $(\ln \ln \Delta)[\star]$	$\ln \Delta - O$ $(\ln \ln \Delta)[\star]$	$\ln \Delta - O$ $(\ln \ln \Delta)[\star]$

Symbol $[\star]$ means results is derived from this chapter. The hardness are proved with the assumption $P \neq NP$

the considered problems are not approximated within $\ln \Delta - O(\ln \ln \Delta)$, unless $P = NP$.

- If the network is scale-free, i.e., the degree sequence follows a power-law distribution or the network is dense, the greedy algorithm obtains a constant factor approximation algorithm for “PIDS-like” domination problems.
- In networks with tree topologies, it is possible to find the optimal solution in linear time for all considered domination problems.

3.1.1 Feige’s Reduction for Set Cover

This part briefly summarizes the Feige’s proof for set cover (SC) which is essential to understand the incoming proofs. Feige presented a reduction from a k -prover proof system for a MAX 3SAT-5 instance ϕ that is a *conjunctive normal form* formula consists of n variables and $\frac{5n}{3}$ clauses of exactly three literals. The verifier interacts with k provers and asks provers different questions based on a random string r ; each question involves $l/2$ clauses and $l/2$ variables. If the formula ϕ is

satisfiable, then the provers have a strategy that cause the verifier accepts for all random strings. If only a $(1 - \varepsilon)$ fraction of the clauses in ϕ are simultaneously satisfiable, then for all strategies of the provers, the verifier weakly accepts with a probability at most $k^2 \cdot 2^{-cl}$, where c is a constant that depends only on ε .

The core of the SC gadget is a partition system $B(m, L, k, d)$, where B is a ground set of m points. The partition system is a collection of $L = 2^l$ partitions P_1, \dots, P_L of B , each partition P_i has exactly k disjoint subsets $p_{i,1}, \dots, p_{i,k}$. Any cover of m points in B requires at least $d = (1 - \frac{2}{3})k \ln m$ subsets. The condition to make constructing such a system possible is that $k < \frac{\ln m}{3 \ln \ln m}$.

Let $R = (5n)^l$ denote the number of possible random strings for the verifier. Make R copies of partition system B . Let B_r denote the copy of the partition associated with the random string r and $p_{i,j}^r$ the copy of set $p_{i,j}$ in B_r .

The instance of SC in the Feige's reduction is now presented. The universal set $\mathcal{U} = \bigcup_{r \in R} B_r$ contains $N = |\mathcal{U}| = mR$ points; and the set system is $\mathcal{S} = \{S_{q,a,i}\}_{q,a}$, where i can be deduced from syntax of (q, a) . Each set $S_{q,a,i}$ corresponds to a question-answer pair (q, a) of the i th prover and $S_{q,a,i} = \bigcup_{(q,i) \in r} p_{a_r,i}^r$ where $(q, i) \in r$ means on random string r , the i th prover receives question q , and a_r is the assignment of variables extracted from a .

As long as $k^2 2^{-cl} < \frac{8}{k^3 \ln^2 m}$, the hardness result will be $(1 - \frac{4}{k}) \ln m$, i.e., if formula ϕ is satisfiable, then mR points in \mathcal{U} can be covered by kQ subsets, and if only $(1 - \varepsilon)$ fraction of the clauses are simultaneously satisfiable, the minimum set cover has size at least $(1 - \frac{4}{k}) \ln m / kQ$. Here, Q is the set of all $n^l (5/3)^{l/2}$ possible questions. The condition can be satisfied with $l > \frac{1}{c} (5 \log k + 2 \log \ln m)$.

The hardness ratio $(1 - f(k)) \ln m$ of the set cover is obtained from the following key lemma.

Lemma 1 (Lemma 4.1 [13]) *If ϕ is satisfiable, then the above set of $N = mR$ points can be covered by kQ subsets. If only a $(1 - \varepsilon)$ fraction of the clauses in ϕ are simultaneously satisfiable, the above set requires $(1 - 2f(k))kQ \ln m$ subsets in order to be covered, where $f(k) \rightarrow 0$ as $k \rightarrow \infty$.*

Note that $\ln m = (1 - \varepsilon) \ln N$ by the setting of n, l , and m in the proof. Thus, the final hardness ratio is $(1 - \varepsilon) \ln N$, where $N = |\mathcal{U}|$. However, choosing different settings of n, l , and m yields different hardness ratios.

Upper bounds for quantities that appear in later proofs are presented for convenience.

- The *number of subsets* $|\mathcal{S}| \leq |Q|2^{2l}$. Since, for each question $q \in Q$, there are at most 2^{2l} answers of $2l$ bit length.
- The *maximum size* of a subset $\Delta_{\mathcal{S}} = \max_{S \in \mathcal{S}} |S| \leq m3^{l/2}$. Since each i and $q \in Q$ there are at most $3^{l/2}$ random strings r such that the verifier makes query q to the i th prover and $|p_{a_r,i}^r| \leq m$.

- The *maximum frequency* of a point (element) in \mathcal{U} : $f \leq k2^l$. Because, for a pair (q, i) , each partition $p_{a_r, i}^r$ is included at most 2^l times, plus each point in B_r appears in exactly k partitions.

3.1.2 Hardness of Approximation: $O(\ln \Delta)$

The hardness results $\ln \Delta - O(\ln \ln \Delta)$ for domination problems are shown indirectly by proving the hardness $\ln B - O(\ln \ln B)$ in the graphs with degree bounded by a constant B . In the first part, hardness results for PIDS and its variations are established. In the second part, the hardness of domination problems in the families GDS, T-GDS, kC -GDS, and d BD-GDS is proved with subtle modifications on the reductions in the first part.

Positive Influence Dominating Set. The inapproximability of PIDS and its variants is given in the following theorem.

Theorem 1 *Neither PIDS, T-PIDS, nor kC -PIDS can be approximated within $\ln B - O(\ln \ln B)$ in B -bounded graphs, unless $P=NP$.*

The proof is based on a reduction from an instance of the *bounded set cover* problem (SC_B) to an instance of PIDS problem whose degrees are also bounded by $B' = B \text{ poly log } B$.

BOUNDED SET COVER (SC_B)

Input: A set system $(\mathcal{U}, \mathcal{S})$, where $\mathcal{U} = \{e_1, e_2, \dots, e_n\}$, is a universe and \mathcal{S} is a collection of subsets of \mathcal{U} . Each subset in \mathcal{S} has at most B elements and each point belongs to at most B subsets, for a predefined constant $B > 0$.

Problem: Find a cover that is a subfamily $\mathcal{C} \subseteq \mathcal{S}$ of sets whose union is \mathcal{U} with the minimum number of subsets.

For a sufficient large constant $B_0 > 0$, set cover problem where each set has at most $B > B_0$ elements is hard to approximate to within a factor of $\ln B - O(\ln \ln B)$, unless $P = NP$ [34].

The proof [34] maps an instance of $GAP - SAT_{1,\gamma}$ to an instance $\mathcal{F} = (\mathcal{U}, \mathcal{S})$ of set cover with $\Delta_S \leq B$. Parameters l, m in Feige's construction [13] are fixed to $\theta(\ln \ln B)$ and $\frac{B}{\text{poly log}(B)}$, respectively. Since the parameters can be found in constant time using brute-force search, the assumption for the hardness is $P \neq NP$ instead of $NP \not\subset \text{DTIME}(n^{O(\log \log n)})$. The produced instance has the following properties that will be used later in our proofs:

- $|\mathcal{U}| = mn^l \text{ poly log } B$, $|\mathcal{S}| = n^l \text{ poly log } B$.
- $\Delta_S \leq B$, $F_{\mathcal{U}} \leq \text{poly log } B$ for sufficient large B .

A sufficient large constant B_0 gives us $f \leq \text{poly log}(B) \leq B$ for all $B \geq B_0$. \square

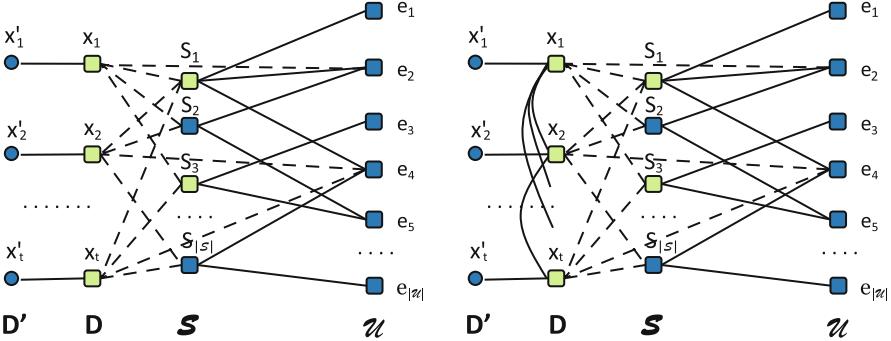

Fig. 1 Reduction from SC_B to PIDS (left) and T-PIDS (right)

SC_B-PIDS Reduction. For each instance $\mathcal{F} = (\mathcal{U}, \mathcal{S})$ of SC_B, construct a graph $\mathcal{H} = (V, E)$ as follows (Fig. 1):

- Construct a bipartite graph with the vertex set $\mathcal{U} \cup \mathcal{S}$ and edges between \mathcal{S} and all elements $x \in \mathcal{S}$, for each $S \in \mathcal{S}$.
- Add a set D consisting of t vertices and a set D' with same number of vertices, say $D = \{x_1, x_2, \dots, x_t\}$ and $D' = \{x'_1, x'_2, \dots, x'_t\}$. The value of t will be determined later.
- Connect x_i to x'_i , $\forall i = 1 \dots t$ to force the selection of x_i in the optimal PIDS.
- Connect each vertex $e_j \in \mathcal{U}$ to $\lceil \frac{\rho}{1-\rho} f(e_j) \rceil - 1$ and each vertex $S_k \in \mathcal{S}$ to $\lceil \frac{\rho}{1-\rho} |S_k| \rceil$ vertices in D , where $f(e_j)$ is the frequency of point e_j . The connection minimizes the degree differences of vertices in D .

Lemma 2 *The size difference between the optimal PIDS of \mathcal{H} and the optimal SC_B of \mathcal{F} is exactly the cardinality of D , i.e., $\text{OPT}_{\text{PIDS}}(\mathcal{H}) = \text{OPT}_{\text{SC}}(\mathcal{F}) + t$.*

Proof Let P be an optimal PIDS of \mathcal{H} . Since either x_i or x'_i must be selected into P , and $x'_i \in P$ can be always replaced with x_i inside P , thus, it is safe to assume that $D' \cap P = \emptyset$ and $D \subset P$.

By the construction, each vertex $S_k \in \mathcal{S}$ has enough required neighbors in P , while each vertex $e_i \in \mathcal{U}$ needs at least one more neighbors in P or it has to be selected. Since all vertices in \mathcal{U} must be adjacent to at least one vertex in \mathcal{S} , it is possible to replace each vertex $e_i \in P$ with one of its neighbors in \mathcal{S} without increasing the size of P . Thus, w.l.o.g. assumes that the optimal solution will contain vertices in \mathcal{S} but not in \mathcal{U} .

Hence, $P \setminus D$ must induce a cover for $\mathcal{F} = (\mathcal{U}, \mathcal{S})$. In other words, $\text{OPT}_{\text{PIDS}}(\mathcal{H}) \geq \text{OPT}_{\text{SC}}(\mathcal{F}) + t$.

Besides, given a cover $\mathcal{C} \subseteq \mathcal{S}$ for $(\mathcal{U}, \mathcal{S})$, it is easy to check that $\mathcal{C} \cup D$ gives a PIDS for \mathcal{H} . Thus, $\text{OPT}_{\text{SC}}(\mathcal{F}) + t \geq \text{OPT}_{\text{PIDS}}(\mathcal{H})$ that completes the proof. \square

The requirements to transfer hardness results of set cover to PIDS problem are to keep the degree of vertices in \mathcal{H} bounded by B' and keep t sufficiently small in comparison with the optimal solution of the SC_B instance in order to derive the ratio.

Lemma 3 *There exists a construction of \mathcal{H} with $t \leq \frac{\text{OPT}_{SC}}{\ln^2 B}$ and $B' = \Delta(\mathcal{H}) = O(B \text{ poly log } B)$.*

Proof First, the total degree of vertices in D , $\text{vol}(D)$, is bounded. For two sets of vertices A and B , define $\phi(A, B)$ the set of edges crossing between them.

$$\begin{aligned} \text{vol}(D) &= |\phi(D, D')| + |\phi(D, \mathcal{U})| + |\phi(D, \mathcal{S})| \\ &= |D| + \sum_{S_k \in \mathcal{S}} \lceil \frac{\rho}{1-\rho} |S_k| \rceil + \sum_{e_j \in \mathcal{U}} \lceil \frac{\rho}{1-\rho} f(e_j) - 1 \rceil \\ &\leq \frac{2\rho}{1-\rho} |\mathcal{S}| B + |\mathcal{S}| + t = \left(\frac{2\rho}{1-\rho} B + 1 \right) |\mathcal{S}| + t. \end{aligned} \quad (1)$$

The above inequalities hold because of $\sum_{S_k \in \mathcal{S}} |S_k| = \sum_{e_j \in \mathcal{U}} f(e_j)$ and $|S_k| \leq B$,

$\forall S_k \in \mathcal{S}$.

Select $t = \frac{|\mathcal{U}|}{B \ln^2 B}$. Since each set in \mathcal{S} can cover at most B elements, it follows that $\text{OPT}_{SC} \geq \frac{|\mathcal{U}|}{B}$; hence, $\frac{\text{OPT}_{SC}}{\ln^2 B} \geq t$.

To have a valid construction of \mathcal{H} , it is sufficient that $t \cdot B' \geq \text{vol}(D)$. Thus, select B' satisfying

$$\begin{aligned} B' &\geq \frac{1}{t} \left(\left(\frac{2\rho}{1-\rho} B + 1 \right) |\mathcal{S}| + t \right) \\ &\approx \left(\frac{2\rho}{1-\rho} B + 1 \right) \frac{B \ln^2 B n^l \text{ poly log } B}{mn^l \text{ poly log } B} \approx B \text{ poly log } B. \end{aligned} \quad (2)$$

Hence, setting $B' = B \text{ poly log } B$ gives us the desired construction of \mathcal{H} . \square

Theorem 2 *There exist constants B_1, c_1 such that for every $B' \geq B_1$, it is NP-hard to approximate the PIDS problem in graphs with degrees bounded by B' within a factor of $\ln B' - c_1 \ln \ln B'$.*

Proof Assume that there exists an algorithm that finds a PIDS of size at most $\ln B' - c_1 \ln \ln B'$ the optimal size in graph with degrees bounded by B' . Then the contradiction is obtained by showing how to approximate the SC_B problem with ratio $\ln B - c_0 \ln \ln B$. Selecting sufficient large B_1 is not difficult and shall be ignored to make the proof simpler.

Let $\mathcal{F} = (\mathcal{U}, \mathcal{S})$ be an instance of SC_B . Construct an instance \mathcal{H} of PIDS problem using the reduction SC_B -PIDS. From (2), there exists constant $\beta > 0$

so that $B' \leq B \ln^\beta B$. The approximation for PIDS returns a solution of size at most $(\ln B' - c_1 \ln \ln B') \text{OPT}_{PIDS}$. Then, that can be converted into a solution of SC_B by excluding vertices in D (see [Lemma 2](#)) and obtain a cover of size at most

$$\begin{aligned} & (\ln B' - c_1 \ln \ln B')(\text{OPT}_{SC} + t) - t \\ & \leq (\ln B' - c_1 \ln \ln B')\text{OPT}_{SC} + (\ln B' - c_1 \ln \ln B') \frac{\text{OPT}_{SC}}{\ln^2 B} \\ & \leq \left(\ln B + \beta \ln \ln B - c_1 \ln(\ln B + \theta(\ln \ln B)) + O\left(\frac{1}{\ln B}\right) \right) \text{OPT}_{SC}. \end{aligned}$$

Select $c_1 = c_0 + \beta + 1$. The solution for SC_B problem is then smaller than $\ln B - c_0 \ln \ln B$ times OPT_{SC} which implies $P = NP$. \square

Theorem 3 *It is NP-hard to approximate T-PIDS and kC-PIDS problems in graphs of bounded degree $B' > B_2$ within a factor of $\ln B' - c_2 \ln \ln B'$ for some constants $B_2, c_2 > 0$.*

Proof The reduction SC_B -PIDS shall be adjusted to achieve the same hardness result. The following adjustments are made to guarantee *total* and *k-connected* properties:

- On top of the subgraph induced by D , construct $(2 + O(1))k$ -regular Ramanujan graphs so that the subgraph has vertex expansion at least k [\[35\]](#). At the same time, connect S to D so that each vertex in S has at least k neighbors in D . It is easy to check that the subgraph induced by the solution to the dominating set problem is k -vertex connected.
- Connect a vertex $x_i \in D$ with $\lceil \frac{\rho}{1-\rho} d(x_i) \rceil$ other nodes in D , balancing nodes' degrees in D , so that D can dominate themselves. Thus, the degree of each node in D is roughly multiplied by a constant. Since $t = \frac{|U|}{B \ln^2 B} \gg \lceil \frac{\rho}{1-\rho} B' \rceil$, there are always enough vertices in D to connect x_i to.

The rest of the proof is straightforward. \square

Generalized Dominating Set Problems. By modifying the construction in the hardness proof for PIDS, the hardness results for GDS and its variants are obtained in the following theorem.

Theorem 4 *Domination problems in families GDS, T-GDS, and kC-GDS with threshold functions $r_v(x)$ cannot be approximated within $\ln B - O(\ln \ln B)$ in B-bounded graphs, unless $P = NP$.*

Proof Given a B -bounded graph $G = (V, E)$ and a functions $r_v(x)$ satisfying the conditions of a threshold function, let $\rho^* = \max_{v \in V} \lim_{x \rightarrow \infty} \frac{r_v(x)}{x}$. By the third condition,

$\rho^* < 1$ and $\rho = \frac{1}{2}(\rho^* + 1) < 1$. Since $\rho > \rho^*$, there exists an absolute constant $x_0 > 0$ such that $r_v(x) < \rho x \quad \forall x > x_0$ and $\forall v \in V$. Assume through the proof that B is sufficiently large so that $l = \theta(\log \log B) > x_0$.

The main idea in the reduction from dominating set with domination requirement $r_v(d(v))$ is to add connections from v to some $a(v)$ more vertices that are guaranteed to be in the optimal solution so that the remaining domination requirement on v becomes one for vertices in \mathcal{U} and zero for vertices in \mathcal{S} . It is necessary to find $x_v \in \mathbb{N}$ so that

$$c_v(x_v) = r_v(d(v) + x_v) - x_v \in \begin{cases} (0, 1] & \text{if } v \in \mathcal{U} \\ (-1, 0] & \text{if } v \in \mathcal{S}. \end{cases} \quad (3)$$

Claim For $\mu_v = \max\{\lceil \frac{\rho}{1-\rho} d(v) \rceil, x_0\}$, $c_v(\mu_v) \leq 0$.

Proof $c_v(\mu_v) = \rho(d(v) + \mu_v) - x_v = \rho(d(v) - \frac{1-\rho}{\rho} \mu_v) < 0$. □

Since

- $c_v(0) = r_v(d(v)) > 0$.
- $\Delta c_v = c_v(x+1) - c_v(x) \in (-1, 0]$.
- $c_v(\mu_v) < 0$.

There exists some $0 \leq x_v \leq \mu_v$ such that $c_v(x_v)$ satisfies Eq. 3. Notice that x_0 is substantially smaller than B . Hence, the same construction in the case of PIDS with influence factor ρ will work for the general cases as well. The only exception is that vertices in $v \in (\mathcal{S} \cup \mathcal{U})$ where x_v is connected to vertices in D . □

The following result is a direct corollary of the hardness result for the bounded degree case.

Theorem 5 Unless $P = NP$, domination problems in families GDS, T-GDS, and kC -GDS cannot be approximated within a factor of $\ln \Delta - O(\ln \ln \Delta)$, where Δ is the maximum degree.

3.1.3 Hardness of Approximation: $O(\ln n)$

Ideally, since the maximum degree Δ in the graph can be as large as the number of vertices n , it is natural to expect that the PIDS problem cannot be approximated within a factor $\ln n$. However, the hardness result for PIDS with the best parameter settings is only $(1/2 - o(1)) \ln n$. It is conjectured that there is a $1/2 \ln n$ approximation for the PIDS and T-PIDS problem.

Generalized Dominating Set Problems

Theorem 6 Domination problems in families GDS, T-GDS, and kC -GDS with threshold functions $r_v(x)$ cannot be approximated within $\frac{1}{2}(1 - o(1)) \ln n$ where n is the number of vertices, unless $NP \subset DTIME(n^{O(\log \log n)})$.

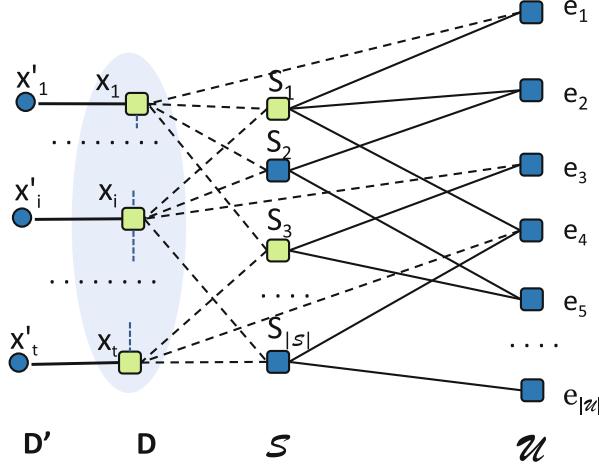

Fig. 2 Reduction from SC_B to GDS, T-GDS, and $k\text{C-GDS}$

Proof The same gadget in Fig. 2 is used to prove for the three general problems. From the gadget in the proof of Theorem 4, it is not necessary to keep degree of vertices in the gadget bounded. Thus, vertices in D are all connected to each other.

Let ρ, x_0, μ_v be the same parameters as in the proof of Theorem 4. The sufficient conditions to make the construction feasible are:

- (GDS): To be able to connect each vertex $v \in (\mathcal{S} \cup \mathcal{U})$ to μ_v vertices in D :

$$|D| = O\left(\max_{v \in (\mathcal{S} \cup \mathcal{U})} \theta\left(\frac{\rho}{1-\rho} \Delta_S\right)\right) = O(\Delta_S) = O(m^{3/2})$$

- ($k\text{C-GDS}$): To add at least k edges from each vertex in \mathcal{S} to vertices in D :

$$|D| = O(k|\mathcal{S}|) = O(|\mathcal{S}|) = O(n^l (5/3)^{l/2} 2^{2l}) = O(n^l 2^{\theta(l)})$$

- (T-GDS): Vertices in D have to dominate themselves. Since $\mu_v = \max\{\lceil \frac{\rho}{1-\rho} d(v) \rceil, x_0\}$, this can be satisfied when

$$|D| - 1 = O\left(\frac{\rho}{1-\rho} \frac{1}{|D|} \sum_{v \in (\mathcal{S} \cup \mathcal{U})} \mu_v\right).$$

Or equivalently

$$|D|^2 = O\left(\sum_{v \in (\mathcal{S} \cup \mathcal{U})} d(v) + x_0(|\mathcal{S}| + |\mathcal{U}|)\right)$$

$$= O\left(2 \sum_{v \in \mathcal{U}} d(v) + |\mathcal{S}| + |\mathcal{U}|\right) = O(m R k 2^l)$$

To summarize, the sufficient condition so that the dominating set of the graph is k -connected and total at the same time is

$$|D| = O(m 2^{\theta(l)} + n^l 2^{\theta(l)} + (m R k 2^l)^{1/2}). \quad (4)$$

Notice that, from the proof of [Theorem 2](#), the hardness ratio is in the form $\frac{(1 - \frac{4}{k})kQ \ln m + |D|}{kQ + |D|}$. In the Feige's reduction, $|D| = O(\Delta_S) = O((5n)^{\frac{2l}{\varepsilon}} 2^{\theta(l)})$ that yields the $(1 - \varepsilon) \ln n$ hardness ratio for set cover but makes the hardness ratio of the domination problem gets arbitrary close to 1. Fortunately, it is possible to reduce the maximum degree by setting $m = (5n)^{cl}$ with a small constant $c > 0$. The consequence is that $\ln m$ is no longer $\ln N + O(1)$; thus, the inapproximability ratio is reduced.

The optimal setting to get the best inapproximability ratio is to set $m = (5n)^{l(1-\varepsilon)}$ for some $\varepsilon > 0$. Then, $N = mR = (5n)^{l(2-\varepsilon)}$, or $m = N^{\frac{1-\varepsilon}{2-\varepsilon}}$. Hence, from (4), it is sufficient that

$$|D| = n^l \frac{2^{\theta(l)}}{n^{l\frac{\varepsilon}{2}}} = o(Q)$$

for sufficiently large l and n . Hence, the hardness ratio will be

$$\frac{(1 - \frac{4}{k})kQ \ln m + o(Q)}{kQ + o(Q)} > \left(1 - \frac{5}{k}\right) \ln m.$$

The number of vertices in the graph is

$$n_H = 2|D| + |\mathcal{S}| + |\mathcal{U}| < \theta(m 3^{l/2}) + n^l 2^{2l} \left(\frac{5}{3}\right)^{l/2} + (5n)^{2l-\varepsilon} < 2|\mathcal{U}| = 2N.$$

Thus, the hardness ratio is at least

$$\left(1 - \frac{5}{k}\right) \ln \left(\frac{n_H}{2}\right)^{1/2 - \frac{\varepsilon}{4-2\varepsilon}} > \left(1 - \frac{5}{k}\right) \frac{1}{2} \left(1 - \frac{\varepsilon}{2-\varepsilon}\right) \ln n_H - \theta(1) > \frac{1}{2}(1-\varepsilon) \ln n_H$$

for sufficiently large k and sufficiently small ε . □

Theorem 7 Domination problems in families GDS, T-GDS, and kC -GDS with threshold functions $r_v(x) = O(\log x)$ cannot be approximated within $(1 - o(1)) \ln n$ where n is the number of vertices, unless $\text{NP} \subset \text{DTIME}(n^{O(\log \log n)})$.

Proof When $r_v(x) = O(\log x)$, the size of $|D|$ is only $O(\log \Delta_S)$. The original settings in the Feige's reduction will give the ratio $(1 - \varepsilon) \ln n_H$. □

Multiple-Hop PIDS Problem. The hardness is shown through a reduction from the one-hop PIDS problem to the multiple-hop PIDS problem with $d \geq 2$. The hardness result follows immediately by the [Theorem 2](#) in the previous section. Given a graph $G = (V, E)$ as an instance of the PIDS problem, construct an instance $G' = (V', E')$ of the PIDS problem as follows (and as illustrated in [Fig. 5](#)).

Replace each edge $(u, v) \in E$ by a gadget called transmitter. The transmitter connecting vertices u and v is a chain of $d - 1$ path, named uv_1 to uv_{d-1} . The vertex u is connected to uv_1 , uv_1 is connected to uv_2 and so on, and vertex uv_{d-1} is connected to v . Each vertex uv_i , $i = 1 \dots d - 1$, is connected to all flash points. An example for transmitter is shown in [Fig. 3](#). The transmitter is designed so that if all flash points and vertex u are selected at the beginning, then vertex uv_{d-1} will be activated after $d - 1$ rounds. Hence, the number of activated neighbors of v after $d - 1$ rounds will equal the number of selected neighbors of v in the original graph ([Fig. 4](#)).

Finally, each edge (w_p, z_p) is replaced with a transmitter. In order to activate all dummy vertices z_p after d rounds, assume, w.l.o.g., that all flash points must be selected in an optimal solution. The following lemma follows directly from the construction.

Lemma 4 *Every solution of size k for the one-hop ($d = 1$) PIDS problem in G induces a solution of size $k + c(\rho)$ for the d -hop PIDS problem in G' .*

On another direction, the following lemma holds.

Lemma 5 *An optimal solution of size k' for the d -hop PIDS problem induces a size $k' - c(\rho)$ solution for the one-hop PIDS problem in G .*

Proof For a transmitter connecting u to v , if the solution of the d -hop PIDS problem contains any of the intermediate vertices uv_1, \dots, uv_{d-1} , that intermediate vertex can be replaced with either u or v to obtain a new solution of same size (or less). Hence, assume, w.l.o.g., that none of the intermediate vertices are selected. Therefore, all flash points must be selected in order to activate the dummy vertices. It is easy to see that the solution of d -hop PIDS excluding the flash points will be a solution of one-hop PIDS in G with size $k' - c(\rho)$. \square

Note that the number of vertices in G' is upper bounded by dn^2 , i.e., $\ln |V'| < 2\ln|V| + \ln d$. Thus, using the same arguments used in the proof of [Theorem 6](#), it can be shown that a $(\frac{1}{4} - \varepsilon) \ln n$ approximation algorithm leads to a $(\frac{1}{2} - \varepsilon) \ln n$ approximation algorithm for the one-hop PIDS problem (contradicts [Theorem 6](#)).

Theorem 8 *The PIDS problem cannot be approximated within $(\frac{1}{4} - \varepsilon) \log n$ for $d \geq 1$, unless $NP \subset DTIME(n^{O(\log \log n)})$.*

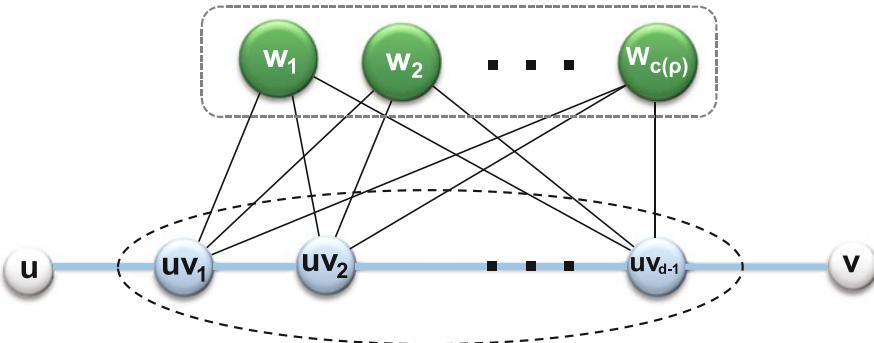

Fig. 3 The transmitter gadget

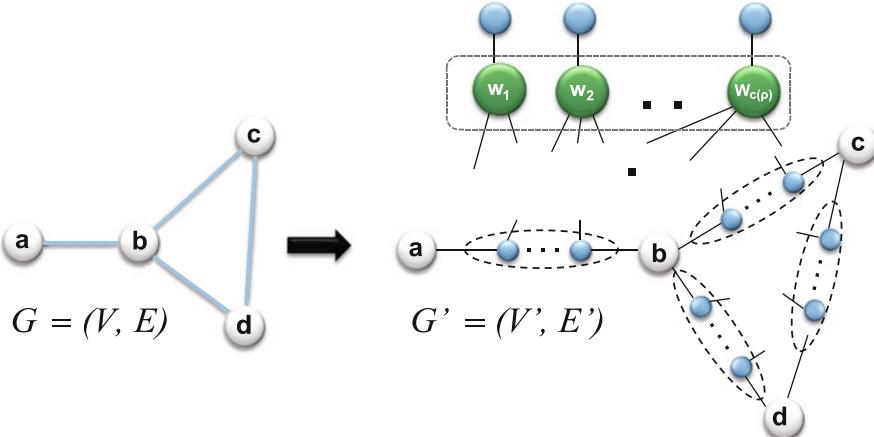

Fig. 4 Gap reduction from one-hop PIDS to d -hop PIDS

3.2 Approximation Algorithm

This part presents briefly how approximation algorithms for studied domination problems can be obtained via a simple reduction to the constrained multiset multicover (CMM) problem. In turn, the MMC problem can be seen as an integer covering problem. Thus, the domination problems benefit directly from advances in integer linear programming and the integer covering problems in particular.

Generalized Dominating Sets. It is easy to show that all domination problems in the generalized class can be approximated within a factor $\ln \Delta + O(1)$.

Theorem 9 Given a graph $G = (V, E)$, there exist $O((|V| + |E|) \log \log |V|)$ algorithms that approximate GDS within $H(2\Delta)$ and T-GDS within $H(\Delta)$.

Proof The proof begins with the definition of the constrained multiset multicover problem (CMM).

CONSTRAINED MULTISET MULTICOVER (CMM)

Input: A set cover instance $(\mathcal{U}, \mathcal{S})$. Each point e has an integer requirement r_e and occurs in a set S with arbitrary multiplicity, denoted $m(S, e)$. Moreover, associate a cost, c_S , with each set $S \in \mathcal{S}$.

Problem: The minimum cost subcollection which fulfils all elements' cover requirements provided each multiset is picked at most once.

Lemma 6 ([36]) There is a natural greedy algorithm that finds a constrained multiset multicover within an H_k factor of the optimal solution, where $k = \max_S \sum_e m(S, e)$.

The GDS problem on the graph $G = (V, E)$ can be reduced to the following instance of CMM:

- $\mathcal{U} = \{e_u : u \in V\}$.
- The cover requirement of e_u is set to $r_u = \lceil r_u(d(u)) \rceil$.
- $\mathcal{S} = \{S_v : v \in V\}$, where S_v contains $\{e_u : u \in N(v)\}$ plus r_v copies of e_v . That is, $m(S_v, e_u) = 1, \forall u \in N(v)$, and $m(S_v, e_v) = \lceil r_v(d(v)) \rceil$.

It follows that the GDS problem can be approximated within

$$H \left(\max_{v \in V} d(v) + r_v(d(v)) \right) \leq H(2\Delta) = H(\Delta) + O(1).$$

In case of T-GDS, the only difference in the reduction is that each multiset S_v contains all the neighbors of v , but not any copies of v . The approximation ratio is, hence, $H(\Delta)$.

Implementation Issue: Straightforward implementations might incur high time complexity. In each step, the greedy algorithms select the node with the highest coverage which is bounded by $O(n)$. Hence, using van Emde Boas priority queue [37] to maintain and update nodes' coverages, the total time complexity can be brought down to $O((|V| + |E|) \log \log |V|)$. Details are presented in the [Algorithm 1](#). \square

Corollary 1 There are polynomial time algorithms that approximate PIDS and T-PIDS problems within ratios $\ln \Delta + \frac{4}{3}$ and $\ln \Delta + 1$, respectively.

Proof Apply [Theorem 9](#) with $r_v(x) = \rho x$ and use the approximation $H(n) \approx \ln n + 0.58$; the approximation ratios for PIDS and T-PIDS can be rewritten as $(\ln \Delta + \frac{4}{3})$ and $(\ln \Delta + 1)$. \square

Connected Generalized Dominating Sets. The connected version of GDS problem requires either submodular theory or a conversion to the Steiner tree problem to obtain the approximation factor as presented in the proof of the following theorems.

Theorem 10 *There is a polynomial time algorithm that finds a weighted C-GDS of size at most $1.55 \ln \Delta + \frac{5}{2}$ time that of the minimum C-GDS.*

Proof The same approach for connected dominating problem in [17] can be applied. In the first stage, a GDS is found using the greedy heuristic described in **Theorem 9**. In the second stage, the vertices in the DS are connected using Steiner tree algorithm.

Since a GDS is also a (normal) dominating set, adding the optimal solution of C-GDS to the found GDS in the first stage gives a Steiner tree of the GDS.

Hence, using a c -approximation algorithm for Steiner tree to connect vertices in a GDS yields a $c(H(\Delta) + \ln 2 + 1)$ approximation algorithm for C-GDS problem. Apply the best known approximation ratio for Steiner tree problem $c \approx 1.55$ by Robins and Zelikovsky [38]; the two-stage algorithm admits a $1.55 \ln \Delta + 2.5$ approximation algorithm. \square

Theorem 11 *There are polynomial time algorithms that approximate unweighted C-GDS, and TC-GDS within ratios $H(3\Delta)$ and $H(2\Delta)$, respectively.*

Proof The greedy algorithm presented in [11] can be extended to work with arbitrary threshold function $r_v(x)$ instead of $r_v(x) = \lceil x/2 \rceil$. The analysis involves a non-submodular potential function that can be overcome with techniques in [39, 40]. Though, it is unclear if the technique can be extended for the weighted cases. \square

4 Domination Problems in Special Graph Classes

This section studies hardness and approximation algorithms for domination problems in special graph classes. In most cases, better approximation algorithms with improved ratio can be obtained. For example, almost all domination problems in power-law networks admit trivial constant factor approximation algorithms as shown later. In planar graphs and disk graphs, there exist *polynomial time approximation scheme* (PTAS) that approximate the optimal solution within a factor arbitrary close to one [41–46]. In the context of wireless sensor networks (WSNs), distributed $(1 + \varepsilon)$ approximation algorithm on unit disk graphs (UDGs) with $O(\log^* |G|)$ rounds is known [47]. However, PTAS is not known for the weighted version of the problem on UDGs. The latest result for that problem is a $5 + \varepsilon$ approximation algorithm [48].

4.1 Power-Law Networks

Many social, biological, and technology networks including OSNs display a non-trivial topological feature: their degree sequences can be well approximated by a power-law distribution [49]. Many optimization problems that are hard on general graphs can be solved much more efficient in power-law graphs [50, 51].

The analysis in this part uses the well-known $P(\alpha, \beta)$ model [52] in which there are y vertices of degree x , where x and y satisfy $\log y = \alpha - \beta \log x$. In other words,

$$|\{v : d(v) = x\}| = y = \frac{e^\alpha}{x^\beta}.$$

Basically, α is the logarithm of the size of the graph and β is the log-log growth rate of the graph. Graphs with the same β value often express the same behaviors and common characteristics. Hence, it is natural to categorize all graphs sharing a β value into a family of graphs and regard to β as a constant (not a part of the input). Without affecting the conclusions, real numbers will be used instead of rounding down to integers. The error terms can be easily bounded and are sufficiently small in the proofs.

The maximum degree in a $P(\alpha, \beta)$ graph is $e^{\frac{\alpha}{\beta}}$. The number of vertices and edges are

$$n = \sum_{x=1}^{e^{\frac{\alpha}{\beta}}} \frac{e^\alpha}{x^\beta} \approx \begin{cases} \zeta(\beta)e^\alpha & \text{if } \beta > 1 \\ \alpha e^\alpha & \text{if } \beta = 1 \\ \frac{e^{\frac{\alpha}{\beta}}}{1-\beta} & \text{if } \beta < 1 \end{cases}, \quad m = \frac{1}{2} \sum_{x=1}^{e^{\frac{\alpha}{\beta}}} x \frac{e^\alpha}{x^\beta} \approx \begin{cases} \frac{1}{2}\zeta(\beta-1)e^\alpha & \text{if } \beta > 2 \\ \frac{1}{4}\alpha e^\alpha & \text{if } \beta = 2 \\ \frac{1}{2} \frac{e^{\frac{2\alpha}{\beta}}}{2-\beta} & \text{if } \beta < 2 \end{cases}$$

where $\zeta(\beta) = \sum_{i=1}^{\infty} \frac{1}{i^\beta}$ is the Riemann zeta function.

Theorem 12 *Minimum PIDS is APX-hard, i.e., there is a positive constant ε depends only on the log-log growth rate β such that approximating PIDS within $1 + \varepsilon$ is NP-hard [53].*

Theorem 13 *In a power-law graph $G \in P(\alpha, \beta)$, the size of the optimal PIDS*

$$\text{OPT}_{\text{PIDS}} = \begin{cases} \Omega(n^\beta) & \text{if } \beta < 1 \\ \Omega(n/\log n) & \text{if } \beta = 2 \\ \Omega(n) & \text{if } \beta > 2. \end{cases}$$

Proof 1. Let k be the size of the optimal PIDS. Note that all nodes of degree more than k/ρ must be selected (otherwise, the number of selected neighbors will exceed k). The number of nodes with degree larger than k will be

$$k > \sum_{x=k/\rho}^{e^{\frac{\alpha}{\beta}}} \frac{e^\alpha}{x^\beta} > \sum_{x=k/\rho}^{e^{\frac{\alpha}{\beta}}} \frac{e^\alpha}{x} = e^\alpha (\ln e^{\frac{\alpha}{\beta}} - \ln k). \quad (5)$$

Solving the above relation gives us $k > \Omega(e^\alpha) = \Omega(n^\beta)$.

2. Similarly, if $\beta = 2$, then $k = \Omega(e^\alpha) = \Omega(n/\log n)$.
3. The lower bound is obtained through a dual-setting approach. Consider the following linear program and its dual of the PIDS problem:

$$\begin{array}{ll} \textbf{LP:} \min & \sum_{v \in V} x_v \\ & \text{s. t. } r_v x_v + \sum_{u \in N(v)} x_u \geq r_v \\ & \quad -x_u \geq -1 \\ & \quad x_u \geq 0 \end{array} \quad \begin{array}{ll} \textbf{DP:} \max & \sum_{u \in V} r_u y_u - \sum_{v \in V} z_v \\ & \text{s. t. } r_u y_u + \sum_{v \in N(u)} y_v - z_u \leq 1 \\ & \quad z_v \geq 0 \\ & \quad y_v \geq 0 \end{array} \quad (6)$$

where $r_u = \rho d_u$. Note that for the integral versions of LP (16) and DP (16), both settings $r_u = \rho d_u$ and $r_u = \lceil \rho d_u \rceil$ yield the same optimal solutions; however, setting $r_u = \rho d_u$ simplifies the approximation ratio analysis.

Set $y_u = \gamma \forall u \in V$. The goal is to look for value of γ that achieves the tightest lower bound on the size of the optimal PIDS.

To satisfy constraints in the dual, set $z_u = \max\{(\rho + 1)d_u\gamma - 1, 0\}$. Then the objective value becomes

$$DP = \rho\gamma \sum_{u \in V} d_u - \sum_{u \in V} \max\{(\rho + 1)d_u\gamma - 1, 0\} \quad (7)$$

$$= \rho\gamma \sum_{u \in V} d_u - \sum_{d_u > \tau(\gamma)} ((\rho + 1)d_u\gamma - 1) \quad (8)$$

where $\tau(\gamma)$ denotes $(\rho + 1)^{-1}\gamma^{-1}$.

Substituting $\gamma = \frac{1}{(\rho+1)\tau}$ into (8), this leads to

$$DP = \frac{\rho}{(\rho + 1)\tau} \sum_{x=1}^{e^{\frac{\alpha}{\beta}}} \frac{e^\alpha}{x^\beta} x - \sum_{x>\tau} \left(\frac{1}{\tau} \frac{e^\alpha}{x^\beta} x - \frac{e^\alpha}{x^\beta} \right) \quad (9)$$

$$= \frac{\rho \zeta(\beta - 1)}{(\rho + 1)\tau} e^\alpha - \sum_{x>\tau} \left(\frac{1}{\tau} \frac{e^\alpha}{x^{\beta-1}} - \frac{e^\alpha}{x^\beta} \right). \quad (10)$$

Except for at most $\lfloor e^{\frac{\alpha}{\beta}} \rfloor$ points $\tau = 1, 2, \dots, \lfloor e^{\frac{\alpha}{\beta}} \rfloor$, the derivative of the objective function, $\frac{dDP}{d\tau}$, is defined. Moreover, at those integral points, both one-sided limits,

$\lim_{\tau \rightarrow i^-} DP$ and $\lim_{\tau \rightarrow i^+} DP$, agree, i.e., DP is a continuous function everywhere with respect to τ .

Lemma 7 For every $\tau \in (i, i + 1), i \in \mathbb{N}^+$, the derivative $\frac{d DP}{d \tau}$ is defined and satisfies

$$\frac{d DP}{d \tau} = -\frac{1}{\tau^2} \left(\frac{\rho \zeta(\beta - 1)}{\rho + 1} e^\alpha - \sum_{x > \tau} \frac{e^\alpha}{x^{\beta-1}} \right). \quad (11)$$

By (11), there exists a fixed dividing point $x_0 \in \mathbb{N}^+$ that depends only on β , satisfying $\frac{d DP}{d \tau}(\tau) \geq 0, \forall \tau < x_0$ and $\frac{d DP}{d \tau}(\tau) < 0, \forall \tau > x_0$. Since DP is continuous everywhere, it obtains the global maximum value at $\tau = x_0$.

It is needed to show that the value of DP at $\tau = x_0$ is $\Omega(n)$, and since the objective of the primal is lower bounded by DP , it follows that the size of the minimum PIDS will be at least $\Omega(n)$.

$$\begin{aligned} DP(x_0) &= \frac{1}{x_0} \left(\frac{\rho \zeta(\beta - 1)}{\rho + 1} e^\alpha - \sum_{x > x_0} \frac{e^\alpha}{x^{\beta-1}} \right) + \sum_{x > x_0} \frac{e^\alpha}{x^\beta} \\ &\geq \sum_{x > x_0} \frac{e^\alpha}{x^\beta} \approx \left(\zeta(\beta) - \sum_{x \leq x_0} \frac{1}{x^\beta} \right) e^\alpha \approx \left(1 - \frac{\sum_{x \leq x_0} \frac{1}{x^\beta}}{\zeta(\beta)} \right) n = \Omega(n). \square \end{aligned}$$

Using the same approach in [Theorem 13](#) gives the similar bounds for T-PIDS in the following theorem.

Theorem 14 In a power-law graph $G \in P(\alpha, \beta)$, the size of the optimal T-PIDS.

$$\text{OPT}_{\text{T-PIDS}} = \begin{cases} \Omega(n) & \text{if } \beta < 1 \text{ or } \beta > 2 \\ \Omega(n/\log n) & \text{if } \beta = 1. \end{cases}$$

Theorem 15 In a power-law graph $G \in P(\alpha, \beta)$, the size of the optimal C-PIDS

$$\text{OPT}_{\text{C-PIDS}} = \begin{cases} \Omega(n) & \text{if } \beta > 2 \\ \Omega(n/\log n) & \text{if } \beta = 1. \end{cases}$$

If networks have optimal PIDS/T-PIDS/C-PIDS of $\Omega(n)$ size, clearly, any algorithms that produce valid PIDS/T-PIDS/C-PIDS will be constant factor approximation algorithms.

Theorem 16 Given a power-law $P(\alpha, \beta)$ graph $G = (V, E)$:

1. $\beta < 1$: PIDS is not in APX (cannot be approximated within a constant factor), while T-PIDS admits a constant factor approximation algorithm.
2. $\beta > 2$: There exist constant factor approximation algorithms for PIDS, T-PIDS, and C-PIDS problems.

Theorem 17 Given a power-law network $G \in P(\alpha, \beta)$, with $\beta > 2$ and constant $0 < \rho < 1$, any d -seeding is of size at least $\Omega(n)$.

Proof The proof consists of two parts. It is shown in the first part that the volume, i.e., the total degree of vertices, of any d -seeding must be $\Omega(m)$. The second part shows that any subset of vertices $S \subset V$ with volume $\text{vol}(S) = \Omega(m)$ in a power-law network with power-law exponent $\beta > 2$ will imply that $|S| = \Omega(n)$. Thus, the theorem follows.

In the first part, there are two following cases.

Case $\rho > \frac{1}{2}$: Let $S = R_0$ be the optimal solution for the PIDS problem on $G = (V, E)$, and $S = R_0, R_1, R_2, \dots, R_d$ are vertices that become active at round $0, 1, 2, \dots, d$, respectively (see Fig. 5). Thus, $\{R_i\}_{i=0}^d$ form a partition of V . Moreover, for each $1 \leq t \leq d$ the following inequality holds:

$$|\phi(R_t, \bigcup_{i=1}^{t-1} R_i)| \geq \frac{\rho}{1-\rho} \left(|\phi(R_t, \bigcup_{j=t+1}^d R_j)| + 2|\phi(R_t, R_t)| \right) \quad (12)$$

where $\phi(A, B)$ denotes the set of edges connecting one vertex in A to one vertex in B . This can be seen as at least a fraction $\frac{\rho}{1-\rho}$ among edges incident with the vertices activated in round t must be incident with active vertices in the previous rounds.

Sum up all inequalities in (12) for $t = 1 \dots d$. This yields

$$\sum_{t=1}^d |\phi(R_t, \bigcup_{i=1}^{t-1} R_i)| \geq \frac{\rho}{1-\rho} \sum_{t=1}^d \left(|\phi(R_t, \bigcup_{j=t+1}^d R_j)| + 2|\phi(R_t, R_t)| \right).$$

After eliminating the common factors in both sides,

$$\begin{aligned} & \sum_{i=0}^{d-1} |\phi(R_i, \bigcup_{t=i+1}^d R_t)| \\ & \geq \frac{\rho}{1-\rho} \sum_{j=1}^{d-1} |\phi(R_j, \bigcup_{t=j+1}^d R_t)| + 2 \sum_{t=1}^{d-1} |\phi(R_t, R_t)|. \end{aligned}$$

And after some algebra,

$$\text{vol}(R_0) \geq |\phi(R_0, \bigcup_{t=1}^d R_t)|$$

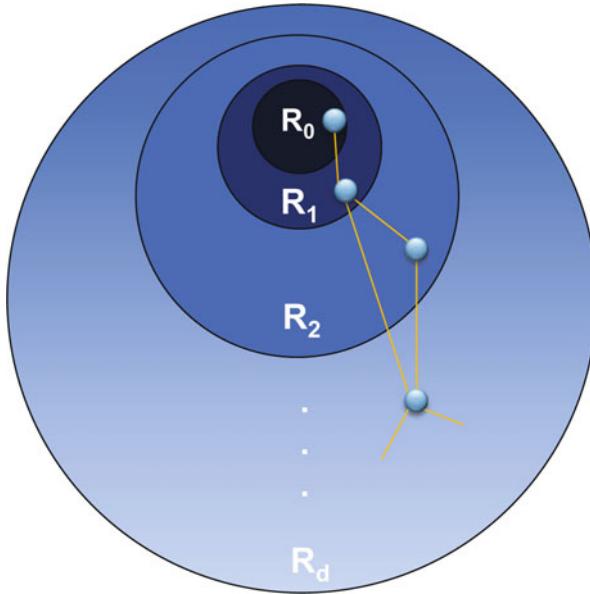

Fig. 5 The influence propagation in the network

$$\begin{aligned}
 &\geq \frac{2\rho - 1}{1 - \rho} \sum_{j=1}^{d-1} |\phi(R_i, \bigcup_{t=j+1}^d R_t)| + 2 \sum_{t=1}^d |\phi(R_t, R_t)| \\
 &\Leftrightarrow \frac{\rho}{1 - \rho} |\phi(R_0, V)| - |\phi(R_0, R_0)| \\
 &\geq \frac{2\rho - 1}{1 - \rho} |E| + \frac{3 - 4\rho}{1 - \rho} \sum_{t=1}^d |\phi(R_t, R_t)|. \tag{13}
 \end{aligned}$$

Hence, when $\rho > 1/2$, $\text{vol}(R_0) \geq \frac{2\rho-1}{1-\rho} |E| = \Omega(m)$ for any d -seeding R_0 .

Case $\rho \leq \frac{1}{2}$: An edge is said to be active if it is incident to at least one active vertex. At round $t = 0$, there are at most $\text{vol}(R_0)$ active edges, those who are incident to R_0 . Equation 12 implies that the number of active edges in each round increases at most ρ^{-1} times. After d rounds, the number of active edges will be bounded by $\text{vol}(R_0) \times \rho^{-d}$. Since all edges are active at the end, the following inequality holds:

$$\text{vol}(R_0) \geq \rho^{-d} |E|.$$

The second part of the proof shows that if a subset $S \subset V$ has $\text{vol}(S) = \Omega(m)$, then $|S| = \Omega(n)$ whenever the power-law exponent $\beta > 2$. Assume that $\text{vol}(S) \geq cm$, for some positive constant c . The size of S is minimum when S contains only the

highest degree vertices of V . Let k_0 be the minimum degree of vertices in S in that extreme case, it follows that

$$cm = \frac{c}{2} \sum_{k=1}^{e^{\frac{\alpha}{\beta}}} k \frac{e^\alpha}{k^\beta} \leq \text{vol}(S) \leq \frac{1}{2} \sum_{k=k_0}^{e^{\frac{\alpha}{\beta}}} k \frac{e^\alpha}{k^\beta}.$$

Simplifying two sides, it follows that

$$\sum_{k=1}^{k_0-1} \frac{1}{k^{\beta-1}} \leq (1-c) \sum_{k=1}^{e^{\frac{\alpha}{\beta}}} \frac{1}{k^{\beta-1}} = (1-c)\zeta(\beta-1).$$

Since, the zeta function $\zeta(\beta-1)$ converges for $\beta > 2$, there exists a constant $k_{\rho,\beta}$ that depends only on ρ and β that satisfies

$$\sum_{k=1}^{k_{\rho,\beta}} \frac{1}{k^{\beta-1}} > (1-c)\zeta(\beta-1).$$

Obviously, $k_0 \leq k_{\rho,\beta}$. Thus, the number of vertices that are in S is at least

$$\sum_{k=k_{\rho,\beta}}^{e^{\frac{\alpha}{\beta}}} \frac{e^\alpha}{k^\beta} = \left(1 - \sum_{k=1}^{k_{\rho,\beta}} \frac{1}{k^\beta}\right)n = \Omega(n).$$

The last step holds because the sum $\sum_{k=1}^{k_{\rho,\beta}} \frac{1}{k^\beta}$ is bounded by a constant since $k_{\rho,\beta}$ is a constant. \square

In both cases $\rho > 1/2$ and $\rho \leq 1/2$, the size of a d -seeding set is at least $\Omega(n)$. However, there is a clear difference in the propagation speed with respect to d between two cases. When $\rho < 1/2$, the number of active edges can increase exponentially (but is still bounded if d is a constant), and it is likely that the number of active vertices also exponentially increases. In contrast, when $\rho > 1/2$, exploding in the number of active edges (and hence active vertices) is impossible as the volume of the d -seeding is tied to the number of edges m by a fixed constant $\frac{2\rho-1}{1-\rho}$, regardless of the value of d .

Theorem 18 *In power-law networks with power exponent $\beta > 1$, there are $O(1)$ approximation algorithms for the PIDS problem for bounded value of $d \geq 1$.*

4.2 Dense Graphs

Lemma 8 *If P_T is a T-PIDS of $G = (V, E)$, then $|P_T| \geq \Omega(\sqrt{|V| + |E|})$.*

Proof Let $k = |P_T|$ be the size of a T-PIDS. All $v \in V \setminus P_T$ must be adjacent to at least one vertex in P_T . Thus, $|V| \leq |P_T| + \sum_{v \in P_T} |N(v) \setminus P_T|$. Moreover, for each vertex $v \in P_T$, $|N(v) \cap P_T| \geq \rho|N(v)| \Rightarrow |N(v) \setminus P_T| \leq \frac{1-\rho}{\rho}|N(v)| \leq \frac{1-\rho}{\rho}(k-1)$. Therefore,

$$n \leq k + k \frac{1-\rho}{\rho}(k-1) = \frac{1-\rho}{\rho}k^2 + \frac{2\rho-1}{\rho}k. \quad (14)$$

Divide edges in E into three categories: (1) edges whose both ends are in P_T , (2) edges whose exact one end is in P_T , and (3) edges whose both ends are not in P_T . There are at most $\binom{k}{2}$ edges of type 1. For a vertex $v \in P_T$, the number of type 2 edges incident to v is at most $\frac{1-\rho}{\rho}(k-1)$ since v is adjacent to at most $k-1$ vertices in P_T . Hence, the number of type 2 edges is upper bounded by $2k \frac{1-\rho}{\rho}(k-1) = \frac{2(1-\rho)}{\rho} \binom{k}{2}$. For each vertex $u \notin P_T$, the number of type 3 edges incident to u is at most $\frac{1-\rho}{\rho}$ times the number of type 2 edges incident to u . Therefore, the number of type 3 edges is at most $\frac{(1-\rho)^2}{\rho^2} \binom{k}{2}$.

Adding all three types of edges together yields the following:

$$|E| \leq \left(1 + \frac{2(1-\rho)}{\rho} + \frac{(1-\rho)^2}{\rho^2}\right) \binom{k}{2} = \frac{1}{\rho^2} \binom{k}{2}. \quad (15)$$

It follows from (14) and (15) that $|P_T| = k = \Omega(\sqrt{|V| + |E|})$. \square

The bound is tight, i.e., there is a graph in which the minimum T-PIDS has size $\Omega(\sqrt{|V| + |E|})$. For example, consider a “hairy” clique of $n = k + k \cdot \lfloor \frac{1-\rho}{\rho}(k-1) \rfloor$ vertices and $m = \binom{k}{2} + k \cdot \lfloor \frac{1-\rho}{\rho}(k-1) \rfloor$ edges by connecting each vertex in a clique of size k to $\lfloor \frac{1-\rho}{\rho}(k-1) \rfloor$ leaf nodes (Fig. 6). The minimum T-PIDS will be the clique itself that is of size $k = \Omega(\sqrt{n+m})$.

Theorem 19 *For a dense graph $G = (V, E)$ with $|E| = \Omega(|V|^2)$, there exist constant factor approximation algorithms for PIDS, T-PIDS, and C-PIDS problems.*

4.3 Finding Optimal Solutions in Trees

In trees, it is possible to find optimal GDS and T-GDS in polynomial time. However, designing such algorithms in a linear-time fashion is not too obvious. This part

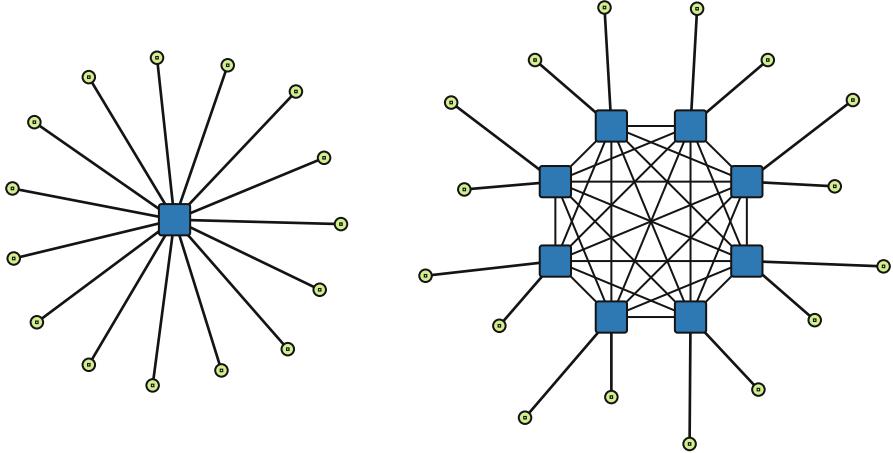

Fig. 6 A PIDS (*left*) may consist of only one node, while a T-PIDS (*right*) must contain at least $O(\sqrt{|V| + |E|})$

2:   T-GDS-VISIT( $v, u$ )
3: if  $r_t(u, \mathcal{T}) > 0$  then
4:    $\mathcal{T} = \mathcal{T} \cup \{p_u\}$ 
5: Select arbitrary  $r_t(u, \mathcal{T})$  unselected
neighbors(children) of  $u$  into  $\mathcal{T}$ .

```

Fig. 8 T-GDS-TREE(G)

presents two depth-first search-based (DFS) algorithms in [Figures 7](#) and [8](#) for GDS and T-GDS, respectively. Notice that the solution for kC -GDS and TC -GDS problems on trees is trivial; the optimal solution is simply the set of all non-leaf nodes.

Theorem 20 *Optimal GDS and T-GDS in trees can be found in linear time.*

Proof At a given step, P/\mathcal{T} denotes the current GDS/T-GDS. For each $v \in V$, define the functions $r_p(v, P) = \lceil r_v(d(v)) \rceil (1 - \mathbf{1}_P(v)) - |N(v) \cap P|$ and $r_t(v, \mathcal{T}) = \lceil r_v(d(v)) \rceil - |N(v) \cap \mathcal{T}|$, where $\mathbf{1}_A(x) = \begin{cases} 1 & \text{if } x \in A, \\ 0 & \text{if } x \notin A. \end{cases}$

Functions $r_p(v, P), r_t(v, \mathcal{T})$ determine the minimum numbers of v 's neighbors to include into the optimal solutions. A node u with $r_p(u, P) > 0$ or $r_t(u, \mathcal{T}) > 0$ is called *uncovered*; otherwise, u is called *covered*.

Assume that the tree is rooted at some vertex u . For an edge (u, v) , if u is visited before v , then u is the parent of v and v is a child of u .

Correctness. Proof by induction that each selection step is optimal.

GDS: Assume that all the selections made so far are optimal. Assume node u , the parent of v is selected in step 3, Fig. 7. From $r_p(v, P) > 0$, it follows that

1. $v \notin P$ or else $r_p(v, P) < 0$.
2. $r_p(v, P) = 1$ if not v has already been selected by the end of GDS-VISIT(v).

To cover v , it is necessary to either select v, u or some children of v . However, since all nodes in the subtree rooted at v have been covered, there will be no extra benefit in selecting v or its children. Formally, if an optimal solution selects v or its children, it is always possible to replace the selected vertex with u and obtain a new optimal PIDS. In case $r_p(u, P) > 1$, the only choice is to select u .

T-GDS: After T-GDS-VISIT(v, p_v) finishes, v always becomes covered. Assume the selection of vertices into \mathcal{T} is optimal so far. During the visit of a node u , if $r_t(u, \mathcal{T}) > 0$, p_u , the parent of u is selected whenever $p_u \notin \mathcal{T}$. Since p_u might cover other vertices, while selecting, children of u will not affect any uncovered vertices other than u . Finally, children of u might be selected to fully covered u (but only after p_u is selected).

Time Complexity. Values of $r_p(v, P)$ and $r_t(v, \mathcal{T})$ can be maintained in $O(|V|)$. After a new vertex is added, it is necessary to update $r_p(\cdot)$ and/or $r_t(\cdot)$ values of that node and all its neighbors. Each node is added at most once; hence, the total cost has the same order with the total degree of all vertices, i.e., $2|V|$. Adding the time $O(|V|)$ taken by the DFS traversal, the overall time complexities are still $O(|V|)$. \square

5 Scalable Algorithm for Multiple-Hop PIDS

In order to understand the influence propagation when the number of propagation hops is bounded, this section introduces VirAds, an efficient algorithm for the PIDS problem. After that, VirAds's performance is examined through experiments in real-world large-scale social networks.

5.1 VirAds: Multiple-Hop PIDS Greedy Algorithm

With the huge magnitude of OSN users and data available on OSNs, scalability becomes the major problem in designing algorithm for PIDS. VirAds is scalable to network of hundred of millions links and provides high-quality solutions in our experiments.

Before presenting VirAds, let us consider a natural greedy for the PIDS problem in which the vertex that can activate the most number of inactive vertices within d hops is selected in each step. This greedy is unlikely to perform well on practice for the following two reasons. First, at early steps, when not many vertices are selected, every vertex is likely to activate only itself after being chosen as a seed. Thus, the algorithm cannot distinguish between good and bad seeds. Second, the algorithm suffers serious scalability problems. To select a vertex, the algorithm has to evaluate for each vertex v how many vertices will be activated after adding v to the seeding, e.g., by invoking an $O(m + n)$ breadth-first search procedure rooted at v . In the worst-case when $O(n)$ vertices are needed to evaluate, this alone can take $O(n(m + n))$. Moreover, as shown in the previous section, the seeding size can be easily $\Omega(n)$; thus, the worst-case running time of the naive greedy algorithm is $O(n^2(m + n))$, which is prohibitive for large-scale networks.

As shown in [Algorithm 1](#), our VirAds algorithm overcomes the mentioned problems in the naive greedy by favoring the vertex which can activate the most number of *edges* (indeed, it also considers the number of active neighbor around each vertex). This avoids the first problem of the naive greedy algorithm. At early steps, the algorithm behaves similar to the degree-based heuristics that favors vertices with high degree. However, when a certain number of vertices are selected, VirAds will make the selection based on the information within d -hop neighbor around the considered vertices rather than only one-hop neighbor as in the degree-based heuristic.

The scalability problem is tackled in VirAds by efficiently keeping track of the following measures for each vertex v :

- r_v : The round in which v is activated
- $N_v^{(e)}$: The number of new active edges after adding v into the seeding
- $N_v^{(a)}$: The number of extra active neighbors v needs in order to activate v
- $r_v^{(i)}$: The number of activated neighbors of v up to round i where $i = 1 \dots d$

Given those measures, VirAds selects in each step the vertex u with the highest *effectiveness* which is defined as $N_u^{(e)} + N_u^{(a)}$. After that, the algorithm needs to update the measures for all the remaining vertices.

Except for $N_v^{(e)}$, all other measures can be effectively kept track of in only $O((m + n)d)$ during the whole algorithm. When a vertex u is selected, it causes a chain reaction and activates a sequence of vertices or lower the rounds in which vertices are activated. New activated vertices are successively pushed into the queue Q for further updating much like what happens in the Bellman-Ford shortest-paths algorithm. Note that for each node $u \in V$, changing of r_u can cause at most d update for $r_w^{(.)}$ where w is a neighbor of u . For all neighbors of u , the total number of update is, hence, $O(d \cdot d(u))$. Thus, the total time for updating $r_w^{(.)} \forall w \in V$ in VirAds will be at most $O((m + n) \cdot d)$.

Algorithm 1: VirAds – Viral Advertising in OSNs

```

Input: Graph  $G = (V, E)$ ,  $0 < \rho < 1$ ,  $d \in \mathbb{N}^+$ 
Output: A small  $d$ -seeding
 $N_v^{(e)} \leftarrow d(v)$ ,  $N_v^{(a)} \leftarrow \rho \cdot d(v)$ ,  $r_v \leftarrow d + 1$ ,  $v \in V$ ;
 $r_v^{(i)} = 0$ ,  $i = 0..d$ ,  $P \leftarrow \emptyset$ ;
while there exist inactive vertices do
  repeat
     $u \leftarrow \text{argmax}_{v \notin P} \{N_v^{(e)} + N_v^{(a)}\}$ ;
    Recompute  $N_v^{(e)}$  as the number of
      new active edges after adding  $u$ .
  until  $u = \text{argmax}_{v \notin P} \{N_v^{(e)} + N_v^{(a)}\}$ ;
   $P \leftarrow P \cup \{u\}$ ;
  Initialize a queue:  $Q \leftarrow \{(u, r_v)\}$ ;
   $r_u \leftarrow 0$ ;
  foreach neighbor  $x$  of  $u$  do
     $N_x^{(a)} \leftarrow \max\{N_x^{(a)} - 1, 0\}$ ;
  while  $Q \neq \text{empty}$  do
     $(t, oldRound_t) \leftarrow Q.pop()$ ;
    foreach neighbor  $w$  of  $t$  do
      foreach  $i = r_t$  to  $\min\{oldRound_t - 1, r_w - 2\}$  do
         $r_w^{(i)} = r_w^{(i)} + 1$ ;
        if  $(r_w^{(i)} \geq \rho \cdot d_w) \wedge (r_w \geq d) \wedge (i + 1 < d)$  then
          foreach neighbor  $x$  of  $w$  do
             $N_x^{(a)} \leftarrow \max\{N_x^{(a)} - 1, 0\}$ ;
           $r_w = i + 1$ ;
          if  $w \notin Q$  then
             $Q.push((w, r_w))$ ;
  Output  $P$ ;

```

To maintain $N_v^{(e)}$, the easiest approach is to recompute all $N_v^{(e)}$. This approach, called *Exhaustive Update*, is extremely time-consuming as discussed in the naive greedy. Instead, $N_v^{(e)}$ is updated only if “necessary.” In details, vertices are stored in a max priority queue in which the priority is their *effectiveness*. In each step, the vertex u with the highest effectiveness is extracted, and $N_u^{(e)}$ is recomputed. If after updating, u still has the highest effectiveness, u is then selected. Otherwise, u is pushed back to the priority queue, the new vertex with the highest effectiveness is considered, and so on.

The PIDS problem can be easily shown to be NP-hard by a reduction from the set cover problem. Thus, there are only two possible choices: either designing heuristics which have no worst-case performance guarantees or designing approximation algorithms which can guarantee the produced solutions are within a certain factor from the optimal. Formally, a β -approximation algorithm for a minimization

(maximization) problem always returns solutions that are at most β times larger (smaller) than an optimal solution.

Unfortunately, there is unlikely an approximation algorithm with factor less than $O(\log n)$ as shown in next section. However, under the assumption that the network is power-law, our VirAds is an approximation algorithm for PIDS with a constant factor.

Theorem 21 *In power-law networks, VirAds is an $O(1)$ approximation algorithm for the PIDS problem for bounded value of d .*

The theorem follows directly from the result in previous section that the optimal solution has size at least $\Omega(n)$ in power-law networks. Thus, the ratio between the VirAds's solution and the optimal solution is bounded by a constant.

5.2 Experimental Study

This section presents experiments on OSNs to show the efficiency of VirAds algorithm in comparison with simple degree centrality heuristic. In addition, the experiments give insight into the trade-off between the number of times the information is allowed to propagate in the network and the seeding size.

5.2.1 Comparing to Optimal Seeding

One advantage of the discrete diffusion model over probabilistic ones [26, 27] is that the exact solution can be found using mathematical programming. This enables us to study the exact behavior of the seeding size when the number of propagation hop varies.

The PIDS problem can be formulated as a 0–1 integer linear programming (ILP) problem below.

$$\text{minimize} \sum_{v \in V} x_v^0 \quad (16)$$

$$\text{subject to} \sum_{v \in V} x_v^d \geq |V| \quad (17)$$

$$\sum_{w \in N(v)} x_w^{i-1} + \lceil \rho \cdot d(v) \rceil x_v^{i-1} \geq \lceil \rho \cdot d(v) \rceil x_v^i \quad (18)$$

$$x_v^i \geq x_v^{i-1} \quad \forall v \in V, i = 1 \dots d \quad (19)$$

$$x_v^i \in \{0, 1\} \quad \forall v \in V, i = 0 \dots d \quad (20)$$

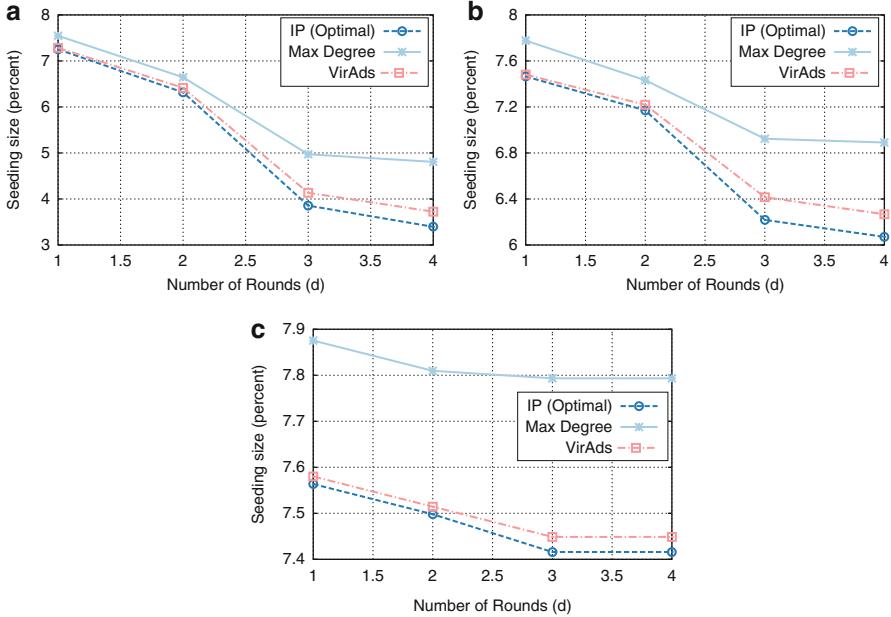

Fig. 9 Seeding size (in percent) on Erdos's collaboration network. VirAds produces close to the optimal seeding in only fractions of a second (in comparison to 2-day running time of the IP(optimal)). (a) $\rho = 0.4$. (b) $\rho = 0.6$. (c) $\rho = 0.8$

$$\text{where } x_v^i = \begin{cases} 0 & \text{if } v \text{ is inactive at round } i \\ 1 & \text{otherwise} \end{cases}.$$

The objective of the ILP is to select a minimum number of seeds at the beginning. The constraint (2) guarantees all nodes are activated at the end, while (3) deals with propagation condition; the constraint (4) is simply to keep vertices active once they are activated.

The ILP problem is solved on Erdos collaboration networks, the social network of the famous mathematician [54]. The network consists of 6,100 vertices and 15,030 edges. The ILP is solved with the optimization package GUROBI 4.5 on Intel Xeon 2.93 Ghz PC and setting the time limit for the solver to be 2 days. The running time of the IP solver increases significantly when d increases. For $d = 1, 2$, and 3 , the solver return the optimal solutions. However, for $d = 4$, the solver cannot find the optimal solutions within the time limit and returns suboptimal solutions with relative errors at most 15 %.

The optimal (or suboptimal) seeding sizes are shown in Fig. 9a–c, for $\rho = 0.4, 0.6$ and 0.8 , respectively. VirAds provides close-to-optimal solutions and performs much better than Max Degree. Especially, when $\rho = 0.8$, the VirAds's

Table 3 Sizes of the investigated networks

	Physics	Facebook	Orkut
Vertices	37,154	90,269	3,072,441
Edges	231,584	3,646,662	223,534,301
Avg. degree	12.5	80.8	145.5

seeding is only different with the optimal solutions by one or two nodes. In addition, VirAds only takes fractions of a second to generate the solutions.

As shown in [Theorem 17](#), the seeding takes a constant fraction of nodes in the network. For Erdos collaboration network, the seeding consists of 3.8–7 % the number of nodes in the networks. Further, the seeding can consist as high as 20–40 % nodes in the network for larger social networks in next section.

Although the mathematical approach can provide accurate measurement on the optimal seeding size, it cannot be applied for larger networks. The rest of our experiments measures the quality and scalability of our proposed algorithm VirAds on a collection of large networks.

5.2.2 Large Social Networks

All the algorithms are tested on networks of various sizes including coauthors network in Physics sections of the e-print arXiv [\[26\]](#), Facebook [\[55\]](#), and Orkut [\[56\]](#), a social networking run by Google. Links in all three networks are undirected and unweighted. The sizes of the networks are presented in [Table 3](#).

Physics: The physics coauthors network shall be referred as Physics network or simply Physics. Each node in the network represents an author, and there is an edge between two authors if they coauthor one or more papers. *Facebook* dataset consists 52 % of the users in the New Orleans [\[55\]](#). *Orkut* dataset is collected by performing crawling in last 2006 [\[56\]](#). It contains about 11.3 % of Orkut’s users.

5.2.3 Solution Quality in Large Social Networks

The VirAds algorithm is compared with the following heuristic *Random* method in which vertices are picked up randomly until forming a d -seeding and *Max Degree* method in which vertices with highest degree are selected until forming a d -hop seeding. Finally, VirAds is compared with its naive implementation, called *Exhaustive Update*, in which after selecting a vertex into the seeding, the effectiveness of all the remaining vertices are recalculated. With more accurate estimation on vertex effectiveness, Exhaustive Search is expected to produce higher-quality solutions than those of VirAds.

The seeding size with different number of propagation hop d when $\rho = 0.3$ is shown in [Fig. 10](#). To our surprise, VirAds even performs equal or better than *Exhaustive Update* despite that it uses significantly less effort to update vertex effectiveness. VirAds has smaller seeding in Physics than *Exhaustive Update*; both of them give similar results for Facebook, while *Exhaustive Update* cannot finish

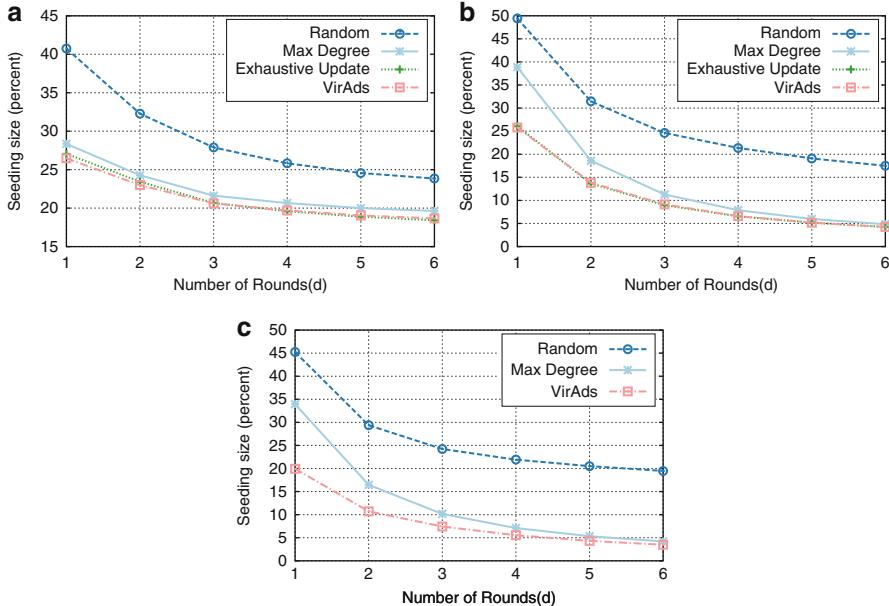

Fig. 10 Seeding size when the number of propagation hop d varies ($\rho = 0.3$). VirAds consistently has the best performance (a) Physics. (b) Facebook. (c) Orkut

on Orkut after 48 h and was forced to terminate. Sparingly update, the vertices' effectiveness turns out to be efficient enough since the influence propagation is locally bounded. In addition, the seeding produced by VirAds is almost two times smaller than those of *Random*.

The gap between VirAds and Max Degree is narrowed when the number of maximum hops increases. Hence, selecting nodes with high degrees as seeding is a good long-term strategy, but might not be efficient for fast propagation when the number of hops is limited. In Facebook and Orkut, when $d = 1$, *Max Degree* has 60–70 % more vertices in the seeding than *VirAds*. In Physics, the gap between *VirAds* and the *Max Degree* is less impressive. Nevertheless, *VirAds* consistently produces the best solutions in all networks.

5.2.4 Scalability

The running time of all methods at different propagation hop d is presented in Fig. 11. The time is measured in second and presented in the log scale. The running times increase slightly together with the number of propagation rounds d and are proportional to the size of the network. The *Exhaustive Update* has the worst running time, taking up to 15 min for Physics and 20 min for Facebook. For Orkut, the algorithm cannot finish within 2 days, as mentioned. The three remaining

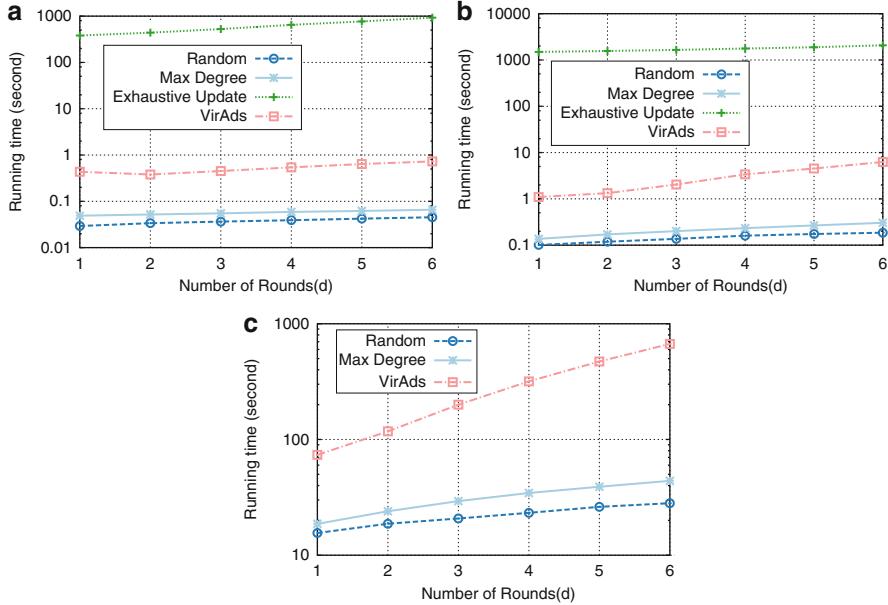

Fig. 11 Running time when the number of propagation hop d varies ($\rho = 0.3$). Even for the largest network of 110 million edges, VirAds takes less than 12 min **(a)** Physics. **(b)** Facebook. **(c)** Orkut

algorithms *VirAds*, *Max Degree*, and *Random* take less than 1 s for Physics and less than 10 s for Facebook. Even on the largest network Orkut with more than 220 million edges, VirAds requires less than 12 min to complete.

5.2.5 Influence Factor

The performance of VirAds and the other method at different influence factor ρ is presented. The number of propagation rounds d is fixed to 4. The size of d -seeding sets are shown in Fig. 12. VirAds is clearly still the best performer. The seeding sizes of VirAds are up to five times smaller than those of Max Degree for small ρ (although it's hard to see this on the charts due to small seeding sizes).

Since all tested networks are social networks with small diameter, the seeding sizes go to zero when ρ is close to zero. The exception is the Physics, in which the seeding sizes do not go below 10 % the number of vertices in the networks even when $\rho = 0.05$. A closer look into the Physics network reveals that the network contains many isolated cliques of small sizes (2, 3, 4, and so on) which correspond to authors that appear in only one paper. In each clique, regardless of the threshold ρ , at least one vertex must be selected; thus the, seeding size cannot

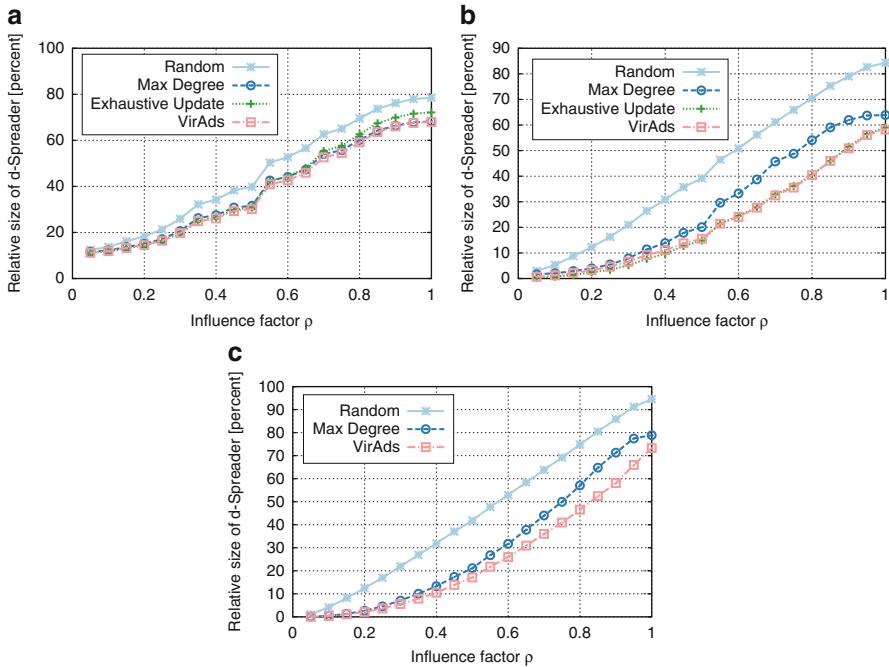

Fig. 12 Seeding size at different influence factors ρ (the maximum number of propagation hops is $d = 4$) **(a)** Physics. **(b)** Facebook. **(c)** Orkut

get below the number of isolated cliques in the networks. To eliminate the effect of isolated cliques, a possible approach is to restrict the problem to the largest component in the network.

6 Conclusion

This chapter studies approximability and inapproximability for important variants of the *dominating set* problems in different network topologies. In general networks, the considered domination problems are hard to approximate within a factor $(1/2 - o(1)) \ln n$, and there exist approximation algorithms with factor $\ln n + O(1)$ for the problems. Thus, there is still a $1/2 \ln n$ gap between the lower bound and upper bound for the approximability of those problems. Note that Srinivasan [57] gives an $\ln \frac{n}{\text{OPT}} + O(\ln \ln \frac{|n|}{\text{OPT}})$ approximation factor for DS which provides a better approximation factor when the optimal solution is relatively large to the input size. In addition, the sizes of PIDS and T-PIDS are at least $\sqrt{|V| + |E|}$; thus, it is conjectured that PIDS and T-PIDS problems can be approximated within a factor $1/2 \ln n + O(1)$.

Abstract

This is an overview over dynamic programming with an emphasis on advanced methods. Problems discussed include path problems, construction of search trees, scheduling problems, applications of dynamic programming for sorting problems, server problems, as well as others. This chapter contains an extensive discussion of dynamic programming speedup. There exist several general techniques in the literature for speeding up naive implementations of dynamic programming. Two of the best known are the Knuth-Yao quadrangle inequality speedup and the SMAWK/LARSCH algorithm for finding the row minima of totally monotone matrices. The chapter includes “ready to implement” descriptions of the SMAWK and LARSCH algorithms. Another focus is on dynamic programming, online algorithms, and work functions.

1 Introduction

Dynamic programming, formally introduced by Richard Bellman (August 26, 1920–March 19, 1984) at the Rand Corporation in Santa Monica in the 1940s, is a versatile method to construct efficient algorithms for a broad range of problems. As with many tools which evolved over time, the original paper sounds antiquated. In his monograph “Dynamic Programming,” Bellman [25] describes the principle of optimality, which is central to dynamic programming: “An optimal policy has the property that whatever the initial state and initial decisions are, the remaining decisions must constitute an optimal policy with regard to the state resulting from the first decision.” Not exactly what is found in textbooks today. But then in those days the focus was more on stochastic processes and not so much on combinatorial optimization. The term “programming” is outdated as well, as it does not refer to programming in a modern programming language. Instead, programming means planning by filling in tables. The term “linear programming” derives in the same way. Over the decades, dynamic programming has evolved and is now one of the “killer” techniques in algorithmic design. And, of course, the laptop computer on which this chapter was written is more powerful than anyone in Bellman’s days could have imagined.

Today, the emphasis is on how to organize dynamic programming in a way that makes it possible to solve massive problems (which – again – would have never been considered in Bellman’s days) in reasonable time. The focus is on dynamic programming speedup. Such speedup comes from carefully observing what values are essential and need to be computed and which might be unnecessary. Keeping

proper look-up tables on the side can accomplish this sometimes. But there are many situations where there are inherent monotonicity properties which can be exploited to only calculate a fraction of what is necessary in a simple-minded approach.

The goal of this chapter is to briefly introduce dynamic programming, show some of the diversity of problems that can be tackled efficiently with dynamic programming, and – centrally – focus on the issue of dynamic programming speedup. Clearly, the chapter does not cover all of dynamic programming, but there is a section on recommended reading, [Sect. 8](#), which covers some ground.

The chapter is organized as follows: [Sect. 2](#) starts with a simple introduction to dynamic programming using a few standard examples, described more tersely than in a textbook and augmented with a general few themes. A reader altogether unfamiliar with dynamic programming might utilize some of the resources given in [Sect. 8](#).

[Section 3](#) contains “open-ended dynamic programming,” where a process is updated continuously. This is closely related to the theory of online optimization. In online computation, an algorithm must make decisions without knowledge of future inputs. Online problems occur naturally across the entire field of discrete optimization, with applications in areas such as robotics, resource allocation in operating systems, and network routing. Dynamic programming plays an important role in this kind of optimization. Notably, work functions replace tables or matrices used in offline optimization.

[Section 4](#) contains an example from sorting. The intent of this section is twofold: First, lesser-known dynamic programming techniques for sorting are highlighted. Second, here is an example where a straightforward simple-minded implementation might give an algorithm of cubic complexity or worse, and a more intricate setup solves the problem in quadratic time, thus achieving substantial dynamic programming speedup.

[Section 5](#) gives an example from scheduling (a batching problem) to illustrate important properties for dynamic programming speedup: the Monge property and total monotonicity. Techniques exploiting these techniques are now standard, and the reader might consult [Sect. 8](#) to see how prolific such techniques are.

Speedup is based on two important and intricate algorithms: SMAWK and LARSCH. Use of these is essential for many fast dynamic programming algorithms. However, these algorithms are currently only accessible through the original publications. [Section 6](#) contains “ready to implement” descriptions of the SMAWK and LARSCH algorithms.

Another type of speedup is based in the Knuth-Yao quadrangle inequality; this dynamic programming speedup works for a large class of problems. Even though both the SMAWK algorithm and the Knuth-Yao (KY) speedup use an implicit quadrangle inequality in their associated matrices, on second glance, they seem quite different from each other. [Section 7](#) discusses the relation between these kinds of speedup in greater detail.

Finally, [Sect. 8](#) is a cross-reference list with other chapters, and [Sect. 8](#) gives concluding remarks.

2 A Few Standard Introductory Examples

As mentioned earlier, this section has a few introductory examples.

2.1 A Brief Introduction to Dynamic Programming: Fibonacci, Pascal, and Making Change

Many problems can be solved recursively by dividing an instance into subinstances. But a direct implementation of a recursion is often inefficient because subproblems overlap and are recomputed numerous times. The calculation of the Fibonacci numbers provides a simple example:

$$f_n = \begin{cases} f_{n-1} + f_{n-2} & \text{if } n > 1 \\ 1 & \text{if } n = 1 \\ 0 & \text{if } n = 0. \end{cases} \quad (1)$$

Recursively, the Fibonacci numbers can be calculated in the following way:

```
function fib(n)
    if n = 0 or n = 1 return n
    else return fib(n - 1) + fib(n - 2).
```

This is extremely inefficient; many values will be recalculated; see Fig. 1. Instead, one could use an array and would simply fill in values from “left to right,” starting with F_0 and F_1 and the using Eq. 1 to continue. This way every value is only calculated once.

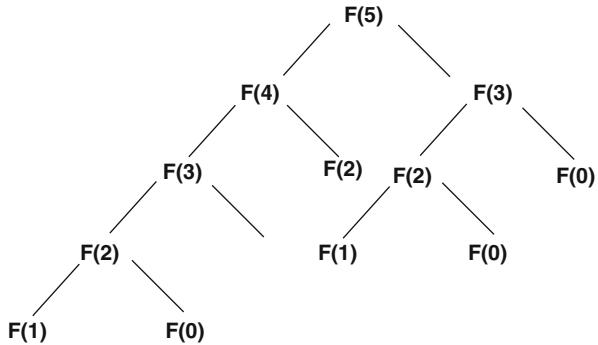

The Pascal triangle for calculating binomial coefficients provides a good example for the use of *tables* in dynamic programming. Recall the definition of the binomial coefficient:

$$\binom{n}{k} = \begin{cases} \binom{n-1}{k-1} + \binom{n-1}{k} & \text{if } 0 < k < n \\ 1 & \text{if } k = 0 \text{ or } k = n \\ 0 & \text{else.} \end{cases} \quad (2)$$

Clearly, the coefficients can be calculated using the following recursive program:

```
function c(n, k)
    if k = 0 or k = n return 1
    else return c(n - 1, k - 1) + c(n - 1, k).
```

Fig. 1 Recursive calculation of the fifth Fibonacci number

But again this is inefficient, as terms are recalculated over and over. Indeed, since the solution is ultimately made up of terms of value 1, the run time of this algorithm is $\Omega(\binom{n}{k})$. This problem consists of *overlapping subproblems*, which often makes it inefficient to use recursions directly. Instead, one can calculate the coefficients *bottom up* using a table to store intermediate results. In the case of the binomial coefficient, this is the Pascal triangle Fig. 2. With it the run time is $\Theta(nk)$ with space requirement $\Theta(k)$ (as only two rows at a time need to be stored).

Most often dynamic programming is used for optimization problems. As an example consider the problem of making change with the minimum number of coins. Given are n denominations of value $\{d_1, \dots, d_n\}$, an unlimited supply of these coins, and the problem is to make change for amount A . For example, if the denominations are 1, 5, 10, 12, and $A = 21$, then the minimum number of coins is 3. Note that the greedy algorithm uses 6 coins. What is important here is that the principle of optimality holds: If optimal change for amount C involves making change into amounts A and B , $C = A + B$, then change for A and B is also optimal. More generally, the principle states that in an optimal sequence of decisions or choices, each subsequence must also be optimal.

Let

$C[i, j] =$ minimum number of coins required to make change for amount j
using only coins of denomination $\{1, \dots, i\}$,

where $i = 1, \dots, n$ and $j = 1, \dots, A$. The principle of optimality implies the following recurrence:

$$C[i, j] = \min\{C[i - 1, j], 1 + C[i, j - d_i]\}, \quad (3)$$

where out-of-bounds values are set to ∞ .

Just as before with Fibonacci and Pascal, one uses a table to calculate values “bottom-up.” The table is initialized by setting all $C[i, 0]$ to 0. Then the table is filled row by row using Eq. 3. An example is in Table 1.

Fig. 2 The Pascal triangle

	0	1	2	3	...	$k-1$	k
0	0						
1		1	1				
2			1	2	1		
3				1	3	3	1
\vdots							
$n-1$						$c(n-1, k-1)$	$c(n-1, k)$
n						$\searrow + \downarrow$	$c(n, k)$

Table 1 An instance of the change-making problem: There are four types of coins with denominations $d_1 = 1, d_2 = 5, d_3 = 10$, and $d_4 = 12$. The amount is $A = 21$. The last entry in the table gives the minimum number of coins, which is 3. Note that the greedy algorithm uses six coins

A	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21
d_1	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21
d_2	0	1	2	3	4	1	2	3	4	5	2	3	4	5	6	3	4	5	6	7	4	5
d_3	0	1	2	3	4	1	2	3	4	5	1	2	3	4	5	2	3	4	5	6	2	3
d_4	0	1	2	3	4	1	2	3	4	5	1	2	1	2	3	2	3	2	3	4	2	3

2.2 Chained Matrix Multiplication Problem

Given is a sequence of matrices M_1, \dots, M_n to be multiplied. The dimensions are $d_0 \times d_1, \dots, d_{n-1} \times d_n$, denoted by (d_0, d_1, \dots, d_n) , for short. The question is what parenthesization gives the minimum number of multiplications. For example, given three matrices, A, B, C , with dimensions $(12, 5, 90, 2)$, the calculation $A(BC)$ requires $5 \times 90 \times 2$ multiplications to produce BC and then $12 \times 5 \times 2$ to multiply the result by A , for a total of 1,020. The order $(AB)C$ is much worse: 7500 multiplications. For general n , exhaustive search is prohibitive for the following reason: Let

$$T(n) = \text{number of ways to parenthesize a product of } n \text{ matrices},$$

then

$$T(n) = \sum_{i=1}^{n-1} T(i)T(n-i) \quad (4)$$

with $T(2) = T(1) = 1$. The solution to recurrence 4 is

$$T(n) = \frac{1}{n} \binom{2n-2}{n-1}, \quad (5)$$

which is $\Omega(4^n/n^2)$.

Clearly the principle of optimality applies. If the parenthesization is optimal for $M = M_1, \dots, M_n$ and there are two parts $A = M_1, \dots, M_k$ and $B = M_{k+1}, \dots, M_n$ such that $M = AB$, then the parenthesizations for A and B are optimal. Let

$$M[i, j] = \text{optimal number of multiplications to compute } M_i \cdots M_j.$$

Thus, the recurrence is

$$M[i, j] = \min_{i \leq k < j} \{M[i, k] + M[k + 1, j] + d_{i-1}d_kd_j\} \text{ for } 1 \leq i < j \leq n, \quad (6)$$

with $M[i, i] = 0$.

The dynamic program fills a table with entries for $i \leq j$, starting with the main diagonal, which is set to $M[i, i] = 0$. The computation then progresses to $M[i, i+1]$ and so forth until the element in the north-east corner $M[1, n]$ is reached. In order to be able to recover the solution, the index k which gives the minimum in 6 is also stored. When the algorithm reaches $(1, n)$, this index gives the index of the first cut. One then proceeds recursively on both sides to construct the actual parenthesization. [Figure 3](#) gives an example.

2.3 Shortest Paths

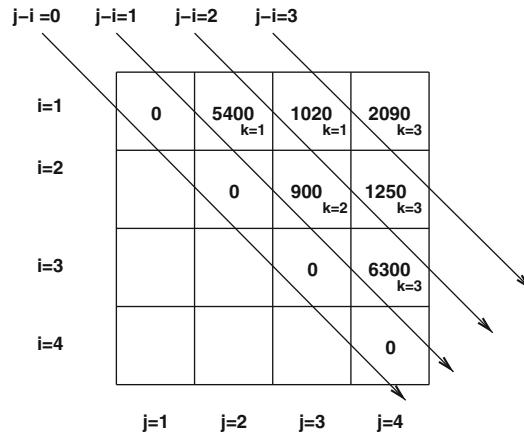

Consider a directed graph on nodes $V = \{1, \dots, n\}$ with distance matrix $D[i, j] \geq 0$, where $D[i, j] = \infty$ if there is no edge between node i and node j . The object is to calculate the shortest path between each pair of nodes. To use dynamic programming, one defines

$$D_k[i, j] = \text{length of a shortest path from } i \text{ to } j \text{ which only uses nodes } \{1, \dots, k\}.$$

Clearly $D_0 = D$. Starting with D_0 one calculates D_1, D_2, \dots, D_n using the following recursion:

$$D_k[i, j] = \min\{D_{k-1}[i, j], D_{k-1}[i, k] + D_{k-1}[k, j]\}. \quad (7)$$

The algorithm, which computes this series of tables, is called the Floyd algorithm. The reader is invited to follow the calculations in [Table 2](#), which gives an example for the graph in [Fig. 4](#). The principle of optimality is at work here: If a path from node i to node j is optimal and passes through node k , then the path from i to k , as well as the path from k to j , is optimal. This is not true for the longest simple path problem. (A simple path is a path without repeated nodes.) In graph of [Fig. 4](#), the longest simple path from node 2 to node 4 is 2, 1, 3, 4, but the path 2, 1 is not a longest simple path from 2 to 1. Indeed the problem “longest simple path” is \mathcal{NP} -hard. This does not contradict the fact that the Floyd algorithm works for

$$M[1, 1] = M[2, 2] = M[3, 3] = 0$$

$$M[1, 2] = \mathbf{M[1, 1]} + \mathbf{M[2, 2]} + 12 \times 5 \times 90 = 5400, \text{ store } k = 1$$

$$M[2, 3] = \mathbf{M[2, 2]} + \mathbf{M[3, 3]} + 5 \times 90 \times 2 = 900, \text{ store } k = 2$$

$$M[3, 4] = M[3, 3] + M[4, 4] + 90 \times 2 \times 35 = 6300, \text{ store } k = 3$$

$$\begin{aligned} M[1, 3] &= \min\{\mathbf{M[1, 1]} + \mathbf{M[2, 3]} + 12 \times 5 \times 2, M[1, 2] + M[3, 3] + 12 \times 90 \times 2\} \\ &= 1020, \text{ store } k = 1 \end{aligned}$$

$$\begin{aligned} M[2, 4] &= \min\{M[2, 2] + M[3, 4] + 5 \times 90 \times 35, \mathbf{M[2, 3]} + \mathbf{M[4, 4]} + 5 \times 2 \times 35\} \\ &= 1250, \text{ store } k = 3 \end{aligned}$$

$$\begin{aligned} M[1, 4] &= \min\{M[1, 1] + M[2, 4] + 12 \times 5 \times 35, M[1, 2] + M[3, 4] + 12 \times 90 \times 35, \\ &\quad \mathbf{M[1, 3]} + \mathbf{M[4, 4]} + 12 \times 2 \times 35\} \\ &= 2090, \text{ store } k = 3 \end{aligned}$$

Optimal Parenthesization: $(M_1(M_2M_3)M_4)$

Fig. 3 An example for the dynamic program for the problem “chained matrix multiplication.” In the example, $n = 4$ and the dimensions are $(12, 5, 90, 2, 35)$. The calculation proceeds by first filling the table for indices with $j - i = 0$ (i.e., initialization of $M[i, i]$) and then continues along the diagonals $j - i = 1, 2, 3$. Calculations which give the minima for each cell in Eq. 6 are shown in bold type, and the corresponding index k is stored. Once the value of $M[1, 4]$ is known, then the solution can be recovered using these indices: $(M_1M_2M_3)M_4$ can be concluded from the index $k = 3$ in cell $(1, 4)$. Next, look up cell $(1, 3)$ to find the parenthesization $M_1(M_2M_3)$.

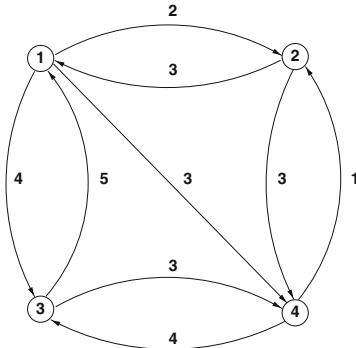

negative distances if there are no negative cycles. (Longest simple path cannot be reduced to shortest path with negative distances because of the cycle restriction.) The Floyd algorithm can be used to detect negative cycles by checking for negative elements in the main diagonal of D_n .

The time complexity of Floyd algorithm is $O(n^3)$. The calculation can be performed by keeping only D_{k-1} and D_k at each iteration, and thus the space

Table 2 The Floyd algorithm for the example of Fig. 4. One proceeds from matrix D_{k-1} to matrix D_k by applying the rule $D_k[i, j] = \min\{D_{k-1}[i, j], D_{k-1}[i, k] + D_{k-1}[k, j]\}$ for all i and j . In the lower right corner of the table, the matrix of pointers P is shown. For example, the length of a shortest path from node 3 to node 2 is 4 since $D_4[3, 2] = 4$. To construct the path look up $P[3, 2] = 4$ to find that the path goes through node 4. Recursively, look up $P[3, 4] = P[4, 2] = 0$. Thus the shortest path is 3, 4, 2

D_0	0	2	4	3	D_1	0	2	4	3
	3	0	∞	3		3	0	7	3
	5	∞	0	3		5	7	0	3
	∞	1	4	0		∞	1	4	0
D_2	0	2	4	3	D_3	0	2	4	3
	3	0	7	3		3	0	7	3
	5	7	0	3		5	7	0	3
	4	1	4	0		4	1	4	0
D_4	0	2	4	3	P	0	0	0	0
	3	0	7	3		0	0	1	0
	5	4	0	3		0	4	0	0
	4	1	4	0		2	0	0	0

Fig. 4 A directed graph with distances

requirement is $O(n^2)$. In order to retrieve the actual path (and not only its length), a matrix P of pointers is used, where $P[i, j]$ contains the number of the last iteration k that causes a change in $D_k[i, j]$ ($P[i, j]$ is initialized to 0). To construct the path between node i and j , look up $P[i, j]$ at the end. If $P[i, j] = 0$, then there was never a change for any D_k and the shortest path is the edge (i, j) , else the shortest path goes through k . Recursively examine $P[i, k]$ and $P[k, j]$.

The resulting algorithm is named after Floyd (It appeared as a one-page note in the Communications of the ACM – together with other algorithms of the time. Therefore, the antiquated title is “Algorithm 97: Shortest Path,” Floyd [55]).

Another algorithm of the time is the matrix algorithm, originally given in the context of the transitive closures by Warshall. The paper is a short two-pager; see Warshall [92].

Define

$D^{(k)}[i, j] = \text{length of a shortest path from } i \text{ to } j \text{ containing at most } k \text{ edges}$

and set

$$D^{(0)} == \begin{cases} 0 & \text{if } i = j \\ \infty & \text{else.} \end{cases}$$

Clearly by the principle of optimality,

$$D^{(k)}[i, j] = \min\{D^{(k-1)}[i, j], \min_{1 \leq l \leq n, l \neq j} \{D^{(k-1)}[i, l] + D[l, j]\}\} \quad (8)$$

$$= \min_{1 \leq l \leq n} \{D^{(k-1)}[i, l] + D[l, j]\}. \quad (9)$$

The previous equation defines a matrix multiplication where the usual multiplication means “+” and the operation “+” means “min.” [Table 3](#) gives an example. In other words,

$$D^{(k)} = D^k.$$

The solution to the shortest path problem is therefore obtained by calculating D^k with the operators properly replaced. The run time of this algorithm is at first glance $O(n^4)$, but it can be improved by “repeated squaring”: Calculate

- $D^2 = D \cdot D$
- then $D^4 = D^2 \cdot D^2$
- then $D^8 = D^4 \cdot D^4$, and so forth

If $n - 1$ is not a power of 2, then D^{n-1} can be obtained by going up to the highest power of 2 smaller than $(n - 1)$ and multiplying the powers of the binary representation of $(n - 1)$. As a result the number of matrix multiplications is only logarithmic, giving a run time of $O(n^3 \log n)$.

2.4 The Knapsack Problem

This is a classical problem in combinatorial optimization: Given are n items $\{1, \dots, n\}$ with weights $w_i > 0$ and profits $p_i > 0$, and there is a knapsack of weight capacity $W > 0$. One is to fill the knapsack in such a way that the profit of the items chosen is maximized while obeying that the total weight be less than W . Let

$P[i, j] = \text{maximum profit, which can be obtained if the}$

$\text{weight limit is } j \text{ and only items from } \{1, \dots, i\} \text{ may be included,}$

Table 3 Example of the progression of the matrix algorithm for the all shortest path problem given in Fig. 4. The operations in the “matrix multiplication” are not the usual “+” and “.” but rather “min” and “+”

$I \cdot D =$	$\begin{pmatrix} 0 & \infty & \infty & \infty \\ \infty & 0 & \infty & \infty \\ \infty & \infty & 0 & \infty \\ \infty & \infty & \infty & 0 \end{pmatrix} \cdot \begin{pmatrix} 0 & 2 & 4 & 3 \\ 3 & 0 & \infty & 3 \\ 5 & \infty & 0 & 3 \\ \infty & 1 & 4 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 2 & 4 & 3 \\ 3 & 0 & \infty & 3 \\ 5 & \infty & 0 & 3 \\ \infty & 1 & 4 & 0 \end{pmatrix} = D^{(1)}$
$D^{(1)} \cdot D =$	$\begin{pmatrix} 0 & 2 & 4 & 3 \\ 3 & 0 & \infty & 3 \\ 5 & \infty & 0 & 3 \\ \infty & 1 & 4 & 0 \end{pmatrix} \cdot \begin{pmatrix} 0 & 2 & 4 & 3 \\ 3 & 0 & \infty & 3 \\ 5 & \infty & 0 & 3 \\ \infty & 1 & 4 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 2 & 4 & 3 \\ 3 & 0 & 7 & 3 \\ 5 & 4 & 0 & 3 \\ 4 & 1 & 4 & 0 \end{pmatrix} = D^{(2)}$
$D^{(2)} \cdot D =$	$\begin{pmatrix} 0 & 2 & 4 & 3 \\ 3 & 0 & 7 & 3 \\ 5 & 4 & 0 & 3 \\ 4 & 1 & 4 & 0 \end{pmatrix} \cdot \begin{pmatrix} 0 & 2 & 4 & 3 \\ 3 & 0 & \infty & 3 \\ 5 & \infty & 0 & 3 \\ \infty & 1 & 4 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 2 & 4 & 3 \\ 3 & 0 & 7 & 3 \\ 5 & 4 & 0 & 3 \\ 4 & 1 & 4 & 0 \end{pmatrix} = D^{(3)}$

where $1 \leq i \leq n$ and $0 \leq j \leq W$. The following recursion is valid:

$$P[i, j] = \max\{P[i - 1, j], P[i - 1, j - w_i + p_i]\}, \quad (10)$$

where $P[0, j] = 0$ and $P[i, j] = -\infty$ when $j < 0$. Equation 10 says that for a new element i one does not include it (left of max) or one does include it (right of max). If one includes the element, then by the principle of optimality the problem with capacity reduced by the weight of element i on the earlier elements $\{1, \dots, i - 1\}$ must be optimal.

The table $P[i, j]$ can be filled in either row by row or column by column fashion. The run time of this algorithm is $\Theta(nW)$. Note that this is not a polynomial algorithm for the knapsack problem. The input size is $O(n \log \max_{i=1,\dots,n} w_i + \log W)$, which means that $\Theta(nW)$ is exponential in the input size. This is, of course, to be expected as the knapsack problem is \mathcal{NP} -hard. The algorithm’s complexity is called *pseudo-polynomial*. Many dynamic programs give pseudo-polynomial algorithms.

Pseudo-polynomial, Strongly Polynomial. Let s be the input to some decision problem Π . Let $|s|_{\log}$ be the length of the input – that is, the length of the binary encoding – and let $|s|_{\max}$ be the magnitude of the largest number in s . A problem Π is pseudo-polynomially solvable if there is an algorithm for Π with run time bounded by a polynomial function in $|s|_{\max}$ and $|s|_{\log}$. A decision problem is a *number problem* if there exists no polynomial p such that $|s|_{\max}$ is bounded by $p(|s|_{\log})$ for all input s . (For example, the decision version of the knapsack problem is a number problem.) Note that by these definitions it immediately follows that an \mathcal{NP} -complete *non-number* problem (such as HAMILTONIAN CIRCUIT, for

Table 4 An example of the pseudo-polynomial dynamic programming algorithm for the knapsack problem on nine items. The weights are $w[1] = 1, w[2] = 2, w[3] = 3, w[4] = 4, w[5] = 5, w[6] = 6, w[7] = 7, w[8] = 8, w[9] = 9$ and the profits are $p[1] = 1, p[2] = 2, p[3] = 5, p[4] = 10, p[5] = 15, p[6] = 16, p[7] = 21, p[8] = 22, p[9] = 35$. The size of the knapsack is 15. The table shows in position (i, j) the maximum profit, which can be obtained if the weight limit is j and only items from $\{1, \dots, i\}$ may be included. Bold entries indicate that in Eq. 10 the second choice is the maximizer, i.e., the new item is considered for inclusion. From the regular-bold information the actual solution can be reconstructed: The last entry in the table is 50. Because of the bold type face item $i = 9$ is included. Thus one looks $w_9 = 9$ many cells to the left in the previous row. The regular type face of 16 in cell (7, 6) means that item 8 is not included, looking at the cells above neither are items 7 and 6. Item 5 is included, next look-up cell (4, 1) to see that no more items are included. The solution is $\{5, 9\}$ with a profit of 50

W	0	1	2	3	4	5	6	7	8	9	11	12	13	14	15
i=1	0	1	1	1	1	1	1	1	1	1	1	1	1	1	1

example) cannot be solved by a pseudo-polynomial algorithm (unless $\mathcal{P} = \mathcal{NP}$). For polynomial p let Π_p denote the subproblem which is obtained by restricting Π to instances with $|s|_{\max} \leq p(|s|_{\log})$. Problem Π is called *strongly \mathcal{NP} -complete* if Π is in \mathcal{NP} and there exists a polynomial p for which Π_p is \mathcal{NP} -complete. It is easy to see (Table 4):

Theorem 1 A strongly \mathcal{NP} -complete problem cannot have a pseudo-polynomial algorithm unless $\mathcal{P} = \mathcal{NP}$.

2.5 Binary Search Tress

The construction of optimal binary search trees is a classic optimization problem. One is interested in constructing a search tree, in which elements can be looked up as quickly as possible. The first dynamic program for this problem was given by Gilbert and Moore [59] in the 1950s. More formally, given are n search keys with known order $\text{Key}_1 < \text{Key}_2 < \dots < \text{Key}_n$. The input consists of $2n + 1$ probabilities p_1, \dots, p_n and q_0, q_1, \dots, q_n . The value of p_l is the probability that a search is for the value of Key_l ; such a search is called *successful*. The value of q_l is the probability that a search is for a value between Key_l and Key_{l+1} (set $\text{Key}_0 = -\infty$

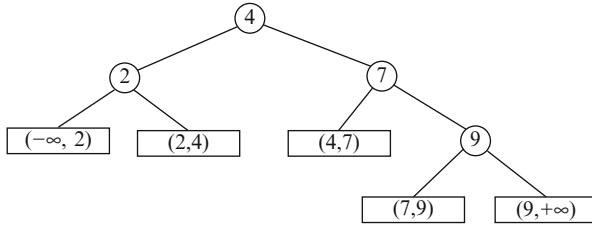

Fig. 5 A binary search tree with successful (round) and unsuccessful (rectangular) nodes

and $\text{Key}_{n+1} = \infty$); such a search is called *unsuccessful*. Note that in the literature the problem is sometimes presented with *weights* instead of *probabilities*, in that case the p_l and q_l are not required to add up to 1.

The binary search tree constructed will have n internal nodes corresponding to the successful searches, and $n+1$ leaves corresponding to the unsuccessful searches. The *depth* of a node is the number of edges from the node to the root. Denote $d(p_l)$ the depth of the internal node corresponding to p_l and $d(q_l)$ the depth of the leaf corresponding to q_l . A successful search requires $1 + d(p_l)$ comparisons, and an unsuccessful search requires $d(q_l)$ comparisons. See Fig. 5. So, the expected number of comparisons is

$$\sum_{1 \leq l \leq n} p_l (1 + d(p_l)) + \sum_{0 \leq l \leq n} q_l d(q_l). \quad (11)$$

The goal is to construct an *optimal binary search tree* that minimizes the expected number of comparisons carried out, which is (11).

Let $B_{i,j}$ be the expected number of comparisons carried out in a optimal subtree containing the keys $\text{Key}_{i+1} < \text{Key}_2 < \dots < \text{Key}_j$. Observing that in a search the probability to search in the region between Key_{i+1} and Key_j is $\sum_{l=i+1}^j p_l + \sum_{l=i}^j q_l$ it is clear that the following recurrence holds:

$$B_{i,j} = \begin{cases} 0, & \text{if } i = j; \\ \sum_{l=i+1}^j p_l + \sum_{l=i}^j q_l + \min_{i < t \leq j} (B_{i,t-1} + B_{t,j}), & \text{if } i < j, \end{cases} \quad (12)$$

where the cost of the optimal binary search tree is $B_{0,n}$. Calculating $B_{i,j}$ requires $O(j - i)$ time, thus calculating all of the $B_{i,j}$ requires $O(n^3)$ time.

2.6 Pyramidal Tours for the Traveling Salesman Problem

In the traveling salesman problem one is given a set of n “cities” $V = \{1, \dots, n\}$ as well as a distance matrix $d[i, j]$. Find a permutation t (“the tour”), such that

$$f(t) = d(t(n), t(1)) + \sum_{i=1}^{n-1} d(t(i), t(i+1))$$

is minimized. This problem is well studied and it is known to be \mathcal{NP} -hard. (A good resource on the Traveling Salesman Problem is the “guided tour book” by Lawler, Lenstra, Rinnoy Kan, and Shmoys [79]). A tour t is said to be *pyramidal* if, t is of the form $1, i_1, i_2, i_3, \dots, n, j_1, \dots, j_{n-r-2}$, where $1 < i_1 < i_2 < i_3 < \dots < n$ and $j_1 > j_2 > j_3 > \dots > j_{n-r-2}$. A pyramidal tour can be found by dynamic programming in $\Theta(n^2)$. To this end, let $H[i, j]$ be the length of a shortest Hamiltonian path from i to j subject to the condition that the path goes from i to 1 in descending order followed by the rest in ascending order from 1 to j . The reader is encouraged to verify that by the principle of optimality the following recursion holds:

$$H[i, j] = \begin{cases} H[i, j-1] + d[j-1, j] & \text{for } i < j-1, \\ \min_{k < i} \{H[i, k] + d[k, j]\} & \text{for } i = j-1, \\ H[i-1, j] + d[i, i-1] & \text{for } i < j+1, \\ \min_{k < j} \{H[k, j] + d[j, k]\} & \text{for } i = j+1. \end{cases} \quad (13)$$

Then the cost of shortest pyramidal tour is

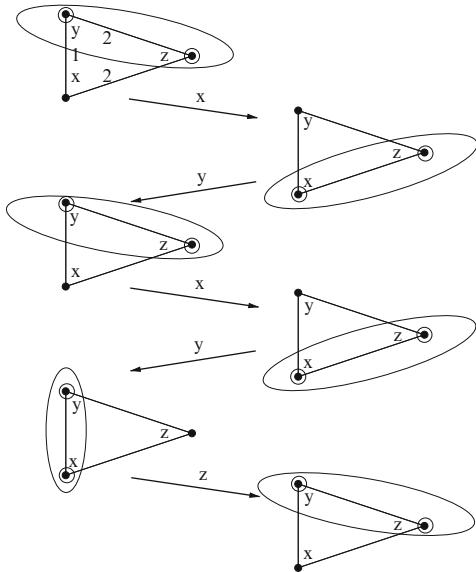

$$\min\{H[n, n-1] + d[n-1, n], H[n-1, n] + d[n, n-1]\}.$$

A matrix d is *Monge* if for all $i < i'$ and $j < j'$, $d[i, j] + d[i', j'] \leq d[i', j] + d[i, j']$. If the matrix d is a Monge matrix then it is easy to see that there exists an optimal tour, which is pyramidal.

3 Open-ended Dynamic Programming: Work Functions

Dynamic programs are useful in decision making for problems where new requests are constantly added, and updates need to be performed. The *k-server problem*, originally given by Manasse, McGeoch, and Sleator [82], is defined as follows: one is given $k \geq 2$ mobile servers which reside in a metric space M . A sequence of

Fig. 6 The two points x and y are at distance 1 and a point z is at distance 2 from x and y . The request sequence is $xyxyz$. The solution, i.e., the positions of the servers for each request, are circled. The solution has a cost of 7, which is not optimal since it is better to move the server at point z for the first and last request

requests is issued, where each request is specified by a point $r \in M$. To “satisfy” this request, one of the servers must be moved to r , at a cost equal to the distance from its current location to r . (If a request is to a point that already has a server the cost is zero.) The goal is to minimize the total service cost. An algorithm \mathcal{A} for the k -server problem computes a solution which determines which server is moved at each step. [Figure 6](#) gives a very simple example for the 2-server problem, i.e., the server problem for $k = 2$ in a metric space with only three points. Interestingly, a very similar metric space is powerful enough to model the noted “ski rental problem”, see Karlin, Manasse, Rudolph, and Sleator [68] for details.

This problem can be solved by dynamic programming calculating *work functions*, when the length of the request sequence and all the requests are known in advance. This standard version of the problem is also called the offline version of the k -server problem. Credit for introducing work functions goes to Larmore and Chrobak [42].

Work functions provide information about the optimal cost of serving the past request sequence. For a request sequence ϱ , by $\omega_\varrho(X)$ one denotes the minimum cost of serving ϱ and ending in configuration X – an unordered k -tuples of points. The function ω_ϱ is called the work function after request sequence ϱ . The notation ω is used to denote any work function ω_ϱ , for some request sequence ϱ . Immediately from the definition of work functions it can be concluded that the optimal cost to service ϱ is $opt(\varrho) = \min_X \omega_\varrho(X)$.

For given ϱ , the work function ω_ϱ can be computed using dynamic programming. Initially, $\omega_\epsilon(X) = S^0 X$, for each configuration X (ϵ is the empty request sequence). For a non-empty request sequence ϱ , if r is the last request in ϱ , write $\varrho = \sigma r$.

Then ω_ϱ can be computed recursively as $\omega_\varrho = \omega_\sigma \wedge r$, where “ \wedge ” is the *update operator* defined as follows:

$$\omega \wedge r(X) = \min_{Y \ni r} \{\omega(Y) + \text{dist}(Y, X)\} \quad (14)$$

Here $\text{dist}(Y, X)$ denotes the minimum-matching distance between X and Y . Note that $|\omega(X) - \omega(Y)| \leq XY$ for any work function ω and any configurations X and Y . This inequality is called the *Lipschitz property*. A set of configurations $S = \{X_1, X_2, \dots\}$ is said to support a work function ω if, for any configuration Y , there exists some $X \in S$ such that $\omega(Y) = \omega(X) + \text{dist}(X, Y)$. If ω is supported by a finite set (which it usually is), then there is a unique minimal set S which supports ω , which is called the work function support of ω . Note the following: If $r \in X$, then $\omega \wedge r(X) = \omega(X)$. If $r \notin X$, let Y be the configuration that contains r and minimizes $\omega(Y) + YX$, and let x be the point in X that is matched to r in the minimum matching between X and Y . Then $\omega(Y) + YX = \omega(Y) + rx + Y(X - x + r) \geq \omega(X - x + r) + rx$. Thus the update formula Eq. 14 can be rewritten as $\omega \wedge r(X) = \min_{x \in X} \{\omega(X - x + r) + rx\}$. Also note that in calculating the functions ω_ϱ one need only keep track of the value of the function at their support. This is important as the number of configurations in the domain of ω_ϱ grows as requests grows. Figure 7 shows how to calculate an optimal solution, the progression of ω_ϱ and support for the example in Fig. 6.

In practice, requests might be given one at a time and the algorithm then has to make a decision about which server to move before future requests are known. An algorithm \mathcal{A} is said to be *online* if its decisions are made without the knowledge of future requests. It is unlikely that such an algorithm would achieve optimality. Similar to approximation algorithms, the quality of the algorithm is measured by comparing against the offline cost: \mathcal{A} is *C-competitive* if the cost incurred by \mathcal{A} to service each request sequence ϱ is at most C times the optimal (offline) service cost for ϱ , plus possibly an additive constant independent of ϱ . The *competitive ratio* of \mathcal{A} is the smallest C for which \mathcal{A} is C -competitive. The competitive ratio is frequently used to study the performance of online algorithms for the k -server Problem, as well as other optimization problems. The reader is referred to the book of Borodin and El-Yaniv [30] for a comprehensive discussion of competitive analysis.

It is interesting to note that the work functions ω_ϱ play a central role in the algorithm with current best competitiveness for the k -server problem: Work Function Algorithm. The Work Function Algorithm chooses its service of the request sequence ϱ as follows: Suppose that WFA is in configuration S , and that the current work function is ω . On request r , WFA chooses some $x \in S$ which minimizes $rx + \omega \wedge r(S - x + r)$, and moves the server from x to r . If there is more than one choice which minimizes that quantity, the choice is arbitrary. WFA can be seen as a “linear combination” of two greedy strategies. The first one, a *short-sighted greedy*, minimizes the cost rx in the given step. The second, a *retrospective greedy*, chooses the optimal configuration after r , that is, the configuration $S - x + r$ that minimizes $\omega \wedge r(S - x + r)$. The short-sighted greedy strategy is not competitive for any k . The retrospective greedy strategy is not competitive for $k \geq 3$, and its

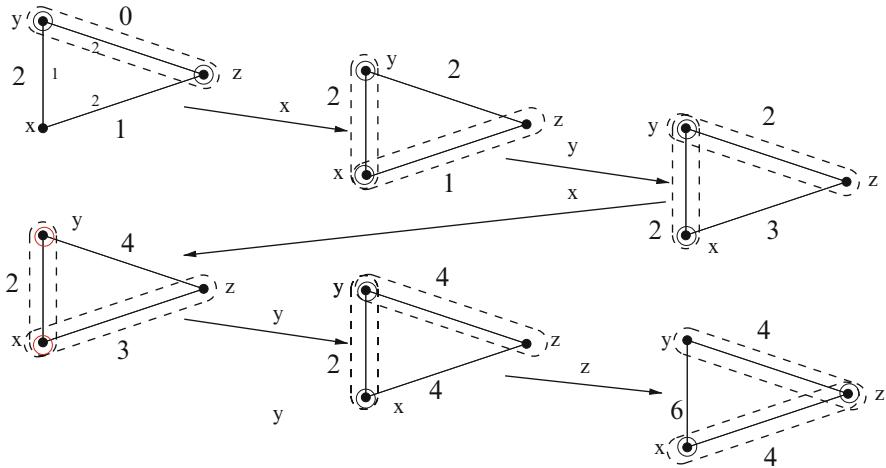

Fig. 7 Calculating the optimal solution using dynamic programming for the example in Fig. 6. The work functions ω_ϱ are shown in the figure as values adjacent to the corresponding pairs of points. Equivalently, the work functions can be written into the traditional dynamic programming table (top). The support is marked by *ovals* in the figure and is *underlined* in the table. The minimum value of the last row is 4 – the optimal value

competitive ratio for $k = 2$ is at least 3. The reader might verify that the service sequence depicted in Fig. 6 shows the steps of WFA for that example.

Manasse, McGeoch, and Sleator [82], have proved the following:

Theorem 2 *No online algorithm for k servers has competitive ratio smaller than k if a metric space has at least $k + 1$ points.*

They also give the *k-server conjecture* which states that, for each k , there exists an online algorithm for k servers which is k -competitive in any metric space. For $k > 2$, this conjecture has been settled only in a number of special cases, including trees and spaces with at most $k + 2$ points. (cf. the work of Chrobak, Karloff, Payne, and Vishwanathan [44], the work of Chrobak and Larmore [41] and the work of Koutsoupias and Papadimitriou [72].) Koutsoupias and Papadimitriou have shown:

Theorem 3 *The Work Function Algorithm is $(2k - 1)$ -competitive for k servers in arbitrary metric spaces.*

Thus a wide gap remains. Even some simple-looking special cases remain open, for example the 3-server problem on the circle, in the plane, or in 6-point spaces. Chrobak and Larmore [42] (see also [43]) prove:

Theorem 4 *The Work Function Algorithm is 2-competitive for $k = 2$.*

Bein, Chrobak, and Larmore [15] show:

Theorem 5 *The Work Function Algorithm is 3-competitive for $k = 3$ if the metric space M is the Manhattan plane.*

4 Intricate Dynamic Programming: Block Deletion in Quadratic Time

Sorting problems under various operations have been studied extensively, including work on sorting with prefix reversals, transpositions and block moves. This section contains an example from this realm and shows that intricate setup of dynamic programming can speed up dynamic programming schemes.

4.1 Preliminaries

Define a *permutation* of length n to be a list $x = (x_1, \dots, x_n)$ consisting of the integers $\{1, \dots, n\}$ where each number occurs exactly once. For any $1 \leq i \leq j \leq n$ denote the sublist of x that starts at position i and ends with position j by $x_{i\dots j}$. A list y is a *subsequence* of x if y is obtained from x by deleting any number of elements. For example, $(2, 3)$ is a subsequence of $(2, 4, 3, 1)$, but not a sublist. Since x has no duplicate symbols, a subsequence of x is uniquely characterized by its set of items. By a slight abuse of notation, one identifies a subsequence with the set of its items. Define the *closure* of a subsequence of x to be the smallest sublist of x which contains it. For example, the closure of the subsequence $(2, 3)$ of $(2, 4, 3, 1)$ is the sublist $(2, 4, 3)$. If A and A' are subsequences of a list x , say that A and A' are *separated* if the closures of A and A' are disjoint.

A block deletion sequence for a subsequence y of x consists of a sequence A_1, \dots, A_m of disjoint non-empty subsequences of y such that

1. for all $i = 2, \dots, m$, A_i is a block in $y - \bigcup_{u=1}^{i-1} A_u$, and
2. $y - \bigcup_{u=1}^m A_u$ is a monotone increasing list.

For example, a minimum length block deletion sequence for the list $(1, 4, 2, 5, 3)$ consists of two steps. First delete the block (2) , obtaining $(1, 4, 5, 3)$, then delete the block $(4, 5)$, obtaining the sorted list $(1, 3)$. Figure 8 shows another example of a block deletion sequence. A complete block deletion sequence for a subsequence y

Fig. 8 A block deletion sequence. There are five steps: A_1, \dots, A_5

of x consists of a block deletion sequence A_1, \dots, A_m of y such that $y - \bigcup_{u=1}^m A_u$ is the empty list.

4.2 A Dynamic Program for Complete Block Deletion

Consider first the complete block deletion problem for all sublists of x , which will be solved in quadratic time by dynamic programming. Once the $O(n^2)$ answers to this problem are obtained, the original block deletion problem can be solved in quadratic time. The following three lemmas are used:

Lemma 1 *If A_1, \dots, A_m is a block deletion sequence for a sublist y of x , and $1 \leq u < v \leq m$, then either A_u and A_v are separated, or A_u is a subsequence of the closure of A_v .*

Proof The closure of A_u cannot contain any item of A_v , since otherwise A_u could not be deleted before A_v . If all items of A_v are before A_u or all items of A_v are after A_u , then A_u and A_v are separated. If some items of A_v are before A_u and some items are after A_u , then A_u is a subsequence of the closure of A_v . \square

Lemma 2 *If $A_1, \dots, A_t, A_{t+1}, \dots, A_m$ is a block deletion sequence for a sublist y of x , and A_t and A_{t+1} are separated, then A_t and A_{t+1} may be transposed, i.e., $A_1, \dots, A_{t+1}, A_t, \dots, A_m$ is a block deletion sequence for y .*

Proof For any u , let $y_u = x - \bigcup_{v < u} A_v$. By definition, A_t is a block of y_t , and A_{t+1} is a block of $y_{t+1} = y_t - A_t$. Since A_t and A_{t+1} are separated, A_{t+1} is also a block of y_t . Thus, A_{t+1} can be deleted before A_t . \square

Lemma 3 *For any $1 \leq i \leq j \leq n$, if there is a complete block deletion sequence for $x_{i \dots j}$ of length m , then there is a complete block deletion sequence for $x_{i \dots j}$ of length m such that x_i is deleted in the last step.*

Proof Let A_1, \dots, A_m be a complete block deletion sequence of $x_{i \dots j}$. Suppose that $x_i \in A_t$ for some $t < m$. Since x_i is deleted in the t^{th} move of the sequence, all deletions after that must involve blocks whose first symbol occurs to the right of x_i in x . That is, for any $v > t$, x_i cannot be an item of the closure of A_v , hence, by [Lemma 1](#), A_t and A_v must be separated. By [Lemma 2](#), one can transpose A_t with A_v for each $v > t$ in turn, moving A_t to the end of the deletion sequence. \square

Next is given a recurrence to compute the minimum length of a complete block deletion sequence. This recurrence will be used in [Algorithm 1](#).

Theorem 6 *Given a permutation x , let $t_{i,j}$ denote the minimum length of any complete block deletion sequence for the sublist $x_{i \dots j}$. The values of $t_{i,j}$ can be computed inductively by the following: Set $t_{i,i} = 1$, $t_{i,j} = 0$ for $i > j$, and for $i < j$ set*

$$t_{i,j} = \begin{cases} \min\{1 + t_{i+1,j}, t_{i+1,\ell-1} + t_{\ell,j}\}, & \text{if } \exists \ell \in \{i+1, \dots, j\} \text{ such that } x_\ell = x_i + 1, \\ 1 + t_{i+1,j}, & \text{otherwise.} \end{cases} \quad (15)$$

Proof The proof is by induction on $j - i$ to show that $t_{i,j}$ is computed correctly. The base case is trivial, namely $t_{i,i} = 1$, because it takes one block deletion to delete a sublist of length 1.

For the inductive step, assume that $t_{i,j}$ is the length of a minimum block deletion sequence for $x_{i \dots j}$ when $j - i < k$. For $j - i = k$, let $m = t_{i,j}$ and let A_1, \dots, A_m be a corresponding minimum length complete block deletion sequence of $x_{i \dots j}$. By [Lemma 3](#), one can insist that $x_i = a$ is an item in A_m . Consider now two cases based on whether there is an ℓ with $i < \ell \leq j$ such that $x_\ell = a + 1$ (The reader might also consult [Fig. 9](#)).

If the element $a + 1$ does not occur in the interval $\{i + 1, \dots, j\}$, then the element a is not part of a block in this interval and must be deleted by itself. So, A_1, \dots, A_{m-1} is a complete block deletion sequence of $x_{i+1 \dots j}$. Note that it must be of optimum length, for if B_1, \dots, B_r were a shorter complete block deletion sequence of $x_{i+1 \dots j}$, then $B_1, \dots, B_r, \{a\}$ would be shorter than A_1, \dots, A_m . Thus, as $j - (i + 1) = k - 1$, by the induction hypothesis $t_{i+1,j} = m - 1$. So $t_{i,j} = 1 + t_{i+1,j}$, which is optimum.

Now for the case that the element $x_\ell = a + 1$ does occur in the interval $\{i + 1, \dots, j\}$. This means that $a + 1$ and possibly other larger values can be included in A_m when element a is deleted. If element $a + 1$ is not included in A_m then the same argument used in the previous paragraph shows that $m = 1 + t_{i+1,j}$. If on the other hand $a + 1$ is included in A_m , then by [Lemma 1](#), for any t , $(1 \leq t \leq m)$, A_t is either completely before or completely after the element $a + 1$, since A_m is deleted after A_t . By [Lemma 2](#), one can permute the indices so that, for some $u < m$,

1. if $t \leq u$, then A_t is a subsequence of $x_{i+1 \dots \ell-1}$, and
2. if $u < t \leq m$, then A_t is a subsequence of $x_{\ell+1 \dots j}$.

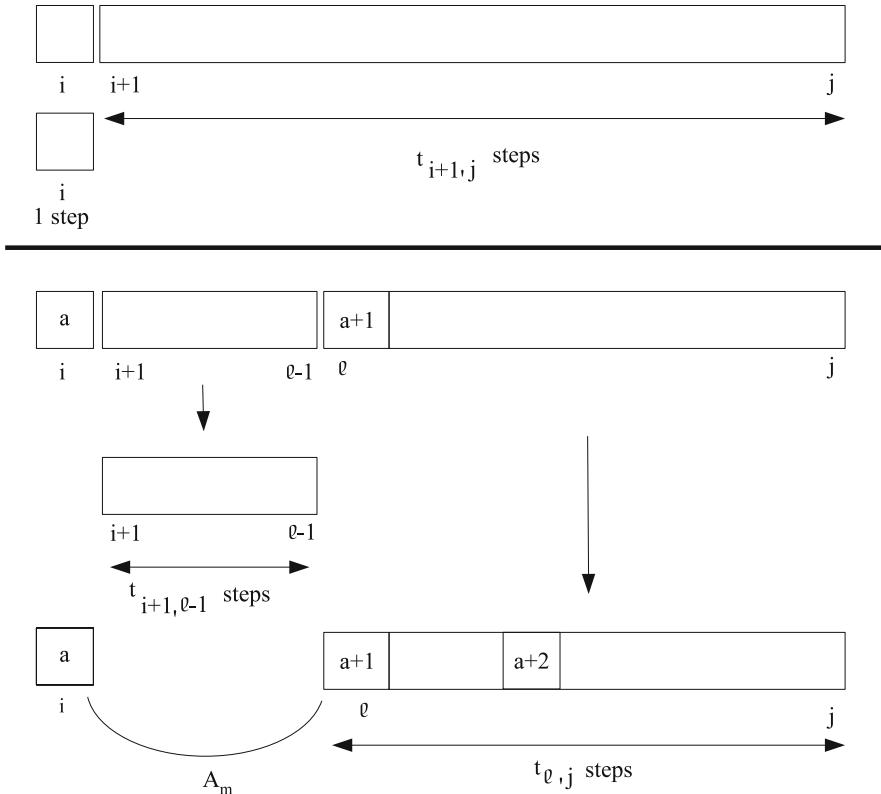

Fig. 9 The recurrence for the $t_{i,j}$ values

Consequently, A_1, \dots, A_u is a block deletion sequence for $x_{i+1 \dots \ell-1}$ and $A_{u+1}, \dots, A_m - \{a\}$ is a block deletion sequence for $x_{\ell+1 \dots j}$. Both of these block deletion sequences must be optimum for their respective intervals. That is, for example, if B_1, \dots, B_r were a shorter complete block deletion sequence for $x_{i+1 \dots \ell-1}$, then $B_1, \dots, B_r, A_{u+1}, \dots, A_m$ would be a complete block deletion sequence for $x_{i \dots j}$, contradicting the minimality of m . By the induction hypothesis, as $\ell - 1 - (i + 1) < j - i$ and $j - \ell < j - i$, it follows that $t_{i+1,\ell-1} = u$ and $t_{\ell,j} = m - u$, so $t_{i,j} = t_{i+1,\ell-1} + t_{\ell,j} = u + (m - u) = m$. \square

The resulting dynamic programming algorithm **BLOCKDELETION**, which is derived from the recurrence of **Theorem 6**, is shown below.

Next the analysis of the run time of algorithm **BLOCKDELETION** is considered. Let $z = (z_1, \dots, z_n)$ be the inverse permutation of x , i.e., $x_i = k$ if and only if $z_k = i$. Note that z can be computed in $O(n)$ preprocessing time.

Theorem 7 Algorithm **BLOCKDELETION** has run time $O(n^2)$.

Algorithm 1 BLOCKDELETION(x)

Let n be the number of elements in x

```

for  $i \leftarrow 1$  to  $n$  do
     $t[i, i] \leftarrow 1$ 
for  $k \leftarrow 2$  to  $n$  do
    for  $i \leftarrow 1$  to  $n - k + 1$  do
        Let  $x_\ell \leftarrow x_i + 1$ ;  $j \leftarrow i + k - 1$ 
        if  $i < \ell \leq j$ 
            then  $t[i, j] \leftarrow \min\{1 + t[i + 1, j], (t[i + 1, \ell - 1] + t[\ell, j])\}$ 
        else  $t[i, j] \leftarrow 1 + t[i + 1, j]$ 
return

```

Proof. To prove the theorem one shows that if $t_{u,v}$ are already known for all $i < u \leq v \leq j$, then $t_{i,j}$ can be computed in $O(1)$ time. Let $m = t_{i,j}$ for $i < j$ and let A_t be the subsequence of $x_{i\dots j}$ that is deleted at step t of the complete block deletion sequence of $x_{i\dots j}$ of length m . By Lemma 3, assume that $x_i \in A_m$. If $|A_m| > 1$, the index $\ell = z_{x_i+1}$, i.e., $x_\ell = 1 + x_i$, can be found in $O(1)$ time, since one has already spent $O(n)$ preprocessing time to compute the array z . The recurrence thus takes $O(1)$ time to execute for each i, j . \square

Note that to obtain the actual sequence of steps in the optimum complete block deletion sequence one can store appropriate pointers as the $t_{i,j}$ are computed.

4.3 Computing Block Deletion

The reader is reminded that for the block deletion problem one needs to find the minimum length sequence of block deletions to transform a permutation into a monotone increasing list. Next it is shown how one obtains a solution to the block deletion problem for x in $O(n^2)$ -time given that all $t_{i,j}$ are known for $1 \leq i \leq j \leq n$. Define a weighted acyclic directed graph G with one node for each $i \in \{0, \dots, n+1\}$. There is an edge from i to j if and only if $i < j$ and $x_i < x_j$, and the weight of that edge is $t_{i+1,j-1}$. Simply observe that there is a path $\langle 0, i_1, i_2, \dots, i_k, n+1 \rangle$ in G exactly when x_{i_1}, \dots, x_{i_k} is a monotone increasing list. Furthermore the weight of the edge $\langle i_\ell, i_{\ell+1} \rangle$ gives the minimum number of block deletions necessary to delete elements between position i_ℓ and $i_{\ell+1}$ in x . Thus if there is a block deletion sequence of x of length m , there must be a path from 0 to $n+1$ in G of weight m , and vice-versa.

Using standard dynamic programming, a minimum weight path from 0 to $n+1$ can be found in $O(n^2)$ time. Let $0 = i_0 < i_1 < \dots < i_\ell = n+1$ be such a minimum weight path, and let $w = \sum_{u=1}^\ell t_{i_{u-1}+1, i_u-1}$ be the weight of that minimum path. Since every deletion is a block deletion, the entire list can be deleted to a monotone list in w block deletions. Thus it follows:

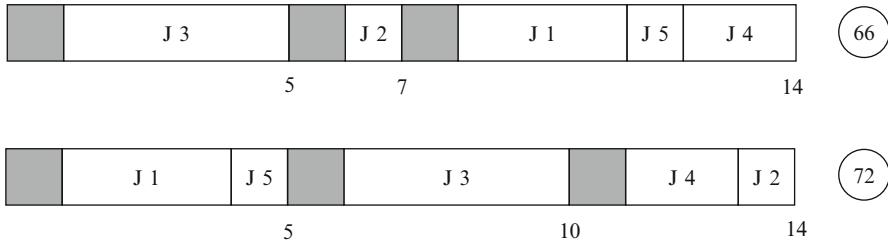

Fig. 10 A batching example. Shown are two feasible schedules for a 5-job problem where processing times are $p_1 = 3, p_2 = 1, p_3 = 4, p_4 = 2, p_5 = 1$ and the weights are $w_1 = w_4 = w_5 = 1$ and $w_2 = w_3 = 2$. The encircled values give the sum of weighted completion times of the depicted schedules

Theorem 8 *The block deletion problem can be solved in time $O(n^2)$.*

5 Total Monotonicity and Batch Scheduling

Although dynamic programming has been around for decades there have been more recent techniques for making dynamic programming more efficient. This section describes an example from scheduling, where such a technique is applied. Before the technique is shown, the simple traditional dynamic programming for the scheduling problem is given and then the dynamic programming speedup technique is described.

5.1 The Problem $1|s - \text{batch}| \sum w_i C_i$

Consider the *batching problem* where a set of jobs $\mathcal{J} = \{J_i\}$ with processing times $p_i > 0$ and weights $w_i \geq 0, i = 1, \dots, n$, must be scheduled on a single machine, and where \mathcal{J} must be partitioned into *batches* $\mathcal{B}_1, \dots, \mathcal{B}_r$. All jobs in the same batch are run jointly and each job's completion time is defined to be the completion time of its batch. One assumes that when a batch is scheduled it requires a setup time $s = 1$. The goal is to find a schedule that minimizes the *sum of completion times* $\sum w_i C_i$, where C_i denotes the completion time of J_i in a given schedule. Given a sequence of jobs, a batching algorithm must assign every job J_i to a batch. More formally, a feasible solution is an assignment of each job J_i to the m_i^{th} batch, $i \in \{1, \dots, n\}$ (Fig. 10).

The problem considered has the jobs executed sequentially, thus the problem is more precisely referred to as the *s-batch* problem. There is a different version of the problem not studied here, where the jobs of a batch are executed in parallel, known as the *p-batch* problem. In that case, the length of a batch is the maximum of the processing times of its jobs. The s-batch is also denoted in $\alpha|\beta|\gamma$ notation as the $1|s\text{-batch}| \sum w_i C_i$ problem. Brucker and Albers [6] showed that the

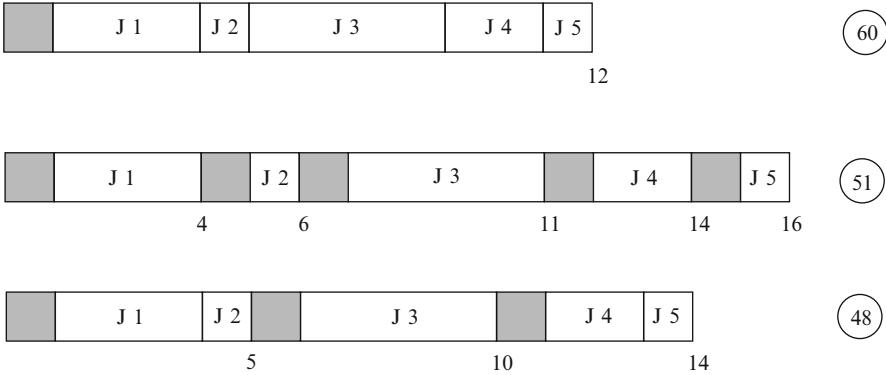

Fig. 11 List batching. Shown are three schedules for a 5-job problem where all weights are 1 and the processing requirements are $p_1 = 3, p_2 = 1, p_3 = 4, p_4 = 2, p_5 = 1$. The encircled values give the sum of weighted completion times of the depicted schedules

$1|s\text{-batch}| \sum w_i C_i$ problem is \mathcal{NP} -hard in the strong sense by giving a reduction from 3-PARTITION.

There is a large body of work on dynamic programming and batching; see the work of Baptiste [12], Baptiste and Jouglet [13], Brucker, Gladky, Hoogeveen, Kovalyov, Potts Tautenhahn, and van de Velde [36], Brucker, Kovalyov, Shafransky, and Werner [37], and Hoogeveen and Vestjens [64], as well as the scheduling text book by Peter Brucker [33]. Batching has wide application in manufacturing (see e.g., [34, 85, 98]), decision management (see, e.g., [74]), and scheduling in information technology (see e.g., [46]). More recent work on online batching is related to the TCP (Transmission Control Protocol) acknowledgment problem (see [20, 49, 67]).

5.2 List Batching

A much easier version of the problem is the *list* version of the problem where the order of the jobs is given, i.e., $m_i \leq m_j$ if $i < j$. An example is given in Fig. 11.

Assume that the jobs are $1, \dots, n$ and are given in this order. One can then reduce the list batching problem to a shortest path problem in the following manner: Construct a weighted directed acyclic graph G with nodes $i = 1, \dots, n$ (i.e., one node for each job) and add a dummy node 0. There is an edge (i, j) if and only if $i < j$. (See Fig. 12 for a schematic.) Let edge costs $c_{i,j}$ for $i < j$ be defined as

$$c_{i,j} = \left(\sum_{\ell=i+1}^n w_\ell \right) \left(s + \sum_{\ell=1}^j p_\ell \right). \quad (16)$$

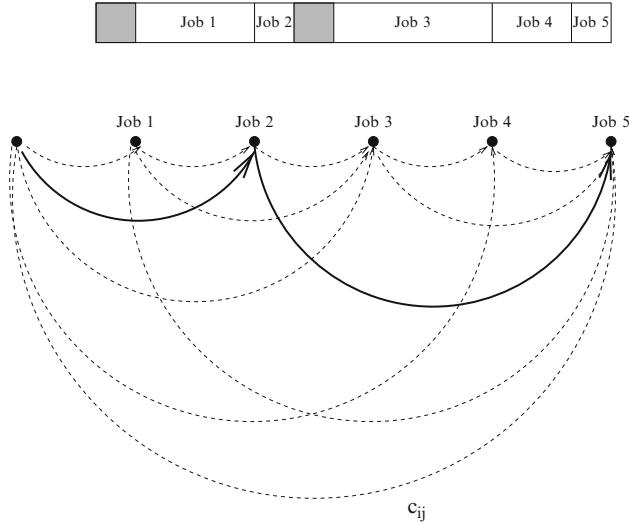

Fig. 12 Reduction of the list batching problem to a path problem

It is easily seen (see [6] for details) that the cost of path $< 0, i_1, i_2, \dots, i_k, n >$ gives the $\sum C_i w_i$ value of the schedule which batches at each job i_1, i_2, \dots, i_k . Conversely, any batching with cost A corresponds to a path in G with path length A .

A shortest path can be computed in time $O(n^2)$ using the following dynamic program:

Let

$$E[\ell] = \text{cost of the shortest path from } 0 \text{ to } \ell,$$

then

$$E[\ell] = \min_{0 \leq k < \ell} \{E[k] + c_{k,\ell}\} \text{ with } E[0] = 0, \quad (17)$$

which results in a table, in which elements can be computed row by row (see Fig. 13).

In other words, the dynamic program computes the row minima of the $n \times n$ matrix E , where

$$E[\ell, k] = \begin{cases} E[k] + c[k, \ell] & \text{if } \ell < k \\ \infty & \text{else} \end{cases} \quad (18)$$

with $\ell = 1, \dots, n$ and $k = 0, \dots, n - 1$.

As it turns out it is not necessary to calculate all entries of E to calculate the optimal solution. Surprisingly, only $O(n)$ have to be looked up throughout the entire calculation. The reason that this is possible is that E is a matrix with special properties discussed next.

Row 1	$c[0,1]+E[0]$	$\min \rightarrow E[1]$
Row 2	$c[0,2]+E[0] \quad c[1,2]+E[1]$	$\min \rightarrow E[2]$
Row 3	$c[0,3]+E[0] \quad c[1,3]+E[1] \quad c[2,3]+E[3]$	$\min \rightarrow E[3]$
Row 4	$c[0,4]+E[0] \quad c[1,4]+E[1] \quad c[2,4]+E[2] \quad c[3,4]+E[4]$	$\min \rightarrow E[4]$

Fig. 13 Dynamic programming tableau

5.3 The Monge Property and Total Monotonicity

Definition 1 A matrix A is Monge if for all $i < i'$ and $j < j'$,

$$A[i, j] + A[i', j'] \leq A[i', j] + A[i, j']. \quad (19)$$

Definition 2 A 2×2 matrix is monotone if the rightmost minimum of the upper row is not to the right of the rightmost minimum of the lower row. More formally, $\begin{bmatrix} a & b \\ c & d \end{bmatrix}$ is monotone if $b \leq a$ implies that $d \leq c$.

Definition 3 A matrix A is called totally monotone if all 2×2 dimensional submatrices are monotone.

Observation 1 Every Monge matrix is totally monotone.

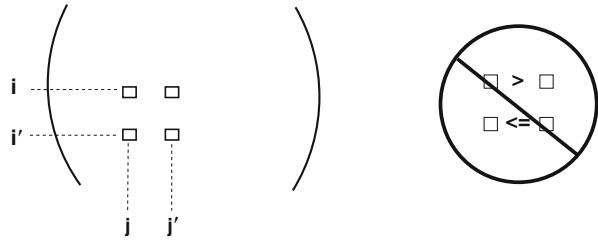

The reader is referred to Fig. 14. Monge matrices occur routinely. For example in the batching to shortest path reduction, the cost matrix C is a Monge matrix:

Lemma 4 The matrix $C = (c_{i,j})$ defined in (16) is Monge for all choices of $p_i, w_i \geq 0$. Furthermore values can be queried in $O(1)$ time after linear preprocessing.

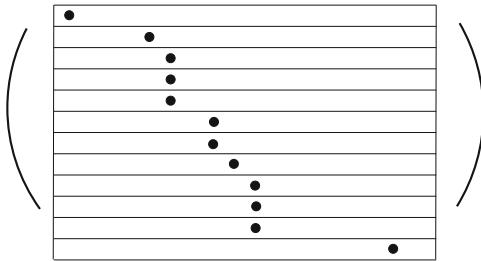

Proof Let $W_i = \sum_{v=1}^i w_v$ and $P_i = \sum_{v=1}^i p_v$ be the partial sum of the p_i and w_i values. Then

$$c[i, j] = c_{i,j} = (W_n - W_i)(s + P_j - P_i)$$

Fig. 14 Monge and monotonicity. Top left the Monge property is shown, which prohibits the situation top right. Thus row minima veer to the right (bottom figure)

$$A_{ii'} + A_{jj'} \leq A_{i'j} + A_{j'i}$$

For $i < i'$ and $j < j'$

$$c[i, j] + c[i', j'] - c[i', j] - c[i, j'] \quad (20)$$

$$= (P_{j'} - P_j)(W_{i'} - W_i) \quad (21)$$

$$\geq 0. \quad (22)$$

Also, notice that these values can be queried in $O(1)$ time after linear preprocessing by setting up arrays of partial sums for W_i and P_i in linear time. \square

Furthermore, the matrix E is also a Monge matrix:

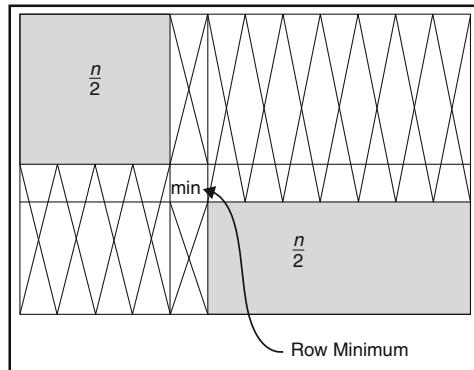

Lemma 5 *The matrix $E = (E_{\ell,k})$ defined in (18) is Monge.*

Proof Monge is preserved under addition and taking the minimum. \square

Computing the row minima of a Monge (or totally monotone) matrix can be done trivially in $O(n \log n)$, cf. Fig. 15. A complex recursive procedure by Agarwal, Klawé, Moran, Shor, and Wilber [3] known as the SMAWK algorithm (the name was derived using the initials of authors of the original paper in which the algorithm was introduced), which has linear run time.

Note that the dynamic program of Fig. 13 is essentially used to calculate the row minima of E – a Monge matrix. However, the trivial $O(n \log n)$ cannot be used here since that algorithm requires all elements of E to be available offline,

Fig. 15 Calculating all row minima of a Monge matrix. The algorithm finds the minimum of the middle row in linear time and then recurses on the upper left and lower right parts of the matrix

i.e., before the computation begins. Instead, there is a protocol by which each element can be queried: Once the minimum of row 1 is known, then any element in column 1 can be generated in constant time; once the minimum of row 2 is known then any element of row 1 and 2 are “knowable”; and so forth. (See also Fig. 16.)

More formally the protocol is as follows:

1. For each row index ℓ of E , there is a column index γ_ℓ such that for $k > \gamma_\ell$, $E_{\ell,k} = \infty$. Furthermore, $\gamma_\ell \leq \gamma_{\ell+1}$.
2. If $k \leq \gamma_\ell$, then $E[\ell, k]$ can be evaluated in $O(1)$ time *provided that the row minima of the first ℓ rows are already known*.
3. E is a totally monotone matrix.

Larmore and Schieber [77] have developed an algorithm that generalizes the SMAWK to run in linear time in this case as well. Their algorithm is also known as the LARSCH algorithm – again, as with the SMAWK algorithm, the name was derived using initials of authors of the original paper in which the algorithm was introduced in Larmore and Schieber [77]. Both SMAWK and LARSCH are important in dynamic programming speedup and are explained in the next section.

6 The SMAWK and LARSCH Algorithm

This section gives “ready to implement” descriptions of the SMAWK and LARSCH algorithms mentioned in the previous section.

6.1 The Matrix Searching Problem

The *matrix searching problem* is the problem of finding all row minima of a given matrix M . If n, m are the number of rows columns, respectively, of M , the problem clearly takes $\Theta(nm)$ time in the worst case. However, if M is *totally monotone* the problem can be solved in $O(n + m)$ time using the SMAWK algorithm [3].

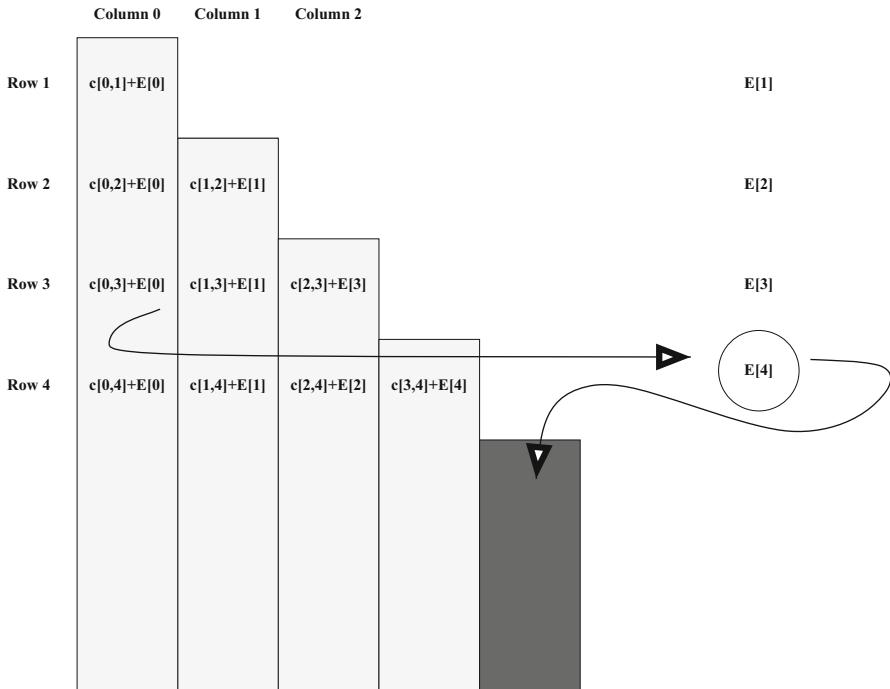

Fig. 16 The “online” protocol of the tableau. Note that once the minimum of row 4 is known, column 4 is “knowable”

SMAWK is recursive, but uses two kinds of recursion, called INTERPOLATE and REDUCE, which are described in the following. Let $1 \leq J(i) \leq m$ be the index of the minimum element of the i^{th} row.¹ Since M is totally monotone, $J(i) \leq J(k)$ for any $i < k$.

1. For small cases, SMAWK uses a trivial algorithm. If $m = 1$, the problem is trivial. If $n = 1$, simply use linear search.
2. If $n \geq 2$, then INTERPOLATE can be used. Simply let M' be the $\lfloor n/2 \rfloor \times m$ submatrix of M consisting of all even indexed rows of M . Recursively, find all row minima of M' , and then use linear search to find the remaining minima of M in $O(n + m)$ time.
3. If $m > n$, then REDUCE can be used. The set $\{J(i)\}$ clearly has cardinality at most n . REDUCE selects a subset of the columns of M which has cardinality at most n , and which includes Column $J(i)$ for all $1 \leq i \leq n$. Let M' be the submatrix of M consisting of all the columns selected by REDUCE. Then, recursively, find all row minima of M' . These will exactly be the row minima of M . The time required to select the columns of M' is $O(n + m)$.

¹Use the leftmost rule to break ties.

SMAWK then operates by alternating the two kinds of recursion. If the initial matrix is $n \times n$, then INTERPOLATE reduces to the problem on a matrix of size roughly $n/2 \times n$, and then REDUCE reduces to the problem on a matrix of size roughly $n/2 \times n/2$, and so forth.

Time Complexity

Let $T(n)$ be the time required by SMAWK to find all row minima of an $n \times n$ totally monotone matrix. Applying both INTERPOLATE and REDUCE, obtain the recurrence

$$T(n) = O(n) + T(n/2)$$

and thus $T(n) = O(n)$. By a slight generalization of the recurrence, one can show that SMAWK solves the problem for an $n \times m$ matrix in $O(n + m)$ time.

INTERPOLATE is explained using the code below.

Code for INTERPOLATE

```

1: { $M$  is an  $n \times m$  totally monotone matrix, where  $m \leq n$ .}
2: if  $n = 1$  then
3:    $J(1) = 1$ 
4: else
5:   Let  $M'$  be the matrix consisting of the even indexed rows of  $M$ .
6:   Obtain  $J(i)$  for all even  $i$  by a recursive call to REDUCE on  $M'$ .
7:   for all odd  $i$  in the range 1 to  $n$  do
8:     if  $i = n$  then
9:       Find  $J(n) \in [J(n - 1), n]$  by linear search.
10:    else
11:      Find  $J(i) \in [J(i - 1), J(i + 1)]$  by linear search.
12:    end if
13:   end for
14: end if
```

The total number of comparisons needed to find the minima of all odd rows is at most $n - 1$, as illustrated in Fig. 17 below.

Now for REDUCE. The procedure REDUCE operates by maintaining a stack, where each item on the stack is a column (actually, a column index). Initially the stack is empty, and columns are pushed onto the stack one at a time, starting with Column 1. The capacity of the stack is n , the number of rows.

But before any given column is pushed onto the stack, any number (zero or more) of earlier columns are popped off the stack. A column is popped if it is determined that it is *dominated*, which implies that none of its entries can be the minimum of any row. In some cases, if the stack is full, a new column will not be pushed.

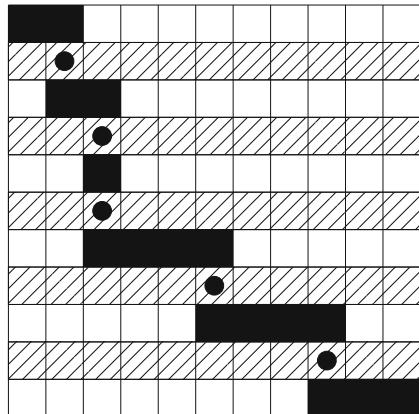

At the end, those columns which remain on the stack form the matrix M' .

Dominance

There is a loop invariant, namely that if the stack size is at least i , and if $S[i] = j$, then all entries of Column j above Row i are known to be useless, i.e., will

Fig. 17 INTERPOLATE.

M' consists of the hatched rows, and the minima of those rows are indicated by *black dots*. By the monotonicity property of J , only search the interval indicated in *black* to find the minimum of any odd numbered row

not be the minima of any row. Formally, $M[i', S[i - 1]] \leq M[i', j]$ for all $1 \leq i' < i$.

Suppose that Column k is the next column to be possibly pushed onto the stack. If the stack is empty, then $S[1] \leftarrow k$, and one is done. Otherwise, it must be checked to see whether the top column in the stack is dominated. Let i be the current size of the stack, and let $S[i] = k$. Then, necessarily, $i \leq j < k$. Column j is dominated if $M[i, k] < M[i, j]$. The reason is that $M[i', j] \geq M[i', S[i - 1]]$ for any $i' < i$ by the loop invariant, and that $M[i', j] < M[i', k]$ for all $i' \geq i$ by monotonicity.

If the stack is popped, then the new top is tested for being dominated. This continues until the test fails. If the stack size is currently less than n , k is pushed onto the stack; otherwise, Column k is useless and is discarded.

Code for REDUCE

```

1: { $M$  is an  $n \times m$  totally monotone matrix.}
2:  $top \leftarrow 0$  {Initialize the stack to empty}
3: for  $j$  from 1 to  $m$  do
4:   while  $top > 0$  and  $M[top, j] < M[top, S[top]]$  do
5:      $top \leftarrow top - 1$  {Pop the stack.}
6:   end while
7:   if  $top < n$  then
8:      $top \leftarrow top + 1$  and then  $S[top] \leftarrow j$  {Push  $j$  onto the stack.}
9:   end if
10: end for
11: Call INTERPOLATE on  $M'$ , consisting of columns remaining on the stack.
The total number of comparisons needed to execute REDUCE (other than the recursive call) is at most  $2m$ . One sees this using an amortization argument. Each column is given two credits initially. When a column is pushed onto the stack, it spends one credit, and when it is popped off the stack it spends one credit. Each of those two events requires at most one comparison. Thus, the total number of comparisons is at most  $2m$ .

```

Fig. 18 REDUCE. M' consists of the hatched columns. All row minima, indicated by black dots, lie within those columns, although possibly not all columns contain minima

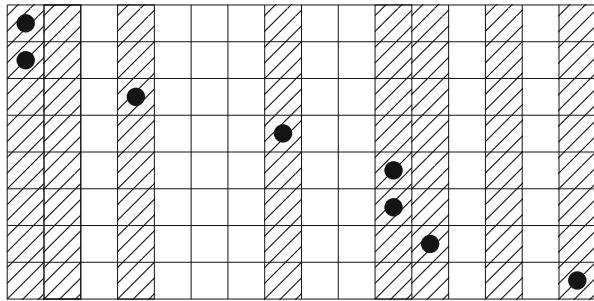

Figure 18 shows an example of an 8×16 matrix M , where the shaded columns survive to form M' .

6.2 The Online Matrix Searching Problem

Define an *almost lower triangular matrix* to be matrix M of n rows, numbered $1 \dots n$, and m columns such that the length of the rows increases as n increases. More formally, let the columns be numbered $0 \dots m - 1$. Then there must exist n row lengths, $1 \leq \ell[1] \leq \ell[2] \leq \dots \leq \ell[n] = m$, such that $M[i, j]$ is defined if and only if $1 \leq i \leq n$ and $0 \leq j < \ell[i]$. If $\ell[i] = i$ for all i , then M is a standard lower triangular matrix.

Given an almost lower triangular matrix, let $J(i)$ be the column index of the minimum entry in the i^{th} row of M . (Ties are broken arbitrarily). The *online matrix search problem* is the problem of finding all row minima of M , with the condition that a given entry $M[i, j]$ is available if and only if $J(k)$ has been computed for every k such that $\ell[k] < j$. For example, if M is a standard lower triangular matrix, $M[i, j]$ is available if and only if $J[k]$ has been computed for all $k \leq j$. Note that $M[i, 0]$ is available initially.

Assume that the computation is done by a process B which is in communication with a supervisor A . The online computation then proceeds as follows.

- A grants permission for B to see Column 0.
- B reports $J[1]$ (which is certainly 0) to A .
- A grants permission for B to see Column 1.
- B reports $J[2]$ to A .
- A grants permission for B to see Column 1.
- B reports $J[3]$ to A .
- etc.

Note that B is unable to compute $J(i)$ until it has seen Columns 0 through $i - 1$, since the minimum of Row i could be in any of those columns. Conversely, one must have computed $J(1)$ through $J(i - 1)$ in order to be allowed to see those columns. Thus, the order of the events in the above computation is strict.

6.3 Algorithm LARSCH

In general, it takes $O(nm)$ time to solve the online matrix search problem. However, if M is totally monotone, the values of J are monotone increasing, and the online matrix search problem can be solved in $O(n + m)$ time by using an online algorithm LARSCH, which is the online version of SMAWK, with some adaptations.

Let M be the input matrix. LARSCH works using a chain of processes, each of which is in communication with its *supervisor*, the process above it in the chain. The supervisor of the top process is presumably an application program. Refer to the process below a process as its *child*.

Each process in the chain works an instance of the online matrix searching problem. The top process works the instance given by the application. Each process reports results interleaved with messages received from its supervisor.

Each process P works the problem on a strictly monotone almost lower triangular matrix M_P , which is a submatrix of M . If Q is the child of P , then P creates a submatrix M_Q of M_P and passes that submatrix to Q . Of course, P never passes the entries of the matrix to Q ; rather, it tells Q which entries of M it is allowed to see. For clarity assume that each process uses its own local row and column indices, but is aware of the global indices of each entry. For example, in example calculation in [Table 5](#), $M_5[3, 2] = M[15, 11]$.

Alternating Types.

In the following detailed description of LARSCH, assume that the initial matrix M is standard lower triangular. (The algorithm can easily be generalized to cover other cases.)

Let P_0, P_1, \dots, P_h , $h = 2(\lfloor \log_2(n+1) \rfloor - 1)$, be the processes, where P_{t+1} is the child of P_t . The processes are of alternating *types*. If t is even, say that P_t has *standard type*, while if t is odd, say that P_t has *stretched type*.

Let M_t be the submatrix of M visible to P_t . $M_0 = M$. If t is odd, then M_t has $n_t = \lfloor 2^{-t/2}(n - 2^{t/2} - 1) \rfloor$ rows and $m_t = 2n_t$ columns, and the length of its i^{th} row is $2i$. If $t \geq 2$ is even, the M_t has $n_t = n_{t-1}$ rows and $m_t = n_t$ columns, and the length of its i^{th} row is i .

The choice of M_{t+1} as a submatrix of M_t is illustrated below. If t is even, then the rows of M_{t+1} are rows $3, 5, 7, \dots, \lfloor \frac{n-1}{2} \rfloor$ of M_t , ie. all rows of odd index other than 1. Row i of M_{t+1} consists of all but the last entry of Row $2i + 1$ of M_t .

If t is odd, then M_{t+1} has the same number of rows as M_t , but only half the columns. Since there are n_t rows in M_t , the number of possible columns of M_t which contain values of J cannot exceed n_t . The REDUCE procedure of LARSCH chooses exactly n_t columns of M_t in a way that makes certain that all columns which contain row minima of M_t are chosen. The figure below illustrates one possible choice ([Fig. 19](#)). The shaded entries are passed to M_{t+1} . Note that not every entry of a selected column is part of M_{t+1} .

Table 5 LARSCH algorithm example: INTERPOLATE and REDUCE

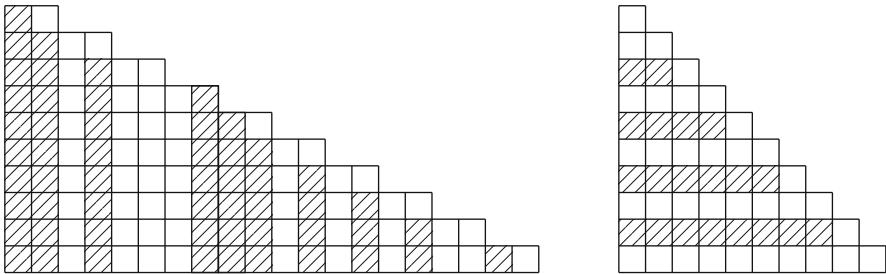

Fig. 19 Shaded entries of M_t indicate the submatrix M_{t+1} passed to the child process. *Left:* odd t . *Right:* even t

6.4 Standard Type Process: P_t for t Even (INTERPOLATE)

Code for a Process of Standard Type: P_t for t Even.

```

1: {Matrix  $M_t$  with  $n_t$  rows and  $n_t$  columns}
2: for  $i$  from 1 to  $n_t$  do
3:   Receive permission to view Column  $i - 1$  from supervisor.
4:   if  $i = 1$  then
5:      $J(1) \leftarrow 0$ 
6:   else if  $i$  is even and  $i < n_t$  then
7:     Grant permission to child to view Columns  $i - 2$  and  $i - 1$ .
8:     Receive  $J\_Partial$  from child.
9:     {Min of all entries but last of Row  $i + 1$  is in Column  $J\_Partial$ .}
10:    Find  $J(i) \in [J(i - 1), J\_Partial]$  by linear search.
11:   else if  $i$  is even and  $i = n_t$  then
12:     Find  $J(n_t) \in [J(i - 1), n_t - 1]$  by linear search.
13:   else [ $i \geq 3$  is odd]
14:     if  $M_t[i, i - 1] < M_t[i, J\_Partial]$  then
15:        $J(i) \leftarrow i - 1$ 
16:     else
17:        $J(i) \leftarrow J\_Partial$ 
18:     end if
19:   end if
20:   Send  $J(i)$  to supervisor. {Min of Row  $i$  is in Column  $J(i)$ }
21: end for

```

6.5 Standard Type Process: P_t for t Odd (REDUCE)

A stack called the *column stack* is maintained. Let *top* be the number of items (which are column indices) stored in the stack, and let $S[i]$ be the i th entry (counting from the bottom) of the stack. That is, $S[i]$ is defined for all $1 \leq i \leq top$.

Each time process P_t is able to view a new column, if the column stack is not empty, it pops all columns which are *dominated* by the new column off the stack, and then pushes the new column. The domination rule is that Column $S[i]$ is dominated by the new column, say Column j , if $M_t[i, j] < M_t[i, S[i]]$. Of course, it is possible that $j \geq 2i$, in which case $M_t[i, j]$ is taken to be infinity.

Code for a Process of Stretched Type: P_t for t Odd.

```

1: {Matrix  $M_t$  with  $n_t$  rows and  $2n_t$  columns}
2:  $top \leftarrow 0$       {Initialize the column stack to empty}
3: for  $i$  from 1 to  $n_t$  do
4:   Receive permission to view Columns  $2i - 2$  and  $2i - 1$  from supervisor.
5:   Pop all columns dominated by Column  $2i - 2$  from column stack.
6:   Push Column  $2i - 2$  onto column stack.
7:   Pop all columns dominated by Column  $2i - 1$  from column stack.
8:   Push Column  $2i - 1$  onto column stack.
9:   Grant permission to child to view Column  $S[i]$ .
10:  {The  $i^{\text{th}}$  column on the stack, which will become Column  $i - 1$  of  $M_{t+1}$ }
11:  Receive  $J(i)$  from child.    {Min of Row  $i$  is in Column  $J(i)$ }
12:  Send  $J(i)$  to supervisor.
13: end for
```

How may a new column possibly dominate existing columns on the column stack? Lines 2, 3, and 4 of the code below are the detail of Line 5 and Line 7 of the code above, while Lines 5 and 6 are the detail of Line 6 and Line 8 of the code above.

Code for Popping and Pushing the Column Stack.

```

1: {Column  $j$  is the new column}
2: while  $top > 0$  and  $2 \cdot top > j$  and  $M_t[top, j] < M_t[top, S[top]]$  do
3:    $top \leftarrow top - 1$       {Pop off the dominated column}
4: end while
5:  $top \leftarrow top + 1$ 
6:  $S[top] \leftarrow j$       {Push the new column}
```

7 The Quadrangle Inequality and Binary Search Trees

Another type of speedup is based in the Knuth-Yao quadrangle inequality. This section discusses this kind of speedup and the relation with SMAWK/LARSCH speedup.

7.1 Background

Recall construction of optimal binary search trees discussed in Sect. 2.5. Gilbert and Moore [59] gave a $O(n^3)$ time algorithm. More than a decade later, in 1971,

it was noticed by Knuth [71] that, using a complicated amortization argument, the $B_{i,j}$ can all be computed using only $O(n^2)$ time. Around another decade later, in the early 1980s, Yao (see [96, 97]) simplified Knuth's proof and, in the process, showed that this *dynamic programming speedup* worked for a large class of problems satisfying a *quadrangle inequality* property. Many other authors then used the Knuth-Yao technique, either implicitly or explicitly, to speed up different dynamic programming problems. For this see for example the work of Wessner [93], the work of Atallah, Kosaraju, Larmore, Miller, and Teng [9] and Bar-No and Ladner [14].

Even though both the SMAWK algorithm and the Knuth-Yao (KY) speedup (best described in [71, 96, 97]) use an implicit quadrangle inequality in their associated matrices, on second glance, they seem quite different from each other. In the SMAWK technique, the quadrangle inequality is on the entries of a given $m \times n$ *input* matrix, which can be any totally monotone matrix. The KY technique, by contrast, uses a quadrangle inequality in the upper-triangular $n \times n$ matrix B . That is, it uses the QI property of its *result* matrix to speed up the evaluation, via dynamic programming, of the entries in the same result matrix. Aggarwal and Park [2] demonstrated a relationship between the KY problem and totally-monotone matrices by building a *3-D monotone matrix* based on the KY problem and then using an algorithm due to Wilber [94] to find *tube* minima in that 3-D matrix. They left as an open question the possibility of using SMAWK directly to solve the KY problem.

Definition 4 A two dimensional upper triangular matrix A , $0 \leq i \leq j \leq n$ satisfies the *quadrangle inequality* (QI) if for all $i \leq i' \leq j \leq j'$,

$$A(i, j) + A(i', j') \leq A(i', j) + A(i, j'). \quad (23)$$

Observation 2 A Monge matrix satisfies a quadrangle inequality, but a totally monotone matrix may not.

Yao's result (of [96]) was formulated as follows: For $0 \leq i \leq j \leq n$ let $w(i, j)$ be a given function and

$$B_{i,j} = \begin{cases} 0, & \text{if } i = j; \\ w(i, j) + \min_{i < t \leq j} (B_{i,t-1} + B_{t,j}), & \text{if } i < j. \end{cases} \quad (24)$$

Definition 5 $w(i, j)$ is *monotone in the lattice of intervals* if $[i, j] \subseteq [i', j']$ implies $w(i, j) \leq w(i', j')$.

As an example, it is not difficult to see that the $w(i, j) = \sum_{l=i+1}^j p_l + \sum_{l=i}^j q_l$ of the BST recurrence (12) satisfies the quadrangle inequality and is monotone in the lattice of intervals.

Definition 6 Let

$$K_B(i, j) = \max\{t : w(i, j) + B_{i,t-1} + B_{t,j} = B_{i,j}\},$$

i.e., the largest index which achieves the minimum in (24).

Yao then proves two Lemmas (see Fig. 21 for an example):

Lemma 6 (Lemma 2.1 in [96]) *If $w(i, j)$ satisfies the quadrangle inequality as defined in Definition 4, and is also monotone on the lattice of intervals, then the $B_{i,j}$ defined in (24) also satisfy the quadrangle inequality.*

Lemma 7 (Lemma 2.2 in [96]) *If the function $B_{i,j}$ defined in (24) satisfies the quadrangle inequality then*

$$K_B(i, j) \leq K_B(i, j+1) \leq K_B(i+1, j+1) \quad \forall i < j.$$

[Lemma 6](#) proves that a QI in the $w(i, j)$ implies a QI in the $B_{i,j}$. Suppose then that one evaluates the values of the $B_{i,j}$ in the order $d = 1, 2, \dots, n$, where, for each fixed d , one evaluates all of $B_{i,i+d}$, $i = 0, 1, \dots, n-d$. Then [Lemma 7](#) says that $B_{i,i+d}$ can be evaluated in time $O(K_B(i+1, i+d) - K_B(i, i+d-1))$. Note that

$$\sum_{i=0}^{n-d} (K_B(i+1, i+d) - K_B(i, i+d-1)) \leq n,$$

and thus all entries for fixed d can be calculated in $O(n)$ time. Summing over all d , it follows that all $B_{i,j}$ can be obtained in $O(n^2)$ time.

As mentioned, [Lemma 7](#) and the resultant $O(n^2)$ running time have long been viewed as unrelated to the SMAWK algorithm. While they seem somewhat similar (a QI leading to an order of magnitude speedup) they appeared not to be directly connected until very recently. In the next section it is shown how to solve the Knuth-Yao problem directly using decompositions into total monotone matrices.

7.2 Decomposition Techniques

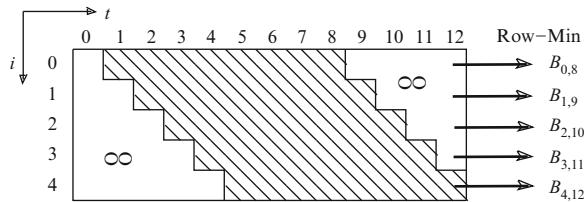

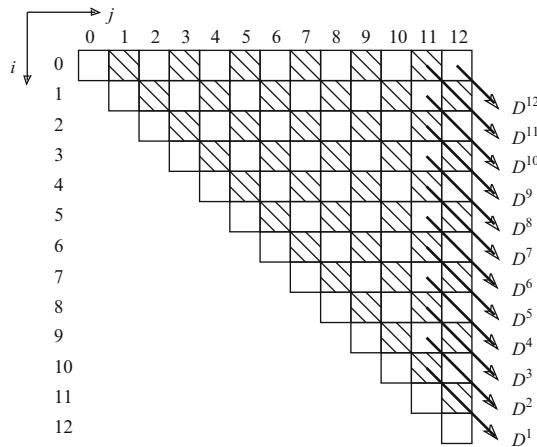

Definition 7 For $1 \leq d \leq n$ define the $(n-d+1) \times (n+1)$ matrix D^d by

$$D_{i,t}^d = \begin{cases} w(i, i+d) + B_{i,t-1} + B_{t,i+d}, & \text{if } 0 \leq i < t \leq i+d \leq n; \\ \infty & \text{otherwise.} \end{cases} \quad (25)$$

[Figure 20](#) illustrates a first decomposition. Note that (24) immediately implies

$$B_{i,i+d} = \min_{0 \leq t \leq n} D_{i,t}^d \quad (26)$$

Fig. 20 The top figure on shows the $B_{i,j}$ matrix for $n = 12$. Each diagonal, $d = j - i$, in the matrix will correspond to a totally monotone matrix D^d . The minimal item of row i in D^d will be the value $B_{i,i+d}$. The other figure shows D^8

so finding the row-minima of D^d yields $B_{i,i+d}$, $i = 0, \dots, n-d$. Put another way, the $B_{i,j}$ entries on diagonal $d = j - i$ are exactly the row-minima of matrix D^d .

Lemma 8 If $w(i, j)$ and the function $B_{i,j}$ defined in (24) satisfies the QI then, for each d ($1 \leq d \leq n$), D^d is a totally monotone matrix.

Proof It suffices to prove that

$$D_{i,t}^d + D_{i+1,t+1}^d \leq D_{i+1,t}^d + D_{i,t+1}^d \quad (27)$$

Note that if $i+1 < t < i+d$, then from Lemma 6,

$$B_{i,t-1} + B_{i+1,t} \leq B_{i+1,t-1} + B_{i,t} \quad (28)$$

and

$$B_{t,i+d} + B_{t+1,i+1+d} \leq B_{t+1,i+d} + B_{t,i+1+d}. \quad (29)$$

Thus,

$$\begin{aligned}
& D_{i,t}^d + D_{i+1,t+1}^d \\
&= [w(i, i+d) + B_{i,t-1} + B_{t,i+d}] + [w(i+1, i+1+d) + B_{i+1,t} + B_{t+1,i+1+d}] \\
&= w(i, i+d) + w(i+1, i+1+d) + [B_{i,t-1} + B_{i+1,t}] + [B_{t,i+d} + B_{t+1,i+1+d}] \\
&\leq w(i, i+d) + w(i+1, i+1+d) + [B_{i+1,t-1} + B_{i,t}] + [B_{t+1,i+d} + B_{t,i+1+d}] \\
&= [w(i+1, i+1+d) + B_{i+1,t-1} + B_{t,i+1+d}] + [w(i, i+d) + B_{i,t} + B_{t+1,i+d}] \\
&= D_{i+1,t}^d + D_{i,t+1}^d
\end{aligned}$$

and (27) is correct (where it is noted that the right hand side is ∞ if $i+1 \not< t$ or $t \not< i+d$). \square

Lemma 9 Assuming that all of the row-minima of D^1, D^2, \dots, D^{d-1} have already been calculated, all of the row-minima of D^d can be calculated using the SMAWK algorithm in $O(n)$ time.

Proof From the previous lemma, D^d is a totally monotone matrix. Also, by definition, its entries can be calculated in $O(1)$ time, using the previously calculated row-minima of $D^{d'}$ where $d' < d$. Thus SMAWK can be applied. \square

Combined with (26) this immediately gives a new $O(n^2)$ algorithm for solving the KY problem; just run SMAWK on the D^d in the order $d = 1, 2, \dots, n$ and report all of the row-minima.

7.3 Online Decomposition

The online problem restricted to the optimal binary search tree would be to construct the OBST for items $\text{Key}_{L+1}, \dots, \text{Key}_R$, and, at each step, add either Key_{R+1} , a new key to the right, or Key_L , a new key to the left. Every time a new element is added, it is desired to update the $B_{i,j}$ (dynamic programming) table and thereby construct the optimal binary search tree of the new full set of elements. (See Fig. 21.)

KY speedup *cannot* be used to do this. The reason that the speedup fails is that the KY speedup is actually an amortization over the evaluation of all entries when done in a particular order. In the online case, adding a new item n to previously existing items $1, 2, \dots, n-1$ requires using (24) to compute the n new entries $B_{i,n}$, in the fixed order $i = n, n-1, \dots, 1, 0$ and it is not difficult to construct an example in which calculating these new entries in this order using (24) requires $O(n^2)$ work.

Neither can the decomposition technique from the previous section solve the online problem. To see why, suppose that items $1, \dots, n$ have previously been given, new item $n+1$ has just been added, and one needs to calculate the values $B_{i,n+1}$ for $i = 0, \dots, n+1$. In this formulation it would correspond to adding a new bottom row to *every* matrix D^d and creating a new matrix D^{n+1} and one would need to

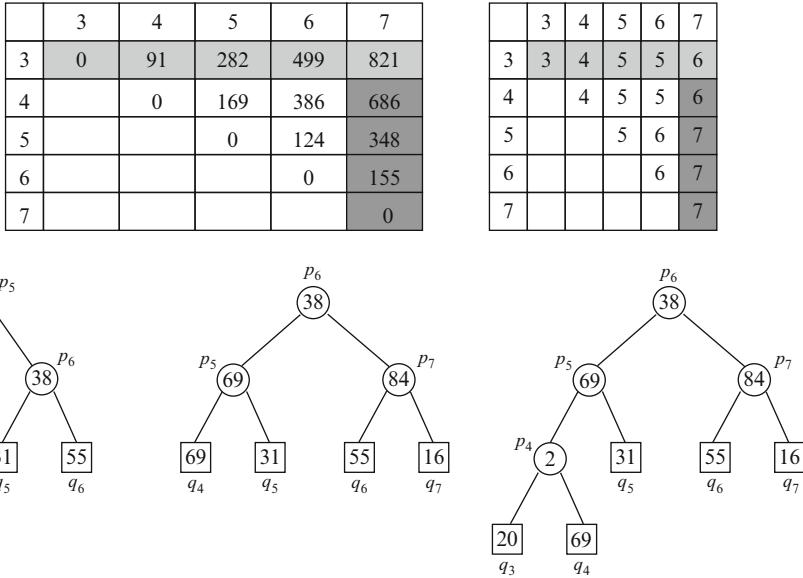

Fig. 21 An example of the online case for optimal binary search trees where $(p_4, p_5, p_6, p_7) = (2, 69, 38, 84)$ and $(q_3, q_4, q_5, q_6, q_7) = (20, 69, 31, 55, 16)$. The left table contains the $B_{i,j}$ values; the right one, the $K_B(i, j)$ values. The unshaded entries in the table are for the problem restricted to only keys 5, 6. The dark gray cells are the entries added to the table when key 7 is added to the right. The light gray cells are the entries added when key 4 is added to the left. The corresponding optimal binary search trees are also given, where circles correspond to successful searches and squares to unsuccessful ones. The values in the nodes are the weights of the nodes (not their keys)

find the row-minima of all of the n new bottom rows. Unfortunately, the SMAWK algorithm only works on the rows of matrices all at once and cannot help to find the row-minima of a single new row.

Note that for the online problem it is certainly possible to *recompute* the entire table; however this comes at the price of $O(n^2)$ time, where $n = R - L$ is the number of keys currently in the table, leading to a total running time of $O(n^3)$ to insert all of the keys. Of interest here is the question of whether one can maintain the speedup while inserting the keys in an online fashion. The goal is an algorithm in which a sequence of n online key insertions will result in a worst case $O(n)$ per step to maintain an optimal tree, yielding an overall run time of $O(n^2)$ (Fig. 22).

To this end now a second decomposition. It is indexed by the *leftmost* element seen so far. See Fig. 23.

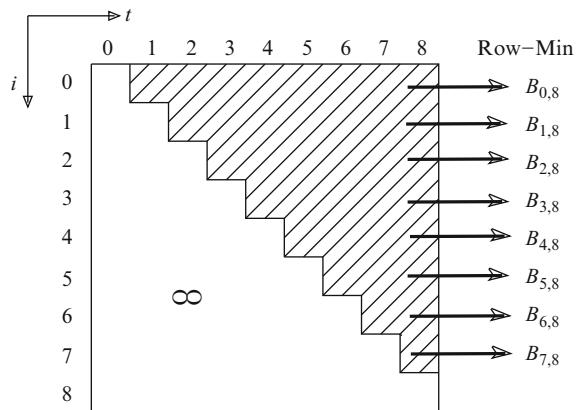

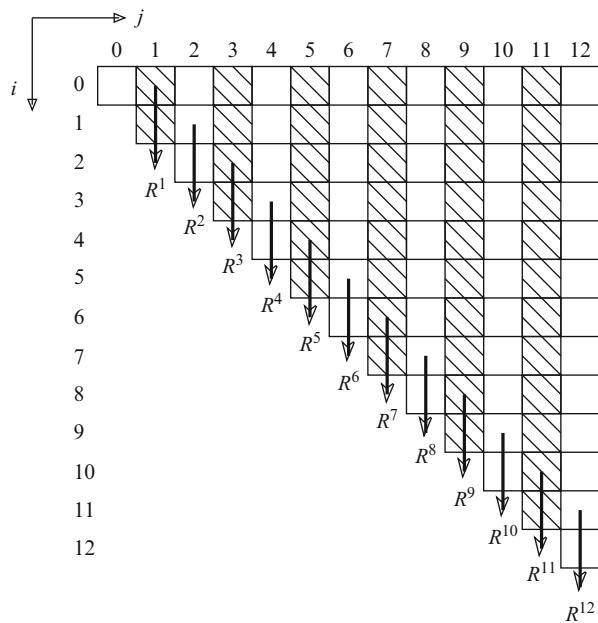

Definition 8 For $0 \leq i < n$ define the $(n - i) \times (n - i)$ matrix L^i by

$$L_{j,t}^i = \begin{cases} w(i, j) + B_{i,t-1} + B_{t,j}, & \text{if } i < t \leq j \leq n; \\ \infty, & \text{otherwise.} \end{cases} \quad (30)$$

Fig. 22 The top figure shows the $B_{i,j}$ matrix for $n = 12$.

Each column in the $B_{i,j}$ matrix will correspond to a totally monotone matrix R^j .

The minimal element of row i in R^j will be the value $B_{i,j}$.
The other figure shows R^8

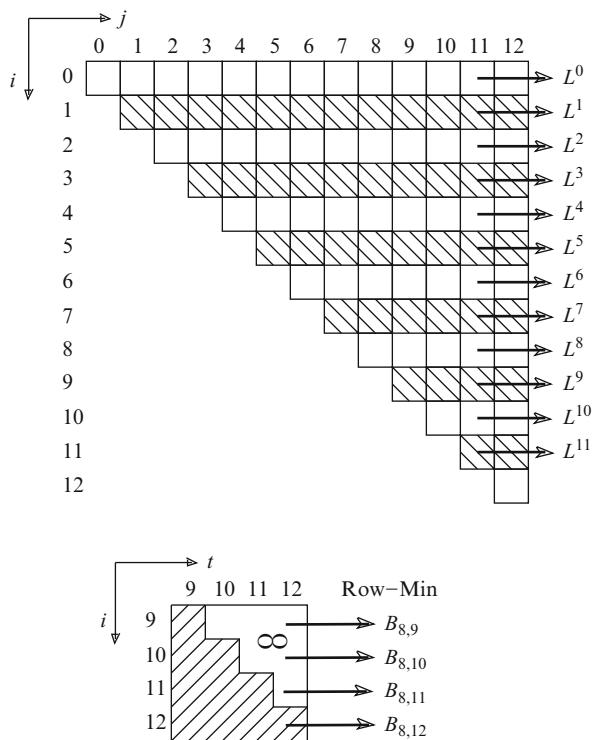

(For convenience, set the row and column indices to run from $(i + 1) \dots n$ and not $0 \dots (n - i - 1)$.) Note that (24) immediately implies

$$B_{i,j} = \min_{i < t \leq n} L_{j,t}^i \quad (31)$$

so finding the row-minima of L^i yields $B_{i,j}$ for $j = i + 1, \dots, n$. Put another way, the $B_{i,j}$ entries in row i are exactly the row minima of matrix L^i .

Lemma 10 If the function defined in (24) satisfies the QI then R^j (resp. L^i) are totally monotone matrices for each fixed j (resp. i).

Fig. 23 The top figure on the left shows the $B_{i,j}$ matrix for $n = 12$. Each row in the $B_{i,j}$ matrix will correspond to a totally monotone matrix L^i . The minimal element of row j in L^i will be the value $B_{i,j}$. The other figure shows L^8 .

Proof The proofs are very similar to that of Lemma 8. To prove R^j is totally monotone, note that if $i + 1 < t < j$, one can again use (28); writing the entries from (28) in boldface gives

$$\begin{aligned} & R_{i,t}^j + R_{i+1,t+1}^j \\ &= [w(i, j) + \mathbf{B}_{i,t-1} + B_{t,j}] + [w(i+1, j) + \mathbf{B}_{i+1,t} + B_{t+1,j}] \\ &\leq [w(i+1, j) + \mathbf{B}_{i+1,t-1} + B_{t,j}] + [w(i, j) + \mathbf{B}_{i,t} + B_{t+1,j}] \\ &= R_{i+1,t}^j + R_{i,t+1}^j \end{aligned}$$

and thus R^j is Monge (where the right hand side is ∞ if $i + 1 \not\prec t$) and thus totally monotone. To prove L^i is totally monotone, if $i < t < j$ then again use (28) (with j replaced by $j + 1$) to get

$$\begin{aligned} & L_{j,t}^i + L_{j+1,t+1}^i \\ &= [w(i, j) + B_{i,t-1} + \mathbf{B}_{t,j}] + [w(i, j+1) + B_{i,t} + \mathbf{B}_{t+1,j+1}] \\ &\leq [w(i, j+1) + B_{i,t-1} + \mathbf{B}_{t,j+1}] + [w(i, j) + B_{i,t} + \mathbf{B}_{t+1,j}] \\ &= L_{j+1,t}^i + L_{j,t+1}^i \end{aligned}$$

and thus L^i is Monge (where the right hand side is ∞ if $t \not\prec j$) and thus totally monotone. \square

Note that this decomposition immediately imply a new proof of [Lemma 7](#) (Lemma 2.2 in [96]) which states that

$$K_B(i, j) \leq K_B(i, j + 1) \leq K_B(i + 1, j + 1). \quad (32)$$

To see this note that $K_B(i, j + 1)$ is the location of the rightmost row-minimum of row i in matrix R^{j+1} , while $K_B(i + 1, j + 1)$ is the location of the rightmost row-minimum of row $i + 1$ in matrix R^{j+1} . Thus, the definition of total monotonicity immediately gives

$$K_B(i, j + 1) \leq K_B(i + 1, j + 1). \quad (33)$$

Similarly, $K_B(i, j)$ is the rightmost row-minimum of row j in L^i while $K_B(i, j + 1)$ is the location of the rightmost row-minimum of row $j + 1$ in L^i . Thus

$$K_B(i, j) \leq K_B(i, j + 1). \quad (34)$$

Combining (33) and (34) yields (32). Since the actual speedup in the KY technique comes from an amortization argument based on (32), it follows that the original KY-speedup itself is also a consequence of total monotonicity.

Up to this point it is not clear how to actually calculate the $B_{i,j}$ using the R^j and L^i . Note first that even though the R^j are totally monotone, their row minima *cannot* be calculated using the SMAWK algorithm. This is because, for $0 \leq i < t \leq j$, the value of entry $R_{i,t}^j = w(i, j) + B_{i,t-1} + B_{t,j}$, which is dependent upon $B_{t,j}$ which is itself the row-minimum of row t in the *same* matrix R^j . Thus, the values of the entries of R^j depend upon other entries in R^j which is something that SMAWK does not allow. The same problem occurs with the L^i .

But despite this dependence, the LARSCH algorithm can still be used to find the row-minima of the R^j . Recall that to execute the LARSCH algorithm one needs only that the matrix X satisfy the following conditions:

1. X is an $n \times m$ totally monotone matrix.
2. For each row index i of X , there is a column index C_i such that for $j > C_i$, $X_{i,j} = \infty$. Furthermore, $C_i \leq C_{i+1}$.
3. If $j \leq C_i$, then $X_{i,j}$ can be evaluated in $O(1)$ time *provided that the row minima of the first $i - 1$ rows are already known*.

If these conditions are satisfied, the LARSCH algorithm then calculates all of the row minima of X in $O(n + m)$ time. This algorithm can now be used to derive

Lemma 11

- Given that all values $B_{i',j}$, $i' < i' \leq j \leq n$ have already been calculated, all of the row-minima of L^i can be calculated in $O(n - i)$ time.
- Given that all values $B_{i,j'}$, $0 \leq i \leq j' < j$ have already been calculated, all of the row-minima of R^j can be calculated in $O(j)$ time.

Proof For the first part, it is easy to see that L^i satisfies the first two conditions required by the LARSCH algorithm with $C_j = j$. For the third condition, note that, for $i < t \leq j$, $L_{j,t}^i = w(i, j) + B_{i,t-1} + B_{t,j}$. The values $w(i, j)$ and $B_{t,j}$ are already known and can be retrieved in $O(1)$ time. $B_{i,t-1}$ is the minimum of row $t - 1$ of L^i but, since we are assuming $t \leq j$, this means that $B_{i,t-1}$ is the minimum of an earlier row in L^i , and the third LARSCH condition is satisfied. Thus, all of the row-minima of the $(n - i) \times (n - i)$ matrix L^i can be calculated in $O(n - i)$ time.

For the second part set X to be the $(j + 1) \times (j + 1)$ matrix defined by $X_{i,t} = R_{j-i,j-t}^j$. Then X satisfies the first two LARSCH conditions with $C_i = i - 1$. For the third condition note that $X_{i,t} = R_{j-i,j-t}^j = w(j - i, j) + B_{j-i,j-t-1} + B_{j-t,j}$. The values $w(j - i, j)$ and $B_{j-i,j-t-1}$ are already known and can be calculated in $O(1)$ time. $B_{j-t,j}$ is the row minima of row t of X ; but, since we are assuming $t \leq C_i = i - 1$ this means that $B_{j-t,j}$ is the row minima of an earlier row in X so the third LARSCH condition is satisfied. Thus, all of the row-minima of X and equivalently R^j can be calculated in $O(j)$ time. \square

Note that [Lemma 11](#) immediately solves the “right-online” and “left-online” problems. Given the new values $w(i, R + 1)$ for $L \leq i \leq R + 1$, simply find the row minima of R^{R+1} in time $O(R - L)$. Given the new values $w(L - 1, j)$ for $L - 1 \leq j \leq R$, simply find the row minima of R^{L-1} . Therefore it was just shown that *any* dynamic programming problem for which the KY speedup can statically improve run time from $O(n^3)$ to $O(n^2)$ time can be solved in an online fashion in $O(n)$ time per step. That is, online processing incurs no penalty compared to static processing. In particular, the optimum binary search tree can be maintained in $O(n)$ time per step as nodes are added to both its left and right.

At this point note that decompositions L^i could also be derived by careful cutting of the 3-D monotone matrices of Aggarwal and Park [2] along particular planes. Aggarwal and Park [2] used an algorithm of Wilber [94] (derived for finding the maxima of certain concave-sequences) to find various tube maxima of their matrices, leading to another $O(n^2)$ algorithm for solving the KY-problem. In fact, even though their algorithm was presented as a static algorithm, careful decomposition of what they do permits using it to solve what is called here the left-online KY-problem. A symmetry argument could then yield a right-online algorithm. This never seems to have been noted in the literature, though.

8 Conclusion

Too small an academic community is aware of the many advanced tools available related to dynamic programming. Routinely, applications are solved by simple-minded dynamic programs, where much faster solutions are possible. In fact, for many massively large problems arising in Molecular Biology, for example, a quadratic solution might be completely useless, equivalent to no solution at all.

It is the hope of the author that this book chapter will open up some of these advanced techniques to a larger community of scientists.

As well the use of dynamic programming in online optimization and by extension the concept of work functions is not as widely embraced as is desirable. Many online algorithms are ad-hoc and work functions make it possible to “de-adhocify” the construction of competitive and efficient algorithms in this setting. The very recent concept of *knowledge states* (see [23]), which has dynamic programming at its core, makes it possible to derive online algorithms even in the randomized case in a systematic way.

Readers are invited to go beyond the obvious when using dynamic programming and to avail themselves of these powerful techniques.

Further Reading

Introductions to dynamic programming with numerous elementary examples can be found in the textbooks by Brassard and Gilles [32], Cormen, Leiserson, Rivest, and Stein [45], Baase and van Gelder [10] and Dasgupta, Papadimitriou, and Vazirani [47].

The classical treatises by Bellmann [24] and [25] are still relevant today though the language is somewhat antiquated and the applications outdated. Other general reading is Dreyfus and Law [50], Stokey, Lucas, and Prescott [88], Bertsekas [28], Denardo [48], Meyn [83], and more recently Sniedovich [87]. One classical algorithm worth mentioning is the algorithm by Viterbi [90] for Hidden Markov Model inference. Many problems in areas such as digital communications can be cast in the Hidden Markov Model. Another classic is Hu and Tucker [65] on alphabetic trees. Bellmore and Nemhauser [27] as well as Lawler, Lenstra, Rinnoy Kan, and Shmoys [79] and Burkard, Deineko, Dal, van der Veen, and Woeginger [39] contain material regarding the use of dynamic programming for the traveling salesman problem. Gusfield [60] is good general resource on dynamic programming for computational biology. Examples with regards to scheduling can be found in Bellman, Esogbue, and Nabeshima [26] as well as in Brucker [33] and in Brucker and Knust [35]. David Eppstein, Zvi Galil, Raffaele Giancarlo, and Giuseppe F. Italiano [52, 53] give a two paper sequence in the Journal of the ACM for sparse dynamic programming.

Regarding online algorithms (discussed in Sect. 3) the book by Borodin and El-Yanif [30] is the standard text. Of note is also the monograph by Karlin [66]. The article Larmore and Chrobak [42], which introduced work functions, extends the material in Sect. 3. For further immersion into the realm of work functions the article by Bein, Chrobak, and Larmore [16] is recommended. Recent work by Bein, Larmore, Noga, and Reischuk [23] on knowledge states has extended the use of work functions to randomized online algorithms: such algorithms are “guided” in their operation by work functions.

Some of the material presented in Sect. 4 can be found in greater detail in Bein, Larmore, Morales, and Sudborough [22]. Further reading regarding this section:

Sorting problems under various operations have been studied extensively, including work on sorting with prefix reversals Gates and Papadimitriou [58] (Gates of Microsoft fame) as well as Heydari and Sudborough [62], transpositions [11] and block moves ([17, 80] as well as Mahajan, Rama, and Vijayakumar [81]).

Some of the material presented in Sect. 5 can found in greater detail in Bein, Noga, and Wiegley [19]. The paper by Brucker and Albers [6] contains an alternate linear time algorithm for list batching. There is a large body of work on dynamic programming and batching; see the work of Baptiste [12], Baptiste and Jouplet [13], Brucker, Gladky, Hoogeveen, Kovalyov, Potts Tautenhahn, and van de Velde [36], Brucker, Kovalyov, Shafransky, and Werner [37], Hoogeveen, and Vestjens [64], as well as the scheduling text book by Peter Brucker [33]. Batching has wide application in manufacturing (see, e.g., [34, 85, 98]), decision management (see, e.g., [74]), and scheduling in information technology (see, e.g., [46]). More recent work on online batching is related to the TCP (Transmission Control Protocol) acknowledgment problem (see [20, 49, 67]).

Regarding Monge properties and total monotonicity the best resource is Park's thesis, [84]. Another excellent survey on Monge properties is Burkard, Klinz and Rudolf [38]. A generalization of the Monge property to an algebraic property is in Bein, Brucker, Larmore, and Park [18]. Interesting applications are in Woeginger [95]. Burkard, Deineko, and Woeginger [40] survey the traveling salesman problem on Monge matrices. Agarwal and Sen [1] give results for selection in monotone matrices for computing k th nearest neighbors. Schieber [86] gives results on k -link paths in graphs with Monge properties.

Section 6 is based on Agarwal, Klawe, Moran, Shor, and Wilber [3] and Larmore and Schieber [78]. Generalizations of the matrix searching techniques are in Klawe [69] and Klawe and Kleitman [70], as well as in Kravets and Park [73], Aggarwal and Park [5] (Parallel Searching). and Wilber [94]. A good survey paper is Galil and Park [57].

An extended version of the material of Sect. 7 can be found in Bein, Larmore, Golin, and Zhang [21]. For Sect. 7 the papers of Knuth [71] followed by Yao [97] are key. Aggarwal and Park used an algorithm of Wilber [94] to find various tube maxima of their matrices, leading to another $O(n^2)$ algorithm for solving the KY-problem. There are two extensions of the Knuth-Yao quadrangle inequality: the first is due to Wachs [91] and the second to Borchers and Gupta (BG) [29]. This is discussed in detail in Bein, Larmore, Golin, and Zhang [21]. Belatedly, Aggarwal, Bar-Noy, Khuller, Kravets, and Schieber [4] describe solutions for matching using the quadrangle inequality.

The main gist of this chapter is dynamic programming speedup: Applications abound. Classic examples include the work by Hirschberg and Larmore [63] on the weight subsequence problem, Larmore and Przytycka [76] on parallel construction of trees with optimal path length, and Larmore and Hirschberg [75] on length limited coding. David Eppstein [51] considers sequence comparisons. Apostolico, Atallah, Larmore, and McFaddin [7] give algorithms for string editing. Highly recommended is the paper by Galil and Giancarlo [56] on speeding up dynamic programming in Molecular Biology. Work by Arslan and Egecioglu [8] is on sequence alignment

Bradford, Golin, Larmore, and Rytter [31] give dynamic programs for optimal prefix-free codes. Recent speedup work is for the online maintenance of k -medians by Fleischer, Golin, and Zhang [54] (see also [61, 89]).

Acknowledgements This chapter is dedicated to Lawrence L. Larmore, a great mentor. A sabbatical (academic year 2006/07) granted by the University of Nevada, Las Vegas, which benefited this book chapter, is acknowledged.

Abstract

In *combinatorial group testing*, there are n items; each has an unknown binary status, *positive* (i.e., *defective*) or *negative* (i.e., *good*), and the number of positives is upper bounded by an integer d . Suppose there is some method to test whether a subset of items contains at least one positive or not. The test result is said to be positive if it indicates that the subset contains at least one positive item; otherwise, the test result is called negative. The problem is to resolve the status of every item using the minimum number of tests.

Group testing (GT) algorithms can be *adaptive* or *nonadaptive*. An adaptive algorithm conducts the tests one by one and allows to design later tests using the outcome information of all previous tests. A nonadaptive group testing (NGT) algorithm specifies all tests before knowing any test results, and the benefit is that all tests can be performed in parallel. For the above group testing problem, nonadaptive algorithms require inherently more tests than adaptive ones.

Though the research of group testing dates back to Dorfman's 1943 paper, a renewed interest in the subject occurred recently mainly due to the applications of group testing to the area of computational molecular biology. In applications of molecular biology, a group testing algorithm is called a *pooling design*, and the composition of each test is called a *pool*. While it is still important to minimize the number of tests, there are two other goals. First, in the biological setting, screening one pool at a time is far more expensive than screening many pools in parallel; this strongly encourages the use of nonadaptive algorithms. Second, DNA screening is error prone, so it is desirable to design *error-tolerant* algorithms, which can detect or correct some errors in the test results.

In this monograph, some recent algorithmic, complexity, and mathematical results on nonadaptive group testing (and on pooling design) are presented.

1 Introduction

In *combinatorial group testing*, there are n items; each has an unknown binary status, *positive* (i.e., *defective*) or *negative* (i.e., *good*), and the number of positives is upper bounded by an integer d . Suppose there is some method to test whether a subset of items contains at least one positive or not. The test result is said to be positive if it indicates that the subset contains at least one positive item; otherwise, the test result is called negative. The problem is to resolve the status of every item using the minimum number of tests.

Group testing (GT) algorithms can be *adaptive* or *nonadaptive*. An adaptive algorithm conducts the tests one by one and allows to design later tests using the outcome information of all previous tests. A nonadaptive group testing (NGT) algorithm must specify all tests before knowing any test results, and the benefit is that all tests can be performed in parallel. For the above group testing problem, nonadaptive algorithms require inherently more tests than adaptive ones. It is known

that any nonadaptive algorithm must use a number of $\Omega(\frac{d^2 \log n}{\log d})$ tests, and the best known nonadaptive algorithm uses $O(d^2 \log n)$ tests. In contrast, the best adaptive algorithm requires $O(d \log n)$ tests (see, e.g., [17]) in the worst case.

Pooling Design. Though the research of combinatorial group testing dates back to Dorfman's 1943 paper [15], probably the most important modern applications of group testing are in the area of computational molecular biology, in which one important subject is clone library screening [3, 17, 26]. In applications to molecular biology, a group testing procedure is called a *pooling design*, and the composition of each test is called a *pool*.

A DNA library consists of thousands of separate DNA *clones*. The basic task of DNA library screening is, for a collection of *probes*, to determine which clone from the library contains which probe. Given a probe, a clone is said to be positive if it contains the probe; otherwise, it is said to be negative. In practice, to identify all positive clones from a library, clones are often pooled together to be tested against each probe, since checking each clone-probe pair is expensive and usually only a few clones in the library contain a given probe. An example is when sequenced-tagged site markers (also called STS probes) are used [46]. In practice, there are experimental tests, for example, the polymerase chain reaction, which can determine in a given pool whether or not there exists at least one clone containing a given probe.

In applications to molecular biology, while it is still important to minimize the number of tests, there are two other goals. First, in the biological setting, screening one pool at a time is far more expensive than screening many pools in parallel; this strongly encourages the use of nonadaptive algorithms. Second, DNA screening is error prone, so it is desirable to design *error-tolerant* algorithms, which can detect or correct some errors in the test outcomes. The reader is referred to the monograph by Du and Hwang [17] for a comprehensive discussion of this topic.

Between fully adaptive and nonadaptive (one stage) algorithms, the so-called trivial two-stage algorithms [36] are of considerable interest for screening problems. Such an algorithm has two stages. In the first stage, the pools are tested in parallel, and a set CP of *candidate positives* from the items is chosen based on the test results; in the second stage, individual tests are performed on all the items in CP to resolve the status of each item. Previous works on two-stage group testing algorithms are, among others, [4, 14, 24, 36, 41]. The following quotation from Knill [36] well emphasizes the importance of such algorithms: "It is generally feasible to construct a number of pools (much fewer than the number of clones) initially by exploiting parallelism, but adaptive construction of pools with many clones during the testing procedure is discouraged. The technicians who implement the pooling strategies generally dislike even the 3-stage strategies that are often used. Thus the most commonly used strategies for pooling libraries of clones rely on a fixed but reasonably small set of non-singleton pools. The pools are either tested all at once or in a small number of stages (usually at most 2) where the previous stage determines which pools to test in the next stage. The potential positives are then inferred and confirmed by testing of individual clones. In most biological applications each

positive clone must be confirmed even if the pool results unambiguously indicate that it is positive. This is to improve the confidence in the results, given that in practice the tests are prone to errors.”

Separating Matrices. A nonadaptive group testing procedure can be represented as a 0-1 matrix $M = (m_{ij})$, in which the columns are associated with the items and the rows are associated with the tests, and $m_{ij} = 1$ indicates that item j is contained in test i . The test outcomes can be represented by a 0-1 vector, the *outcome vector*, where 0 indicates a negative outcome and 1 indicates a positive outcome. It is not hard to verify that if a subset S of columns exactly corresponds to all the positive items, then the outcome vector is equal to vector $U(S)$, the *union* (i.e., the componentwise Boolean sum) of all column vectors in S . Given the matrix representation of an algorithm and the outcome vector, the process of identifying all the positive items is called decoding. For a 0/1 matrix to be a valid nonadaptive group testing algorithm, some separating property is often required. This monograph focuses on two most used and studied separating properties: disjunctness and separability.

In order to identify all positives as long as the number of positives is no more than d , matrix M should satisfy that for any two distinct subsets S_1 and S_2 of columns such that $|S_1| \leq d$ and $|S_2| \leq d$, $U(S_1) \neq U(S_2)$. A matrix satisfying this property is called \bar{d} -separable. In the definition, if the condition “ $|S_1| \leq d$ and $|S_2| \leq d$ ” is replaced by “ $|S_1| = |S_2| = d$,” a matrix satisfying this property is called d -separable. If the matrix representing a nonadaptive pooling design is \bar{d} -separable (or d -separable), then theoretically based on the test outcomes one can unambiguously identify all the up to d (or exactly d) positives. However, the actual process of determining the positives from the outcome vector, that is, the *decoding* process, could be very time-consuming. In practice, one can adopt matrices with stronger property to make the decoding process more efficient.

For two 0-1 vectors u and v with the same number of components, if for any component of u with value 1, the corresponding component of v is also 1, then u is said to be *covered* by v . A 0-1 matrix is said to be d -disjunct if no column is covered by the union of any d other columns. The same structure is also called *cover-free family* in combinatorics [25, 29, 53], and *superimposed code* in information theory [22, 23, 34], and has been extensively studied. Obviously if a matrix is d -disjunct, then it is also \bar{d} -separable, and thus is d -separable. If the matrix M representing a nonadaptive pooling design is d -disjunct and the number of positives is no more than d , then the following efficient decoding procedure exists with running time linear in the size of M : A column c corresponds to a positive item if and only if c is covered by the outcome vector. d -disjunct matrices are important structures in pooling design, and there have been a lot of works on their constructions [2, 10, 20, 23–25, 28, 32–34, 38, 44, 45, 49, 50].

A 0/1 matrix is said to be $(d; z)$ -disjunct [22, 39] if for any set D of d columns and any column $c \notin D$, there exist at least z rows such that each of them has value 1 at column c and value 0 at all the d columns of D . Clearly, d -disjunctness

is just $(d; 1)$ -disjunctness. As mentioned above, if the matrix M representing a nonadaptive group testing algorithm is d -disjunct and the number of positives is no more than d , then there exist efficient decoding procedures with running time linear in the size of M . However, when there are errors in the test outcomes, the above decoding procedure generally does not work, and in this case, the matrix is required to be $(d; z)$ -disjunct, which results in a $\lfloor \frac{z-1}{2} \rfloor$ -error-correcting NGT algorithm. In this case, linear decoding that successfully identifies all positives still exists, provided that there are no more than d positives and at most $\lfloor \frac{z-1}{2} \rfloor$ errors in the test outcomes. d -disjunct and $(d; z)$ -disjunct matrices form the basis of error-free and error-tolerant nonadaptive group testing.

Main Contents. In this monograph, some recent algorithmic, complexity, and mathematical results on nonadaptive group testing (and on pooling design) are presented. The main contents consist of five parts. In the first part, new randomized constructions of one- and two-stage nonadaptive group testing are presented. Comparisons with other known constructions on the number of required tests are also discussed.

In the second part, some complexity results for problems that are basic to nonadaptive group testing are given. The problem to determine whether a given matrix H is \bar{d} -separable and minimal, MIN-SEPARABILITY, is showed to be DP -complete. Here the meaning of being minimal is that the removal of any row from H will make it no longer \bar{d} -separable. The second problem is, given a binary matrix M and a positive integer d , find a minimum \bar{d} -separable submatrix of M with the same number of columns. The complexity of the decision version of this problem, \bar{d} -separable submatrix, is conjectured to be Σ_2^P -complete. As an evidence to support this conjecture, the Σ_2^P -completeness of a problem which is a little more general than \bar{d} -separable submatrix is established.

In the third part, the parameterized complexities of three basic problems in nonadaptive group testing are studied. They are, given an $m \times n$ binary matrix and a positive integer d , to determine whether the matrix is d -separable (\bar{d} -separable, or d -disjunct). Though the three problems are all known to be coNP-complete in the classical complexity theory, the motivation of this study is that in most applications d is very small compared to n ; it is interesting to investigate whether there are efficient algorithms solving the above problems when the value of d is small. In this part, the parameterized versions of the three problems, with d as the parameter, are showed to be co-W[2]-complete. The immediate implications of the results are that, given an $m \times n$ binary matrix and a positive integer d , a deterministic algorithm with running time $f(d) \times (mn)^{O(1)}$ (where f is an arbitrary computable function) to determine whether the matrix is d -separable (\bar{d} -separable, or d -disjunct) should not be expected.

In the fourth part, upper bounds on the minimum number of rows required by any d -disjunct matrix and any $(d; z)$ -disjunct matrix with n columns, $t(d, n)$ and $t(d, n; z)$, respectively, are studied. A very short proof is given for the currently best upper bound on $t(d, n)$; the method is also generalized to obtain a new upper bound

on $t(d, n; z)$. In the final part, a way to transform an error-tolerant separable matrix to an error-tolerant disjunct matrix is given; the optimality of this transformation in some senses is also discussed. If no base is specified, then \log is of base 2 throughout.

2 New Constructions of One- and Two-Stage Pooling Design

In [10] new constructions of one- and two-stage pooling design are given. For one-stage pooling design, the focus is on the construction of disjunct matrices, which are widely studied for various applications including the design of nonadaptive group testing algorithms. There have been a lot of works on the construction of disjunct matrices [2, 10, 20, 23–25, 28, 32–34, 38, 44, 45, 49, 50].

For two-stage pooling designs, De Bonis et al. [14] first present an asymptotically optimal two-stage algorithm that requires a number of tests within a constant factor $7.54(1 + o(1))$ of the information theoretic lower bound $d \log(n/d)$. Eppstein et al. [24] improve the constant factor to $4(1 + o(1))$ by using the concept of (d, k) -*resolvable* matrices (which will be explained later), which is currently the best. There are also probabilistic pooling designs [40, 41, 44] with good performance in practice.

In the sequel of this section, two Las Vegas algorithms for constructing d -disjunct and $(d; z)$ -disjunct matrices are presented. For two-stage pooling designs, an algorithm using a number of $C_d(1 + o(1)) \log n$ tests is presented, where $C_d \leq \frac{3}{\log 3} d$ for $d \geq 1$ and $C_d \rightarrow d \log e$ as $d \rightarrow \infty$. This improves the previously best bound given in [24] by a factor of more than 2. New probabilistic pooling designs are also proposed. Compared to [44], the new probabilistic designs have different type of possible errors and require much fewer tests. All the results presented in this section are from [10].

2.1 Preliminaries

Transversal Design. A pooling design is transversal if the pools can be divided into disjoint families, each of which is a partition of all items. The concept of q -ary $(d, 1)$ -*disjunct* matrix will be first introduced: A q -ary matrix is $(d, 1)$ -disjunct if for any column c and any set D of d other columns, there exists at least one element in c such that the element does not appear in any column of D in the same row.

As described in [17, 20], one can transform a q -ary $(d, 1)$ -disjunct matrix M' into a (binary) d -disjunct matrix M as follows. Replace each row R_i of M' by several rows indexed with entries of R_i ; for each entry x of R_i , the row with index x is obtained from R_i by turning all x 's into 1's and all others into 0's. Thus, the following theorem holds.

Theorem 1 ((Theorem 3.6.1 in [17])) *A $t_0 \times n$ q -ary $(d, 1)$ -disjunct matrix M' yields a $t \times n$ d -disjunct matrix M with $t \leq t_0 q$.*

Clearly, one can perform the above transformation even when the q -ary matrix M' is not $(d, 1)$ -disjunct. Transversal designs are favorable in practice because every column of the resulting matrix M has equal weight, which means that every item is contained in equal number of pools, so that to perform the tests, one needs the same number of copies for each item.

Two Probabilistic Lemmas. The following two lemmas will be useful later. The first is the Markov inequality (see, e.g., Theorem 3.2 in [42]), and the second is commonly known as Chernoff's bounds (Theorems 4.1 and 4.2 in [42]).

Lemma 1 (Markov inequality) *Let Y be a random variable assuming only nonnegative values, then for all $t > 0$,*

$$\Pr[Y \geq t] \leq \frac{E[Y]}{t},$$

where $E[Y]$ is the expectation of Y .

Lemma 2 (Chernoff's bounds) *Let X_1, X_2, \dots, X_n be independent 0/1 random variables, for $1 \leq i \leq n$, $\Pr[X_i = 1] = p_i$, where $0 < p_i < 1$. Let $X = \sum_{i=1}^n X_i$ and $\mu = E[X] = \sum_{i=1}^n p_i$. Then, for any $\delta > 0$,*

1. $\Pr[X \geq (1 + \delta)\mu] \leq \left(\frac{e^\delta}{(1+\delta)^{1+\delta}}\right)^\mu$.
2. $\Pr[X \leq (1 - \delta)\mu] \leq e^{-\mu\delta^2/2}$.

2.2 One-Stage Pooling Designs

Two efficient randomized constructions will be given for d -disjunct and $(d; z)$ -disjunct matrices, respectively. The constructions are based on the transversal design.

2.2.1 A New Construction of d -Disjunct Matrices

A Las Vegas algorithm will be presented next, which for given n, d and $0 < p < 1$, successfully constructs a $t \times n$ d -disjunct matrix with probability at least p , with

$$t \leq cd^2 \left(\log \frac{2}{1-p} + \log n \right),$$

where $c \approx 4.28$ is constant.

For given n, d and $0 < p < 1$, define $n_0 = 2n$. Let ϵ be the unique positive root of

$$\ln(1 + \epsilon) = \frac{2\epsilon}{1 + \epsilon}.$$

$\epsilon \approx 3.92$ is chosen to minimize the leading constant of t (see the remarks in later part). Let

Algorithm 1 (constructing d -disjunct matrix $M_{t \times n}$)

1. Construct a random q -ary matrix $M'_{t_0 \times n_0}$ with each cell randomly assigned from $\{1, 2, \dots, q\}$, independently and uniformly.
2. For any $1 \leq i < j \leq n_0$, let $w_{i,j}$ be the random variable denoting the number of rows r such that the two entries $M'(r, i)$ and $M'(r, j)$ are equal. Then,

$$E[w_{i,j}] = \mu \quad (= \frac{t_0}{q}).$$

Create an edge between columns i and j if $w_{i,j} \geq (1 + \epsilon)\mu$.

3. For each edge created in Step 2, remove one of its two columns arbitrarily. Let M'' denote the resulting matrix.
 4. If M'' has less than n ($= \frac{n_0}{2}$) columns, exit and the algorithm fail.
 5. Using the transformation in [Theorem 1](#), turn the first n columns of M'' into a binary matrix $M_{t \times n}$ with $t \leq t_0q$.
-

$$q = (1 + \epsilon)d, \quad t_0 = \frac{1 + \epsilon}{\epsilon} d \ln \frac{2n - 1}{1 - p}, \quad \mu = \frac{t_0}{q}.$$

Please see [Algorithm 1](#) as the algorithm for constructing d -disjunct matrices.

In [Algorithm 1](#), at Step 3, M'' must be q -ary $(d, 1)$ -disjunct since for any column i , the union of any d other columns can only cover less than

$$d \times (1 + \epsilon)\mu = d \times \frac{t_0}{d} = t_0$$

entries of column i . Therefore, if the algorithm successfully returns a matrix, it must be d -disjunct. Moreover,

$$\begin{aligned} t &\leq t_0q \\ &= \frac{(1 + \epsilon)^2}{\epsilon \log e} d^2 \log \frac{2n - 1}{1 - p} \\ &< c d^2 \left(\log \frac{2}{1 - p} + \log n \right), \end{aligned}$$

where $c = \frac{(1 + \epsilon)^2}{\epsilon \log e} \approx 4.28$.

2.2.2 Analysis of Algorithm 1

The analysis of the success probability and running time of [Algorithm 1](#) will be presented next.

Success Probability. First, the expectation of the number of edges created at Step 2 is estimated.

Lemma 3 *Let m be the random variable denoting the number of edges created at Step 2 of [Algorithm 1](#), then $E[m] \leq n(1 - p)$.*

Proof For $1 \leq i < j \leq n_0$, $1 \leq k \leq t_0$, at Step 2 of [Algorithm 1](#), define 0/1 random variable $X_k^{i,j}$ such that

$$X_k^{i,j} = 1 \text{ if and only if } M'(k, i) = M'(k, j).$$

Then,

$$w_{i,j} = X_1^{i,j} + X_2^{i,j} + \cdots + X_{t_0}^{i,j}.$$

Let $X^{i,j}$ be the indicator random variable for the event that there is an edge between column i and column j , that is,

$$X^{i,j} = \begin{cases} 1 & \text{there is an edge between column } i \text{ and column } j, \text{ that is, } w_{i,j} \geq (1+\epsilon)\mu; \\ 0 & \text{otherwise.} \end{cases}$$

Since $w_{i,j}$ is the sum of t_0 -independent 0/1 random variables, the Chernoff bound, (1) in [Lemma 2](#), implies that

$$\Pr[X^{i,j} = 1] = \Pr[w_{i,j} \geq (1+\epsilon)\mu] \leq \left(\frac{e^\epsilon}{(1+\epsilon)^{1+\epsilon}} \right)^\mu.$$

Notice that $q = (1+\epsilon)d$, and

$$t_0 = \frac{1+\epsilon}{\epsilon} d \ln \frac{2n-1}{1-p}.$$

Then,

$$\mu = E[w_{i,j}] = \frac{t_0}{q} = \frac{1}{\epsilon} \ln \frac{2n-1}{1-p}.$$

From

$$\ln(1+\epsilon) = \frac{2\epsilon}{1+\epsilon},$$

it follows that $(1+\epsilon)^{1+\epsilon} = e^{2\epsilon}$, and so

$$\frac{e^\epsilon}{(1+\epsilon)^{1+\epsilon}} = e^{-\epsilon},$$

which implies that

$$\left(\frac{e^\epsilon}{(1+\epsilon)^{1+\epsilon}} \right)^\mu = (e^{-\epsilon})^{\frac{1}{\epsilon} \ln \frac{2n-1}{1-p}} = \frac{1-p}{2n-1}.$$

Thus,

$$E[X^{i,j}] = \Pr[X^{i,j} = 1] \leq \frac{1-p}{2n-1},$$

for $1 \leq i < j \leq n_0$. Since $m = \sum_{1 \leq i < j \leq n_0} X^{i,j}$ and all the $X^{i,j}$'s are identically distributed, and $n_0 = 2n$, it follows that

$$E[m] = \binom{n_0}{2} E[X^{1,2}] \leq \binom{n_0}{2} \frac{1-p}{2n-1} = n(1-p). \quad \square$$

Clearly, m denotes the most number of columns that may be removed at Step 3. Since $E[m] \leq n(1-p)$, by applying the Markov inequality ([Lemma 1](#)), the probability that there are less than n columns left in M'' at Step 4 (i.e., the failure probability of [Algorithm 1](#)) is at most $\Pr[m > n] \leq \frac{E[m]}{n} \leq 1-p$.

Running Time. The time required by [Algorithm 1](#) is dominated by Step 2, which is

$$\binom{n_0}{2} t_0 = O(dn^2 \ln n),$$

by simply counting, for all pairs of columns, the number of rows at which the two columns have equal entry. In fact, an expected $O(n^2 \ln n)$ running time can be obtained by counting along the rows.

For $1 \leq i < j \leq n_0$, let $n(i, j)$ denote the number of equal entries between column i and column j in the same row. Initially, set $n(i, j) = 0$ for $1 \leq i < j \leq n_0$. For each row r , let $S_{r,1}, S_{r,2}, \dots, S_{r,q}$ denote the sets of column indices such that

$$S_{r,k} = \{i : M'(r, i) = k\}.$$

Clearly, the sets $S_{r,k}$, $1 \leq k \leq q$, can be constructed in n_0 time. For each k , increase the values of $n(i, j)$ by 1 for all $i < j$ and $i, j \in S_{r,k}$. The expected number of such pairs (i, j) for each $S_{r,k}$ is $E[\binom{|S_{r,k}|}{2}]$. Since $|S_{r,k}|$ are identically distributed for $1 \leq k \leq q$, the expected running time of Step 2 is

$$t_0 \times \left(n_0 + qE \left[\binom{|S_{r,1}|}{2} \right] \right).$$

Notice that $|S_{r,1}|$ has the binomial distribution with parameters n_0 and $1/q$; thus,

$$n_0 + qE \left[\binom{|S_{r,1}|}{2} \right] = n_0 + q \frac{1}{q^2} (n_0^2 - n_0) = O(n^2/d),$$

and so the expected running time of Step 2, which is also the expected running time of [Algorithm 1](#), is $t_0 \times O(n^2/d) = O(n^2 \ln n)$.

Therefore, the following theorem is established.

Theorem 2 *Given n, d , and $0 < p < 1$, [Algorithm 1](#) successfully constructs a $t \times n$ d -disjunct matrix with probability at least p , with*

$$t < cd^2 \left(\log \frac{2}{1-p} + \log n \right),$$

where $c \approx 4.28$ is constant. The algorithm runs in expected $O(n^2 \ln n)$ time.

Remarks In [Algorithm 1](#), ϵ is chosen to minimize the leading constant of t . It is required that

$$(1 + \epsilon)\mu \leq \frac{t_0}{d},$$

where $\mu = \frac{t_0}{q}$, that is, $q \geq (1 + \epsilon)d$, to guarantee that matrix M'' is $(d, 1)$ -disjunct. To guarantee that with reasonable probability M'' has at least n columns, it is required that

$$n_0 - E[m] \geq n,$$

where $E[m] = \binom{n_0}{2}E[X^{1,2}]$. This implies that

$$\Pr[X^{1,2} = 1] \leq \frac{n_0 - n}{\binom{n_0}{2}}.$$

Since

$$\max_{n_0} \frac{n_0 - n}{\binom{n_0}{2}} = \frac{1}{2n - 1},$$

which can be achieved when $n_0 = 2n - 1$ or $n_0 = 2n$, it should have that

$$\Pr[X^{1,2} = 1] \leq \frac{1}{2n - 1}.$$

This can be guaranteed by

$$\left(\frac{e^\epsilon}{(1 + \epsilon)^{1+\epsilon}} \right)^\mu \leq \frac{1}{2n - 1},$$

that is,

$$\mu \ln \frac{(1 + \epsilon)^{1+\epsilon}}{e^\epsilon} \geq O(1) + \ln n.$$

By plugging in $\mu = \frac{t_0}{q} = \frac{t}{q^2}$ and $q \geq (1 + \epsilon)d$, it follows that

$$t \geq \frac{(1 + \epsilon)^2}{\ln \frac{(1 + \epsilon)^{1+\epsilon}}{e^\epsilon}} d^2 (O(1) + \ln n).$$

Define

$$f(\epsilon) = \frac{(1 + \epsilon)^2}{\ln \frac{(1 + \epsilon)^{1+\epsilon}}{e^\epsilon}} = \frac{(1 + \epsilon)^2}{(1 + \epsilon) \ln(1 + \epsilon) - \epsilon}.$$

To minimize $f(\epsilon)$ for $\epsilon > 0$, from basic calculus, $f'(\epsilon) = 0$ implies that

$$\ln(1 + \epsilon) = \frac{2\epsilon}{1 + \epsilon}.$$

It is easy to verify that this equation has one unique positive root $\epsilon \approx 3.92$. Also, the equation implies that

$$f(\epsilon) = \frac{(1 + \epsilon)^2}{(1 + \epsilon) \ln(1 + \epsilon) - \epsilon} = \frac{(1 + \epsilon)^2}{\epsilon}.$$

2.2.3 Error-Tolerance Case

[Algorithm 1](#) is modified next, so that given $n, d, z > 1$ and $0 < p < 1$, the modified algorithm successfully constructs a $t \times n$ $(d; z)$ -disjunct matrix with probability at least p , with

$$t \leq cd^2 \left(\log \frac{2}{1-p} + \log n \right) + 2(1 + \epsilon)dz + O\left(\frac{z^2}{\ln n}\right),$$

where $\epsilon \approx 3.92$ and $c \approx 4.28$ are constants, and the $O(\cdot)$ notation hides dependencies on p .

First a generalization of $(d, 1)$ -disjunct matrices is given. A q -ary matrix is $(d, 1; z)$ -*disjunct* if for any column c and any set D of d other columns, there exist at least z elements in c such that each of these elements does not appear in any column of D in the same row. Clearly, by applying the same transformation in [Theorem 1](#), one can turn a $t_0 \times n$ q -ary $(d, 1; z)$ -disjunct matrix into a $(d; z)$ -disjunct matrix with n columns and at most t_0q rows.

For given $n, d, z > 1$ and $0 < p < 1$, let n_0, ϵ be as in [Algorithm 1](#). Let

$$q = (1 + \epsilon)d + \frac{\epsilon z}{\ln \frac{2n-1}{1-p}}, \quad t_0 = z + \frac{1 + \epsilon}{\epsilon} d \ln \frac{2n-1}{1-p}, \quad \mu = \frac{t_0}{q}.$$

It can be verified that by this assignment,

$$(1 + \epsilon)\mu = \frac{t_0 - z}{d},$$

and

$$\left(\frac{e^\epsilon}{(1 + \epsilon)^{1+\epsilon}} \right)^\mu = \frac{1-p}{2n-1}.$$

Please see [Algorithm 2](#) as the algorithm for constructing $(d; z)$ -disjunct matrices.

Firstly, at Step 3 of [Algorithm 2](#), M'' must be q -ary $(d, 1; z)$ -disjunct because for any column i , any d other columns can only cover less than $d \times (1 + \epsilon)\mu = t_0 - z$ of its entries. Therefore, if the algorithm successfully returns a matrix, it must be $(d; z)$ -disjunct. Secondly, when $z = o(d \ln n)$, by similar arguments, [Algorithm 2](#) runs in time $O(dn^2 \ln n)$ in the straightforward manner, and can be improved to expected $O(n^2 \ln n)$ time by counting the pairs of equal entries along the rows. Thirdly,

Algorithm 2 (constructing $(d; z)$ -disjunct matrix $M_{t \times n}$)

[Algorithm 2](#) works in the same way as [Algorithm 1](#), except that with $q = (1 + \epsilon)d + \frac{\epsilon z}{\ln \frac{2n-1}{1-p}}$ and $t_0 = z + \frac{1+\epsilon}{\epsilon} d \ln \frac{2n-1}{1-p}$.

$$\begin{aligned} t &\leq t_0 q \\ &= \frac{(1 + \epsilon)^2}{\epsilon \log e} d^2 \log \frac{2n - 1}{1 - p} + 2(1 + \epsilon)dz + \frac{(\epsilon \log e)z^2}{\log \frac{2n-1}{1-p}} \\ &\leq cd^2 \left(\log \frac{2}{1-p} + \log n \right) + 2(1 + \epsilon)dz + O\left(\frac{z^2}{\ln n}\right), \end{aligned}$$

where $c = \frac{(1+\epsilon)^2}{\epsilon \log e} \approx 4.28$.

For the success probability, if one let m^* be the random variable denoting the number of edges created at Step 2, since

$$\left(\frac{e^\epsilon}{(1 + \epsilon)^{1+\epsilon}} \right)^\mu = \frac{1 - p}{2n - 1}$$

still holds, the same result in [Lemma 3](#) also holds here, that is,

$$E[m^*] \leq n(1 - p).$$

Therefore, the probability that there are less than n columns left at Step 4 (i.e., the failure probability of [Algorithm 2](#)) is at most $\Pr[m^* > n] \leq 1 - p$. The following theorem is established.

Theorem 3 *Given $n, d, z > 1$ and $0 < p < 1$, [Algorithm 2](#) successfully constructs a $t \times n$ $(d; z)$ -disjunct matrix with probability at least p , with*

$$t \leq cd^2 \left(\log \frac{2}{1-p} + \log n \right) + 2(1 + \epsilon)dz + O\left(\frac{z^2}{\ln n}\right),$$

where $\epsilon \approx 3.92$ and $c \approx 4.28$ are constants. When $z = o(d \ln n)$, the algorithm runs in expected $O(n^2 \ln n)$ time.

2.3 Two-Stage Pooling Designs

New two-stage pooling designs, which require a number of tests asymptotically no more than a factor of $\frac{3}{\log 3}$ (the factor approaches $\log_2 e \approx 1.44$ as d tends to infinity) of the information-theoretic lower bound $d \log(n/d)$, will be presented next.

This improves the previously best upper bound of $4(1 + o(1))$ times the information theoretic bound in [24] by a factor of more than 2.

For a 0/1 matrix M , let C denote the set of columns of M , recall that M is d -disjunct if for any d -sized subset D of C , each column in $C - D$ is not covered by $U(D)$, where $U(D)$ denotes the union of the columns in D . Such matrices form the basis for nonadaptive (one-stage) pooling designs. However, a d -disjunct matrix with n columns requires no less than $\Omega(\frac{d^2 \log n}{\log d})$ rows, which is a factor of $d / \log d$ of the information-theoretic lower bound.

Instead of determining all the positives immediately, in [24] the authors relax the property of M by introducing the concept of (d, k) -resolvable matrices, which form a good two-stage group testing regimen. A 0/1 matrix M is called (d, k) -resolvable if, for any d -sized subset D of C , there are fewer than k columns in $C - D$ that are covered by $U(D)$. Thus, a matrix is d -disjunct if and only if it is $(d, 1)$ -resolvable.

For a set of n items in which at most d are positives, one can construct a “trivial two-stage” pooling design based on a $t \times n$ (d, k) -resolvable matrix as follows. Define the first round tests according to the rows of the matrix. By identifying the items in a negative pool (a pool with negative test outcome) as negatives, one can restrict the positives to a set D' of size smaller than $d + k$. Then, perform an additional round of tests on each item in D' individually. Thus, the total number of tests of the two stages is less than $t + d + k$.

2.3.1 Near Optimal Two-Stage Pooling Designs

Let M_1 be a q -ary matrix, and let C denote the set of columns of M_1 . Matrix M_1 is said to be $(d, 1; k)$ -resolvable if, for any d -sized subset D of C , there are fewer than k columns in $C - D$ that are *covered* by D . Here by saying a column c is *covered* by D , it means that for each element of c , the element appears at least once in some column of D in the same row. By applying the transformation in [Theorem 1](#), one can turn a $t_0 \times n$ q -ary $(d, 1; k)$ -resolvable matrix into a $t \times n$ (d, k) -resolvable matrix with $t \leq t_0 q$.

Let M' be a random $t_0 \times n$ q -ary (where q will be specified later) matrix with each cell assigned randomly from $\{1, 2, \dots, q\}$, independently and uniformly. For each set D of d columns and a column $c \notin D$, for each element c_i ($i = 1, 2, \dots, t_0$) in c , the probability that c_i appears in some column of D in the same row is $1 - \left(1 - \frac{1}{q}\right)^d$; thus, the probability that every element in c appears in some column of D in the same row, that is, c is covered by D , is $[1 - \left(1 - \frac{1}{q}\right)^d]^{t_0}$. Parameter t_0 is chosen such that

$$\left[1 - \left(1 - \frac{1}{q}\right)^d\right]^{t_0} = \frac{1}{n - d},$$

that is,

$$t_0 = -\frac{\log(n-d)}{\log \left[1 - \left(1 - \frac{1}{q} \right)^d \right]}.$$

Let C denote the set of columns of M' . For any set D of d columns of M' , and for each $c \in C - D$, let X_c be the indicator variable such that $X_c = 1$ if and only if c is covered by D . Then,

$$\Pr[X_c = 1] = \frac{1}{n-d}.$$

Define

$$X_D = \sum_{c \in C-D} X_c.$$

Then, X_D is the random variable denoting the number of columns in $C - D$ that are covered by D . Since X_D is the sum of $(n-d)$ i.i.d. 0/1 random variables and $E[X_D] = 1$, the Chernoff's bound implies that the probability that D covers at least $(1 + \delta)$ columns in $C - D$ is

$$\Pr[X_D \geq (1 + \delta)] \leq \frac{e^\delta}{(1 + \delta)^{1+\delta}}.$$

Therefore, the probability that M' is not $(d, 1; 1 + \delta)$ -resolvable, that is, there exists some set D of d columns that covers at least $(1 + \delta)$ columns in $C - D$, is at most

$$p = \binom{n}{d} \frac{e^\delta}{(1 + \delta)^{1+\delta}}.$$

In order to satisfy $p < 1$, it suffices to assign δ such that

$$\left(\frac{1 + \delta}{e} \right)^{1+\delta} = n^d,$$

since which implies that

$$\frac{(1 + \delta)^{1+\delta}}{e^\delta} > \frac{(1 + \delta)^{1+\delta}}{e^{1+\delta}} = n^d > \binom{n}{d}.$$

Notice that $(\frac{1+\delta}{e})^{1+\delta} = n^d$ implies $(\frac{1+\delta}{e})^{\frac{1+\delta}{e}} = n^{\frac{d}{e}}$; thus,

$$1 + \delta = (1 + o(1)) \frac{d \ln n}{\ln(d \ln n)}.$$

Hence, by probabilistic arguments, the existence of a $t_0 \times n$ q -ary $(d, 1; 1 + \delta)$ -resolvable matrix with t_0 and δ as specified above has been proved.

By applying the transformation in [Theorem 1](#), one can turn the $t_0 \times n$ q -ary $(d, 1; 1 + \delta)$ -resolvable matrix M' into a (binary) $t \times n$ $(d, 1 + \delta)$ -resolvable matrix M with

$$t \leq t_0 q < -\frac{q \log n}{\log \left[1 - (1 - \frac{1}{q})^d \right]}.$$

Define

$$C_d(x) = \frac{x}{-\log \left[1 - (1 - \frac{1}{x})^d \right]}, \quad \text{for } x > 1.$$

Choosing q to be the positive integer that minimizes $C_d(x)$, and let $C_d = C_d(q)$. Then, $t \leq C_d \log n$. For $d \geq 1$,

$$C_d/d \leq C_d(3d)/d = \frac{3}{-\log \left[1 - (1 - \frac{1}{3d})^d \right]} \leq \frac{3}{\log 3}.$$

Also it is not hard to see that when $d = 1$, $C_1 = C_1(3) = \frac{3}{\log 3}$ indeed holds. Furthermore, the following lemma estimates that $q = \Theta(d)$ and $C_d \rightarrow d \log e$ as $d \rightarrow \infty$.

Lemma 4 *For $d \geq 1$, let $q = q(d)$ be the point that minimizes $C_d(x) = \frac{x}{-\log[1-(1-\frac{1}{x})^d]}$ for $x > 1$, and let $C_d = C_d(q)$. Then, $q(d) = \Theta(d)$, and $\lim_{d \rightarrow \infty} C_d/d = \log e$.*

To prove [Lemma 4](#), the following useful fact is proved first.

Fact 1 *Let $f(y) = \ln y \ln(1 - y)$, $0 < y < 1$. Then $f(y)$ achieves maximum at $y = \frac{1}{2}$.*

Proof of Fact 1: By symmetry, it is sufficient to show that $f'(y) > 0$ for $0 < y < \frac{1}{2}$. Since

$$\begin{aligned} f'(y) &= \frac{1}{y} \ln(1 - y) - \frac{1}{1 - y} \ln y \\ &= \frac{1}{y(1 - y)} [(1 - y) \ln(1 - y) - y \ln y], \end{aligned}$$

let

$$g(y) = (1 - y) \ln(1 - y) - y \ln y,$$

Next it will be showed that $g(y) > 0$ for $0 < y < \frac{1}{2}$.

Rewrite

$$g(y) = \ln(1 - y) + y \ln \frac{1}{y(1 - y)}.$$

For $0 < y < \frac{1}{2}$, $\ln \frac{1}{y(1-y)} > \ln 4$ since $y(1-y) < \frac{1}{4}$; thus,

$$g(y) > \ln(1 - y) + y \ln 4.$$

Let

$$h(y) = \ln(1 - y) + y \ln 4.$$

Notice that $h'(y) = \ln 4 - \frac{1}{1-y}$, $h'(y) > 0$ for $0 < y < 1 - \frac{1}{\ln 4}$ and $h'(y) < 0$ for $1 - \frac{1}{\ln 4} < y < \frac{1}{2}$. Thus, $h(y)$ is monotone increasing when $0 < y < 1 - \frac{1}{\ln 4}$ and monotone decreasing when $1 - \frac{1}{\ln 4} < y < \frac{1}{2}$. From $h(0) = h(\frac{1}{2}) = 0$, one can obtain that

$$h(y) > 0 \text{ for } 0 < y < \frac{1}{2}.$$

Therefore, for $0 < y < \frac{1}{2}$, $g(y) > h(y) > 0$, and so $f'(y) = \frac{1}{y(1-y)}g(y) > 0$. \square

Proof of Lemma 4: Notice that if q_1 satisfies $(1 - \frac{1}{q_1})^d = \frac{1}{2}$, then $q_1 = \Theta(d)$ since $\frac{q_1}{d} \rightarrow \log e$ as $d \rightarrow \infty$. Moreover,

$$C_d(q_1) = q_1 = \Theta(d).$$

The lemma is proved by contradiction. First assume that $q(d) = O(d)$ does not hold, that is, for any $c > 0$ and any $d_0 > 0$, there exists $d > d_0$ such that $q(d) > cd$. Then, since $\frac{q}{d} > c$ (for simplicity q is used instead of $q(d)$, if it is clear from the context), as $c \rightarrow \infty$,

$$\begin{aligned} C_d(q) &= \frac{q}{-\log \left[1 - \left(1 - \frac{1}{q} \right)^d \right]} \\ &\sim \frac{q}{-\log \left[1 - \left(1 - \frac{d}{q} \right) \right]} \\ &= d \frac{\frac{q}{d}}{\log \frac{q}{d}} \\ &= \omega(d); \end{aligned}$$

here, $a \sim b$ means that $\lim_{c \rightarrow \infty} \frac{a}{b} = 1$. However, this contradicts since q is the point that minimizes $C_d(q)$ and on the other hand $C_d(q_1) = \Theta(d)$. On the other hand, assume that $q(d) = \Omega(d)$ does not hold, that is, for any $c > 0$ and any $d_0 > 0$, there exists $d > d_0$ such that $q(d) < cd$. Write

$$\begin{aligned} C_d(q) &= \frac{q}{-\log \left[1 - \left(1 - \frac{1}{q} \right)^d \right]} \\ &= \frac{q \ln 2}{-\ln \left\{ 1 - \left[\left(1 - \frac{1}{q} \right)^q \right]^{\frac{d}{q}} \right\}}. \end{aligned}$$

Since $0 < \left(1 - \frac{1}{q}\right)^q < \frac{1}{e}$ for $q > 1$, as $c \rightarrow 0$, $\frac{d}{q} > \frac{1}{c} \rightarrow \infty$, and $\left[\left(1 - \frac{1}{q}\right)^q\right]^{\frac{d}{q}} < e^{-\frac{d}{q}} \rightarrow 0$; thus,

$$C_d(q) \sim \frac{q \ln 2}{\left[\left(1 - \frac{1}{q}\right)^q\right]^{\frac{d}{q}}} > e^{\frac{d}{q}} q \ln 2 = d \frac{e^{\frac{d}{q}} \ln 2}{\frac{d}{q}} = \omega(d);$$

this also contradicts (here $a \sim b$ means that $\lim_{c \rightarrow 0} \frac{a}{b} = 1$). Therefore, $q(d) = \Theta(d)$.

Next C_d as $d \rightarrow \infty$ is estimated. Since $\left(1 - \frac{1}{q}\right)^q < \frac{1}{e}$ for $q > 1$, thus

$$\left(1 - \frac{1}{q}\right)^d < \left(\frac{1}{e}\right)^{\frac{d}{q}} = e^{-\frac{d}{q}},$$

and

$$-\log \left[1 - \left(1 - \frac{1}{q}\right)^d \right] < -\log \left(1 - e^{-\frac{d}{q}}\right),$$

it follows that

$$\begin{aligned} C_d(q) &= \frac{q}{-\log \left[1 - \left(1 - \frac{1}{q}\right)^d \right]} \\ &> \frac{q}{-\log \left(1 - e^{-\frac{d}{q}}\right)} \\ &= \frac{d \ln 2}{\left[-\frac{d}{q} \ln \left(1 - e^{-\frac{d}{q}}\right)\right]}. \end{aligned}$$

Let $y = e^{-\frac{d}{q}}$, then $-\frac{d}{q} = \ln y$, and $C_d(q) > \frac{d \ln 2}{\ln y \ln(1-y)}$. Since $\ln y \ln(1-y)$ achieves maximum at $y = \frac{1}{2}$ (Fact 1), $C_d(q) > d \log e$ for $q > 1$, thus $C_d > d \log e$ for $d \geq 1$. On the other hand, as mentioned at the beginning of the proof, as $d \rightarrow \infty$, $\frac{q_1}{d} \rightarrow \log e$, and $C_d(q_1) = q_1 \rightarrow d \log e$. Therefore, as $d \rightarrow \infty$, $C_d \rightarrow d \log e$. \square

The above arguments showed existence of a $t \times n$ ($d, 1 + \delta$)-resolvable matrix with $t \leq C_d \log n$ and $1 + \delta = (1 + o(1)) \frac{d \ln n}{\ln(d \ln n)}$, which implies the following theorem.

Theorem 4 *Given n and d , there exists a two-stage pooling design for finding up to d positives from n items using no more than $C_d \log n + d + \delta + 1$ tests, where*

$$C_d = \min_{x \in \mathcal{N}} \frac{x}{-\log \left[1 - \left(1 - \frac{1}{x}\right)^d \right]} \leq \frac{3}{\log 3} d,$$

for $d \geq 1$, and $\delta = (1 + o(1)) \frac{d \ln n}{\ln(d \ln n)}$. Moreover,

$$\lim_{d \rightarrow \infty} C_d/d = \log e.$$

2.4 Probabilistic Pooling Designs

A probabilistic pooling design identifying up to d positives from n items with high probability will be presented next. In a probabilistic group testing algorithm, one may identify a positive item as negative; such a wrongly identified item is called a *false negative*; a negative item which is wrongly identified as positive is called a *false positive*. Clearly, the algorithm correctly identifies all positives if and only if there are no false positives or false negatives. Previous works on probabilistic nonadaptive group testing algorithms can be found from, among others, [40, 41, 44].

Algorithm. Given n and d , first construct a $t_0 \times n$ random q -ary matrix M' with each cell randomly assigned from $\{1, 2, \dots, q\}$ independently and uniformly (where t_0 and q will be specified later). Then, use the transformation in [Theorem 1](#) to obtain a $t \times n$ 0/1 matrix M with $t \leq t_0 q$. Associate the n items with the columns of M , and test the pools indicated by the rows of M . The items not in any negative pool are identified as positives.

Analysis. Let D be the set of columns corresponding to the positives, then $|D| \leq d$. First, it is easy to see that no positive item will be identified as negative if there is no error in the test outcomes. For any negative item, let c denote the column associated with it, then the item is wrongly identified if and only if c is covered by $U(D)$ in M , or equivalently, c is covered by D in M' (here the same notations c and D are used for different matrices M and M' , to denote the corresponding columns). The probability that c is covered by D , as analyzed in [Sect. 2.3](#), is

$$\left[1 - \left(1 - \frac{1}{q} \right)^{|D|} \right]^{t_0} \leq \left[1 - \left(1 - \frac{1}{q} \right)^d \right]^{t_0}.$$

Choosing q and t_0 such that

$$\left[1 - \left(1 - \frac{1}{q} \right)^d \right]^{t_0} = \frac{1-p}{n},$$

that is,

$$t_0 = -\frac{\log n + \log \frac{1}{1-p}}{\log[1 - (1 - \frac{1}{q})^d]}.$$

Then, the probability that there exists some negative item wrongly identified is no more than

$$(n - |D|)[1 - (1 - \frac{1}{q})^d]^{t_0} \leq 1 - p,$$

which implies that with probability at least p , the above algorithm successfully identifies all the positives. The number of pools required is no more than

$$t \leq t_0 q = -\frac{q}{\log[1 - (1 - \frac{1}{q})^d]}(\log n + \log \frac{1}{1 - p}).$$

By choosing q to be the positive integer minimizing

$$C_d(x) = \frac{x}{-\log[1 - (1 - \frac{1}{x})^d]} \text{ for } x > 1,$$

obtaining

$$t \leq C_d(\log n + \log \frac{1}{1 - p}).$$

Theorem 5 *The above one-stage algorithm, with probability at least p , correctly identifies up to d positives from n items using no more than $C_d(\log n + \log \frac{1}{1-p})$ tests.*

Remarks

1. The one-stage probabilistic pooling design is also transversal. This design never gets false negatives, while the probabilistic algorithms in [40, 41, 44] never get false positives. The algorithm in [44] identifies up to 9 positives from 18,918,900 items using 5,460 tests, with success probability of 98.5 %. For the method proposed here, $n = 18,918,900$, $d = 9$, and $p = 0.985$, by choosing $q = 14$, it requires $C_d(q)(\log n + \log \frac{1}{1-p}) < 408$ tests, which is much fewer.
2. In contrast to the two-stage design in Sect. 2.3, this probabilistic algorithm is explicitly given and can be easily implemented in practice. In addition, one can extend this algorithm to two stage, by performing an additional round of individual tests on the candidate positives identified by the first round, so that no item will be wrongly identified. It is easy to verify that, for this extended two-stage probabilistic algorithm, by choosing the same value q , and choosing t_0 such that $[1 - (1 - \frac{1}{q})^d]^{t_0} = \frac{1}{n}$, the expected total number of tests required is no more than $C_d \log n + d + 1$, which is better than the deterministic two-stage design in Sect. 2.3.

2.5 Conclusion and Future Studies

New one- and two-stage pooling designs, together with new probabilistic pooling designs, are presented in this section. The approach presented works for both error-free and error-tolerance scenarios. The following remarks end off this section:

1. The constructions of pooling designs in Sects. 2.3 and 2.4 can also be generalized to error-tolerance case, in a similar manner as in the construction of $(d; z)$ -disjunct matrices in Sect. 2.2.3. The details are omitted due to the similarities.

2. Efficient constructions (i.e., in time polynomial in n and d) of the two-stage designs in Sect. 2.3 are not given. Up to now, no efficient construction of two-stage pooling designs using the number of tests within a constant factor of the information theoretic lower bound is known. In [14], the construction requires $\left(\frac{n}{2d}\right)$ time, and in [24], the authors gave existence proof as in this section. Although once such a design is found it can be used as many times as wanted, efficient construction is an important issue.
3. The two-stage pooling design presented in Sect. 2.3 uses the number of tests asymptotically within a factor of C_d/d ($\leq \frac{3}{\log 3}$ for general d , and tends to $\log_2 e \approx 1.44$ as $d \rightarrow \infty$) of the information theoretic bound $d \log(n/d)$. Can two-stage algorithms do as good as fully adaptive algorithms, that is, achieve a factor of asymptotically 1 of the information theoretic bound? Or, how good could it be?
4. Last but the least, efficient (i.e., polynomial time in n and d) deterministic constructions of d -disjunct matrices with $t = O(d^2 \log n)$ are known [2, 50]. Regarding the leading constant within the big-O notation, the results indicate that they are considerably larger than the result given in this section (where the leading constant is approximately 4.28). An efficient randomized construction of d -disjunct matrices with $t = O(d^2 \log n)$ and efficient decoding (in time polynomial in t) is given in [33], and an efficient deterministic construction with the same properties is obtained recently [45]. Improved constructions of disjunct matrices are interesting to investigate.

3 New Complexity Results on Nonunique Probe Selection

Given a collection of n targets and a sample S containing at most d of these targets, and a collection of m probes each of them hybridizes to a subset of the given targets, the goal is to select a subset of probes, such that all targets in S can be identified by observing the hybridization reactions between the selected probes and S . For each probe p , there is hybridization reaction between p and S if S contains at least one target that hybridizes with p , otherwise there is no hybridization reaction. The above probe selection problem has been extensively studied recently [5, 31, 51, 52, 56] due to its important applications, particularly in molecular biology. For example, one application of this identification problem is to identify viruses (targets) from a blood sample. The presence or absence of the viruses is established by observing the hybridization reactions between the blood sample and some probes; here, each probe is a short oligonucleotide of size 8–25 that can hybridize to one or more of the viruses.

A probe is called *unique* if it hybridizes to only one target; otherwise, it is called *nonunique*. Identifying targets using unique probes is straightforward. However, in situations where the targets have a high degree of similarity, for instance when identifying closely related virus subtypes, finding unique probes for every target is difficult. In [54], Schliep, Torney, and Rahmann proposed a group testing method using nonunique probes to identify targets in a given sample. Since each

nonunique probe can hybridize with more than one target, the identification problem becomes more complicated. One important issue is to select a subset from the given nonunique probes so that the hybridization results can be decoded, that is, determine the presence or absence of targets in sample S . Also, the number of selected probes is exactly the number of hybridization experiments required, and it is desirable to select as few probes as possible to reduce the experimental cost. In [35, 54], two heuristics using greedy and linear programming-based techniques, respectively, are proposed for choosing a suitable subset of nonunique probes. In [11], the computational complexities of some basic problems in nonunique probe selection are studied, in the context of the theory of NP -completeness (see Chap. 10 in [17, 19] and [30]). The complexity results in [11] will be presented in this section.

3.1 Preliminaries

The nonunique probe selection problem can be formulated as follows. Given a collection of n targets t_1, t_2, \dots, t_n , and a collection of m nonunique probes p_1, p_2, \dots, p_m , a sample S is known to contain at most d of the n targets. The probe-target hybridizations can be represented by an $m \times n$ 0-1 matrix M . $M_{i,j} = 1$ indicates that probe p_i hybridizes to target t_j , and $M_{i,j} = 0$ indicates otherwise. The subset of probes selected corresponds to a subset of rows in M , which forms a submatrix H of M with the same number of columns. The hybridization results between the selected probes and S also can be represented as a 0-1 vector V . $V_i = 1$ indicates that there is hybridization reaction between p_i and S , that is, p_i hybridizes to at least one target in S , and $V_i = 0$ indicates otherwise. If there is no error in the hybridization experiments, then V is equal to the union of the columns of H that correspond to the targets in S . Here, the union of a subset of columns is simply the Boolean sum of these column vectors. In order to identify all targets in S , the submatrix H should satisfy that all unions of up to d columns in H are different; in other words, H should be \bar{d} -separable. Also, as mentioned above, it is desirable to minimize the number of rows in H .

A matrix H is said to be \bar{d} -separable if all unions of up to d columns in H are different. However, the following equivalent definition is more useful in the proofs here. Let H be a $t \times n$ Boolean matrix. For each $i \in \{1, 2, \dots, t\}$, define

$$H_i = \{j \mid 1 \leq j \leq n, H_{i,j} = 1\}.$$

For any subset S of $\{1, 2, \dots, n\}$ and any $i \in \{1, 2, \dots, t\}$, write

$$H_i(S) = \begin{cases} 1 & \text{if } H_i \cap S \neq \emptyset; \\ 0 & \text{otherwise.} \end{cases}$$

Two sets $S_1, S_2 \subseteq \{1, 2, \dots, n\}$ are said to be *separated* by H if there exists an integer i , $1 \leq i \leq t$, such that $H_i(S_1) \neq H_i(S_2)$. Matrix H is said to be \bar{d} -separable if for any two different subsets S_1, S_2 of $\{1, 2, \dots, n\}$, with $|S_1| \leq d$ and $|S_2| \leq d$, S_1 and S_2 can be separated by H .

3.2 Complexity of Minimal \bar{d} -Separable Matrix

In nonunique probe selection, one natural problem of interests is to determine whether a submatrix H chosen is \bar{d} -separable and minimal. By minimal, it means that the removal of any row from H will make it no longer \bar{d} -separable. The problem can be formulated as follows.

MIN-SEPARABILITY (MINIMAL SEPARABILITY): Given a $t \times n$ Boolean matrix H and an integer $d \leq n$, determine whether it is true that (a) H is \bar{d} -separable, and (b) for any submatrix Q of H of size $(t - 1) \times n$, Q is not \bar{d} -separable.

For a given binary matrix H and a positive integer d , the problem to determine whether H is \bar{d} -separable is known to be $coNP$ -complete ([17], Theorem 10.2.1). Here a DP -completeness proof of problem MIN-SEPARABILITY will be presented.

The class DP is the collection of sets A which are the intersection of a set $X \in NP$ and a set $Y \in coNP$. The notion of DP -completeness has been used to characterize the complexity of the “exact-solution” version of many NP -complete problems. For instance, the exact traveling salesman problem, which asks, for a given edge-weighted complete graph G and a constant K , whether the minimum weight of a traveling salesman tour of the graph G is equal to K , is DP -complete (see [47], Theorem 17.2). In addition, the “critical” version of some NP -complete problems is also known to be DP -complete. For instance, the following problem is the critical version of the 3-satisfiability problem and has been shown to be DP -complete by Papadimitriou and Wolfe [48]:

MIN-3-UNSAT: Given a 3-CNF Boolean formula φ which consists of clauses C_1, C_2, \dots, C_m , determine whether it is true that (a) φ is not satisfiable, and (b) for any j , $1 \leq j \leq m$, the formula φ_j that consists of all clauses C_ℓ , $\ell \in \{1, 2, \dots, m\} - \{j\}$, is satisfiable.

Although most exact-solution version of NP -complete problems have been shown to be DP -complete, many critical versions are not known to be DP -complete. The problem MIN-SEPARABILITY may be viewed as a critical version of the \bar{d} -separability problem. Its DP -completeness will be proved by constructing a reduction from MIN-3-UNSAT.

Theorem 6 MIN-SEPARABILITY is DP -complete.

Proof Recall that $DP = \{X \cap Y \mid X \in NP, Y \in coNP\}$. A problem A is DP -complete if $A \in DP$ and, for all $B \in DP$, $B \leq_m^P A$. For convenience, for any $t \times n$ matrix H , \tilde{H}_j is used to denote the $(t - 1) \times n$ submatrix of H with the j th row removed. First, to see that $\text{MIN-SEPARABILITY} \in DP$, let

$$X = \{(H, d) \mid H \text{ is a } t \times n \text{ 0/1 matrix, } 1 \leq d \leq n, (\forall j, 1 \leq j \leq t) \tilde{H}_j \text{ is not } \bar{d}\text{-separable}\},$$

and

$$Y = \{(H, d) \mid H \text{ is a } t \times n \text{ 0/1 matrix, } 1 \leq d \leq n, H \text{ is } \bar{d}\text{-separable}\}.$$

It is clear that $\text{MIN-SEPARABILITY} = X \cap Y$. It is also not hard to see that $X \in NP$ and $Y \in coNP$. In particular, to see that $X \in NP$, note that $(H, d) \in X$ if and only if there exist $2t$ subsets $S_{j,1}, S_{j,2}$ of $\{1, 2, \dots, n\}$, for $j \in \{1, 2, \dots, t\}$, such that, for each j , $H_k(S_{j,1}) = H_k(S_{j,2})$ for all $k \in \{1, 2, \dots, t\} - \{j\}$.

Next, a reduction from MIN-3-UNSAT to MIN-SEPARABILITY will be described. Let φ be a 3-CNF Boolean formula which consists of m clauses C_1, C_2, \dots, C_m , over n variables x_1, x_2, \dots, x_n . For each $j \in \{1, 2, \dots, m\}$, let φ_j denote the Boolean formula that consists of all clauses C_ℓ for $\ell \in \{1, 2, \dots, m\} - \{j\}$. From φ , a $(3n + m + 1) \times (2n + 2)$ Boolean matrix H will be constructed, and define $d = n + 1$. For convenience, the columns of H are denoted by

$$X = \{x_i, \bar{x}_i \mid 1 \leq i \leq n\} \cup \{y, z\},$$

and denote the rows of H by

$$T = \{x_i, \bar{x}_i, u_i \mid 1 \leq i \leq n\} \cup \{y\} \cup \{C_j \mid 1 \leq j \leq m\}.$$

Next H is defined by specifying each row of it:

1. For each $1 \leq i \leq n$, let $H_{x_i} = \{x_i\}$, $H_{\bar{x}_i} = \{\bar{x}_i\}$, and $H_{u_i} = \{x_i, \bar{x}_i, z\}$.
2. $H_y = \{y\}$.
3. For each $1 \leq j \leq m$, let $H_{C_j} = \{x_i \mid x_i \in C_j\} \cup \{\bar{x}_i \mid \bar{x}_i \in C_j\} \cup \{y, z\}$ (so that $|H_{C_j}| = 5$).

To prove the correctness of the reduction, first verify that if φ is not satisfiable, then H is \bar{d} -separable. To see this, let S_1 and S_2 be two subsets of X , each of size $\leq n + 1$.

Case 1. $S_1 - \{z\} \neq S_2 - \{z\}$. Then, there exists $v \in X - \{z\}$ such that $v \in S_1 \Delta S_2$. Then, $H_v(S_1) \neq H_v(S_2)$.

Case 2. $S_1 - \{z\} = S_2 - \{z\}$. Then, it must be true that $S_1 \Delta S_2 = \{z\}$. Without loss of generality, assume $S_2 = S_1 \cup \{z\}$. Note that $|S_2| \leq n + 1$ implies $|S_1| \leq n$.

Subcase 2.1. There exists an integer i such that $|S_1 \cap \{x_i, \bar{x}_i\}| \neq 1$. First, if $|S_1 \cap \{x_i, \bar{x}_i\}| = 0$ for some i , then $H_{u_i}(S_1) = 0$ and $H_{u_i}(S_2) = 1$ (because $z \in S_2$). Next, if $|S_1 \cap \{x_i, \bar{x}_i\}| = 2$ for some i , then it must have $|S_1 \cap \{x_k, \bar{x}_k\}| = 0$ for some k , because $|S_1| \leq n$. Then, again $H_{u_k}(S_1) = 0 \neq 1 = H_{u_k}(S_2)$.

Subcase 2.2. $|S_1 \cap \{x_i, \bar{x}_i\}| = 1$ for all $i \in \{1, 2, \dots, n\}$. Note that, in this case, $y \notin S_1$. Define a Boolean assignment $\tau : \{x_1, x_2, \dots, x_n\} \rightarrow \{\text{TRUE}, \text{FALSE}\}$ by

$$\tau(x_i) = \text{TRUE} \text{ if and only if } x_i \in S_1.$$

Since φ is not satisfiable, there exists a clause C_j that is not satisfied by τ . It means that $C_j \cap S_1 = \emptyset$, and so $H_{C_j}(S_1) = 0$. However, $H_{C_j}(S_2) = 1$ since $z \in S_2$.

The above completes the proof that H is \bar{d} -separable.

Next, it will be showed that if φ_j is satisfiable for all $j = 1, 2, \dots, m$, then \widetilde{H}_v is not \bar{d} -separable for all $v \in T$. First, for $v \in X - \{z\}$, let $S_1 = \{z\}$ and $S_2 = \{v, z\}$.

Then, for all rows $w \in X - \{z, v\}$, $H_w(S_1) = 0 = H_w(S_2)$. Also, for all other rows $w \in T - X$, $H_w(S_1) = H_w(S_2) = 1$ since $z \in H_w$. So, S_1 and S_2 are not separable by \tilde{H}_v .

Next, consider the case $v = u_i$ for some $i \in \{1, 2, \dots, n\}$. Let

$$S_1 = \{x_k \mid 1 \leq k \leq n, k \neq i\} \cup \{y\},$$

and $S_2 = S_1 \cup \{z\}$. It is clear that $|S_1| = n$ and $|S_2| = n + 1$. Now the following claim is made: S_1 and S_2 are not separable by \tilde{H}_{u_i} .

To prove the claim, note that the rows H_{x_k} , $H_{\bar{x}_k}$, for $1 \leq k \leq n$, and row H_y cannot separate S_1 from S_2 , since $S_1 - \{z\} = S_2 - \{z\}$. Also, rows $H_{u_k}(S_1) = H_{u_k}(S_2) = 1$, for all $k \in \{1, 2, \dots, n\} - \{i\}$, because $|S_1 \cap \{x_k, \bar{x}_k\}| = 1$ if $k \neq i$. In addition, for any $j = 1, 2, \dots, m$, $H_{C_j}(S_1) = 1 = H_{C_j}(S_2)$, since $y \in S_1$. It follows that \tilde{H}_{u_i} cannot separate S_1 from S_2 .

Finally, consider the case $v = C_j$ for some $j \in \{1, 2, \dots, m\}$. Note that φ_j is satisfiable. So, there is a Boolean assignment $\tau : \{x_1, x_2, \dots, x_n\} \rightarrow \{\text{TRUE}, \text{FALSE}\}$ satisfying all clauses C_ℓ , except C_j . Define

$$S_1 = \{x_i \mid \tau(x_i) = \text{TRUE}\} \cup \{\bar{x}_i \mid \tau(x_i) = \text{FALSE}\},$$

and $S_2 = S_1 \cup \{z\}$. Then, similar to the argument for the case $v = u_i$, one can verify that $H_w(S_1) = H_w(S_2)$ for $w \in X - \{z\}$, and for $w \in \{u_i \mid 1 \leq i \leq n\}$. In addition, for any clause C_ℓ , with $\ell \neq j$, C_ℓ is satisfied by τ . It follows that $C_\ell \cap S_1 \neq \emptyset$ and $H_{C_\ell}(S_1) = 1 = H_{C_\ell}(S_2)$. This completes the proof that \tilde{H}_v is not \bar{d} -separable, for all $v \in T$.

Conversely, it will be showed that if $\varphi \notin \text{MIN-3-UNSAT}$, then $(H, n + 1) \notin \text{MIN-SEPARABILITY}$. First, consider the case that φ is a satisfiable formula. Let $\tau : \{x_1, x_2, \dots, x_n\} \rightarrow \{\text{TRUE}, \text{FALSE}\}$ be a Boolean assignment satisfying φ . Define

$$S_1 = \{x_i \mid \tau(x_i) = \text{TRUE}\} \cup \{\bar{x}_i \mid \tau(x_i) = \text{FALSE}\},$$

and $S_2 = S_1 \cup \{z\}$. Then, similar to the earlier proof, one can verify that H cannot separate S_1 from S_2 . In particular, $H_{C_j}(S_1) = 1$ for all $j \in \{1, 2, \dots, m\}$, because τ satisfies C_j and so $C_j \cap S_1 \neq \emptyset$. Thus, $(H, n + 1) \notin \text{MIN-SEPARABILITY}$.

Next, assume that there exists an integer $j \in \{1, 2, \dots, m\}$ such that φ_j is not satisfiable. The following claim is made: \tilde{H}_{C_j} is \bar{d} -separable. The proof of the claim is similar to the first part of the proof (for the statement that if φ is not satisfiable then H is \bar{d} -separable).

Case 1. $S_1 - \{z\} \neq S_2 - \{z\}$. Then, there exists $v \in X - \{z\}$ such that $v \in S_1 \Delta S_2$. So, $H_v(S_1) \neq H_v(S_2)$.

Case 2. $S_1 - \{z\} = S_2 - \{z\}$. Then, it must be true that $S_1 \Delta S_2 = \{z\}$, and one may assume $S_2 = S_1 \cup \{z\}$. It must have $|S_2| \leq n + 1$ and $|S_1| \leq n$.

Subcase 2.1. There exists an integer i such that $|S_1 \cap \{x_i, \bar{x}_i\}| \neq 1$. Similar to the earlier proof, if $|S_1 \cap \{x_i, \bar{x}_i\}| = 0$ for some $i = 1, 2, \dots, n$, then H_{u_i} can be

used to separate S_1 from S_2 . If $|S_1 \cap \{x_i, \bar{x}_i\}| = 2$ for some $i = 1, 2, \dots, n$, then $|S_1 \cap \{x_k, \bar{x}_k\}| = 0$ for some k , and again H_{u_k} separates S_1 from S_2 .

Subcase 2.2. $|S_1 \cap \{x_i, \bar{x}_i\}| = 1$ for all $i \in \{1, 2, \dots, n\}$. Then, since $|S_1| \leq n$, $y \notin S_1$. Define a Boolean assignment $\tau : \{x_1, x_2, \dots, x_n\} \rightarrow \{\text{TRUE}, \text{FALSE}\}$ by $\tau(x_i) = \text{TRUE}$ if and only if $x_i \in S_1$. Since φ_j is not satisfiable, there exists a clause C_ℓ , $\ell \neq j$, such that $\tau(C_\ell) = \text{FALSE}$. It means that $C_\ell \cap S_1 = \emptyset$, and so $H_{C_\ell}(S_1) = 0$. However, $H_{C_\ell}(S_2) = 1$ since $z \in S_2$. So, H_{C_ℓ} separates S_1 from S_2 . This completes the proof that \tilde{H}_{C_j} is \bar{d} -separable, and hence $(H, n + 1) \notin \text{MIN-SEPARABILITY}$. \square

3.3 Minimum \bar{d} -Separable Submatrix

A more important problem in nonunique probe selection is to find a minimum subset of probes that can identify up to d targets in a given sample. In the matrix representation, the problem can be formulated as the following: Given a binary matrix M and a positive integer d , find a minimum \bar{d} -separable submatrix of M with the same number of columns (problem MIN- \bar{d} -SS in [17], Chap. 10).

For $d = 1$, MIN- \bar{d} -SS has been proved to be NP -hard ([17], Theorem 10.3.2), by modifying a reduction used in the proof of the NP -completeness of the problem MINIMUM-TEST-SETS in [30]. For fixed $d > 1$, MIN- \bar{d} -SS is believed to be NP -hard; however, up to now, no formal proof is known. Next the decision version of MIN- \bar{d} -SS is considered.

\bar{d} -SS (\bar{d} -SEPARABLE SUBMATRIX): Given a $t \times n$ Boolean matrix M and two integers $d, k > 0$, determine whether there is a $k \times n$ submatrix H of M that is \bar{d} -separable.

Recall that Σ_2^P is the complexity class of problems that are solvable in nondeterministic polynomial time with the help of an NP -complete set as an oracle. For instance, the following problem SAT₂ is Σ_2^P -complete ([19], Theorem 3.13): Given a Boolean formula φ over two disjoint sets X and Y of variables, determine whether there exists an assignment to variables in X so that the resulting formula (over variables in Y) is a tautology. It is easy to see that \bar{d} -SS is in Σ_2^P . It is conjectured to be Σ_2^P -complete. Here a similar problem that is a little more general than \bar{d} -SS will be considered, and its Σ_2^P -completeness will be proved.

\bar{d} -SSRR (\bar{d} -SEPARABLE SUBMATRIX WITH RESERVED ROWS): Given a $t \times n$ Boolean matrix M and three integers $d > 0$, s , and $k \geq 0$, determine whether there is a \bar{d} -separable $(s + k) \times n$ submatrix H of M that contains the first s rows of M and k rows from the remaining $t - s$ bottom rows of M .

Let φ be a Boolean formula, an *implicant* of φ is a conjunction C of literals that implies φ . The following problem is proved to be Σ_2^P -complete by Umans [55].

SHORTEST IMPLICANT CORE: Given a DNF formula $\varphi = T_1 + T_2 + \dots + T_m$, and an integer p , determine whether φ has an implicant C that consists of p literals from the last term T_m .

By a reduction from SHORTEST IMPLICANT CORE, one can obtain the following result.

Theorem 7 \bar{d} -SSRR is Σ_2^P -complete.

Proof The problem \bar{d} -SSRR can be solved by a nondeterministic machine that guesses a $(s+k) \times n$ submatrix H of M which contains the first s rows of M and then determines whether H is \bar{d} -separable. Note that the problem of determining whether a given matrix H is \bar{d} -separable is in coNP. Thus, \bar{d} -SSRR $\in \Sigma_2^P$.

Next, \bar{d} -SSRR is proved to be Σ_2^P -complete by constructing a polynomial-time reduction from SHORTEST IMPLICANT CORE to it. To define the reduction, let (φ, p) be an instance of the problem SHORTEST IMPLICANT CORE, that is, let

$$\varphi = T_1 + T_2 + \cdots + T_m$$

be a DNF formula over n variables x_1, x_2, \dots, x_n , and let p be an integer > 0 . Note that each term T_j , $1 \leq j \leq m$, of φ is a conjunction of some literals. Also, T_j is used to denote the set of these literals. Assume that the last term T_m of φ has q literals $\ell_1, \ell_2, \dots, \ell_q$. Define a $(3n+m+q) \times (2n+1)$ Boolean matrix M as follows:

1. Let the $2n+1$ columns of M be $X = \{x_1, \bar{x}_1, x_2, \bar{x}_2, \dots, x_n, \bar{x}_n, z\}$ and the $3n+m+q$ rows of M be $T = \{x_i, \bar{x}_i, u_i \mid 1 \leq i \leq n\} \cup \{t_j \mid 1 \leq j \leq m\} \cup \{c_j \mid 1 \leq j \leq q\}$.
2. For $i = 1, 2, \dots, n$, $M_{x_i} = \{x_i\}$, $M_{\bar{x}_i} = \{\bar{x}_i\}$, and $M_{u_i} = \{x_i, \bar{x}_i, z\}$.
3. For $j = 1, 2, \dots, m$, $M_{t_j} = \{x_i \mid \bar{x}_i \in T_j\} \cup \{\bar{x}_i \mid x_i \in T_j\} \cup \{z\}$. (Note that $M_{t_j} \cap T_j = \emptyset$).
4. The bottom q rows of M are $M_{c_j} = \{\ell_j, z\}$, for $j = 1, 2, \dots, q$.

Let $d = n+1$, $s = 3n+m$, and $k = p$, and consider the instance (M, d, s, k) for the problem \bar{d} -SSRR.

First assume that φ has an implicant C of size p that is a subset of T_m . Let H be the submatrix of M that consists of the first $s = 3n+m$ rows plus the $k = p$ rows M_{c_j} for which $\ell_j \in C$. The following claim is made: H is \bar{d} -separable. That is, for any subsets S_1 and S_2 of $\{x_1, \bar{x}_2, \dots, x_n, \bar{x}_n, z\}$ of size $\leq d$, there exists a row in H that separates them.

Case 1. $S_1 - \{z\} \neq S_2 - \{z\}$. Then, there exists $v \in X - \{z\}$ such that $v \in S_1 \Delta S_2$. Then, $M_v(S_1) \neq M_v(S_2)$, and so H separates S_1 from S_2 .

Case 2. $S_1 - \{z\} = S_2 - \{z\}$. Then, it must be true that $S_1 \Delta S_2 = \{z\}$. Without loss of generality, assume $S_2 = S_1 \cup \{z\}$. Note that $|S_2| \leq n+1$ implies $|S_1| \leq n$.

Subcase 2.1. There exists an integer i such that $|S_1 \cap \{x_i, \bar{x}_i\}| \neq 1$. First, if $|S_1 \cap \{x_i, \bar{x}_i\}| = 0$ for some i , then $M_{u_i}(S_1) = 0$ and $M_{u_i}(S_2) = 1$ (because $z \in S_2$). Next, if $|S_1 \cap \{x_i, \bar{x}_i\}| = 2$ for some i , then it must have $|S_1 \cap \{x_k, \bar{x}_k\}| = 0$ for some k , because $|S_1| \leq n$. Then, again $M_{u_k}(S_1) = 0 \neq 1 = M_{u_k}(S_2)$. It follows that H separates S_1 from S_2 .

Subcase 2.2. $|S_1 \cap \{x_i, \bar{x}_i\}| = 1$ for all $i \in \{1, 2, \dots, n\}$. Define a Boolean assignment $\tau : \{x_1, x_2, \dots, x_n\} \rightarrow \{\text{TRUE}, \text{FALSE}\}$ by $\tau(x_i) = \text{TRUE}$ if and only if $x_i \in S_1$. This is further divided into two subcases:

Subcase 2.2.1. τ satisfies the conjunction C . Since C is an implicant of $\varphi = T_1 + T_2 + \dots + T_m$, τ must satisfy some T_j , $1 \leq j \leq m$. Thus, $T_j \subseteq S_1$: For any $x_i \in T_j$, $\tau(x_i) = \text{TRUE}$, and so $x_i \in S_1$, and for any $\bar{x}_i \in T_j$, $\tau(\bar{x}_i) = \text{FALSE}$, and so $\bar{x}_i \in S_1$. It follows that $M_{t_j}(S_1) = 0$ since $M_{t_j} \cap T_j = \emptyset$. On the other hand, $M_{t_j}(S_2) = 1$ since $z \in M_{t_j} \cap S_2$. So, M_{t_j} , and hence H , separates S_1 from S_2 .

Subcase 2.2.2. τ does not satisfy C . Then, for some literal $\ell_j \in C$, $\tau(\ell_j) = 0$. Thus, $\ell_j \notin S_1$, and $M_{c_j}(S_1) = 0$. On the other hand, $M_{c_j}(S_2) = 1$ since $z \in M_{c_j}$. Thus, M_{c_j} , which is a row in H , separates S_1 from S_2 .

Conversely, assume that H is a $(3n + m + k) \times (2n + 1)$ submatrix of M that contains the first $3n + m$ rows of M and is \bar{d} -separable. Let C be the conjunction of literals ℓ_j for which M_{c_j} is a row in H . Then, obviously, $|C| = k$. Now the following claim is made: C is an implicant of φ .

Let $\tau : \{x_1, x_2, \dots, x_n\} \rightarrow \{\text{TRUE}, \text{FALSE}\}$ be a Boolean assignment that satisfies C . It will be showed that τ satisfies φ . Let

$$S_1 = \{x_i \mid \tau(x_i) = \text{TRUE}\} \cup \{\bar{x}_i \mid \tau(x_i) = \text{FALSE}\},$$

and $S_2 = S_1 \cup \{z\}$. Then, S_1 and S_2 can be separated by some row in H . Since $S_2 = S_1 \cup \{z\}$, they are not separable by a row M_{x_i} or $M_{\bar{x}_i}$, for any $i = 1, 2, \dots, n$. In addition, since $|S_1 \cap \{x_i, \bar{x}_i\}| = 1$ for all $i = 1, 2, \dots, n$, they cannot be separated by row M_{u_i} , for any $i = 1, 2, \dots, n$. Furthermore, note that for any literal $\ell_j \in C$, $\tau(\ell_j) = 1$ and so $\ell_j \in S_1$ and $M_{c_j}(S_1) = M_{c_j}(S_2) = 1$. Thus, S_1 and S_2 cannot be separated by any row M_{c_j} of H .

Therefore, S_1 and S_2 must be separable by a row M_{t_j} , for some $j = 1, 2, \dots, m$. That is, $M_{t_j}(S_1) = 0 \neq 1 = M_{t_j}(S_2)$. Since M_{t_j} contains the complements of the literals in T_j , $T_j \subseteq S_1$. It follows that τ satisfies the term T_j , and hence φ . \square

3.4 Conclusion

In this section, the computational complexities of problems related to nonunique probe selection are presented. The problem of verifying the minimality of a \bar{d} -separable matrix is showed to be DP -complete, and hence is intractable, unless $DP = P$. For the problem of finding a minimum \bar{d} -separable submatrix, it is conjectured to be Σ_2^P -complete and, hence, is even more difficult than the minimal \bar{d} -separability problem. To support this conjecture, the problem \bar{d} -SSRR, which is a little more general than the minimum \bar{d} -separable submatrix problem, is shown to be Σ_2^P -complete. The complexity of the original problem MIN- \bar{d} -SS remains open.

4 Parameterized Complexity Results on NGT

Given an $m \times n$ binary matrix and a positive integer d , to decide whether the matrix is d -separable (\bar{d} -separable, or d -disjunct) is a basic problem in nonadaptive group testing (NGT). They are known to be coNP-complete in classical complexity theory [18]. Thus, one should not expect any polynomial time algorithm to solve any of them. However, since in most applications $d \ll n$, an interesting question is whether there are efficient algorithms solving the above decision problems for small values of d .

In [12] by studying the parameterized complexity of the above three problems with d as the parameter, the authors gave a negative answer to the above question. More formally, they studied the parameterized decision problems p -DISJUNCTNESS-TEST, p -SEPARABILITY-TEST, and p -SEPARABILITY*-TEST defined as follows (where \mathcal{N} denotes the set of positive integers).

p -DISJUNCTNESS-TEST

Instance: A binary matrix \mathcal{M} and $d \in \mathcal{N}$.

Parameter: d .

Problem: Decide whether \mathcal{M} is d -disjunct.

p -SEPARABILITY-TEST

Instance: A binary matrix \mathcal{M} and $d \in \mathcal{N}$.

Parameter: d .

Problem: Decide whether \mathcal{M} is d -separable.

p -SEPARABILITY*-TEST

Instance: A binary matrix \mathcal{M} and $d \in \mathcal{N}$.

Parameter: d .

Problem: Decide whether \mathcal{M} is \bar{d} -separable.

The main results obtained in [12] will be presented in this section; they are summarized in the following theorem.

Theorem 8 *p -DISJUNCTNESS-TEST, p -SEPARABILITY*-TEST, and p -SEPARABILITY-TEST are all co-W[2]-complete.*

W[2] is the parameterized complexity class at the second level of the W-hierarchy, and co-W[2] is the class of all parameterized problems whose complements are in W[2]. They will be formally introduced in the sequel.

Theorem 8 indicates that, given an $m \times n$ binary matrix and a positive integer d , a deterministic algorithm with running time $f(d) \times (mn)^{O(1)}$ (where f is an arbitrary computable function) to decide whether the matrix is d -separable (\bar{d} -separable, or d -disjunct) does not exist unless the class W[2] collapses to FPT (the class of all fixed-parameter tractable problems), which is commonly conjectured to be false.

4.1 Preliminaries

Before proving [Theorem 8](#), the notions of fixed-parameter tractability, relational structures, first-order logic, and the W-hierarchy of parameterized complexity classes are formally introduced.

4.1.1 Fixed-Parameter Tractability

The theory of *fixed-parameter tractability* [16, 27] has received considerable attention in recent years, for both theoretical research and practical computation. The notations and conventions in [27] are adopted here. Let Σ denote a fixed finite alphabet. A *parameterization* of Σ^* is a polynomial time computable mapping $\kappa : \Sigma^* \rightarrow \mathcal{N}$. A *parameterized problem* (over Σ) is a pair (Q, κ) consisting of a set $Q \subseteq \Sigma^*$ and a parameterization κ of Σ^* .

An algorithm A with input alphabet Σ is an *fpt-algorithm with respect to κ* , if for every $x \in \Sigma^*$ the running time of A on input x is at most $f(\kappa(x))|x|^{O(1)}$, for some computable function f . A parameterized problem (Q, κ) is *fixed-parameter tractable* if there is an fpt-algorithm with respect to κ that decides Q . The key point of the definition of fpt-algorithm is that the superpolynomial growth of running time is confined to the parameter $\kappa(x)$, which is usually known to be comparatively small. The class of all fixed-parameter tractable problems is denoted by FPT.

Many NP-hard problems such as the VERTEX COVER problem [8] and the ML TYPE-CHECKING problem [37] have been shown to be fixed-parameter tractable. On the other hand, there is strong theoretical evidence that certain well-known parameterized problems, for instance the INDEPENDENT SET problem and the DOMINATING SET problem, are not fixed-parameter tractable [16]. This evidence is provided, similar to the theory of NP-completeness, via a completeness theory based on the following notion of reductions: Let (Q, κ) and (Q', κ') be parameterized problems over alphabets Σ and Σ' , respectively. An *fpt-reduction* from (Q, κ) to (Q', κ') is a mapping $R : \Sigma^* \rightarrow (\Sigma')^*$ such that:

1. For all $x \in \Sigma^*, x \in Q$ if and only if $R(x) \in Q'$.
2. R is computable by an fpt-algorithm (with respective to κ). That is, there is a computable function f such that $R(x)$ is computable in time $f(\kappa(x))|x|^{O(1)}$.
3. There is a computable function $g : \mathcal{N} \rightarrow \mathcal{N}$ such that $\kappa'(R(x)) \leq g(\kappa(x))$, for all $x \in \Sigma^*$.

In the above definition, the last requirement is to ensure that class FPT is closed under fpt-reductions, that is, if a parameterized problem (Q, κ) is reducible to another parameterized problem (Q', κ') and $(Q', \kappa') \in \text{FPT}$, then $(Q, \kappa) \in \text{FPT}$.

4.1.2 Relational Structures

In later discussions, the conventions in descriptive complexity theory are adopted, in which instances of decision problems are viewed as structures of some vocabulary instead of languages over some finite alphabet.

A (*relational*) *vocabulary* τ is a set of relation symbols. Each relation symbol $R \in \tau$ has an *arity* $\text{arity}(R) \geq 1$. A *structure* \mathcal{A} of vocabulary τ consists of a set A called the *universe* and an interpretation $R^{\mathcal{A}} \subseteq A^{\text{arity}(R)}$ of each relation symbol $R \in \tau$. For a tuple $\bar{a} \in A^{\text{arity}(R)}$, write $R^{\mathcal{A}}\bar{a}$ (or $\bar{a} \in R^{\mathcal{A}}$) to denote that \bar{a} belongs to the relation $R^{\mathcal{A}}$. Here only nonempty finite vocabularies and structures with a finite universe are considered.

Recall that a hypergraph is a pair $H = (V, E)$ consisting of a set V of vertices and a set E of hyperedges. Each hyperedge is a subset of V . Graphs are hypergraphs with hyperedges of cardinality two. The following example illustrates how to represent a hypergraph using a relational structure.

Example 1 Let τ_{HG} be the vocabulary consisting of the unary relation symbols *VERT* and *EDGE* and the binary relation symbol *I*. A hypergraph $H = (V, E)$ can be represented by a relational structure \mathcal{H} of vocabulary τ_{HG} as follows:

- The universe of \mathcal{H} is $V \cup E$.
- $\text{VERT}^{\mathcal{H}} := V$ and $\text{EDGE}^{\mathcal{H}} := E$.
- $I^{\mathcal{H}} := \{(v, e) : v \in V, e \in E, \text{ and } v \in e\}$ is the *incidence relation*.

4.1.3 First-Order Logic

First the syntax of first-order logic is briefly recalled. Let τ be a vocabulary. *Atomic* first-order formulas of vocabulary τ are of the form $x = y$ or $Rx_1 \dots x_\ell$, where $R \in \tau$ is ℓ -ary (i.e., has arity ℓ) and x, y, x_1, \dots, x_ℓ are variables. First-order formulas of vocabulary τ are built from atomic formulas using Boolean connectives \wedge (and), \vee (or), \neg (negation), together with the existential and universal quantifiers \exists and \forall . The connectives \rightarrow (implication) and \leftrightarrow (equivalence) are not part of the language defining first-order formulas, but they are used as abbreviations: $\varphi \rightarrow \psi$ stands for $\neg\varphi \vee \psi$, and $\varphi \leftrightarrow \psi$ stands for $(\varphi \rightarrow \psi) \wedge (\psi \rightarrow \varphi)$.

A variable x is called a free variable of φ if x occurs in φ but is not in the scope of a quantifier binding x . Write $\varphi(x_1, \dots, x_\ell)$ to indicate that all free variables of φ belong to set $\{x_1, \dots, x_\ell\}$. A formula without free variables is called a *sentence*. Let both Σ_0 and Π_0 denote the class of quantifier-free first-order formulas. For $t \geq 0$, let Σ_{t+1} be the class of all formulas $(\exists x_1 \dots \exists x_\ell)\varphi$, where $\varphi \in \Pi_t$, and let Π_{t+1} be the class of all formulas $(\forall x_1 \dots \forall x_\ell)\varphi$, where $\varphi \in \Sigma_t$.

For formulas of second-order logic, in addition to the individual variables, they may also contain *relation variables*; each of the relation variables has a prescribed arity. Here lowercase letters (e.g., x, y, z) are used to denote individual variables, and uppercase letters (e.g., X, Y, Z) are used to denote relation variables. As in [27], for convenience *free* relation variables are allowed to be in first-order formulas, since the crucial difference between first-order and second-order logic is not that second-order formulas can have relation variables, but that second-order formulas can quantify over relations. Therefore, here the syntax of first-order logic is enhanced by

including new atomic formulas of the form $Xx_1 \dots x_\ell$, where X is an ℓ -ary relation variable. The meaning of formula $Xx_1 \dots x_\ell$ is: The tuple of elements interpreting (x_1, \dots, x_ℓ) is contained in the relation interpreting the relation variable X . The classes such as Σ_t and Π_t are also extended to include formulas with free relation variables. It is worth emphasizing again that in first-order logic quantification over relation variables is now allowed.

4.1.4 W-Hierarchy

First a brief introduction to the W-hierarchy of parameterized complexity classes is given. Roughly speaking, the W-hierarchy classifies problems according to the syntactic form of their definitions, and the definitions are formalized using languages of mathematical logic. The W-hierarchy can be defined in several different ways; here the following definition based on the *weighted Fagin-defined problems* is adopted.

Let $\varphi(X)$ be a first-order formula with a free relation variable X of arity s . Define $p\text{-WD}_\varphi$ to be the following parameterized decision problem.

$p\text{-WD}_\varphi$:

Instance: A structure \mathcal{A} and $k \in \mathcal{N}$.

Parameter: k .

Problem: Decide whether there is a relation $S \subseteq A^s$ of cardinality k such that $\mathcal{A} \models \varphi(S)$.

Here, $\mathcal{A} \models \varphi(S)$ stands for that structure \mathcal{A} satisfies sentence $\varphi(S)$ (or, \mathcal{A} is a model of $\varphi(S)$), and S is called a *solution* for φ in structure \mathcal{A} . The readers are referred to, for example, Sect. 4.2 of [27], for more detailed introduction to the semantics of first-order formulas.

For a class Φ of first-order formulas, let $p\text{-WD-}\Phi$ be the class of all parameterized problems $p\text{-WD}_\varphi$ with $\varphi \in \Phi$. For $t \geq 1$, define $W[t] := [p\text{-WD-}\Pi_t]^{\text{fpt}}$, which is the class of all parameterized problems that are fpt-reducible to some problems in $p\text{-WD-}\Pi_t$. The classes $W[t]$, for $t \geq 1$, form the W-hierarchy. Thus, the levels of W-hierarchy essentially correspond to the number of alternations between universal and existential quantifiers in the definitions of their complete problems. Problems hard for $W[1]$ or higher class are assumed not to be fixed-parameter tractable. For instance, the INDEPENDENT SET problem is $W[1]$ -complete, and the DOMINATING SET problem is $W[2]$ -complete.

For a parameterized problem (Q, κ) over the alphabet Σ , let $(Q, \kappa)^c$ denote its complement, that is, the parameterized problem $(\Sigma^* \setminus Q, \kappa)$. Let C be a parameterized complexity class. Then $\text{co-}C$ is defined to be the class of all parameterized problems (Q, κ) such that $(Q, \kappa)^c \in C$. Clearly, $\text{FPT} = \text{co-FPT}$. From the definition of fpt-reductions, it is easy to see that if class C is closed under fpt-reductions, so is $\text{co-}C$. In particular, each class $W[t]$, $t \geq 1$, gives rise to a new parameterized complexity class $\text{co-}W[t]$. Also, it is easy to prove that if (Q, κ) is complete in parameterized complexity class C under fpt-reductions, then $(Q, \kappa)^c$ is complete in class $\text{co-}C$ under fpt-reductions.

4.2 Proof of Theorem 8

Now the proof of [Theorem 8](#) is ready to presented. For a binary matrix M , let R_M be the set consisting of all rows in M , and let C_M be the set consisting of all columns in M .

Relational Structure for a Binary Matrix. Let τ_{BM} be the vocabulary consisting of the unary relation symbols ROW and $COLUMN$ and the binary relation symbol I . Then, the binary matrix M can be represented by a structure \mathcal{M} of vocabulary τ_{BM} , where the universe of \mathcal{M} is $R_M \cup C_M$, and the interpretations for the relation symbols in τ_{BM} are as follows:

- $ROW^{\mathcal{M}} := R_M$.
- $COLUMN^{\mathcal{M}} := C_M$.
- $I^{\mathcal{M}} := \{(r, c) : r \in R_M, c \in C_M, \text{ and } M(r, c) = 1\}$, which is the incidence relation.

The proof of [Theorem 8](#) is partitioned into the following six lemmas:

Lemma 5 p -DISJUNCTNESS-TEST $\in \text{co-W[2]}$.

Proof Consider the following complement problem of p -DISJUNCTNESS-TEST.

p -NONDISJUNCTNESS-TEST

Instance: A binary matrix \mathcal{M} and $d \in \mathcal{N}$.

Parameter: d .

Problem: Decide whether \mathcal{M} is NOT d -disjunct.

A Π_2 formula $nondisj(X)$ with a free relation variable X of arity 2 will be defined, and p -NONDISJUNCTNESS-TEST will be showed to be equal to p -WD $_{nondisj(X)}$ (see [Sect. 4.1.4](#) for the definition of problem p -WD $_{\varphi}$). This implies that p -NONDISJUNCTNESS-TEST is in p -WD- Π_2 , therefore is in W[2].

A binary matrix is not d -disjunct if and only if there is a set D of d columns and another column $c \notin D$ such that $U(D)$ covers c . The idea here is assuming that the solution S to X is of the form $\{(c_i, c) : c_i \in D\}$. Therefore, X should be a binary relation variable, and the solution S to X should have cardinality d .

Define

$$\chi_1 := \forall c_1 \forall c_2 (Xc_1c_2 \rightarrow (COLUMN c_1 \wedge COLUMN c_2 \wedge (c_1 \neq c_2))),$$

and define

$$\chi_2 := \forall c_3 \forall c_4 \forall c_5 \forall c_6 ((Xc_3c_4 \wedge Xc_5c_6) \rightarrow (c_4 = c_6)).$$

Here χ_1 and χ_2 are to guarantee that the solution S to X of cardinality d has the form $\{(c_1, c), \dots, (c_d, c)\}$, where $c \in C_M$, $c_i \in C_M$, and $c_i \neq c$, for $1 \leq i \leq d$. Define

$$\text{nondisj}'(X) := \forall r \exists c_7 \exists c_8 (ROWr \rightarrow (Xc_7c_8 \wedge (Irc_8 \rightarrow Irc_7))).$$

Here $\text{nondisj}'(X)$ is to guarantee that the solution S to X satisfies that the union of columns in $\{c_i : (c_i, c) \in S\}$ covers c (so that \mathcal{M} is not d -disjunct). Finally, define

$$\text{nondisj}(X) := \chi_1 \wedge \chi_2 \wedge \text{nondisj}'(X),$$

which is equivalent to a Π_2 formula.

From the above definition, clearly if there exists a relation $S \subseteq C_M^2$ of cardinality d such that $\mathcal{M} \models \text{nondisj}(S)$, then \mathcal{M} is not d -disjunct. On the other hand, if \mathcal{M} is not d -disjunct, then there exist a subset D of d columns c_1, \dots, c_d and another column $c \notin D$ such that c is covered by $U(D)$. It is not hard to verify that the relation $S = \{(c_1, c), \dots, (c_d, c)\}$ satisfies $\mathcal{M} \models \text{nondisj}(S)$. Therefore, \mathcal{M} is not d -disjunct if and only if there exists a relation S of cardinality d such that $\mathcal{M} \models \text{nondisj}(S)$. That is, p -NONDISJUNCTNESS-TEST is p -WD _{$\text{nondisj}(X)$} . Thus, p -NONDISJUNCTNESS-TEST \in W[2], and so p -DISJUNCTNESS-TEST \in co-W[2]. \square

Lemma 6 p -SEPARABILITY-TEST \in co-W[2].

Proof Consider the following complement problem of p -SEPARABILITY-TEST.

p -NONSEPARABILITY-TEST

Instance: A binary matrix \mathcal{M} and $d \in \mathcal{N}$.

Parameter: d .

Problem: Decide whether \mathcal{M} is NOT d -separable.

A formula $\text{nonsep}(Y)$ with a free relation variable Y of arity 2 will be defined, and p -NONSEPARABILITY-TEST will be shown to be equal to p -WD _{$\text{nonsep}(Y)$} .

A binary matrix is not d -separable if and only if there exist two distinct subsets D_1 and D_2 , each contains d columns such that $U(D_1) = U(D_2)$. Assume that $D_1 = \{c_{11}, c_{12}, \dots, c_{1d}\}$ and $D_2 = \{c_{21}, c_{22}, \dots, c_{2d}\}$. The idea is to assume that the solution S to Y is of the form $\{(c_{11}, c_{21}), (c_{12}, c_{22}), \dots, (c_{1d}, c_{2d})\}$, and so Y should be a binary relation variable, and the solution S to Y should have cardinality d . Define the formula $\text{nonsep}(Y)$ such that it satisfies the following: There exists a relation $S \subseteq C_M^2$ of cardinality d such that $\mathcal{M} \models \text{nonsep}(S)$ if and only if \mathcal{M} is not d -separable.

Define

$$\chi_3 := \forall c_1 \forall c_2 (Yc_1c_2 \rightarrow (\text{COLUMN}c_1 \wedge \text{COLUMN}c_2)),$$

$$\chi_4 := \forall c_3 \forall c_4 \forall c_5 \forall c_6 ((Yc_3c_4 \wedge Yc_5c_6) \rightarrow ((c_3 = c_5) \leftrightarrow (c_4 = c_6))),$$

and

$$\chi_5 := \exists c_7 \exists c_8 \forall c_9 ((Yc_7c_8 \wedge \neg Yc_9c_7)).$$

Here χ_3 is to guarantee that the relation variable $Y \subseteq C_M^2$; χ_4 is to build a bijection between the first component of elements in S and the second component of elements in S , which guarantees that the two subsets $\{c_{1i} : \exists c \text{ s.t. } (c_{1i}, c) \in S\}$ and $\{c_{2j} : \exists c \text{ s.t. } (c, c_{2j}) \in S\}$ (which intend to be D_1 and D_2 , respectively) have the same cardinality; χ_5 is to guarantee that the two subsets $\{c_{1i} : \exists c \text{ s.t. } (c_{1i}, c) \in S\}$ and $\{c_{2j} : \exists c \text{ s.t. } (c, c_{2j}) \in S\}$ are distinct from each other. Define

$$\begin{aligned} \text{nonsep}'(Y) &:= \forall r(\text{ROWr} \rightarrow ((\exists c_{10} \exists c_{11} Y c_{10} c_{11} \wedge Irc_{10}) \\ &\quad \Leftrightarrow (\exists c_{12} \exists c_{13} Y c_{12} c_{13} \wedge Irc_{13}))), \end{aligned}$$

which is to guarantee that the solution S to Y satisfies that the union of columns in $\{c_{1i} : \exists c \text{ s.t. } (c_{1i}, c) \in S\}$ is equal to the union of columns in $\{c_{2j} : \exists c \text{ s.t. } (c, c_{2j}) \in S\}$. From basic logic computation, it is not hard to verify that $\text{nonsep}'(Y)$ is a Π_2 formula with free relation variable Y . Finally, define

$$\text{nonsep}(Y) := \chi_3 \wedge \chi_4 \wedge \chi_5 \wedge \text{nonsep}'(Y).$$

From the above definition of $\text{nonsep}(X)$, if a relation $S \subseteq C_M^2$ of cardinality d satisfies that $\mathcal{M} \models \text{nonsep}(S)$, then the two subsets $\{c_{1i} : \exists c \text{ s.t. } (c_{1i}, c) \in S\}$ and $\{c_{2j} : \exists c \text{ s.t. } (c, c_{2j}) \in S\}$ both contain d columns of \mathcal{M} and are distinct from each other; moreover, their unions are identical. This implies that \mathcal{M} is not d -separable. On the other hand, if \mathcal{M} is not d -separable, then there exist two distinct subsets D_1 and D_2 , each contains d columns such that $U(D_1) = U(D_2)$. Assume that $D_1 = \{c_{11}, \dots, c_{1d}\}$ and $D_2 = \{c_{21}, \dots, c_{2d}\}$. It is not hard to verify that the relation

$$S = \{(c_{11}, c_{21}), (c_{12}, c_{22}), \dots, (c_{1d}, c_{2d})\}$$

satisfies $\mathcal{M} \models \text{nonsep}(S)$.

From above, there exists a relation $S \subseteq C_M^2$ of cardinality d such that $\mathcal{M} \models \text{nonsep}(S)$ if and only if \mathcal{M} is not d -separable; therefore, p -NONSEPARABILITY-TEST is p -WD _{$\text{nonsep}(Y)$} . χ_3 and χ_4 are Π_1 formulas; χ_5 is a Σ_2 formula; $\text{nonsep}'(Y)$ is a Π_2 formula; therefore,

$$\text{nonsep}(Y) = \chi_3 \wedge \chi_4 \wedge \chi_5 \wedge \text{nonsep}'(Y)$$

is equivalent to a Σ_3 formula, which implies that p -NONSEPARABILITY-TEST is in p -WD- Σ_3 . Here the following fact is applied: p -WD- $\Sigma_3 \subseteq p$ -WD- Π_2 (more generally, p -WD- $\Sigma_{t+1} \subseteq p$ -WD- Π_t , for $t \geq 1$). The main idea to prove this conclusion is not complicated; the reader is referred to, e.g., Proposition 5.4 in [27] for the proof). Thus, p -NONSEPARABILITY-TEST $\in W[2]$, and so p -SEPARABILITY-TEST $\in \text{co-W}[2]$. \square

Lemma 7 p -SEPARABILITY*-TEST $\in \text{co-W}[2]$.

Proof Since $\text{W}[2]$ is closed under fpt-reductions, so is $\text{co-W}[2]$. It will be shown next that $p\text{-SEPARABILITY}^*\text{-TEST}$ is fpt-reducible to $p\text{-SEPARABILITY-TEST}$. Since the latter is in $\text{co-W}[2]$ ([Lemma 6](#)), this implies that $p\text{-SEPARABILITY}^*\text{-TEST} \in \text{co-W}[2]$. The reduction can be obtained immediately from the following fact ([Lemma 2.1.6 in \[17\]](#)): A binary matrix M' containing a zero column is d -separable if and only if the matrix M obtained by removing this zero column from M' is \bar{d} -separable.

Let (M, d) be an instance of $p\text{-SEPARABILITY}^*\text{-TEST}$, where M is a binary matrix and the parameter d is a positive integer. Map (M, d) to (M', d) , where M' is obtained by adding a zero column to M . From the above lemma, $(M, d) \in p\text{-SEPARABILITY}^*\text{-TEST}$ if and only if $(M', d) \in p\text{-SEPARABILITY-TEST}$. It is easy to see that this is an fpt-reduction from $p\text{-SEPARABILITY}^*\text{-TEST}$ to $p\text{-SEPARABILITY-TEST}$.

Lemma 8 $p\text{-DISJUNCTNESS-TEST}$ is $\text{co-W}[2]$ -complete.

Proof A *hitting set* in a hypergraph $\mathcal{H} = (V, E)$ is a set T of vertices that intersects each hyperedge, that is, $T \cap e \neq \emptyset$ for all $e \in E$. The classical **HITTING-SET** problem is to find a hitting set of a given cardinality k in a given hypergraph \mathcal{H} , which is known to be NP-complete. The following parameterized hitting set problem is $\text{W}[2]$ -complete (see, e.g., [Theorem 7.14 in \[27\]](#)).

$p\text{-HITTING-SET}$

Instance: A hypergraph \mathcal{H} and $k \in \mathcal{N}$.

Parameter: k .

Problem: Decide whether \mathcal{H} has a hitting set of k vertices.

An fpt-reduction from $p\text{-HITTING-SET}$ to $p\text{-NONDISJUNCTNESS-TEST}$ will be given, based on an idea similar to that in [\[18\]](#). Let (\mathcal{H}, k) with $\mathcal{H} = (V, E)$ be an instance of $p\text{-HITTING-SET}$, where $V = \{1, \dots, n\}$, $E = \{e_1, \dots, e_m\}$, and each e_i , $1 \leq i \leq m$, is a subset of V . Define $d = k$, and define an $(n+m) \times (n+1)$ binary matrix M with rows R_i as follows (here each row is represented as a subset of the set of all columns $\{1, 2, \dots, n+1\}$, in the most natural way):

$$\begin{aligned} R_i &= \{i\}, & i &= 1, \dots, n; \\ R_{n+j} &= e_j \cup \{n+1\}, & j &= 1, \dots, m. \end{aligned}$$

First, assume that \mathcal{H} has a hitting set $T \subseteq V$ of size k . Consider the subset $S_1 = T$ of columns of M . Since T is a hitting set of \mathcal{H} , $U(S_1)$ covers column $n+1$. Notice that $|S_1| = d$ and column $n+1$ is not in S_1 , M is not d -disjunct.

Conversely, assume that M is not d -disjunct. Then, there exist a subset S_1 of d columns in $\{1, 2, \dots, n+1\}$ and another column $c \notin S_1$ such that $U(S_1)$ covers c . From the way the first n rows of matrix M are defined, c can only be column $n+1$. Thus, column $n+1$ is not in S_1 . Set $T = S_1$, then $|T| = k$, and T is a subset of V . Since $U(S_1)$ covers column $n+1$, it is easy to see that T is a hitting set of \mathcal{H} .

It is not hard to verify that the above is an fpt-reduction. Therefore, p -NONDISJUNCTNESS-TEST is W[2]-complete, and so p -DISJUNCTNESS-TEST is co-W[2]-complete. \square

Lemma 9 p -SEPARABILITY*-TEST is co-W[2]-complete.

Proof To prove the lemma, an ftp-reduction from p -HITTING-SET to p -NONSEPARABILITY*-TEST will be given. For an instance (\mathcal{H}, k) of p -HITTING-SET, define matrix M in the same way as in the proof of Lemma 8, and define $d = k + 1$. Next the correctness of this reduction will be shown.

First, assume that \mathcal{H} has a hitting set $T \subseteq V$ of size k . Consider the following two subsets of columns in M : $S_1 = T$ and $S_2 = T \cup \{n + 1\}$. Then, for $1 \leq i \leq n$, it is obvious that $U(S_1)_i = U(S_2)_i$; for $n < i \leq n + m$, since T is a hitting set of \mathcal{H} , $U(S_1)_i = 1 = U(S_2)_i$. Notice that $|S_1|, |S_2| \leq d$ and $S_1 \neq S_2$, M is not \bar{d} -separable.

Conversely, assume that M is not \bar{d} -separable. Then, there exist two subsets S_1 and S_2 of columns in $\{1, 2, \dots, n + 1\}$ such that $|S_1|, |S_2| \leq d$, $S_1 \neq S_2$, and $U(S_1) = U(S_2)$. Since $U(S_1)_i = U(S_2)_i$ for $1 \leq i \leq n$, it follows that

$$S_1 \cap \{1, \dots, n\} = S_2 \cap \{1, \dots, n\}.$$

To have $S_1 \neq S_2$, column $n + 1$ must belong to exactly one of S_1 and S_2 . Without loss of generality, assume that $n + 1 \notin S_1$ and $n + 1 \in S_2$. Set $T = S_1$, then

$$|T| = |S_1| = |S_2| - 1 \leq d - 1 = k,$$

and T is a subset of V . From $U(S_1)_i = U(S_2)_i = 1$ for $n < i \leq n + m$, T is a hitting set of \mathcal{H} .

Therefore, p -NONSEPARABILITY*-TEST is W[2]-complete, and so p -SEPARABILITY*-TEST is co-W[2]-complete.

Lemma 10 p -SEPARABILITY-TEST is co-W[2]-complete.

Proof Since as proved before in Lemma 7 that p -SEPARABILITY*-TEST is fpt-reducible to p -SEPARABILITY-TEST, and in Lemma 9 that p -SEPARABILITY*-TEST is co-W[2]-complete, p -SEPARABILITY-TEST is co-W[2]-hard. Together with Lemma 6 that p -SEPARABILITY-TEST \in co-W[2], it is obtained that p -SEPARABILITY-TEST is co-W[2]-complete.

4.3 Discussion

In this section, the parameterized complexity is established for the following three basic problems in pooling design: Given an $m \times n$ binary matrix and a positive integer d , to decide whether the matrix is d -separable (\bar{d} -separable), or

d -disjunct). It is showed that these problems are co-W[2]-complete; thus, do not admit algorithms with running time $f(d) \times (mn)^{O(1)}$ for any computable function f . The best known algorithms for the above general problems are all in a brute-force manner. It is interesting to investigate that whether these problems admit better algorithms. For instance, are there algorithms with running time $n^{o(d)} O(m)$ to solve these problems when d is small compared to n ?

5 Upper Bounds on the Minimum Number of Rows of Disjunct Matrices

A 0-1 matrix is d -*disjunct* if no column is covered by the union of any d other columns, where the union means the bitwise Boolean sum of these d column vectors. In other words, a 0-1 matrix is called d -disjunct if for any column C and any d other columns, there exists at least one row such that the row has value 1 at column C and value 0 at all d other columns. The same structure is also called *cover-free family* [25, 29, 53] in combinatorics and *superimposed code* [22, 23, 34] in information theory. It is called a d -disjunct matrix in group testing [17, 32, 39]. A 0-1 matrix is $(d; z)$ -*disjunct* [22, 39] if for any column C and any d other columns, there exist at least z rows such that each of them has value 1 at column C and value 0 at all the other d columns. Thus, d -disjunct is $(d; 1)$ -disjunct. Besides other applications, d -disjunct and $(d; z)$ -disjunct matrices form the basis for error-free and error-tolerant nonadaptive group testing algorithms, respectively. These algorithms have applications in many practical areas such as DNA library screening [3, 6, 17, 43] and multi-access communications [57].

Let $t(d, n)$ denote the minimum number of rows required by a d -disjunct matrix with n columns. The bounds on $t(d, n)$ have been extensively studied in the fields of combinatorics, information theory, and group testing, under different terminologies. For lower bounds, it is known that $t(d, n) = \Omega\left(\frac{d^2 \log n}{\log d}\right)$ [21, 29, 53]. In particular, D'yachkov and Rykov [21] proved that $t(d, n) \geq \frac{d^2}{2 \log d} (1 + o(1)) \log n$, which is the best lower bound so far. For upper bounds on $t(d, n)$, it is known that $t(d, n) = O(d^2 \log n)$ [2, 22, 32, 33, 45, 50]. In [22], Dyachkov, Rykov, and Rashad obtained the following asymptotic upper bound on $t(d, n)$ with a rather involved proof, which is currently the best.

Theorem 9 (Dyachkov, Rykov, and Rashad [22]) *For d constant and $n \rightarrow \infty$,*

$$t(d, n) \leq \frac{d}{A_d} [1 + o(1)] \log n,$$

where

$$A_d = \max_{0 \leq p \leq 1} \max_{0 \leq P \leq 1} \left\{ -(1 - P) \log(1 - p^d) + d \left[P \log \frac{p}{P} + (1 - P) \log \frac{1 - p}{1 - P} \right] \right\}.$$

Moreover, $A_d \rightarrow \frac{1}{d \log e}$ as $d \rightarrow \infty$.

For $(d; z)$ -disjunct matrices, let $t(d, n; z)$ denote the minimum number of rows required by a $(d; z)$ -disjunct matrix with n columns. For given d and z , D'yachkov, Rykov, and Rashad [22] studied the value of $\lim_{n \rightarrow \infty} \frac{\log n}{t}$, among others, and they proved that $t(d, n; z) \geq c \left[\frac{d^2 \log n}{\log d} + (z - 1)d \right]$ where c is a constant.

In [13], by using q -ary $(d, 1)$ -disjunct matrices [17, 20] and the probabilistic method (see, e.g., [1]), the authors gave a very short proof for the currently best upper bound on $t(d, n)$. In contrast to the previous result in [22] (**Theorem 9**), which is an asymptotic upper bound, the upper bound on $t(d, n)$ in [13] does not contain the asymptotic term $o(1)$. Also, the method in [13] is generalized to obtain a new upper bound on $t(d, n; z)$. These results will be presented in this section.

5.1 Upper Bounds on $t(d, n)$

Theorem 10 For $n > d \geq 1$,

$$t(d, n) \leq \frac{d + 1}{B_d} \log n,$$

where $B_d = \max_{q > 1} \frac{-\log \left[1 - \left(1 - \frac{1}{q}\right)^d \right]}{q}$. Moreover, $B_d \rightarrow \frac{1}{d \log e}$ as $d \rightarrow \infty$.

Before proving the above theorem, the concept of q -ary $(d, 1)$ -disjunct matrix will be first introduced: A matrix is called q -ary $(d, 1)$ -disjunct if it is q -ary, and for any column C and any set D of d other columns, there exists an element in C such that the element does not appear in any column of D in the same row.

As described in [17, 20], one can transform a q -ary $(d, 1)$ -disjunct matrix M to a (binary) d -disjunct matrix M' as follows. Replace each row R_i of M by several rows indexed with entries of R_i . For each entry x of R_i , the row with index x is obtained from R_i by turning all x 's into 1's and all others into 0's. The following fact is useful in later proof, which is the same as **Theorem 1** only using different notations:

Fact 2 (Theorem 3.6.1 in [17]) A $t \times n$ q -ary $(d, 1)$ -disjunct matrix M yields a $t' \times n$ d -disjunct matrix M' with $t' \leq tq$.

Now it is time to present the proof of **Theorem 10**.

Proof of Theorem 10: Given $n > d \geq 1$, first construct a random $t \times n$ q -ary ($q > 1$) matrix M with each entry assigned randomly and uniformly from $\{1, 2, \dots, q\}$, where q and t will be specified later. For each column C and a set D of d other columns, for each element c_i ($i = 1, 2, \dots, t$) of C , the probability that c_i appears in some column of D in the same row is $1 - (1 - \frac{1}{q})^d$. Thus, the probability that every element of C appears in some column of D in the same row is $[1 - (1 - \frac{1}{q})^d]^t$.

M is not $(d, 1)$ -disjunct if and only if there exist a column C and a set D of d other columns such that the above holds. Therefore, the probability that M is not $(d, 1)$ -disjunct is no more than

$$(n - d) \binom{n}{d} [1 - (1 - \frac{1}{q})^d]^t.$$

What follows next is to try to minimize tq , the number of rows of the d -disjunct matrix M' as in Fact 2, under the condition that q and t satisfy

$$n^{d+1} [1 - (1 - \frac{1}{q})^d]^t \leq 1. \quad (1)$$

Notice that Eq. (1) implies

$$(n - d) \binom{n}{d} [1 - (1 - \frac{1}{q})^d]^t < 1;$$

thus, the probability that M is $(d, 1)$ -disjunct is greater than zero. Therefore, by probabilistic argument, Eq. (1) implies the existence of a $t \times n$ q -ary $(d, 1)$ -disjunct matrix, and so a d -disjunct matrix with n columns and at most tq rows.

To satisfy Eq. (1), let

$$t = \frac{(d + 1) \log n}{-\log[1 - (1 - \frac{1}{q})^d]}.$$

Define

$$B_d(q) = \frac{-\log[1 - (1 - \frac{1}{q})^d]}{q},$$

then

$$tq = \frac{(d + 1) \log n}{B_d(q)}.$$

Let q_0 be the point that maximizes $B_d(q)$, and let $B_d = B_d(q_0)$ (one can estimate that $q_0 = \Theta(d)$ and $B_d = \Theta(\frac{1}{d})$, since the proof here can stand alone without this observation; they are put into Lemma 11) in later part. By assigning $q = q_0$, it follows that

$$t(d, n) \leq (tq)|_{q=q_0} = \frac{(d + 1) \log n}{B_d(q_0)} = \frac{(d + 1) \log n}{B_d}.$$

Next estimate B_d as $d \rightarrow \infty$. Since $(1 - \frac{1}{q})^q < \frac{1}{e}$ for $q > 1$,

$$\left(1 - \frac{1}{q}\right)^d < \left(\frac{1}{e}\right)^{\frac{d}{q}} = e^{-\frac{d}{q}},$$

and

$$-\log[1 - (1 - \frac{1}{q})^d] < -\log(1 - e^{-\frac{d}{q}}).$$

It follows that

$$\begin{aligned} B_d(q) &= \frac{-\log[1 - (1 - \frac{1}{q})^d]}{q} \\ &< \frac{-\log(1 - e^{-\frac{d}{q}})}{q} \\ &= \frac{1}{d \ln 2} \left[-\frac{d}{q} \ln(1 - e^{-\frac{d}{q}}) \right]. \end{aligned}$$

Let $x = e^{-\frac{d}{q}}$, then $-\frac{d}{q} = \ln x$, and

$$B_d(q) < \frac{1}{d \ln 2} \ln x \ln(1 - x).$$

Since $\ln x \ln(1 - x)$ achieves its maximum at $x = \frac{1}{2}$, it follows that $B_d(q) < \frac{\ln 2}{d}$ for $q > 1$. Thus, $B_d < \frac{\ln 2}{d}$ for $d \geq 1$. On the other hand, when q satisfies $(1 - \frac{1}{q})^d = \frac{1}{2}$, as $d \rightarrow \infty$, it is easy to see that $\frac{q}{d} \rightarrow \frac{1}{\ln 2}$, and $B_d(q) = \frac{1}{q} \rightarrow \frac{\ln 2}{d}$. Therefore, as $d \rightarrow \infty$, $B_d \rightarrow \frac{\ln 2}{d} = \frac{1}{d \log e}$. \square

Lemma 11 Given $d \geq 1$, let $q_0 = q_0(d)$ be the point that maximizes $B_d(q) = \frac{-\log[1 - (1 - \frac{1}{q})^d]}{q}$ for $q > 1$. Then, as $d \rightarrow \infty$, $q_0(d) = \Theta(d)$, and $B_d = B_d(q_0) = \Theta(\frac{1}{d})$.

Proof Notice that if q_1 satisfies $(1 - \frac{1}{q_1})^d = \frac{1}{2}$, then $q_1 = \Theta(d)$, since $\frac{q_1}{d} \rightarrow \frac{1}{\ln 2}$ as $d \rightarrow \infty$. Moreover, $B_d(q_1) = \frac{1}{q_1} = \Theta(\frac{1}{d})$. The lemma is proved by contradiction. First assume that $q_0 = O(d)$ does not hold, that is, for any $c > 0$ and any $d_0 > 0$, there exists $d > d_0$ such that $q_0(d) > cd$. Then, since $\frac{q_0}{d} > c$, as $c \rightarrow \infty$,

$$\begin{aligned} B_d(q_0)d &= \frac{-\log[1 - (1 - \frac{1}{q_0})^d]}{q_0}d \\ &\sim \frac{-\log[1 - (1 - \frac{d}{q_0})]}{q_0}d \\ &= \frac{\log \frac{q_0}{d}}{\frac{q_0}{d}} \\ &= o(1), \end{aligned}$$

here $a \sim b$ means that $\lim_{c \rightarrow \infty} \frac{a}{b} = 1$. Thus,

$$B_d(q_0) = \frac{o(1)}{d}.$$

However, this is a contradiction since q_0 is the maximum point of $B_d(q)$ and $B_d(q_1) = \Theta(\frac{1}{d})$ with $(1 - \frac{1}{q_1})^d = \frac{1}{2}$.

On the other hand, assume that $q_0 = \Omega(d)$ does not hold, that is, for any $c > 0$ and any $d_0 > 0$, there exists $d > d_0$ such that $q_0(d) < cd$. Then,

$$\begin{aligned} B_d(q_0)d &= \frac{-\log[1 - (1 - \frac{1}{q_0})^d]}{q_0}d \\ &= \frac{-\ln\{1 - [(1 - \frac{1}{q_0})^{q_0}]^{\frac{d}{q_0}}\}}{q_0 \ln 2}d. \end{aligned}$$

Since $0 < (1 - \frac{1}{q_0})^{q_0} < \frac{1}{e}$ for $q_0 > 1$, as $c \rightarrow 0$, $\frac{d}{q_0} > \frac{1}{c} \rightarrow \infty$, and

$$[(1 - \frac{1}{q_0})^{q_0}]^{\frac{d}{q_0}} < e^{-\frac{d}{q_0}} \rightarrow 0.$$

Thus,

$$\begin{aligned} B_d(q_0)d &\sim \frac{[(1 - \frac{1}{q_0})^{q_0}]^{\frac{d}{q_0}}}{q_0 \ln 2}d \\ &= \frac{1}{\ln 2} \frac{d}{q_0} [(1 - \frac{1}{q_0})^{q_0}]^{\frac{d}{q_0}} \\ &< \frac{1}{\ln 2} \frac{d}{q_0} e^{-\frac{d}{q_0}} \\ &= o(1), \end{aligned}$$

which is also a contradiction (here $a \sim b$ means that $\lim_{c \rightarrow 0} \frac{a}{b} = 1$). Therefore, $q_0(d) = \Theta(d)$. Then, $(1 - \frac{1}{q_0})^d < 1$ is $\Theta(1)$, and thus

$$B_d(q_0) = \frac{\Theta(1)}{q_0} = \Theta\left(\frac{1}{d}\right).$$

□

5.2 New Upper Bounds on $t(d, n; z)$

The above method is now generalized to obtain new upper bounds for $(d; z)$ -disjunct matrices, by establishing the following theorem:

Theorem 11 For d, z constants, and $n \rightarrow \infty$,

$$t(d, n; z) \leq \frac{d+1}{B_d} \log n + \frac{z}{B_d} \log \log n + O(1),$$

where $B_d = \max_{q>1} \frac{-\log[1-(1-\frac{1}{q})^d]}{q}$. Moreover, $B_d \rightarrow \frac{1}{d \log e}$ as $d \rightarrow \infty$.

A q -ary matrix is called $(d, 1; z)$ -disjunct if for any column C and any set D of d other columns, there exists at least z elements in C such that each of these elements does not appear in any column of D in the same row. Clearly, by using the same method mentioned above, one can transform a $t \times n$ q -ary $(d, 1; z)$ -disjunct matrix to a $(d; z)$ -disjunct matrix with n columns and at most tq rows.

Proof of Theorem 14: For given n, d , and z , similarly construct a random $t \times n$ q -ary ($q > 1$) matrix M with each entry assigned randomly and uniformly from $\{1, 2, \dots, q\}$; q and t will be specified later. For each column C and a set D of d other columns, for each element c_i of C , the probability that c_i appears in some column of D in the same row is $1 - (1 - \frac{1}{q})^d$. Thus, the probability that there exist $t - z + 1$ elements of C such that each of them appears in some column of D in the same row is at most

$$\binom{t}{t-z+1} [1 - (1 - \frac{1}{q})^d]^{t-z+1} = \binom{t}{z-1} [1 - (1 - \frac{1}{q})^d]^{t-z+1}.$$

M is not $(d, 1; z)$ -disjunct if and only if there exists a column C and a set D of d other columns such that the above holds. Therefore, the probability that M is not $(d, 1; z)$ -disjunct is no more than

$$(n-d) \binom{n}{d} \binom{t}{z-1} [1 - (1 - \frac{1}{q})^d]^{t-z+1}.$$

The goal is to minimize tq , the number of rows of the corresponding $(d; z)$ -disjunct matrix, under the condition that

$$n^{d+1} t^z [1 - (1 - \frac{1}{q})^d]^{t-z} \leq 1. \quad (2)$$

Notice that Eq. (2) implies

$$(n-d) \binom{n}{d} \binom{t}{z-1} [1 - (1 - \frac{1}{q})^d]^{t-z+1} < 1.$$

Thus, the probability that M is $(d, 1; z)$ -disjunct is greater than zero, which similarly implies the existence of a $t \times n$ q -ary $(d, 1; z)$ -disjunct matrix, and a $(d; z)$ -disjunct matrix with n columns and at most tq rows.

Let q_0 be the point that maximizes

$$B_d(q) = \frac{-\log[1 - (1 - \frac{1}{q})^d]}{q}.$$

Assign $q = q_0$. To satisfy Eq. (2), which is equivalent to

$$(d + 1) \log n + z \log t \leq -(t - z) \log[1 - (1 - \frac{1}{q_0})^d],$$

let

$$t = \frac{(d + 1) \log n}{-\log[1 - (1 - \frac{1}{q_0})^d]} + z + t_1.$$

Then, t_1 should satisfy

$$z \log \left\{ \frac{(d + 1) \log n}{-\log[1 - (1 - \frac{1}{q_0})^d]} + z + t_1 \right\} \leq -t_1 \log[1 - (1 - \frac{1}{q_0})^d] \quad (3)$$

Let

$$t_1 = \frac{z \log \log n}{-\log[1 - (1 - \frac{1}{q_0})^d]} + t_2.$$

From Eq. (3), t_2 should satisfy that

$$\begin{aligned} \frac{z}{-\log[1 - (1 - \frac{1}{q_0})^d]} \log & \left\{ \frac{(d + 1)}{-\log[1 - (1 - \frac{1}{q_0})^d]} \right. \\ & \left. + \frac{1}{\log n} \left(\frac{z \log \log n}{-\log[1 - (1 - \frac{1}{q_0})^d]} + z + t_2 \right) \right\} \leq t_2 \quad (4) \end{aligned}$$

For d and z constants (thus, q_0 is also constant), as $n \rightarrow \infty$, the minimum value of t_2 satisfying Eq. (4) is

$$t_2 = \frac{z}{-\log[1 - (1 - \frac{1}{q_0})^d]} \log \frac{(d + 1)}{-\log[1 - (1 - \frac{1}{q_0})^d]} = O(1).$$

Thus,

$$t = \frac{(d + 1) \log n}{-\log[1 - (1 - \frac{1}{q_0})^d]} + \frac{z \log \log n}{-\log[1 - (1 - \frac{1}{q_0})^d]} + O(1)$$

satisfies Eq. (2) (where the constant term z in t is absorbed in $O(1)$). Therefore, the number of rows of the corresponding $(d; z)$ -disjunct matrix is at most

$$tq_0 = \frac{d+1}{B_d} \log n + \frac{z}{B_d} \log \log n + O(1),$$

where

$$B_d = B_d(q_0) = \max_{q>1} \frac{-\log[1 - (1 - \frac{1}{q})^d]}{q}.$$

Also,

$$B_d \rightarrow \frac{1}{d \log e} \text{ as } d \rightarrow \infty,$$

as proved in [Theorem 10](#). \square

6 Transformation from Error-Tolerant Separable Matrices to Error-Tolerant Disjunct Matrices

Let M be a 0/1 matrix. For any set S of columns of M , $U(S)$ will denote the union of the row indices of 1-entries of all columns in S . When S is the singleton set $\{C\}$, by abusing the notation, $U(S)$ is simply written as C . Matrix M is called d -separable if for any two distinct d -sets S and S' of columns, $U(S) \neq U(S')$. M is called \bar{d} -separable if the restrictions $|S| = d$ and $|S'| = d$ above are changed to $|S| \leq d$ and $|S'| \leq d$, respectively. Finally, M is called d -disjunct if for any d -set S of columns and any column C not in S , C is not contained in $U(S)$. These three properties of 0/1 matrices have been widely studied in the literature of nonadaptive group testing designs (pooling designs), which have applications in DNA screening [[17, 25, 32, 38, 39](#)].

It has long been known that d -disjunctness implies \bar{d} -separability which in turn implies d -separability [[17, Chap. 2](#)]. Recently, Chen and Hwang [[7](#)] found a way to construct a disjunct matrix from a separable matrix to complete the cycle of implications.

Theorem 12 (Chen and Hwang [[7](#)]) *Suppose M is a $2d$ -separable matrix. Then one can construct a d -disjunct matrix by adding at most one row to M .*

The notion of d -separability, \bar{d} -separability, and d -disjunctness has their error-tolerant versions. A 0/1 matrix M is called $(d; z)$ -separable if $|U(S) \Delta U(S')| \geq z$ for any two d -sets of columns of M . It is $(\bar{d}; z)$ -separable if the restriction of d -sets is changed to two sets each with at most d elements. Finally, M is $(d; z)$ -disjunct if for any d -set S of columns and any column C not in S , $|C \setminus U(S)| \geq z$. Note that the variable z represents some redundancy to tolerate errors [[17](#)]. For $z = 1$, the error-tolerant version is reduced to the original version.

In [[17](#)], Du and Hwang attempted to extend [Theorem 12](#) to its error-tolerant version, as stated in the following theorem:

Theorem 13 ([[17](#)], Theorem 2.7.6) *Suppose M is a $(2d; z)$ -separable matrix. Then one can obtain a $(d; z)$ -disjunct matrix by adding at most z rows to M .*

By [Theorem 13](#), Du and Hwang obtained the following corollary:

Corollary 1 ([17], Theorem 2.7.7) *A $(d; 2z)$ -separable matrix can be obtained from a $(2d; z)$ -separable matrix by adding at most z rows.*

Unfortunately, [Theorem 13](#) is incorrect; thus, [Corollary 1](#) is also incorrect, as seen by the following counterexample. Let

$$M_1 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

It is easily verified that M_1 is $(2; 2)$ -separable. It will be showed next adding two rows to M_1 cannot produce a $(1; 2)$ -disjunct matrix.

Let C_1, C_2, C_3 , and C_4 denote the four columns of M_1 . Suppose setting $C = C_i$ and $S = \{C_j\}$, $i \neq j$. Then two rows are needed such that each containing C_i but not C_j . One such row is already provided by M_1 . So one $(1, 0)$ -pair is needed in a new row. Since this is required for each pair of (i, j) with $i \neq j$, there are $4 \times 3 = 12$ choices of (i, j) pair, and each such pair needs a $(1, 0)$ -pair in a new row, or equivalently, the new rows should provide 12 such $(1, 0)$ -pairs. However, one new row can provide at most four $(1, 0)$ -pairs (achieved by a row with two 1-entries and two 0-entries). So two new rows are not sufficient to provide the 12 $(1, 0)$ -pairs required by the $(1; 2)$ -disjunctness property.

In [9], the authors gave a correct version of [Theorem 13](#) and obtained a more rigorous statement of [Theorem 12](#). Their results will be presented in this section.

6.1 Main Results

Lemma 12 ([17], Lemma 2.1.1) *Suppose M is a d -separable matrix with n columns where $d < n$, then it is k -separable for every positive integer $k \leq d$.*

Note that the condition $d < n$ in [Lemma 12](#) is necessary as seen by the following example: Let

$$M_2 = \begin{pmatrix} 1 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 1 \end{pmatrix}$$

M_2 is trivially 3-separable. However, it is not 2-separable, as the union of any pair of its columns is identical. Now [Lemma 12](#) is generalized to an error-tolerant version.

Lemma 13 *If a matrix M with n columns is $(d; z)$ -separable for $d < n$, then it is $(k; z)$ -separable for every positive integer $k \leq d$.*

Proof It suffices to prove M is $(d-1; z)$ -separable. Assume that M is not $(d-1; z)$ -separable. Then there exist two distinct sets S and S' each consisting of $d-1$ columns of M such that $|U(S) \Delta U(S')| < z$.

If $|S \setminus S'| = |S' \setminus S| \geq 2$, then there must exist a pair of columns (C_x, C_y) such that $C_x \in S \setminus S'$ and $C_y \in S' \setminus S$. It is easy to see that

$$|U(S \cup \{C_y\}) \Delta U(S' \cup \{C_x\})| \leq |U(S \cup \{C_y\}) \Delta U(S')| \leq |U(S) \Delta U(S')|.$$

This violates the $(d; z)$ -separability of M , as desired.

Now consider the case of $|S \setminus S'| = |S' \setminus S| = 1$. It is obvious that $|S \cup S'| = d$. Thanks to $d < n$, one can take a column C of M which is in neither S nor S' . It is easily seen that

$$|U(S \cup \{C\}) \Delta U(S' \cup \{C\})| \leq |U(S) \Delta U(S')| < z.$$

This contradicts the $(d; z)$ -separability of M , completing the proof. \square

Now it is ready to give a correct version of [Theorem 13](#).

Theorem 14 Suppose M is a $(2d; z)$ -separable matrix with n columns where $n \geq 2d + 1$. Then one can obtain a $(d; \lceil z/2 \rceil)$ -disjunct matrix by adding at most $\lceil z/2 \rceil$ rows to M .

Proof Suppose M is not $(d; \lceil z/2 \rceil)$ -disjunct. Then there exist a column C and a set S of d other columns such that $|C \setminus U(S)| < \lceil z/2 \rceil$. By adding at most $\lceil z/2 \rceil$ rows to M such that each row has a 1-entry at column C and 0-entries at all columns in S , one can obtain $|C \setminus U(S)| \geq \lceil z/2 \rceil$. Of course, there may exist another pair (C', S') where C' is a column and S' is a set of d columns other than C' , such that $|C' \setminus U(S')| < \lceil z/2 \rceil$ in M . Then break it up by using those $\lceil z/2 \rceil$ rows in the same fashion. Here what one needs to show is that this procedure is not self-conflicting, that is, there does not exist two pairs (C, S) and (C', S') such that $|C \setminus U(S)| < \lceil z/2 \rceil$, yet on the other hand $C \in S'$ while $|C' \setminus U(S')| < \lceil z/2 \rceil$.

Suppose to the contrary that there exist two pairs (C, S) and (C', S') in M as described above with $|S| = |S'| = d$. Define

$$S_0 = \{C'\} \cup S \cup S', \quad S_1 = S_0 \setminus \{C\}, \quad \text{and } S_2 = S_0 \setminus \{C'\}.$$

Let $s = |S_0|$, then $s \leq 2d + 1$ and $|S_1| = |S_2| = s - 1 \leq 2d$.

Note that $S_1 \neq S_2$, but they have the same cardinality which is less than $2d + 1$. Next it will be showed that the symmetric difference of $U(S_1)$ and $U(S_2)$ is less than z , thus violating the assumption of $(2d; z)$ -separability.

Since the only column in S_1 but not in S_2 is C' and $|C' \setminus U(S')| < \lceil z/2 \rceil$, it follows that

$$|U(S_2) \setminus U(S_1)| < \lceil z/2 \rceil. \tag{5}$$

Similarly, one can obtain

$$|U(S_1) \setminus U(S_2)| < \lceil z/2 \rceil. \quad (6)$$

Equation (5) along with Eq. (6) gives $|U(S) \Delta U(S')| < z$, implying that M is not $(s-1; z)$ -separable. This contradicts with Lemma 13, and so the theorem is proved. \square

Corollary 2 Suppose M is a $2d$ -separable matrix with n columns where $n \geq 2d+1$. Then one can obtain a d -disjunct matrix by adding at most one row to M .

Proof It follows from Theorem 14 by setting $z = 1$.

Corollary 2 is a more rigorous version of Theorem 12. The following example shows the necessity of the extra condition $n \geq 2d+1$ in Corollary 2. Let

$$M_3 = \begin{pmatrix} 1 & 1 & 0 & 1 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

Then M_3 is trivially 4-separable, but it can be easily verified that no row can be added to M_3 to make it 2-disjunct. Similarly, any matrix with $2d$ columns is trivially $(2d; z)$ -separable, and one does not expect that adding $\lceil z/2 \rceil$ rows to an arbitrary matrix with $2d$ columns would make it $(d; \lceil z/2 \rceil)$ -disjunct. To see a specific counterexample, note that M_1 is trivially a $(4; 4)$ -separable matrix, but adding two rows does not make it a $(2; 2)$ -disjunct matrix – It is even not $(1; 2)$ -disjunct as indicated at the end of Sect. 1.

Corollary 3 Suppose M is a $(2d; z)$ -separable matrix with n columns where $n \geq 2d+1$. Then, for any positive integer $k \leq \lceil z/2 \rceil$, one can obtain a $(d; k)$ -disjunct matrix by adding at most k rows to M .

Proof The proof of Theorem 14 shows that there does not exist two pairs (C, S) and (C', S') such that $|C \setminus U(S)| < \lceil z/2 \rceil$, yet on the other hand, $C \in S'$ while $|C' \setminus U(S')| < \lceil z/2 \rceil$. In fact, the term $\lceil z/2 \rceil$ can be replaced by any positive integer k which satisfies the symmetric difference of $U(S_1)$ and $U(S_2)$ is less than z . Therefore, for any $k \leq \lceil z/2 \rceil$, one can obtain a $(d; k)$ -disjunct matrix by adding at most k rows to M in the same fashion. \square

The following equivalence relation is given in [17] without giving a proof. Now a proof is given, and a stronger result is obtained by using the equivalence relation.

Lemma 14 ([17], Lemma 2.7.5) A matrix M is $(\bar{d}; z)$ -separable if and only if it is $(d; z)$ -separable and $(d-1; z)$ -disjunct.

Proof Suppose M is $(\bar{d}; z)$ -separable but not $(d - 1; z)$ -disjunct; in other words, there exists a set S of $d - 1$ columns other than a column C such that $|C \setminus U(S)| \leq z$. Then it is easy to see that

$$|U(S \cup \{C\}) \Delta U(S)| = |U(S \cup \{C\}) \setminus U(S)| \leq z,$$

a contradiction to $(\bar{d}; z)$ -separability. Thus, M is $(d - 1; z)$ -disjunct and $(d; z)$ -separable trivially.

Let M be $(d; z)$ -separable and $(d - 1; z)$ -disjunct. It suffices to show that

$$|U(X) \Delta U(Y)| \geq z$$

for any two sets X, Y of at most d columns. If $|X| = |Y| \leq d$, then $|U(X) \Delta U(Y)| \geq z$ by $(d; z)$ -separability and Lemma 13. Assume $|X| < |Y| \leq d$, then there exists a column $C_y \in Y$ but not in X . By $(d - 1; z)$ -disjunctness, it must have $|C_y \setminus U(X)| \geq z$; hence, $|U(X) \Delta U(Y)| \geq z$. It concludes the proof. \square

By Lemmas 14 and 13, Corollary 3 is extended to a stronger version.

Corollary 4 Suppose M is a $(2d; z)$ -separable matrix with n columns where $n \geq 2d + 1$. Then, for any positive integer $k \leq \lceil z/2 \rceil$, one can obtain a $(\bar{d} + 1; k)$ -separable matrix by adding at most k rows to M .

6.2 Concluding Remarks

The following remarks demonstrate the optimality of the results presented in this section.

1. The constraint $k \leq \lceil z/2 \rceil$ in Corollary 3 is necessary to make the number of rows added to be independent of n and d . To see a specific example, consider that M is an $(n \lceil z/2 \rceil) \times n$ matrix such that each column has $\lceil z/2 \rceil$ 1-entries and any 2 columns have no intersection. Then, M is $(2d; z)$ -separable. Since every column has only $\lceil z/2 \rceil$ 1-entries, to make M $(d; k)$ -disjunct by adding rows, the rows added must form a $(d; k - \lceil z/2 \rceil)$ -disjunct submatrix when $k > \lceil z/2 \rceil$. In this case, the minimum number of rows required would depend on n, d , and $k - \lceil z/2 \rceil$.
2. Let N be a 0/1 matrix of constant row sum 1 and constant column sum z , and let M be obtained from N by adding one zero column. It is easy to verify that M is $(2d; z)$ -separable. Since there is a zero column in M , one cannot obtain from M a $(d; k)$ -disjunct matrix by adding less than k rows. This shows that the bound on the number of additional rows given in Corollary 3 is optimal in this sense.

7 Conclusion

Some recent algorithmic, complexity, and mathematical results on nonadaptive group testing (and on pooling design) are presented in this monograph. New construction of disjunct matrices with even reduced number of rows remains interesting to investigate. The complexity of the problem MIN- \bar{d} -SS introduced in Sect. 3.3 remains unsolved. On the bounds of the minimum number $t(d, n)$ of rows of d -disjunct matrices with n columns, closing the gap between $O(d^2 \log n)$ and $\Omega(\frac{d^2 \log n}{\log d})$ remains as a major open problem in extremal combinatorics.

Abstract

This chapter reviews a research focus of scheduling in manufacturing facilities over the last decade. Manufacturing environment has a great influence on the processing times of jobs. The chapter reviews basic concept about past-sequence-dependent delivery times and covers recently results on scheduling with such constraint.

1 Introduction

Scheduling is a form of decision making that plays a crucial role in manufacturing and service industries. Scheduling is a key component of combinatorial optimization. In the current competitive environment, effective scheduling has become a necessity for survival in the marketplace. Companies have to meet shipping dates that have been committed to customers, as failure to do so may result in a significant loss of goodwill. They also have to schedule activities or jobs in such a way as to use the resources available in an efficient manner.

Scheduling deals with the allocation of scarce resources to tasks over time. It is a decision-making process with the goal of optimizing one or more objectives. The resources and tasks in an organization can take many forms. The resources may be machines in a workshop, runways at an airport, crews at a construction site, processing units in a computing environment, and so on. The tasks may be operations in a production process, takeoffs and landings at an airport, stages in a construction project, executions of computer programs, and so on. Each task may have a certain priority level, an earliest possible starting time, and a due date. The objective may be the minimization of the completion time of the last task, and another may be the minimization of the number of tasks completed after their respective due dates [12].

This chapter focuses on a cutting-edge topic in machine scheduling problem, that is, scheduling with past-sequence-dependent (abbr. *psd*) job delivery times. The topic is important because of the theoretical insights it provides and also of its practical implications.

1.1 Emergence of *psd* Delivery Time

In many industries, manufacturing environment has a great influence on the processing times of jobs. A growing body of evidence shows that the manufacturing environment or waiting time may have an adverse effect on the total processing time of a job before its delivery to the customer. In some situations, the waiting time-induced adverse effect does not impede the job's suitability to be processed. Moreover, it can be eliminated after the main processing of the job with an extra

time caused. Such an extra time for eliminating adverse effect between the main processing and the delivery of job is viewed as a *psd* delivery time. Note that the treatment of the adverse effect for a job does not occupy any machine and has no relation with the schedule of the job's main processing. For analysis convenience, it is generally assumed that the *psd* delivery time of a job is proportional to the job's waiting time. One special case is that the *psd* delivery time is a simple linear function of the wait time.

One application with *psd* delivery time is in electronic manufacturing industry. An electronic component may be exposed to certain electromagnetic and/or radioactive fields while waiting in the machine's preprocessing area, and regulatory authorities require the component to be "treated" (e.g., in a chemical solution capable of removing/neutralizing certain effects of electromagnetic/radioactive fields) for an amount of time proportional to the job's exposure time to these fields. The treatment is performed immediately after the component has been processed on the machine to ensure a guaranteed delivery to the customer [6]. Such a postprocessing operation is usually called the job "tail" or the job "delivery time." Unlike the traditional assumption of a job-specific constant delivery time in the scheduling literature [4], it is assumed that the *psd* delivery time of a job is proportional to the job's waiting time.

1.2 Literature Review

It has been widely studied in recent decades for one scheduling scenario such that the waiting time of a job has an adverse effect on the job's main processing. The scenario with waiting time-induced adverse effect is mainly partitioned into three categories.

In the first category, each job has a so-called *deteriorating processing time* such that the processing time of a job increases in its waiting time. The concept of *deterioration* is introduced by Browne and Yechiali [2] and it describes a kind of adverse effect of waiting time.

The second category originated from [5], in which the adverse effect must be removed prior to the main processing of the job by performing a setup operation. The authors introduced the concept of *past-sequence-dependent setup time* to describe the adverse effect.

The third and newest category is from [6], in which the waiting time-induced adverse effect does not impede the suitability to be processed by one machine, and the adverse effect shall be removed prior to delivering the job to the customer. They established a model to incorporate the adverse effect of waiting into a postprocessing operation by introducing the concept of *past-sequence-dependent delivery time*. The treatment of the adverse effect of each job, that is, the job's *psd* delivery time, must follow immediately the main processing of the job. This chapter focuses on this category.

1.3 Notation

In all the following scheduling problems considered, the number of jobs and that of machines are assumed to be finite. Generally, the number of jobs is denoted by n and the number of machines by m (see [12]). The following notations are associated with job J_j :

Processing time (p_{ij}). p_{ij} represents the main processing time of job J_j on machine M_i . It is simply denoted as p_j if the main processing time of J_j is uniform on all machines or if there is only one machine allowed to process job J_j . In the rest of this chapter, sometimes the processing of J_j means its main processing on a machine.

Due date (d_j). d_j represents the committed date at which job J_j is shipped on board or arrived at the customer. There may incur a penalty if the completion time of a job is strictly later than its due date.

Weight (w_j). w_j represents some priority or cost for satisfying job J_j . Its specific meaning depends on manufacturing settings.

Delivery time (q_j). Literally, q_j means the time a completed job needs to be delivered to a customer. In this chapter, delivery time usually represents a postprocessing of a job after its completion on the machine. (Note that this postprocessing operation is not done on the machine).

One scheduling problem is usually described by a triplet $\alpha|\beta|\gamma$ (refer to [1]). The α field describes the machine environment such as single machine or parallel machines, the β field provides details on job-processing characteristics and constraints, and the γ field describes the minimization objectives such as the makespan and the total completion times. Below, possible settings in each of the three fields are given in this chapter.

First, there are two possible machine environments specified in the α field:

Single machine (1). There is a single machine for job processing in the manufacturing system.

Identical machines in parallel (P_m). There are m identical parallel machines in the system. Each job requires only one operation and may be processed on any one of the m machines.

Secondly, there may be multiple entries on job-processing restrictions and constraints specified in the β field, including:

Past-sequence-dependent delivery time (q_{psd}). q_{psd} represents the time required for eliminating waiting time-induced adverse effect after the main processing of job. (Note that this part of processing is not done on the machine).

Release date (r_j). Job J_j becomes available for processing at its release date r_j . If the symbol does not appear in the β field, it implies $r_j = 0$ for any job J_j and all the jobs can be started at the beginning.

Preemption ($prmp$). $prmp$ represents that it is unnecessary to keep a job on a machine, once started, until completion. The scheduler is allowed to interrupt the processing of a job at any time point and arrange another job on the machine instead. In this chapter, the focus is on the resumption case such that if a preempted job is afterward rescheduled on the machine (or another machine in the case of parallel machines), it is started from where it was preempted but not from the start.

Precedence constraint (*prec*). *prec* means that there exist processing precedence constraints among jobs such that one or more jobs are required to be completed before the processing of some other job. In this chapter, three specific forms of precedence constraint are considered: a *chain* in which each job has at most one predecessor and at most one successor, an *intree* in which each job has at most one successor, and an *outtree* in which each job has at most one predecessor.

Before introducing the minimization objectives in the γ field, some fundamental notations are given. In a processing schedule, let C_j be the completion time of job J_j , that is, the completion time of the processing of J_j on a machine plus the job's *psd* delivery time. The *lateness* of job J_j is defined as

$$L_j = C_j - d_j,$$

which is positive or negative when J_j is completed later or earlier than its due date, respectively. The *tardiness* of job J_j is defined as

$$T_j = \max\{C_j - d_j, 0\} = \max\{L_j, 0\}.$$

The difference between the tardiness and the lateness lies in that the former is never negative, that is, the jobs completed earlier than its due date are counted out when counting T_j . The *unit penalty* of job J_j is defined as

$$U_j = \begin{cases} 1, & \text{if } L_j > 0; \\ 0, & \text{otherwise.} \end{cases}$$

The lateness, tardiness, and unit penalty are the three basic due date-related parameters considered in the literature. The possible objective functions specified in γ field are:

Makespan (C_{\max}). The makespan, defined as $\max\{C_1, \dots, C_n\}$, is equivalent to the completion time of the last job to leave the system. A minimum makespan usually implies a high utilization of the machine(s).

Maximum lateness (L_{\max}). The maximum lateness L_{\max} is defined as $\max\{L_1, \dots, L_n\}$. It measures the worst violation of due date among completed jobs.

Maximum tardiness (T_{\max}). The maximum tardiness T_{\max} is defined as $\max\{T_1, \dots, T_n\}$. It also measures the worst violation of due date among completed jobs but omits the jobs with negative lateness.

Total weighted completion time ($\sum w_j C_j$). The sum of the weighted completion times of the n jobs gives an indication of the total holding or inventory costs incurred by the schedule. For the case of $r_j = 0$, the total completion times $\sum C_j$ is equivalent to *total flow time*, and $\sum w_j C_j$ is equivalent to *total weighted flow time*.

Discounted total weighted completion time ($\sum w_j (1 - e^{-r C_j})$). This is a more general cost function than total weighted completion time. The costs are discounted at a rate $r \in (0, 1)$ per unit time. That is, if job J_j is not completed by time t , an additional cost $w_j r e^{-rt} dt$ is incurred over period $[t, t + dt]$. (Note that

$\int_0^{C_j} w_j r e^{-rt} dt = w_j (1 - e^{-rC_j})$ where C_j is a variable). The value of r is usually less than 0.1.

Total weighted tardiness ($\sum w_j T_j$). This objective is also a more general cost function than total weighted completion time.

Number of tardy jobs ($\sum U_j$). This is not only an objective of academic interest but also a measure in common use in practice due to its easy operation.

All the above objective functions belong to so-called *regular* performance measures which are nondecreasing functions of jobs' completion times, that is, C_1, \dots, C_n .

2 Single-Machine Model

This section considers the following single-machine scheduling models related to minimization objectives. For completion time-related objectives, it includes makespan, that is, the maximum completion time, total completion time, and total weighted completion time. For due date-related objectives, it includes maximum lateness and number of tardy jobs. All the objective functions considered in this section are regular, which means the objective function is a nondecreasing function of job's completion time.

For most models considered in this section, jobs are all released at the beginning, and thus there is no advantage in adopting preemptions. For these models, it can be shown that an optimal schedule is a nonpreemptive one, and there are no idle time segments between the processing of any two jobs. However, if jobs are with different release dates in nonpreemptive environment, it may be advantageous to contain unforced idleness.

This section is mainly based on [6, 10, 11].

2.1 Preliminary

Consider a single machine to process a set of n jobs which are available at time zero. Let p_j, d_j denote, respectively, the processing time and due date of job J_j for $j = 1, \dots, n$.

Given a nonpreemptive schedule σ , let $J_{[j]}$, $p_{[j]}$, and $d_{[j]}$ denote the job occupying the j -th position in σ , its processing time, and its due date, respectively. Denote by $S_{[j]}(\sigma)$ or simply $S_{[j]}$ the starting time of job $J_{[j]}$ in σ . In the environment with *psd* delivery time, the processing of $J_{[j]}$ must be followed immediately by its *psd* delivery time $q_{[j]}$. This chapter considers the case of simple linear function for $q_{[j]}$ such that $q_{[j]}$ is proportional to the waiting time or starting time of job $J_{[j]}$. (Readers may extend the discussion to the case of linear or some other function in application necessities). Consequently, $q_{[j]}$ is formulated as

$$q_{[j]} = \gamma S_{[j]}, \quad j = 1, \dots, n, \quad (1)$$

where $\gamma \geq 0$ is a normalizing constant. Observe that in a single-machine environment where the machine is always available for processing and all the n jobs are available at time zero, the starting time $S_{[j]}$ in a schedule without (redundant) idle time satisfies

$$\begin{aligned} S_{[1]} &= 0, \\ S_{[j]} &= \sum_{i=1}^{j-1} p_{[i]}, \quad j = 2, \dots, n. \end{aligned} \tag{2}$$

Let $C_{[j]}$ denote the completion time of job $J_{[j]}$ in a schedule, that is, the completion time of the processing of $J_{[j]}$ on the machine plus the job's *psd* delivery time. Therefore,

$$\begin{aligned} C_{[1]} &= p_{[1]} + q_{[1]} = p_{[1]}, \\ C_{[j]} &= S_{[j]} + p_{[j]} + q_{[j]} \\ &= \sum_{i=1}^{j-1} p_{[i]} + p_{[j]} + q_{[j]} \\ &= (1 + \gamma) \sum_{i=1}^{j-1} p_{[i]} + p_{[j]}, \quad j = 2, \dots, n. \end{aligned} \tag{3}$$

Accordingly,

$$C_{[j]} = (1 + \gamma) \sum_{i=1}^{j-1} p_{[i]} + p_{[j]}, \quad j = 1, \dots, n, \tag{4}$$

where $\sum_{i=1}^0 p_{[i]} = 0$.

2.2 Makespan, Maximum Lateness, Maximum Tardiness, and Number of Tardy Jobs

For convenience, let $P = \sum_{j=1}^n p_j$.

Theorem 1 Problem $1|q_{\text{psd}}|C_{\max}$ can be solved in $O(n)$ time.

Proof It is clear from (Eq. 4) that $C_{[j]} > C_{[j-1]}$, and therefore

$$C_{\max} = C_{[n]} = P + \gamma \sum_{i=1}^{n-1} p_{[i]} = P + \gamma(P - p_{[n]}) = (1 + \gamma)P - \gamma p_{[n]}. \tag{5}$$

Since P is a constant, C_{\max} is minimized when $p_{[n]}$ is maximal. Consequently, any sequence with $p_{[n]} = \max_{j=1,\dots,n}\{p_j\}$ is optimal for the problem. Since the longest job can be identified in $O(n)$ time, the problem can be solved in $O(n)$ time as well. \square

Below it is shown that $1|q_{psd}|L_{\max}$, $1|q_{psd}|T_{\max}$, and $1|q_{psd}|\sum U_j$ problems can be reduced to the corresponding problems without *psd* delivery times by appropriate transformations for p_j and d_j . Specifically, in accordance with expression (Eq. 5), $L_{[j]} = C_{[j]} - d_{[j]} = \sum_{i=1}^j (1 + \gamma) p_{[i]} - (d_{[j]} + \gamma p_{[j]})$ and $T_{[j]} = \max\{L_{[j]}, 0\}$; therefore, the substitutions of $p'_j = (1 + \gamma)p_j$ and $d'_j = d_j + \gamma p_j$, $j = 1, \dots, n$, reduce the above L_j , T_j expressions to the corresponding expressions without *psd* delivery times. Consequently, the $1|q_{psd}|L_{\max}$, $1|q_{psd}|T_{\max}$, and $1|q_{psd}|\sum U_j$ problems reduce to $1||L_{\max}$, $1||T_{\max}$, and $1||\sum_{j=1}^n U_j$ problems, respectively. As a result, $1|q_{psd}|L_{\max}$ and $1|q_{psd}|T_{\max}$ can be solved in $O(n \log n)$ time by implementing the earliest due date (EDD) sequence on due dates d'_j , and $1||\sum U_j$ can be solved in $O(n \log n)$ time by implementing Algorithm 3.3.1 in [12] with processing times p'_j and due dates d'_j ($j = 1, \dots, n$).

2.3 Total Weighted Completion Time

Consider the single-machine scheduling problem to minimize the total weighted completion time with *psd* delivery time. Denote the model as $1|q_{psd}|\sum w_j C_j$. It is shown that shortest weighted processing time (SWPT) rule is optimal for the model.

Theorem 2 For $1|q_{psd}|\sum w_j C_j$, SWPT rule is optimal.

Proof By formula (Eq. 4),

$$\begin{aligned} \sum_{j=1}^n w_{[j]} C_{[j]} &= \sum_{j=1}^n w_{[j]} \left((1 + \gamma) \sum_{i=1}^j p_{[i]} - \gamma p_{[j]} \right) \\ &= (1 + \gamma) \sum_{j=1}^n w_{[j]} \sum_{i=1}^j p_{[i]} - \gamma \sum_{j=1}^n w_{[j]} p_{[j]}. \end{aligned} \quad (6)$$

On the right-hand side of the above second equation, the first item $(1 + \gamma) \sum_{j=1}^n w_{[j]} \sum_{i=1}^j p_{[i]}$ is minimized by SWPT rule, and the second item $\gamma \sum_{j=1}^n w_{[j]} p_{[j]}$ is a constant which has no relation with the processing sequence. This completes the proof. \square

Corollary 1 For $1|q_{psd}|\sum C_j$, SPT rule is optimal.

For an alternative proof of this corollary, readers can refer to [6].

2.3.1 Total Weighted Completion Time with Precedence Constraints

The problem of single-machine scheduling to minimize total weighted completion time with arbitrary precedence constraints is NP-hard, due to the NP-hardness of $1|prec|C_{\max}$ (without *psd* delivery time). So, the focus has now been shifted to several special cases and exploit polynomial time algorithms for the cases.

Consider the simplest form of precedence constraints (i.e., precedence constraints that take the form of parallel chains). This problem can be solved by a relatively simple and efficient (polynomial time) algorithm. The algorithm is based on some fundamental properties of scheduling with precedence constraints.

Consider the case with two job chains. The first chain consists of jobs J_1, \dots, J_k and the second chain consists of jobs J_{k+1}, \dots, J_n . The precedence constraints in the two chains are as follows:

$$J_1 \rightarrow J_2 \rightarrow \dots \rightarrow J_k$$

and

$$J_{k+1} \rightarrow J_{k+2} \rightarrow \dots \rightarrow J_n.$$

In the above chains, J_i precedes J_{i+1} for $i \leq i < k$ and $k+1 \leq i < n$. The following lemma is based on the nonpreemption assumption such that if the first job of one chain is started for processing on the machine, then the whole chain shall be processed till its end without preemption. The lemma answers the question, with the purpose to minimize the total weighted completion time, which one of the two chains should he process first?

Lemma 1 Lemma 3.1.3 [12] If $\frac{\sum_{j=1}^k w_j}{\sum_{j=1}^k p_j} > (<) \frac{\sum_{j=k+1}^n w_j}{\sum_{j=k+1}^n p_j}$, then it is optimal to process the chain of jobs J_1, \dots, J_k before (after) the chain of jobs J_{k+1}, \dots, J_n .

Proof By contradiction. Under sequence $J_1, \dots, J_k, J_{k+1}, \dots, J_n$, the total weighted completion time is

$$\begin{aligned} & w_1 p_1 + \dots + w_k \left((1 + \gamma) \sum_{j=1}^{k-1} p_j + p_k \right) \\ & + w_{k+1} \left((1 + \gamma) \sum_{j=1}^k p_j + p_{k+1} \right) \\ & + \dots + w_n \left((1 + \gamma) \sum_{j=1}^{n-1} p_j + p_n \right), \end{aligned}$$

whereas under sequence $J_{k+1}, \dots, J_n, J_1, \dots, J_k$, it is

$$\begin{aligned} & w_{k+1} p_{k+1} + \dots + w_n \left((1 + \gamma) \sum_{j=k+1}^{n-1} p_j + p_n \right) \\ & + w_1 \left((1 + \gamma) \sum_{j=k+1}^n p_j + p_1 \right) \\ & + \dots + w_k \left((1 + \gamma) (\sum_{j=k+1}^n p_j + \sum_{j=1}^{k-1} p_j) + p_k \right). \end{aligned}$$

The total weighted completion time of the first sequence is strictly less than that of the second sequence if

$$\frac{\sum_{j=1}^k w_j}{\sum_{j=1}^k p_j} > \frac{\sum_{j=k+1}^n w_j}{\sum_{j=k+1}^n p_j}.$$

The lemma follows. \square

Consider the preemptive case other than that in [Lemma 1](#) such that the processing of a chain may be preempted and then it is not necessary to go through each chain at a time. In other words, in the preemptive case, a scheduler may process some jobs of one chain (while adhering to the precedence constraints), switch over to another chain, and later on return to the first chain. A basic concept related to a chain of jobs is present. Given a chain $J_1 \rightarrow J_2 \rightarrow \dots \rightarrow J_k$, let l^* be the smallest index that satisfies

$$\frac{\sum_{j=1}^{l^*} w_j}{\sum_{j=1}^{l^*} p_j} = \max_{l \in \{1, \dots, k\}} \left\{ \frac{\sum_{j=1}^l w_j}{\sum_{j=1}^l p_j} \right\}.$$

The ratio on the left-hand side of the above equation is called the ρ -factor of the chain and it is denoted by $\rho(J_1, \dots, J_k)$. Job J_{l^*} is referred to as the job that determines the ρ -factor of the chain.

For the objective to minimize the total weighted completion time, the following lemma holds in the case of multiple chains.

Lemma 2 *Lemma 3.1.3 [12] If job J_{l^*} determines $\rho(J_1, \dots, J_k)$, then there exists an optimal sequence that processes jobs J_1, \dots, J_{l^*} one after another without any interruption by jobs from other chains.*

Proof See the proof of Lemma 3.1.3 [12]. □

The result of this lemma is intuitive. If one scheduler had decided to start processing a string of jobs, it makes sense to continue processing the string on the machine until job J_{l^*} is completed without processing any other job in between. Given the form of chains for precedence constraints, the above two lemmas are the basis for constructing a simple algorithm that minimizes the total weighted completion time.

Algorithm 3.1.4 [12]:

Whenever the machine is freed, select among the remaining chains the one with the highest ρ -factor. Process this chain without interruption up to and including the job that determines its ρ -factor.

Consider other chains with more general precedence constraints than the parallel chains mentioned above. Some notations on directed tree are introduced, in which each node represents a job and each directed arc represents a precedence constraint between the corresponding two nodes. If there is only one job without successors (or predecessors) in a tree, then it is called an *intree* (or *outtree*). In an intree, the single job with no successors is called the *root* and is located at *level 1*; all jobs immediately preceding the root are at level 2; all those immediately preceding the jobs at level 2 are located at level 3, and so on. All the jobs without predecessors in the intree are referred to in graph theory terminology as *leaves*. In an outtree, the definitions are on the contrary way. The single job without predecessors is called the *root* and is located at level 1; all the jobs immediately following the root are located at level 2, and so on. The jobs without successors in an outtree are called *leaves*.

In both intree and outtree, the jobs with no predecessors are generally referred to as *starting* jobs. There is a single starting job in an outtree while there may be several starting jobs in an intree.

For $1|intree|\sum w_j C_j$ and $1|outtree|\sum w_j C_j$, there are decomposition algorithms (see [13]), which can be directly applied to the corresponding scenarios with *psd* delivery times, that is, $1|q_{psd}, intree|\sum w_j C_j$ and $1|q_{psd}, outtree|\sum w_j C_j$.

2.4 Total Weighted Discounted Completion Time

Consider the objective of total weighted discounted completion time $\sum w_j(1 - e^{-rC_j})$, where r ($0 < r < 1$) is the discount factor. The problem $1|q_{psd}|\sum w_j(1 - e^{-rC_j})$ gives rise to a different priority rule, that is, scheduling jobs in nonincreasing order of $\frac{w_j e^{-rp_j}}{1 - e^{-r(1+\gamma)p_j}}$. This rule is referred to as the Modified weighted discounted shortest processing time (MWDSPT) rule.

Theorem 3 *MWDSPT rule is optimal for $1|q_{psd}|\sum w_j(1 - e^{-rC_j})$.*

Proof By contradiction. Assume otherwise that there exists another optimal schedule S , in which job J_j immediately precedes job J_k , while

$$\frac{w_j e^{-rp_j}}{1 - e^{-r(1+\gamma)p_j}} > \frac{w_k e^{-rp_k}}{1 - e^{-r(1+\gamma)p_k}}.$$

Let t be the time at which job J_j starts its processing in S . An adjacent pairwise interchange between the two jobs results in a new schedule S' . It is observed that for each of the other jobs except J_j and J_k , its starting time and end time in the two sequences are the same. So, the only difference between S and S' related to the objective value is due to jobs J_j and J_k . Together with formula (Eq. 3), the total contribution of the two jobs to the objective under S is

$$\begin{aligned} & w_j(1 - e^{-r(t+p_j+q_j)}) + w_k(1 - e^{-r(t+p_j+p_k+q_k)}) \\ &= w_j(1 - e^{-r(t+p_j+\gamma t)}) + w_k(1 - e^{-r(t+p_j+p_k+\gamma(t+p_j))}). \end{aligned} \tag{7}$$

The total contribution of jobs J_k and J_j to the objective under S' is obtained by interchanging the j s and k s in formula (Eq. 7). By algebraic calculation, it can be shown that the objective value under S' is less than that under S , implying a contradiction. This completes the proof. \square

2.5 Total Weighted Tardiness

It is well known that problem $1||\sum w_j T_j$ is NP-hard in the strong sense, which is a special case of $1|q_{psd}|\sum w_j T_j$. This implies that $1|q_{psd}|\sum w_j T_j$ is also NP-hard

in the strong sense. In this subsection, the main focus is on a polynomially solvable special case. Given a job instance, if any two jobs J_j, J_k with $p_j \leq p_k$ satisfy $d_j \leq d_k$ and $w_j \geq w_k$, then it is said the job instance has *agreeable* due dates and *agreeable* weights.

Theorem 4 *If a job instance has agreeable due dates and agreeable weights, then Earliest Due Date (EDD) rule is optimal for $1|q_{psd}|\sum w_j T_j$.*

Proof Suppose otherwise in an optimal schedule S , there exist two jobs J_j and J_k with $p_j \leq p_k$ such that J_k is scheduled before J_j . By agreeable due dates and weights, $d_j \leq d_k$ and $w_j \geq w_k$ is obtained. Performing a *position interchange* on jobs J_k and J_j in S while keeping the processing order of all the other jobs unchanged, a new schedule S' is obtained. It suffices to prove that the total weighted tardiness under S' is no more than that of S .

Let A and $P(A)$ be the set of jobs between J_j and J_k and its total processing time in S . Let t be the time at which job J_k starts its processing under S . J_k is immediately followed by A and then J_j . Under the new schedule S' , however, J_j will start its processing at time t , and it is immediately followed by A and then J_k . Notice that the total weighted tardiness of all the jobs except J_j and J_k under S' is less than or equal to that under S due to $p_j \leq p_k$. The rest of the proof is to show that the total weighted tardiness of J_j and J_k under S' is no more than that under S .

The total weighted tardiness of J_j and J_k under S is

$$\begin{aligned} w_k T_k + w_j T_j &= w_k \max\{t + p_k + \gamma t - d_k, 0\} \\ &\quad + w_j \max\{t + p_k + P(A) + p_j + \gamma(t + p_k + P(A)) - d_j, 0\}. \end{aligned}$$

While under S' , the total contribution of J_j and J_k is

$$\begin{aligned} w_j T'_j + w_k T'_k &= w_j \max\{t + p_j + \gamma t - d_j, 0\} \\ &\quad + w_k \max\{t + p_j + P(A) + p_k + \gamma(t + p_j + P(A)) - d_k, 0\}. \end{aligned}$$

Define $\Delta = (w_j T'_j + w_k T'_k) - (w_k T_k + w_j T_j)$. Depending on Δ , two cases are discussed.

Case 1: $t + p_k + \gamma t - d_k \geq 0$.

Case 1.1: $t + p_j + \gamma t - d_j \geq 0$.

$$\begin{aligned} \Delta &= [w_j(t + p_j + \gamma t - d_j) \\ &\quad + w_k(t + p_j + P(A) + p_k + \gamma(t + p_j + P(A)) - d_k)] \\ &\quad - [w_k(t + p_k + \gamma t - d_k) \\ &\quad + w_j(t + p_k + P(A) + p_j + \gamma(t + p_k + P(A)) - d_j)] \end{aligned}$$

$$\begin{aligned}
&= (1 + \gamma)[w_k(p_j + P(A)) - w_j(p_k + P(A))] \\
&\leq 0
\end{aligned}$$

where the above inequality is due to $w_j \geq w_k$ and $p_j \leq p_k$.

Case 1.2: $t + p_j + \gamma t - d_j < 0$.

$$\begin{aligned}
\Delta &= w_k[t + p_j + P(A) + p_k + \gamma(t + p_j + P(A)) - d_k] \\
&\quad - [w_k(t + p_k + \gamma t - d_k) \\
&\quad + w_j(t + p_k + P(A) + p_j + \gamma(t + p_k + P(A)) - d_j)] \\
&= w_k(1 + \gamma)(p_j + P(A)) \\
&\quad - w_j(t + p_k + P(A) + p_j + \gamma(t + p_k + P(A)) - d_j) \\
&\leq w_k[(1 + \gamma)(p_j + P(A)) \\
&\quad - (t + p_k + P(A) + p_j + \gamma(t + p_k + P(A)) - d_j)] \\
&= w_k[\gamma(p_j - p_k) - (t + p_k + \gamma t - d_j)] \\
&\leq -w_k(t + p_k + \gamma t - d_j) \\
&\leq -w_k(t + p_k + \gamma t - d_k) \\
&\leq 0
\end{aligned}$$

where the first inequality is due to $w_j \geq w_k$ and $t + p_k + P(A) + p_j + \gamma(t + p_k + P(A)) - d_j \geq t + p_k + \gamma t - d_k \geq 0$ by the condition of Case 1, the second and third inequalities are due to $p_j \leq p_k$ and $d_j \leq d_k$ respectively, and the last inequality is due to case condition $t + p_k + \gamma t - d_k \geq 0$.

Case 2: $t + p_k + \gamma t - d_k < 0$.

Case 2.1: $t + p_j + P(A) + p_k + \gamma(t + p_j + P(A)) - d_k \geq 0$.

Case 2.1.1: $t + p_j + \gamma t - d_j \geq 0$.

$$\begin{aligned}
\Delta &= [w_j(t + p_j + \gamma t - d_j) \\
&\quad + w_k(t + p_j + P(A) + p_k + \gamma(t + p_j + P(A)) - d_k)] \\
&\quad - w_j(t + p_k + P(A) + p_j + \gamma(t + p_k + P(A)) - d_j) \\
&= w_k(t + p_j + P(A) + p_k + \gamma(t + p_j + P(A)) - d_k) \\
&\quad - w_j(1 + \gamma)(p_k + P(A)) \\
&< w_k(1 + \gamma)(p_j + P(A)) - w_j(1 + \gamma)(p_k + P(A)) \\
&\leq 0
\end{aligned}$$

where the first inequality is due to case condition $t + p_k + \gamma t - d_k < 0$ and the second inequality is due to $w_j \geq w_k$ and $p_j \leq p_k$.

Case 2.1.2: $t + p_j + \gamma t - d_j < 0$.

$$\begin{aligned}\Delta &= w_k(t + p_j + P(A) + p_k + \gamma(t + p_j + P(A)) - d_k) \\ &\quad - w_j(t + p_k + P(A) + p_j + \gamma(t + p_k + P(A)) - d_j) \\ &\leq w_j[(\gamma p_j - d_k) - (\gamma p_k - d_j)] \\ &= w_j[\gamma(p_j - p_k) + (d_j - d_k)] \\ &\leq 0,\end{aligned}$$

where the first inequality is due to $w_k \leq w_j$ and the second inequality is due to $p_j \leq p_k$ and $d_j \leq d_k$.

Case 2.2: $t + p_j + P(A) + p_k + \gamma(t + p_j + P(A)) - d_k < 0$.

Case 2.2.1: $t + p_j + \gamma t - d_j \geq 0$.

$$\begin{aligned}\Delta &= w_j(t + p_j + \gamma t - d_j, 0) \\ &\quad - w_j[t + p_k + P(A) + p_j + \gamma(t + p_k + P(A)) - d_j] \\ &= -w_j(1 + \gamma)(p_k + P(A)) \\ &\leq 0\end{aligned}$$

Case 2.2.2: $t + p_j + \gamma t - d_j < 0$.

$$\begin{aligned}\Delta &= 0 - w_j \max\{t + p_k + P(A) + p_j + \gamma(t + p_k + P(A)) - d_j, 0\} \\ &\leq 0.\end{aligned}$$

This completes the proof. \square

2.6 Total Completion Time with Release Dates

It is already known that $1|r_j| \sum C_j$ is NP-hard (see [9]), and therefore $1|r_j, q_{psd}| \sum C_j$ is NP-hard. The focus is to exploit some polynomially solvable cases of the latter problem. Remember that in Sect. 2.3, Corollary 1 shows that SPT rule produces an optimal schedule for the model without release dates, that is, $1|q_{psd}| \sum C_j$.

This subsection deals with the model with release dates and preemption, that is, $1|q_{psd}, prmp, r_j| \sum C_j$. In the preemptive case, one job on processing may be interrupted at some time and resumed from where it was preempted at a later time. It is proved that a modified shortest remaining processing time (MSRPT) rule is optimal for the model. Notice that in the preemption model, on the case where one job J_j has started processing for more than one time, S_j is defined as the first starting time of the job. The value of psd delivery time depends on J_j 's first starting time, that is, $q_j = \gamma S_j$. The following lemma shows one property in an optimal schedule.

Lemma 3 *In an optimal schedule for $1|q_{psd}, prmp, r_j| \sum C_j$, each job starts processing at its release date.*

Proof By contradiction. Suppose otherwise in an optimal schedule π , job J_j starts processing at time S_j with $S_j > r_j$. Construct a new preemptive schedule π' by inserting processing J_j at time r_j with a time length of zero and keep the processing schedule of all jobs in π unchanged. Since the value of S_j decreases from S_j in π to r_j in π' , together with formula (Eq. 4), the psd delivery time and the completion time of J_j in π' are strictly less than that in π . The completion times of all other jobs are the same in π and π' . Hence, the total completion time in π' is less than that in π , contradicting that π is an optimal schedule. \square

Algorithm MSRPT:

(At any time Principle 1 is superior to Principle 2)

Principle 1: At the release date of each job, process it with a time length of zero.

Principle 2: If the machine is idle or a job arrives at time t , schedule a job by SRPT (shortest remaining processing time) rule. Ties are broken arbitrarily. If there is no available job at the time, wait until a new job arrives. Note that the remaining processing time includes psd delivery time.

Theorem 5 *Algorithm MSRPT is optimal for $1|q_{psd}, prmp, r_j| \sum C_j$.*

Proof First, give a sketch of the proof. By Lemma 3, the psd delivery time of each J_j satisfies $q_j = \gamma S_j = \gamma r_j$, and thus it has no relation with the schedule of the processing of J_j . The problem reduces to $1|prmp, r_j| \sum C_j$. By the argument of position interchange on the processing of any two consecutive jobs, it can be proved that MSRPT produces an optimal schedule.

The theorem follows. \square

2.7 Approximation for Total Completion Time with Release Dates

For the model with release dates, if preemption is allowed, the previous subsection shows that there exists an optimal algorithm. However, if preemption is not allowed, the corresponding problem, denoted by $1|q_{psd}, r_j| \sum C_j$, is NP-hard due to the NP-hardness of $1|r_j| \sum C_j$. Due to the NP-hardness result, the approximation algorithm is developed for problem $1|q_{psd}, r_j| \sum C_j$ in this subsection. The main idea of the proposed approximation algorithm below is to transform a preemptive schedule into a corresponding non-preemptive schedule. The total relaxation of jobs' completion times during the transformation is bounded by a constant factor.

Given an instance of problem $1|q_{psd}, prmp, r_j| \sum C_j$ and a preemptive schedule P which is produced by MSRPT algorithm, let $C_j(P)$ be the completion time of job J_j in P . The following algorithm, named CONVERT, reveals how to convert schedule P into a feasible nonpreemptive schedule N .

Algorithm CONVERT:

Input: Preemptive schedule P

Output: Nonpreemptive schedule N

1. Form a list L of jobs J_1, J_2, \dots, J_n in the increasing order of their completion times $C_j(P)$, $j = 1, 2, \dots, n$.
2. Produce a nonpreemptive and feasible schedule of the n jobs in the same completion order as in L , with the constraint that each job starts processing not earlier than its release date.

Theorem 6 *Given an optimal preemptive schedule P for $1|q_{psd}, prmp, r_j| \sum C_j$. Algorithm CONVERT produces in $O(n)$ time a nonpreemptive schedule N in which $C_j(N) \leq 2(1 + \gamma)C_j(P)$ for each job J_j .*

Proof By the description of Algorithm CONVERT, it works as follows. Consider an arbitrary job J_j in P . Let $S_j^l(P)$ be the last starting time of J_j and k_j the length of time for its last processing. That is, the last processing of J_j is within time interval $[S_j^l(P), S_j^l(P) + k_j]$ in schedule P . Remove all the previous processing time segments of J_j in a total length of $p_j - k_j$ before time $S_j^l(P)$, and insert $p_j - k_j$ extra units of time at time $S_j^l(P) + k_j$ for processing J_j continuously within interval $[S_j^l(P), S_j^l(P) + p_j]$. Note that this time interval might overlap with the processing time intervals of either preceding or succeeding jobs. Hence, in the nonpreemptive schedule N , the starting time of job J_j or $S_j(N)$ may be postponed to another time later than $S_j^l(P)$ with the assurance that there is no unforced idle time between the processing of any two jobs.

It is observed that in the worst case of N , all the jobs completed before J_j are started on or after time $S_j^l(P)$. Together with the fact that the jobs completed before J_j in P are the same as that in N , the following is obtained:

$$\begin{aligned} S_j(N) &\leq S_j^l(P) + \sum_{k:C_k(P) < C_j(P)} p_k \\ &\leq S_j^l(P) + (C_j(P) - \gamma r_j - p_j) \\ &< 2C_j(P) - p_j, \end{aligned}$$

where the second inequality holds since the processing of J_j is completed at time $C_j(P) - \gamma r_j$ and then $\sum_{k:C_k(P) \leq C_j(P)} p_k \leq C_j(P) - \gamma r_j$ and the third inequality is due to $S_j^l(P) < C_j(P)$ and $\gamma r_j \geq 0$. Together with formulae (2) and (4),

$$\begin{aligned} C_j(N) &\leq (1 + \gamma)S_j(N) + p_j \\ &\leq (1 + \gamma)(2C_j(P) - p_j) + p_j \\ &< 2(1 + \gamma)C_j(P). \end{aligned}$$

The theorem follows. \square

Corollary 2 $\sum C_j(N) \leq 2(1 + \gamma) \sum C_j(P)$.

Denote by $\sum C_j(OPT)$ the optimal objective value for $1|q_{psd}, r_j| \sum C_j$. It can be claimed that $\sum C_j(OPT)$ is not less than $\sum C_j(P)$ which is the optimal objective value for $1|q_{psd}, prmp, r_j| \sum C_j$. Hence,

$$\begin{aligned}\sum C_j(N) &\leq 2(1 + \gamma) \sum C_j(P) \\ &\leq 2(1 + \gamma) \sum C_j(OPT).\end{aligned}$$

Theorem 7 Algorithm CONVERT is $2(1 + \gamma)$ -approximation for $1|q_{psd}, r_j| \sum C_j$.

3 Parallel Identical Machine Model

In this section, minimizations of the makespan and the total completion time are considered.

3.1 Makespan

Problem $Pm|q_{psd}|C_{\max}$ is studied in this subsection. It is already known that $Pm||C_{\max}$ is NP-hard in the ordinary sense. The problem is a special case of $Pm|q_{psd}|C_{\max}$ when $\gamma = 0$. Therefore, some heuristics are developed for the problem considered.

A simple idea is to investigate the performance of LIST rule. LIST schedules each job on one machine with smallest current workload.

Theorem 8 LIST rule is $(1 + \frac{(1+\gamma)(m-1)}{m})$ -approximation for $Pm|q_{psd}|C_{\max}$.

Proof Let C_{\max}^{LIST} and C_{\max}^* denote the makespan (including *psd* delivery time) of the schedule produced by LIST rule and the optimal objective value, respectively. Let $J_l (1 \leq l \leq n)$ be the job which determines the makespan C_{\max}^{LIST} . Note that J_l might not be the last scheduled job. The start time of J_l satisfies

$$S_l \leq \frac{\sum_{j=1}^{l-1} p_j}{m} \leq \frac{\sum_{j=1}^n p_j - p_l}{m}.$$

Together with formulae (Eq. 2) and (Eq. 4),

$$\begin{aligned}C_{\max}^{LIST} &= (1 + \gamma)S_l + p_l \\ &\leq \frac{(1 + \gamma) \sum_{j=1}^n p_j}{m} + (1 - \frac{1 + \gamma}{m})p_l.\end{aligned}$$

By LIST rule, $C_{\max}^* \geq \max\{\frac{\sum_{j=1}^n p_j}{m}, p_l\}$. Hence,

$$\frac{C_{\max}^{LIST}}{C_{\max}^*} \leq 1 + \frac{(1+\gamma)(m-1)}{m}.$$

The theorem follows. \square

3.1.1 An FPTAS

Let M_i ($i \in \{1, \dots, m\}$) denote the i th machine in the system. Given an arbitrary schedule, let $J_{[i,j]} (j \in \{1, \dots, n_i\})$ be the j th job scheduled on the machine M_i . Denote by $s_{[i,j]}$ and $C_{[i,j]}$ the starting time and the completion time of job $J_{[i,j]}$, respectively. Let $n_i (i \in \{1, \dots, m\})$ be the number of jobs scheduled on machine M_i . It follows that $n_i \in \{1, \dots, n\}$ for $i \in \{1, \dots, m\}$ and $\sum n_i = n$.

For any problem with some minimization objective, an algorithm \mathcal{A} is called $(1 + \epsilon)$ -approximation if it produces a solution with the objective value at most $1 + \epsilon$ times of the optimal value, and its running time is polynomial in input size. A family of approximation algorithms $\{\mathcal{A}_\epsilon\}$ is called a fully polynomial time approximation scheme (FPTAS) if, for each $\epsilon > 0$, \mathcal{A}_ϵ is a $(1 + \epsilon)$ -approximation algorithm running in polynomial time in both input size and $1/\epsilon$. Without loss of generality, it is assumed that $0 < \epsilon \leq 1$.

For the special case with $m = 1$, that is, $1|q_{psd}|C_{\max}$, it is already known that SPT rule produces an optimal schedule. It immediately leads to the following lemma.

Lemma 4 *In an optimal solution of $Pm|q_{psd}|C_{\max}$, all the jobs on each machine $M_i (i \in \{1, \dots, m\})$ are sequenced by SPT rule.*

According to the above lemma, index the n jobs according to SPT rule. Similar to the establishment of FPTAS in [7,8], introduce variables $x_j (j = 1, \dots, n)$ such that $x_j = i$ if job J_j is assigned to machine $M_i (i \in \{1, \dots, m\})$. Let vector $x = (x_1, x_2, \dots, x_n)$ be one assignment of all the n jobs and $X = \{x\}$ be the vector set containing all the solutions to the problem considered. Note that the only concern is nondelay schedule here since an optimal solution must be such a schedule.

For each vector x , adopt function $f_j^i(x)$ and $g_j^i(x)$, respectively, to denote the processing workload (excluding psd delivery time) and the makespan (including psd delivery time) of machine M_i immediately after scheduling job J_j . Let $h_j(x) = \max_{i=1,\dots,m} \{g_j^i(x)\}$. So $h_n(x)$ is our desired value for any given x .

Define the following initial and recursive functions on X :

Initial function:

$$\begin{aligned} f_0^i(x) &= 0, \quad i = 1, \dots, m; \\ g_0^i(x) &= 0, \quad i = 1, \dots, m; \\ h_0(x) &= 0. \end{aligned}$$

Recursive function for $j = 1, \dots, n$:

$$\begin{aligned}
f_j^i(x) &= f_{j-1}^i(x) + p_j, \quad i = x_j; \\
f_j^i(x) &= f_{j-1}^i(x), \quad \text{otherwise.} \\
g_j^i(x) &= (1 + \gamma) f_{j-1}^i(x) + p_j, \quad i = x_j; \\
g_j^i(x) &= g_{j-1}^i(x), \quad \text{otherwise.} \\
h_j(x) &= \max_{i=1,\dots,m} \{g_j^i(x)\}.
\end{aligned}$$

Therefore, problem $Pm|q_{psd}|C_{\max}$ reduces to minimize

$$h_n(x), \quad x \in X.$$

Since the proposed algorithm \mathcal{A}_ϵ contains procedure $\text{Partition}(A, e, \delta)$ which was proposed in [7, 8], restate the procedure for comprehension completion. In $\text{Partition}(A, e, \delta)$, parameter $A \subseteq X$, e is a nonnegative integer function on X , and $0 < \delta \leq 1$. The procedure partitions A into $k(e) \geq 1$ disjoint subsets which satisfy some specific properties. The value of $k(e)$ is to be determined in the procedure.

Procedure $\text{Partition}(A, e, \delta)$:

- Step 1.** Arrange vectors $x \in A$ in the order $x^{(1)}, x^{(2)}, \dots, x^{(|A|)}$ such that $0 \leq e(x^{(1)}) \leq e(x^{(2)}) \leq \dots \leq e(x^{(|A|)})$.
- Step 2.1.** Assign vectors $x^{(1)}, x^{(2)}, \dots, x^{(i_1)}$ to set A_1^e such that $e(x^{(i_1)}) \leq (1 + \delta)e(x^{(1)})$ and $e(x^{(i_1+1)}) > (1 + \delta)e(x^{(1)})$. If such i_1 does not exist, take $A_{k(e)}^e = A_1^e = A$ and stop.
- Step 2.2.** Assign vectors $x^{(i_1+1)}, x^{(i_1+2)}, \dots, x^{(i_2)}$ to set A_2^e such that $e(x^{(i_2)}) \leq (1 + \delta)e(x^{(i_1+1)})$ and $e(x^{(i_2+1)}) > (1 + \delta)e(x^{(i_1+1)})$. If such i_2 does not exist, take $A_{k(e)}^e = A_2^e = A$ and stop.
- Step 2.3.** Recursively, construct vector set A_i^e for $i \geq 3$ as in Step 2.2 until $x^{(|A|)}$ is included in $A_{k(e)}^e$ for some integer $k(e)$.

Procedure $\text{Partition}(A, e, \delta)$ runs in $O(|A| \log |A|)$ time since Step 1 consumes $O(|A| \log |A|)$ time while the rest of the steps for vector partition takes only $O(|A|)$ time. Further, we use two properties of $\text{Partition}(A, e, \delta)$ proposed in [7, 8] in the development of our FPTAS and the establishment of its time complexity.

Property 1 $|e(x) - e(x')| \leq \delta \min\{e(x), e(x')\}$ for any $\{x, x'\} \in A_j^e$ ($j = 1, \dots, k(e)$).

Property 2 $k \leq \frac{\log e(x^{(|A|})}}{\delta} + 2$ for $0 < \delta \leq 1$ and $1 \leq e(x^{(|A|})}$.

It is now ready to present the FPTAS \mathcal{A}_ϵ for $Pm|q_{psd}|C_{\max}$ below.

Algorithm \mathcal{A}_ϵ :

- Step 1.** (Initialization) Reindex the jobs in the nondecreasing order of p_j . Set $Y_0 = \underbrace{\{(0, 0, \dots, 0)\}}_n$ (which means no job is assigned initially) and $j = 1$.

Step 2.1. (Generate Y_1, \dots, Y_n) For set Y_{j-1} , construct Y'_j by adding $x_j \in \{1, \dots, m\}$ in position j of each vector from Y_{j-1} . Calculate the following recursive function for each $x \in Y'_j$:

$$f_j^i(x) = f_{j-1}^i(x) + p_j, \quad i = x_j;$$

$$f_j^i(x) = f_{j-1}^i(x), \quad \text{otherwise.}$$

$$g_j^i(x) = (1 + \gamma)f_{j-1}^i(x) + p_j, \quad i = x_j;$$

$$g_j^i(x) = g_{j-1}^i(x), \quad \text{otherwise.}$$

$$h_j(x) = \max_{i=1, \dots, m} \{g_j^i(x)\}.$$

Step 2.2. If $j = n$, take $Y_n = Y'_n$ and go to Step 3.

Step 2.3. Otherwise, if $j < n$, set $\delta = \frac{\epsilon}{2n}$ and perform the following operations:

Step 2.3.1. Call $\text{Partition}(Y'_j, f_j^i, \delta)$ ($i = 1, \dots, m$) to divide set Y'_j into $k(f^i)$ disjoint subsets $Y_1^{f^i}, Y_2^{f^i}, \dots, Y_{k(f^i)}^{f^i}$.

Step 2.3.2. Call $\text{Partition}(Y'_j, h_j, \delta)$ to divide set Y'_j into $k(h)$ disjoint subsets $Y_1^h, Y_2^h, \dots, Y_{k(h)}^h$.

Step 2.3.3. Divide set Y'_j into disjoint subsets $Y_{a_1 \dots a_m b} = Y_{a_1}^{f^1} \cap \dots \cap Y_{a_m}^{f^m} \cap Y_b^h$ for $a_1 = 1, 2, \dots, k(f^1); \dots; a_m = 1, 2, \dots, k(f^m); b = 1, 2, \dots, k(h)$.

Step 2.3.4. For each nonempty subset $Y_{a_1 \dots a_m b}$, choose a vector $x^{(a_1 \dots a_m b)}$ such that $h_j(x^{(a_1 \dots a_m b)}) = \min\{h_j(x) | x \in Y_{a_1 \dots a_m b}\}$.

Step 2.3.5. Set $Y_j := \{x^{(a_1 \dots a_m b)} | a_1 = 1, 2, \dots, k(f^1); \dots; a_m = 1, 2, \dots, k(f^m); b = 1, 2, \dots, k(h)\}$, and $Y_{a_1}^{f^1} \cap \dots \cap Y_{a_m}^{f^m} \cap Y_b^h \neq \emptyset\}; j = j + 1$, and go to Step 2.1.

Step 3. (Solution) Select vector $x^0 \in Y_n$ such that $h_n(x^0) = \min\{h_n(x) | x \in Y_n\}$.

The purpose of Step 2.3 is to reduce the solution space in the current iteration which will be used to generate the solution space in the next iteration. In each iteration, such reduction guarantees that the function values of omitted solutions are within $(1 + \delta)$ times of the values of remained solutions.

Theorem 9 For $Pm|q_{psd}|C_{\max}$, algorithm \mathcal{A}_ϵ finds a solution x^0 such that $h_n(x^0) \leq (1 + \epsilon)h_n(x^*)$.

Proof Let vector $x^* = (x_1^*, \dots, x_n^*)$ be an optimal solution for $Pm|q_{psd}|C_{\max}$. Suppose there is a partial optimal solution $(x_1^*, \dots, x_j^*, 0, \dots, 0) \in Y_{a_1 \dots a_m b} \subseteq Y'_j$ for some j and a_1, \dots, a_m, b . By Step 2 of algorithm \mathcal{A}_ϵ , such j always exists, for instance, $j = 1$. By Step 2.3.4 of algorithm \mathcal{A}_ϵ , no matter whether or not $(x_1^*, \dots, x_j^*, 0, \dots, 0)$ is chosen as $x^{(a_1 \dots a_m b)}$, it is obtained by [Property 1](#) that

$$|f_j^i(x_1^*, \dots, x_j^*, 0, \dots, 0) - f_j^i(x^{(a_1 \dots a_m b)})| \leq \delta f_j^i(x_1^*, \dots, x_j^*, 0, \dots, 0),$$

$$i = 1, \dots, m,$$

and

$$|h_j(x_1^*, \dots, x_j^*, 0, \dots, 0) - h_j(x^{(a_1 \dots a_m b)})| \leq \delta h_j(x_1^*, \dots, x_j^*, 0, \dots, 0),$$

which means

$$h_j(x^{(a_1 \cdots a_m b)}) \leq (1 + \delta)h_j(x_1^*, \dots, x_j^*, 0, \dots, 0). \quad (8)$$

Now establish the relation between solutions obtained by \mathcal{A}_ϵ and a partial optimal solution in the next iteration.

Consider two vectors which assign $j + 1$ jobs, namely, $(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0)$ and $\hat{x}^{(a_1 \cdots a_m b)} = (x_1^{(a_1 \cdots a_m b)}, \dots, x_j^{(a_1 \cdots a_m b)}, x_{j+1}^*, 0, \dots, 0)$. (\hat{x} is chosen as a bridge connecting a partial optimal solution and the solutions produced by \mathcal{A}_ϵ in the next iteration). Without loss of generality, assume $x_{j+1}^* = u$. It follows that

$$\begin{aligned} & |g_{j+1}^u(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0) - g_{j+1}^u(\hat{x}^{(a_1 \cdots a_m b)})| \\ &= |(1 + \gamma)f_j^u(x_1^*, \dots, x_j^*, 0, \dots, 0) + p_j - (1 + \gamma)f_j^u(x^{(a_1 \cdots a_m b)}) - p_j| \\ &= (1 + \gamma)|f_j^u(x_1^*, \dots, x_j^*, 0, \dots, 0) - f_j^u(x^{(a_1 \cdots a_m b)})| \\ &\leq (1 + \gamma)\delta f_j^u(x_1^*, \dots, x_j^*, 0, \dots, 0) \\ &\leq \delta g_{j+1}^u(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0). \end{aligned}$$

Therefore,

$$g_{j+1}^u(\hat{x}^{(a_1 \cdots a_m b)}) \leq (1 + \delta)g_{j+1}^u(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0).$$

According to the above analysis, the following is obtained:

$$\begin{aligned} & g_{j+1}^i(\hat{x}^{(a_1 \cdots a_m b)}) \\ &\leq (1 + \delta)g_{j+1}^i(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0), \quad i = 1, \dots, m. \end{aligned} \quad (9)$$

Combining inequality (Eq. 9) and the definition of $h_j(x)$,

$$\begin{aligned} & |h_{j+1}(\hat{x}^{(a_1 \cdots a_m b)}) - h_{j+1}(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0)| \\ &= |\max_{i=1, \dots, m}\{g_{j+1}^i(\hat{x}^{(a_1 \cdots a_m b)})\} \\ &\quad - \max_{i=1, \dots, m}\{g_{j+1}^i(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0)\}| \\ &\leq \delta g_{j+1}^i(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0) \\ &\leq \delta \max_{i=1, \dots, m}\{g_{j+1}^i(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0)\} \\ &= \delta h_{j+1}(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0). \end{aligned}$$

Consequently,

$$h_{j+1}(\hat{x}^{(a_1 \cdots a_m b)}) \leq (1 + \delta)h_{j+1}(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0). \quad (10)$$

Set $\delta_j = \delta$ in this, namely, j th, iteration. Then the following inequalities follows directly by inequalities (Eq. 8)–(Eq. 10):

$$h_j(x^{(a_1 \cdots a_m b)}) \leq (1 + \delta_j)h_j(x_1^*, \dots, x_j^*, 0, \dots, 0). \quad (11)$$

$$\begin{aligned} & g_{j+1}^i(\hat{x}^{(a_1 \cdots a_m b)}) \\ & \leq (1 + \delta_j)g_{j+1}^i(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0), \quad i = 1, \dots, m. \end{aligned} \quad (12)$$

$$h_{j+1}(\hat{x}^{(a_1 \cdots a_m b)}) \leq (1 + \delta_j)h_{j+1}(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0). \quad (13)$$

Without loss of generality, assume that $\hat{x}^{(a_1 \cdots a_m b)} \in Y_{c_1 \cdots c_m d} \subseteq Y'_{j+1}$ and algorithm \mathcal{A}_ϵ chooses $x^{(c_1 \cdots c_m d)}$ instead of $\hat{x}^{(a_1 \cdots a_m b)}$ in its $(j+1)$ th iteration. By Property 1 and inequalities (Eq. 12) and (Eq. 13), the following are obtained:

$$\begin{aligned} & |g_{j+1}^i(\hat{x}^{(a_1 \cdots a_m b)}) - g_{j+1}^i(x^{(c_1 \cdots c_m d)})| \\ & \leq \delta g_{j+1}^i(\hat{x}^{(a_1 \cdots a_m b)}) \\ & \leq \delta(1 + \delta_j)g_{j+1}^i(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0), \quad i = 1, \dots, m \end{aligned}$$

and

$$\begin{aligned} & |h_{j+1}(\hat{x}^{(a_1 \cdots a_m b)}) - h_{j+1}(x^{(c_1 \cdots c_m d)})| \\ & \leq \delta h_{j+1}(\hat{x}^{(a_1 \cdots a_m b)}) \\ & \leq \delta(1 + \delta_j)h_{j+1}(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0). \end{aligned} \quad (14)$$

Together with inequalities (Eq. 13) and (Eq. 14),

$$\begin{aligned} & |h_{j+1}(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0) - h_{j+1}(x^{(c_1 \cdots c_m d)})| \\ & \leq |h_{j+1}(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0) - h_{j+1}(\hat{x}^{(a_1 \cdots a_m b)})| \\ & \quad + |h_{j+1}(\hat{x}^{(a_1 \cdots a_m b)}) - h_{j+1}(x^{(c_1 \cdots c_m d)})| \\ & \leq (\delta_j + \delta(1 + \delta_j))h_{j+1}(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0) \\ & = (\delta + (1 + \delta)\delta_j)h_{j+1}(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0). \end{aligned}$$

Set $\delta_{j+1} = \delta + (1 + \delta)\delta_j$ in this $(j+1)$ th iteration. It follows that

$$h_{j+1}(x^{(c_1 \cdots c_m d)}) \leq (1 + \delta_{j+1})h_{j+1}(x_1^*, \dots, x_j^*, x_{j+1}^*, 0, \dots, 0).$$

Repeat the above analysis for $j+2, \dots, n$. There exists an $x' \in Y_n$ such that

$$h_n(x') \leq (1 + \delta_n)h_n(x^*), \quad (15)$$

where δ_n is by the following induction:

$$\begin{aligned} \delta_n &= \delta + (1 + \delta)\delta_{n-1} \\ &= \delta + (1 + \delta)(\delta + (1 + \delta)\delta_{n-2}) \\ &= \dots \\ &= \delta \sum_{i=0}^{n-j-1} (1 + \delta)^i + (1 + \delta)^{n-j}\delta_j. \end{aligned}$$

Remember that it has been set $\delta_j = \delta$. By the above formula, δ_n achieves its maximal value when $j = 1$. That is,

$$\begin{aligned} \delta_n &\leq \delta \sum_{i=0}^{n-2} (1 + \delta)^i + (1 + \delta)^{n-1}\delta \\ &= \delta \sum_{i=0}^{n-1} (1 + \delta)^i \\ &= (1 + \delta)^n - 1 \\ &= \sum_{i=1}^n \frac{n(n-1)\dots(n-i+1)}{i!} \delta^i. \end{aligned}$$

By Step 2.3, substituting $\delta = \frac{\epsilon}{2n}$ in the above formula on the right-hand side of the third equation, the following is obtained:

$$\begin{aligned} \delta_n &\leq \sum_{i=1}^n \frac{n(n-1)\dots(n-i+1)}{i!} \left(\frac{\epsilon}{2n}\right)^i \\ &\leq \sum_{i=1}^n \frac{1}{i!} \left(\frac{\epsilon}{2}\right)^i \\ &\leq \epsilon \sum_{i=1}^n \left(\frac{1}{2}\right)^i \\ &\leq \epsilon. \end{aligned}$$

Together with inequality (Eq. 15),

$$h_n(x') \leq (1 + \epsilon)h_n(x^*).$$

By Step 3 of the algorithm, vector x^0 is chosen such that

$$h_n(x^0) \leq h_n(x') \leq (1 + \epsilon)h_n(x^*).$$

This completes the proof. \square

Theorem 10 Algorithm \mathcal{A}_ϵ requires $O(\frac{m(m+1)n^2}{\epsilon} \log L \log n)$ time.

Proof It suffices to consider the most time-consuming operation of iteration j in Step 2, that is, *Partition*. The time complexity of procedure $\text{Partition}(Y'_j, f_j^i, \delta)$ as well as $\text{Partition}(Y'_j, h_j, \delta)$ is $O(Y'_j \log Y'_j)$. In Step 2, by the construction of Y'_{j+1} , $|Y'_{j+1}| \leq m|Y_j| \leq m \cdot k(f^1) \cdots k(f^m) \cdot k(h)$ is obtained. Define $L = \sum_{i=1}^n p_i$. By Property 2, for each $i \in \{1, \dots, m\}$,

$$k(f^i) \leq \frac{2n}{\epsilon} \log L + 2.$$

Similarly,

$$k(h) \leq \frac{2n}{\epsilon} \log L + 2.$$

Therefore, $|Y'_j| \leq \frac{2mn}{\epsilon} \log L + 2 = O(\frac{mn}{\epsilon} \log L)$ and then $|Y'_j| \log |Y'_j| = O(\frac{mn}{\epsilon} \log L \log n)$. There are at most n iterations, in each of which procedure *Partition* is called $m + 1$ times. So the time complexity of algorithm \mathcal{A}_ϵ is $O(\frac{m(m+1)n^2}{\epsilon} \log L \log n)$. The theorem follows. \square

3.2 Total Completion Time

For problem $Pm|q_{psd}|\sum C_j$, earliest completion time (ECT) rule is equal to SPT rule. Below, a fundamental property for an ECT schedule is presented.

Property 3 Among all feasible schedules for $Pm|q_{psd}|\sum C_j$, an ECT schedule has the most number of completed jobs at any time point during processing.

The above property directly deduces the following theorem.

Theorem 11 *ECT (or SPT) rule is optimal for $Pm|q_{psd}|\sum C_j$.*

4 Conclusion

This chapter has provided an overview of scheduling with past-sequence-dependent delivery times. It has described the major results on single and identical parallel machine settings.

Abstract

Over the past decades, people have dedicated great efforts to solve some NP-complete problems. Hamiltonian path problem is one of classic problems which baffle people many years. In recent years, some algebrization and randomization techniques have been developed and applied in the design of algorithms, which provides a credible alternative to traditional methods. Then the testing monomials theories were developed based on above techniques, which have been found applications in solving some critical problems in graph theory, networking, bioinformatics, etc. We give a self-contained description of the examples of successful applications by combining algebrization techniques and randomization techniques.

1 Introduction

This chapter presents examples to show some important algebrization and randomization techniques that have been effectively applied in the design of algorithms for some classic or burgeoning problems. These techniques were initialized to solve the classic path and packing problem. Then they are found applications in wide range areas such as graph theory, networking, bioinformatics, etc. Through exploiting the techniques of algebrization and randomization and combining them, some classic intractable problems such as k -path problem and Hamiltonian path problem, which baffle people for a long time, have got breakthroughs. Our aim is to make readers recognize that the new developed algebrization and randomization methods are very powerful tools for designing algorithms.

The chapter is organized as follows. [Section 2](#) provides the basic notations and definitions adopted in the rest of this chapter. Also the proof of some well-known results are showed to make the chapter self-contained. The senior readers may skip this section. In the following sections, several examples which are based on the algebrization and randomization techniques are presented. The organization for each section is similar: the beginning paragraphs give a brief glance of the history of the problem, and then the details of the algorithms and the proof the correctness are showed next.

[Section 3](#) presents an $O^*(2^k)$ time algorithm for the k -path problem. The k -path problem, which is also known as the longest path problem, has been studied for decades. With the development of bioinformatics, the k -path problem has found many applications. Combining algebrization and randomization, a big step improvement is achieved to solve the k -path problem.

In [Sect. 4](#), the similar technique is used to solve the famous Hamiltonian path problem. The Hamiltonian path problem is an important graph problem that has

been studied extensively. It is presented as an example for many standard textbooks about complexity and algorithm. For a general graph with n vertices, the fastest algorithm to solve the Hamiltonian path problem runs in $O^*(2^n)$ time. And this runtime went on about half a century since 1950s. This section shows an $O^*(1.657^n)$ time algorithm to solve the Hamiltonian path problem for the general direct graphs.

The theory talked about in Sect. 7, which is named testing monomial theory, comes from the methods used in previous two sections. Because of the important applications, it is necessary to investigate the testing monomial theory and understand how the theory relates to critical problems in complexity. This section works on the question which ask whether a polynomial represented by certain economically compact structure has a multilinear monomial in its sum-product expansion. It discusses the hardness of testing monomial for some special polynomials and gives algorithms to solve it.

Sections 5 and 6 are devoted to discussions on the applications of the testing monomial theory. Two problems, which both are newly burgeoning problems, are presented separately in two sections. Section 5 shows an $O(2^n n^{O(1)})$ time algorithm for minimum common string partition problem (MCSP). Since the applications in genome sequencing of computational biology, the MCSP problem has drawn a lot of attentions. In Sect. 6, algebraic fixed parameter tractable algorithms are presented for Channel Scheduling Problem. The Channel Scheduling Problem focuses on developing efficient scheduling algorithms form the client point of view with the objective of minimizing the access time and number of channel switches for the wireless data broadcast. By solving these two problems, the readers can see the practical applicability of the testing monomial theory. Also it reflects the power of the algebrization and randomization.

As most chapters of this book talk about the approximation algorithms for the combinatorial optimization problems, the reader can see the discussion about the parameterized complexity of combinatorial optimization problems in Chapter ▶ [Connections Between Continuous and Discrete Extremum Problems, Generalized Systems, and Variational Inequalities](#). This chapter contains some recent technologies that combine algebrization and randomization to develop parameterized algorithms and exact algorithms for some NP-hard problems. These methods also bring the new development of complexity theory. We give a self-contained description for all the results in the chapter.

2 Preliminaries

This section reviews some basic notations and theorems which will be adopted throughout the chapter.

2.1 Basic Notations and Definitions

In mathematics, polynomial is one of the most basic algebra concepts. It can be described as an expression constituted by a sum of powers in one or more

variables multiplied by coefficients. It sounds simple, but it hides many profound and complicated computation problems. The concept of polynomial runs through all the chapter. Let $\mathcal{P} \in \{Z, Z_2, \dots, Z_N\}$, $N > 2$. For variables x_1, \dots, x_n , let $\mathcal{P}[x_1, \dots, x_n]$ denote the communicative ring of all the n -variate polynomials with coefficients from \mathcal{P} . For $1 \leq i_1 \leq \dots \leq i_k \leq n$, $\pi = x_{i_1}^{j_1} \dots x_{i_k}^{j_k}$ is called a *monomial*. The *degree* of π , denoted by $\deg(\pi)$, is $\sum_{s=1}^k j_s$. π is *multilinear*, if $j_1 = \dots = j_k = 1$, i.e., π is linear in all its variables x_{i_1}, \dots, x_{i_k} . For any given integer $c \geq 1$, π is called a *c-monomial*, if $1 \leq j_1, \dots, j_k < c$.

An *arithmetic circuit*, or *circuit* for short, is a direct acyclic graph with $+$ gates of unbounded fan-ins, \times gates of two fan-ins, and all terminals corresponding to variables. The *size*, denoted by $s(n)$, of a circuit with n variables is the number of gates in it. A circuit is called a *formula*, if the fan-out of every gate is at most one, i.e., the underlying direct acyclic graph is a tree. A polynomial $p(x_1, \dots, x_n)$ can be represented by a circuit easily.

By definition, any polynomial $p(x_1, \dots, x_n)$ can be expressed as a sum of a list of monomials, called the *sum-product expansion*. The *degree* of the polynomial is the largest degree of its monomials in the expansion.

2.2 Rudimentary Knowledge of Algebra

Senior readers who are familiar with algebra may skip this section. Most of notations which are used in the following sections coincide with standard notations. However, to make the chapter self-contained, it is necessary to introduce some of them which are infrequently seen in combinatorial optimization. Rank and characteristic are very important concepts which appear throughout this chapter. The definitions are given as follows.

Definition 1 Let G be a group and a be an element of G , e is the identity of G , and the *rank* of the element a is defined as the smallest positive integer n which makes $a^n = e$. If n does not exist, a has infinite rank. The rank of a is usually represented as $|a|$.

Definition 2 The characteristic of a ring R , often denoted $Char(R)$, is defined to be the smallest number of times to get the additive identity element 0 by summarizing the multiplicative identity element 1 of R ; the ring R is said to have characteristic zero if this repeated sum never reaches the additive identity.

Theorem 1 ([25]) *If R is a ring with identity and without zero divisors, then all of the elements except the additive identity element 0 have the same characteristic which is either 0 or a prime p .*

In abstract algebra, a field F is a commutative ring whose nonzero elements form a group under multiplication. Thus, each nonzero element a of F has inverse element a^{-1} . It is easy to see that there is no zero divisor in F . Therefore, the above

theorem holds for a field F . Similar to a ring, a field also has its characteristic. Because of [Theorem 1](#), the characteristic of a finite field F must be a prime number.

The main methods based on algebrization and randomization are established over some special algebraic structures. Two special algebraic space $GF(p^n)$ and \mathbb{Z}_2^k are frequently used here. $GF(p^n)$ represents the Galois fields (or finite field) with p^n elements. The Galois fields are classified by size. There is exactly one finite field up to isomorphism of size p^k for each prime p and positive integer k . Specifically, the Galois fields or the finite field has the following properties [44]: first, the Galois fields can be classified by the number of elements, so-called the order, which has the form p^n . Here, p is the characteristic of the field which is a prime number, and n is a positive integer. Second, for every prime number p and positive integer n , there exists a finite field with p^n elements. Third, any two finite fields with the same number of elements are isomorphic. That is, under some renaming of the elements of one of these, both its addition and multiplication tables become identical to the corresponding tables of the other one. For more proofs of the properties, readers can refer to Jacobson's book [44].

For example, the elements of $GF(2^2)$, which has characteristic two, can be represented as the four polynomials $0, 1, x, 1 + x$ over $GF(2)$, where computations are done modulo $x^2 + x + 1$, such as $x^3 = x \cdot x^2 = x \cdot (1 + x) = x + x^2 = 1$ and $x^2 = x \cdot x = (x^2 + 1) \cdot x = x^3 + x = 1 + x$ in $GF(2^2)$. Given the operation with componentwise addition modulo 2 over binary k -vectors, \mathbb{Z}_2^k is the group of all these binary k -vectors. If W_0 is used to denote the all-zeros vector of \mathbb{Z}_2^k , then for each $v \in \mathbb{Z}_2^k$, $v^2 = W_0$ is achieved.

In linear algebra, determinant and permanent are two fundamental concepts over square matrix which has many applications. Given an n -by- n matrix $A = (a_{i,j})$, the *determinant* of A is defined as

$$\det(A) = \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma) \prod_{i=1}^n a_{i,\sigma(i)}$$

Here, the sum is computed over all permutations σ of the $\{1, 2, \dots, n\}$. For each permutation σ , $\operatorname{sgn}(\sigma)$ denotes the signature of σ . It is positive 1 for even σ and negative 1 for odd σ . Evenness or oddness of σ can be defined as follows: the permutation is even(odd) if the new sequence can be obtained by an even(odd) number of switches of numbers. The permanent is a function of the square matrix similar to the determinant. The *permanent* of an n -by- n matrix A is

$$\operatorname{perm}(A) = \sum_{\sigma \in S_n} \prod_{i=1}^n a_{i,\sigma(i)}$$

Over a ring of characteristic two, the well-known fact for a square matrix A is that the determinant is identical to the permanent.

$$\det(A) = \operatorname{perm}(A) \tag{1}$$

2.3 Schwartz-Zippel Lemma

The Schwartz-Zippel lemma is a well-known tool that is commonly used in probabilistic polynomial identity testing. It was developed independently by Schwartz and Zippel in around 1980 [67, 77]. And it is the theoretical basis of the techniques which will be presented in the following sections.

Lemma 1 ([65]) *Let $Q(x_1, \dots, x_n) \in \mathbb{F}[x_1, \dots, x_n]$ be a multivariate polynomial of total degree d . Fix any finite set $\mathbb{S} \subseteq \mathbb{F}$, and let r_1, \dots, r_n be chosen independently and uniformly at random from \mathbb{S} . Then*

$$\Pr[Q(r_1, \dots, r_n) = 0 | Q(x_1, \dots, x_n) \neq 0] \leq \frac{d}{|\mathbb{S}|} \quad (2)$$

Proof The idea derives from single variable case: a single variable polynomial of degree d has no more than d roots. It seems intuitively that a similar statement would hold for multivariate polynomials. The proof is by induction on the number of variables n . As was mentioned before, for base case $n = 1$, the probability that $Q(r_1) = 0$ is at most $\frac{d}{|\mathbb{S}|}$. Assume the lemma holds for a multivariate polynomial with up to $n - 1$ variables. Consider the polynomial $Q(x_1, \dots, x_n)$ by factoring out the variable x_1 :

$$Q(x_1, \dots, x_n) = \sum_{i=0}^k x_1^i Q_i(x_2, \dots, x_n)$$

where $k \leq d$ is the largest exponent of x_1 in Q . Since P is not identical to 0, the coefficient of $x_1^k Q_i(x_2, \dots, x_n)$ is not equal to zero by our choice. It is easy to see that the total degree of $Q_k(x_2, \dots, x_n)$ is at most $d - k$, by induction hypothesis:

$$\Pr[Q_k(r_2, \dots, r_n) = 0] \leq \frac{d - k}{|\mathbb{S}|}$$

Then consider the case that $Q_k(r_2, \dots, r_n) \neq 0$, $Q(x_1, \dots, x_n)$ becomes a univariate polynomial:

$$q(x_1) = Q(x_1, r_2, \dots, r_n) = \sum_{i=0}^k x_1^i Q_i(r_2, \dots, r_n)$$

The polynomial $q(x_1)$ has degree k , so the base case implies that

$$\Pr[Q(r_1, \dots, r_n) = 0 | Q_k(r_2, \dots, r_n) \neq 0] \leq \frac{k}{|\mathbb{S}|}$$

Using events A and B to denote $Q(r_1, \dots, r_n) = 0$ and $Q_k(r_2, \dots, r_n) = 0$, respectively, by probability theory,

$$\begin{aligned}
\Pr[A] &= \Pr[A \cap B] + \Pr[A \cap B^c] \\
&= \Pr[B]\Pr[A|B] + \Pr[B^c]\Pr[A|B^c] \\
&\leq \Pr[B] + \Pr[A|B^c] \\
&\leq \frac{d-k}{|\mathbb{S}|} + \frac{k}{|\mathbb{S}|} \\
&= \frac{d}{|\mathbb{S}|}
\end{aligned}$$

So the induction completes. \square

3 k-Path Problem

In graph theory, given a graph $G = (V, E)$, a *simple path* of G is a path that does not have any repeated vertices. The *longest path problem* is the problem of finding a simple path of maximum length in the given graph G . The decision version of the longest path problem is called the *k-path problem*. The graph G and an integer k are given as input; the aim of the k -path problem is to determine if graph G contains a simple path of length at least k .

Unlike the shortest path problem, even with negative edge weights, as long as the graph G does not have negative-weight cycles, the shortest paths between two vertices can be found in polynomial time. Finding the longest simple path between two vertices is NP-complete even if all edge weights are equal to 1. The NP-completeness of the decision problem can be easily proved by a reduction from the Hamiltonian path problem.

Theorem 2 *The k -path problem is NP-complete.*

Proof For a given graph $G = (V, E)$ and an integer k , a certificate P can be easily verified in polynomial time, so the k -path problem is in class NP.

It is known that Hamiltonian path is NP-complete [23]. The next is to prove Hamiltonian path \leq_p k -path, which shows that the k -path problem is NP-hard. Given a instance of Hamiltonian path $G_1 = (V_1, E_1)$, it can be transformed to a k -path instance by simple asking whether there exists a simple path of length $|V_1|$ in G_1 .

Clearly, if G_1 has a Hamiltonian path, since it traverses all possible vertices, this Hamiltonian path is the simple path of G_1 with length $|V_1|$. Conversely, if there is simple path of length $|V_1|$ in the graph G_1 , it is a path that visits all the vertices of G_1 without repetition, and this is a Hamiltonian path by definition. \square

The longest path problem can be transformed into the shortest path problem by utilizing the dual nature of optimizations. Given a longest path problem with input graph G , G can be converted into the shortest simple path problem on graph H which is same as the original graph G but with edge weights negated. It is

known that the shortest path problem can be solved in polynomial time for graph without negative-weight cycle. This approach cannot be used to solve H because any positive-weight cycle in G produces a negative-weight cycle in H . Thus, the shortest path problem on a graph with negative-weight cycle is also NP-complete. However, the longest path problem is polynomial-time solvable on acyclic graphs. Since the acyclic graph has no cycles, there is no negative-weight cycle on H . Thus, any shortest path algorithm can be used to solve the shortest problem on H .

3.1 A Brief History of the k -Path Problem

For a graph $G = (V, E)$ with the number of nodes $|V| = n$ and an integer k , the naive algorithm of the k -path problem enumerates all sequences of length $k + 1$ with time bound $O(n^k)$. When $k = n$, it has been known very early that the problem can be solved in $O^*(2^k)$ time using dynamic programming method [8, 38, 51]. In 1985, B. Monien first improved the time bound to $O^*(k!)$. Thus, the problem can be solved in polynomial time when $k \leq \log n / \log \log n$. After about 10 years, Papadimitriou and Yannakakis [66] conjectured that the $(\log n)$ -path problem can be solved in polynomial time. Almost in the meantime, Alon, Yuster, and Zwick [2] verified the conjecture. They gave a randomized algorithm running in $O^*((2e)^k) \leq O^*(5.44^k)$ time and a deterministic $O^*(c^k)$ time algorithm, where c is a large constant.

With the development of bioinformatics, the k -path problem has found applications both in biological subnetwork matchings [53] and in detecting signaling pathways in protein interaction networks [68]. Probably driven by the demand of applications, faster algorithms appeared after 2006. J. Kneis et al. [56] provided a $O^*(4^k)$ randomized algorithms and $O^*(c^k)$ deterministic algorithm with $c = 16$. The deterministic complexity was further reduced by Chen et al. [19], who presented more efficient color-coding schemes and gave an $O^*(12.8^k)$ time deterministic algorithm. The space complexity of the algorithm is $O(k \log k n + m)$ which is a remarkable improvement over the exponential $\ln k$ space complexity of the color-coding approach.

Very recently, a big step was taken by Koutis [61] and Williams [74]. Koutis gave a randomized algorithm for k -path that runs in $O^*(2^{3k/2}) \leq O^*(2.83^k)$ time. By improving Koutis's approach, Williams presented a $O^*(2^k)$ time randomized algorithm in 2008. They used very typical approaches which combine algebraization methods with randomization methods to obtain more efficient algorithms.

3.2 $O^*(2^k)$ Time Randomized Algorithm

For this section, the main techniques are from the works of Williams [74] and Koutis [61]. Our objective is to make their works more readable for the inexperienced. Also an introduction of this line of research will make readers have clear mentality. The general idea is to reduce the k -path problem to the

multilinear monomial testing for the sum-product expansion of a polynomial which is constructed by the input graph. Improving Koutis's result [61], Williams [74] developed an $O(2^k n^{O(1)})$ time randomized algorithm such that it outputs yes with high probability if there is a multilinear monomial and always outputs no if there is no multilinear monomial.

According to above idea, the first problem is how to transform the given graph G for the k -path problem into a polynomial. Assume graph G has vertex set v_1, v_2, \dots, v_n . Let A be the adjacency matrix of G , and let x_1, x_2, \dots, x_n be variables. Define a matrix $B[i, j] = A[i, j]x_i$. Let $\vec{1}^T$ be the row n -dimension vector of all 1's and \vec{x} be the column n -dimension vector defined by $\vec{x}[i] = x_i$. So the graph G can be transformed into the k -walk polynomial $P_k(x_1, \dots, x_k) = \vec{1}^T \cdot B^{k-1} \cdot \vec{x}$. The k -walk polynomial has a good property that it reflects all the walk of length k in its sum-product expansion. Then the following claim can be proved.

Define the polynomial

$$P_k(x_1, \dots, x_k) = \sum_{i_1, \dots, i_k \text{ is a walk in } G} x_{i_1} \cdots x_{i_k}$$

It is easy to see that the graph G has a k -path v_{i_1}, \dots, v_{i_k} iff $P_k(x_1, \dots, x_k)$ has a multilinear monomial of $x_{i_1} \cdots x_{i_k}$ of degree k in its sum-product expansion (see an example below). So the k -path problem for G can be reduced to the problem that detects whether $P_k(x_1, \dots, x_k)$ has multilinear monomial in its sum-product expansion. It is trivial to see whether $P_k(x_1, \dots, x_k)$ has a multilinear monomial when its sum-product expansion is already known. Unfortunately, the sum-product expression is essentially a troublesome thing which is infeasible to realize. That is because a polynomial may often have exponentially many monomials in its expansion.

Lemma 2 *There is a polynomial-time algorithm such that given an undirected graph G and a parameter k , it outputs a polynomial size circuit S for a multivariate polynomial $C(\cdot)$ such that G has a k -path if and only if the sum-product expansion of $C(\cdot)$ contains a multilinear monomial.*

Proof For each vertex $v_i \in V$, define a polynomial $p_{k,i}$ as follows:

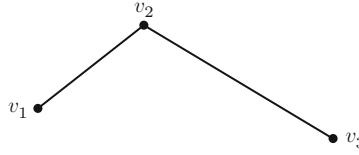

$$\begin{aligned} p_{1,i} &= x_i, \\ p_{k+1,i} &= x_i \left(\sum_{(v_i, v_j) \in E} p_{k,j} \right), \quad k > 1. \end{aligned}$$

A polynomial for G is defined as

$$p(G, k) = \sum_{i=1}^n p_{k,i}.$$

Obviously, $p(G, k)$ can be represented by an arithmetic circuit. It is easy to see that the graph G has a k -path $v_{i_1} \cdots v_{i_k}$ iff $p(G, k)$ has a monomial of $x_{i_1} \cdots x_{i_k}$ in its sum-product expansion. \square

Example 1 Consider the following simple graph G_1 with three nodes:

The adjacency matrix A_1 of G_1 and the matrix $B_1[i, j] = A_1[i, j]x_i$ are given below:

$$A_1 = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix} \quad B_1 = \begin{pmatrix} 0 & x_1 & 0 \\ x_2 & 0 & x_2 \\ 0 & x_3 & 0 \end{pmatrix}$$

Then the 3-walk polynomial $P_3(x_1, x_2, x_3) = \vec{1}^T \cdot B_1^2 \cdot \vec{x} = 2x_1x_2x_3 + x_1^2x_2 + x_1x_2^2 + x_2^2x_3 + x_2x_3^2$. Clearly, $x_1x_2x_3$ is a multilinear monomial in $P_3(x_1, x_2, x_3)$, so there is a corresponding 3-path $v_1 \rightarrow v_2 \rightarrow v_3$ in G_1 . It is easy to see that P_k can be represented by a circuit of size $O(k(m+n))$ where m is the number of edges in G . Let $F = GF(2^{3+\log k})$ and W_0 be the all-zeros vector of \mathbb{Z}_2^k . Williams's randomized algorithm is introduced as follows:

Algorithm 1 Williams's Algorithm

Input: a graph G with vertex set v_1, v_2, \dots, v_n and a parameter k

Output: If G does not have a k -path, the algorithm always outputs *false*; if G has a k -path, the algorithm outputs *true* with probability no less than $1/5$.

Steps:

- 1: Calculate P_k as described above.
- 2: Implement P_k with a circuit C .
- 3: Pick n uniform random vectors z_1, z_2, \dots, z_n from \mathbb{Z}_2^k .
- 4: For each multiplication gate g_i in C , pick a uniform random $w_i \in F \setminus 0$.
Insert a new gate that multiplies the output of g_i with w_i and feeds the output to those gates that read the output of g_i .
- 5: Let C' be the new arithmetic circuit and P' be the new polynomial represented by C' .
Output true iff $P'(W_0 + z_1, \dots, W_0 + z_n) \neq 0$.

End of Algorithm

The basic idea of Williams's algorithm is to substitute variables of P_k with random group algebra elements of \mathbb{Z}_2^k such that in the sum-product expansion of P_k , all the non-multilinear monomials in P_k become zero and some multilinear monomials survive. And in order to avoid making the coefficients of all multilinear monomials zero, the original scalar-free multiplication circuit is augmented by adding random scalar multiplications over a field large enough that the remaining multilinear monomial evaluates to nonzero with decent probability. Let $s(n)$ be the size of the arithmetic circuit used to represent P_k . Then [Theorem 3](#) gives theoretical support for Williams's algorithm.

In above algorithm, readers need to pay attention to two points. First, all the additions and multiplications are over a ring $F(\mathbb{Z}_2^k)$. Elements of $F(\mathbb{Z}_2^k)$ have the form $\sum_{g \in \mathbb{Z}_2^k} a_g g$, where each $a_g \in F$. The addition of $F(\mathbb{Z}_2^k)$ is defined in a point-wise manner:

$$\left(\sum_{g \in \mathbb{Z}_2^k} a_g g \right) + \left(\sum_{g \in \mathbb{Z}_2^k} b_g g \right) = \sum_{g \in \mathbb{Z}_2^k} (a_g + b_g) g$$

The multiplication of two vectors $(a_1, \dots, a_k)^T$ and $(b_1, \dots, b_k)^T$ in $F(\mathbb{Z}_2^k)$ is equal to $(c_1, \dots, c_k)^T$ with $c_i = a_i + b_i \pmod{2}$ for $i = 1, 2, \dots, k$. The multiplication has the form of a convolution:

$$\left(\sum_{g \in \mathbb{Z}_2^k} a_g g \right) \cdot \left(\sum_{g \in \mathbb{Z}_2^k} b_g g \right) = \sum_{g, v \in \mathbb{Z}_2^k} (a_g a_v)(gv) = \sum_{g \in \mathbb{Z}_2^k} \left(\sum_{h \in \mathbb{Z}_2^k} a_h b_{hg} \right) g$$

Example 2 Let $u_1, u_2 \in GF(2^2)[\mathbb{Z}_2^3]$, where

$$u_1 = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix} + x \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix}, \quad u_2 = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix} + \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix} + \begin{pmatrix} 1 \\ 1 \\ 1 \end{pmatrix}.$$

Then

$$\begin{aligned} u_1 + u_2 &= \left[\begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix} + x \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix} \right] + \left[\begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix} + \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix} + \begin{pmatrix} 1 \\ 1 \\ 1 \end{pmatrix} \right] \\ &= (1+x) \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix} + \begin{pmatrix} 1 \\ 1 \\ 1 \end{pmatrix} \end{aligned}$$

$$\begin{aligned}
u_1 \cdot u_2 &= \left[\begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix} + x \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix} \right] \cdot \left[\begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix} + \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix} + \begin{pmatrix} 1 \\ 1 \\ 1 \end{pmatrix} \right] \\
&= (1+x) \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix} + x \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix} + (1+x) \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix} + \begin{pmatrix} 1 \\ 1 \\ 1 \end{pmatrix}
\end{aligned}$$

Second point is that in the evaluation of the k -path polynomial P_k , the algorithm corresponds to picking random $y_{i,j,c}$ in F for $c = 1, \dots, k-1$, $i, j = 1, \dots, n$, letting $B_c[i, j] = y_{i,j,c} B[i, j]$, then evaluating $P'_k(x_1, \dots, x_n) = \vec{1}^T \cdot B_{k-1} \cdots B_1 \cdot \vec{x}$ on the appropriate vectors.

Before proving the correctness of Williams's algorithm, a lemma which was proved by Koutis [61] and then further developed by Williams [74] over any field of characteristic two needs to be shown first.

Lemma 3 *If $z_1, z_2, \dots, z_i \in \mathbb{Z}_2^k$ are linearly dependent over $GF(2)$, then $\prod_{j=1}^i (W_0 + z_j) = 0$ in $F[\mathbb{Z}_2^k]$. Otherwise, if $z_1, z_2, \dots, z_i \in \mathbb{Z}_2^k$ are linearly independent over $GF(2)$, then $\prod_{j=1}^i (W_0 + z_j) = \sum_{z \in \mathbb{Z}_2^k} z$.*

Proof If z_1, z_2, \dots, z_i are linearly dependent, there is a nonempty subset T of the vectors that sum to the all-zeros vector. In $F[\mathbb{Z}_2^k]$, this is equivalent to

$$\prod_{j \in T} z_j = W_0.$$

Let $S \subseteq T$ be arbitrary. By multiplying both sides by $\prod_{j \in (S \Delta T)} z_j$,

$$\prod_{j \in S} z_j = \prod_{j \in (S \Delta T)} z_j.$$

Thus, $\prod_{j \in T} (W_0 + z_j) = \sum_{S \subseteq T} (\prod_{j \in S} z_j) = 0 \bmod 2$, since each product appears twice in the sum. Since F is characteristic two, $\prod_{j=1}^i (W_0 + z_j) = 0$ over $F[\mathbb{Z}_2^k]$.

Therefore, linearly dependent vectors lead to a cancellation of monomials. On the other hand, when z_1, z_2, \dots, z_i are linearly independent, $\prod_{j=1}^i (W_0 + z_j)$ is just the sum over all vectors in the span of z_1, z_2, \dots, z_i , since each vector in the span is of the form $\prod_{j \in S} z_j$ for some $S \subseteq [i]$, and there is a unique way to generate each vector in the span. \square

Lemma 4 *Let v_1, \dots, v_n be n random vectors in \mathbb{Z}_2 . Then with probability at least $\frac{1}{4}$, they are linearly independent.*

Proof. For the first m vectors v_1, \dots, v_k , there are 2^k vectors that can be expressed as $\sum_{i=1}^k a_i v_k$, where $a_i \in Z_2$ for $i = 1, \dots, m$. Thus, for a random n -dimensional vector v_{m+1} from Z_2 , with probability $\frac{2^k}{2^n}$, v_{m+1} cannot be expressed as $\sum_{i=1}^k a_i v_k$ for some $a_i \in Z_2$ for $i = 1, \dots, m$. The probability that v_1, \dots, v_n linearly independent is

$$\left(1 - \frac{1}{2^n}\right) \left(1 - \frac{2}{2^n}\right) \cdots \left(1 - \frac{2^{n-1}}{2^n}\right) \geq \frac{1}{2} \prod_{k=2}^n \left(1 - \frac{1}{k^2}\right) \quad (3)$$

$$= \frac{1}{4}. \quad (4)$$

□

Example 3 Let $z_1, z_2, z_3, z_4 \in \mathbb{Z}_2^3$ be four vectors:

$$z_1 = \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix} \quad z_2 = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} \quad z_3 = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} \quad z_4 = \begin{pmatrix} 1 \\ 1 \\ 0 \end{pmatrix}$$

Since $z_1 \cdot z_2 \cdot z_4 = W_0$, z_1, z_2, z_3, z_4 are linearly dependent. To coincide with above proof, let $T = \{z_1, z_2, z_3\}$. Then $\prod_{j \in T} (W_0 + z_j) = (W_0 + z_1) \cdot (W_0 + z_2) \cdot (W_0 + z_4) = W_0 + z_1 + z_2 + z_4 + z_1 \cdot z_2 + z_1 \cdot z_4 + z_2 \cdot z_4 + z_1 \cdot z_2 \cdot z_4 = 0$. The above equation equals to zero because $z_1 \cdot z_2 \cdot z_4 = W_0$, $z_1 = z_2 \cdot z_4$, $z_2 = z_1 \cdot z_4$, $z_4 = z_1 \cdot z_2$ in the sum-product and F is characteristic two.

On the other hand, it is easy to see that z_1, z_2, z_3 are linearly independent. So it can be easily verified that $\prod_{j=1}^3 (W_0 + z_j)$ is the sum over all vectors in the span of z_1, z_2, z_3 .

Theorem 3 ([74]) Given a graph G with vertex set v_1, v_2, \dots, v_n and a parameter $k \leq n$, Williams's algorithm is a randomized $O^*(2^k n^{O(1)})$ time algorithm such that if there is a k -path in G , it outputs true with probability no less than $1/5$ and always outputs false if there is no k -path in G .

Proof By the observation of Koutis [61] that for any $z_i \in \mathbb{Z}_2^k$,

$$(W_0 + z_i)^2 = W_0^2 + 2v_i + v_i^2 = W_0 + 0 + W_0 = 0 \pmod{2}.$$

Thus, since F has characteristic two, all squares in P equal to 0 in $P'(W_0 + z_1, \dots, W_0 + z_n)$. It illustrates that if $P(x_1, \dots, x_n)$ does not have a multilinear monomial, then for any choice of v_i , $P'(W_0 + z_1, \dots, W_0 + z_n) = 0$ over $F[\mathbb{Z}_2^k]$.

Without loss of generality, assume that every multilinear monomial of P has degree at least k , and at least one multilinear monomial has degree exactly k . If not, let $k' < k$ be the minimum degree of a multilinear monomial in P . By trying

all $j = 1, \dots, k$ and multiplying the final output of the circuit for P by j new variables x_{n+1}, \dots, x_{n+j} , a polynomial P^j is obtained to be fed to the randomized algorithm. Note that when $j = k - k'$, our assumption holds.

By above assumption, every multilinear monomial in the sum-product expansion of P has the form $c \cdot x_{i_1} \cdots x_{i_{k''}}$, where $k'' \geq k$ and $c \in \mathbb{Z}$. For each such monomial, there is a corresponding collection of multilinear monomial P' , each of the form $w_1 \cdots w_{k'-1} \prod_{j=1}^{k'} (W_0 + z_{i_j})$, where the sequence $w_1, \dots, w_{k'-1}$ is distinct for every monomial in the collection (as the sequences of multiplication gates $g_1, \dots, g_{k'-1}$ are distinct). Since there are no scalar multiplication in the arithmetic circuit, these monomials do not have leading coefficients. Then it can be proved that if the sum-product expansion of $P(x_1, \dots, x_n)$ has a multilinear monomial, for random choices of w_i 's and z_i 's, $P'(W_0 + z_1, \dots, W_0 + z_n) \neq 0$ with probability at least $1/5$.

Since $k'' > k$ vectors are linearly dependent, by Lemma 3, $P'(W_0 + z_1, \dots, W_0 + z_n)$ equals to either 0 or $c \sum_{z \in \mathbb{Z}_2^k}$ for some $c \in F$. The vectors z_{l_1}, \dots, z_{l_k} chosen for the variables in a multilinear monomial P are linearly independent with probability at least $1/4$, because the probability that a random $k \times k$ matrix over $GF(2)$ has full rank is at least $1/4$ according to Lemma 4.

If S is used to represent the set of those multilinear monomials in P which correspond to k linearly independent vectors in $P'(W_0 + z_1, \dots, W_0 + z_n)$, then for some $c_i \in F$, the coefficient $c = \sum_i c_i \in F$ mentioned in the last paragraph corresponds to the i th multilinear monomial in S . Here, each coefficient c_i comes from a sum of products of $k - 1$ elements $w_{i,1}, \dots, w_{i,k-1}$ corresponding to some multiplication gates $g_{i,1}, \dots, g_{i,k-1}$. Note that in the k -path case, each c_i is a sum of products of the form $w_{i,1}w_{i,2} \cdots w_{i,k-1}$. Imagining the w_i 's as variables, the sum $Q = \sum_i c_i$ is a *degree-k polynomial* over F . Assuming $S \neq \emptyset$, since each monomial in Q has coefficient 1, Q is not identical to zero. Then by Schwartz-Zippel Lemma 1, randomly assigning values to the variables of Q results in an evaluation of 0 $\in F$ with probability at most $k/|F| = 1/2^3$. Since $S \neq \emptyset$ with probability at least $1/4$, and the coefficient $c \neq 0$ with probability at least $1 - 1/2^3 = 7/8$, the overall probability of success is at least $1/4 \cdot 7/8 > 1/5$.

In the remaining paragraph, the runtime of the algorithm is discussed. However, since all the additions and multiplications takes place over $F[\mathbb{Z}_2^k]$, it is necessary to account for the cost of each arithmetic.

Consider the sum-product expansion of $P'(W_0 + z_1, \dots, W_0 + z_n)$. It will be converted into $\sum C_i(\cdot)v_i$, where each v_i is a k -dimensional vector over Z_2 , and $C_i(\cdot)$ is a circuit for a multivariate polynomial. According to the construction of in Lemma 2, each multiplication gate is for $(m_i v_j)(\sum C_i(\cdot)v_i)$, where m_i is a monomial. It takes $O(2^k)$ steps to convert it into the format $\sum C'_i(\cdot)v_i$.

Assume that the final evaluation has the format $\sum C_i^*(\cdot)v_i$. The size of each $C_i^*(\cdot)$ can be maintained in the size $O(n^{O(1)})$ as the original size of circuit $P(\cdot)$ is $O(n^{O(1)})$. The existing algorithm needs to be used for the polynomial identity, which takes $O(n^{O(1)})$ time for each $C_i^*(\cdot)$, to test if each $C_i(\cdot)^*$ is zero by Lemma 1. Therefore, the total time is $O(2^k n^{O(1)})$. \square

4 Hamiltonian Path Problem

In graph theory, a *Hamiltonian path* is a path in an undirected graph that visits each vertex exactly once. A *Hamiltonian cycle* is a cycle in an undirected cycle which visits each vertex exactly once and also returns to the starting vertex. For example, every cycle graph and complete graph with more than two vertices is Hamiltonian. Hamiltonian paths and cycles are named after William Rowan Hamilton who invented the Icosian game, which involves finding a Hamiltonian cycle in the edge graph of the dodecahedron.

The Hamiltonian path problem and the Hamiltonian cycle problem are two classic problems of determining whether there exists a Hamiltonian path and a Hamiltonian cycle, respectively, for a given directed or undirected graph. For a given graph G , the Hamiltonian path problem is equivalent to the Hamiltonian cycle problem by adding a new vertex and connecting it to all the vertices of G . Both problems are in Karp's original list [51] of NP-complete problems. For the specific proof of NP-completeness of the problems, please refer to standard algorithm books (e.g., [23]). Actually, the NP-hardness of Hamiltonian path problem has been used in the proof of [Theorem 2](#). Through setting the distance between two cities to a finite constant if they are adjacent and infinity otherwise, the Hamiltonian path problem is a special case of the *traveling salesman problem* (TSP). The TSP was first formulated as a mathematical problem in 1930s. It is one of the most intensively studied problems in computational mathematics. Given a list of cities and their pairwise distances, the TSP asks for a shortest possible tour that visits each city exactly once. Even though the problem is computational difficult, a large amount of heuristics and exact methods are given to solve different instances of it [3]. Furthermore, the TSP has many applications in planning, logistics, and the manufacture of microchips. It is also equivalent to some bioinformatics problems such as DNA sequencing after slightly modified.

4.1 A Brief History of TSP and Hamiltonian Path Problem

The TSP was defined formally in the 1800s and was first studied by K. Menger and other mathematicians during the 1930s. The naive solution of the TSP would be try all permutations and see which one is cheapest using brute force search. The running time for this approach is in $O(n!)$, the factorial of the number of cities. So this approach becomes impractical even for only 20 cities. In almost 200 years from 1930s, plenty of algorithms including heuristics, approximations, and exact algorithms have been developed. Since the topic mainly focus on the Hamiltonian path detection problem in this section, we only introduce the exact algorithms for brevity. Later in the 1950s and 1960s, the TSP was reduced to an integer linear program by G. Dantzig et al., and the cutting plane method was developed to solve it. In the same period, Bellman [7, 8] and Karp [38] provided the dynamic programming algorithm for the TSP which runs in $O(n^2 2^n)$ time. Given a complete

graph with n vertices and edge weights $l : E \rightarrow R^+$, the algorithm is based on defining $w_{s,t}(X)$ for $s, t \in X \subseteq V$ as the weight of the lightest path from s to t in the induced graph $G[X]$ visiting all vertices in X exactly once. Here, $w_{s,t}(X)$ obeys the following simple recursive equation:

$$w_{s,t}(X) = \begin{cases} \min_{u \in X \setminus \{s,t\}} w_{s,u}(X \setminus \{t\}) + l(ut) & |X| > 2 \\ l(st) & |X| \leq 2 \end{cases}$$

The dynamic programming solution requires exponential space. Using inclusion-exclusion, the problem can be solved in time within a polynomial factor of 2^n and polynomial space [5, 52, 57]. Then great progress was made by Grotschel et al., which uses cutting planes and branch and bound to solve instances with up to 2,392 cities. After that, Applegate, Bixby, Chvatal, and Cook developed the program Concorde that has been used in many recent record solutions. Except for the improvements for the general graph, there are some commendable results for restricted graph classes. Broersma et al. [13] described how to solve the Hamiltonian path problem for claw-free graphs in $O^*(1.682^n)$ time. Iwama and Nakashima [43] showed that the TSP in cubic graphs admits an $O^*(1.251^n)$ time algorithm by improving slightly on Eppstein [28]. In graphs of maximum degree 4, Gebauer [35] provided an algorithm to count the Hamiltonian cycles in $O^*(1.715^n)$ time. Björklund et al. [12] presented that the traveling salesman problem in bounded degree graphs can be solved in time $O((2 - \epsilon)^n)$, where $\epsilon > 0$ depends only on the degree bound but not on the number of cities, n .

In 2005, by transforming a TSP instance into an instance of microchip layout problem, Cook and others computed an optimal tour for an instance which contains 33,810 cities. Though for the instances with tens of thousands of cities, the TSP can be solved. There is still no algorithm which breaks the time bound $O(2^k)$ for the general graph. So Woeginger [75] asked in open problem that whether there exists an exact algorithm which runs in time $O^*(c^n)$ for the TSP and the Hamiltonian path problem for some $c < 2$. After 7 years, this problem has been solved very recently by Björklund [9], who improved the bounds to $O(1.414^n)$ and $O(1.657^n)$ for the bipartite graph and the general graph, respectively.

4.2 Overall Idea of Björklund's Approach

About 50 years ago, the $O^*(2^n)$ time bound for detecting Hamiltonian path problem has been established. No exact algorithm which was developed to beat the bound until half a century later. Björklund [9] presented a Monte Carlo algorithm for n -vertex undirected graph running in $O^*(1.657^n)$ time, which is a breakthrough for this fundamental and classic problem. This crucial contribution was inspired by the algebraic sieving method for k -path problem [61, 74] which is introduced in Sect. 3.

The basic idea of Björklund's approach is similar to the inclusion-exclusion algorithm which can be summarized as first counting all closed n -walks through

s and then canceling out crossing n -walks. However, comparing with inclusion-exclusion algorithm, Björklund's approach has some limitations. It only works for undirected graph, it is randomized, and also it cannot count the number of solutions. The same as Williams's algorithm [74] for the k -path, Björklund's approach evaluates multivariate polynomials over fields of characteristic two. The difference between them is that instead of sieving the k -path among all the walks, Björklund's approach sieves the Hamiltonian cycles among all the cycle covers. A cycle cover in a directed n -vertex graph is a set of n arcs such that every vertex is the origin of one arc and the end of another. The arcs together describe disjoint cycles covering all vertices of the graph. In particular, the cycle covers contain the Hamiltonian cycle.

The main contribution of Björklund's work is that it not only further develops Koutis-William's ideas but also introduces determinants to count weighted cycle covers to extend the ideas of using determinants to count perfect matchings [10]. However, unlike Koutis-William who construct small arithmetic circuits, Björklund depends on the efficient algorithms for computing a matrix determinant numerically. In the following paragraphs of this section, a concrete introduction about Björklund's approach is given, which further shows the tremendous ability of algebrization and randomization for the algorithm design.

4.3 Notations and Definitions

This section first introduces some particular notations and definitions for Björklund's algorithm. Efforts were made to explain the details of the methods more clearly; however, for letting readers simply refer to the original papers, most of the notations are consistent with Björklund's. A cycle cover can be formally defined as follows.

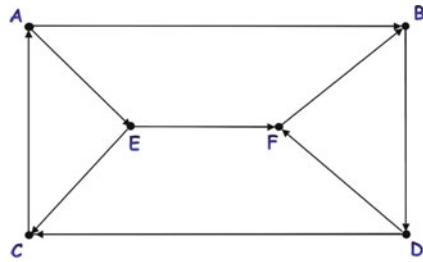

Definition 3 For a direct graph $D = (V, E)$, a *cycle cover* is a subset $C \subseteq E$ such that for every vertex $v \in V$, there is exactly one arc $a_{v_1} \in C$ starting in v and exactly one arc $a_{v_2} \in C$ ending in v . Let $cc(D)$ be the family of all cycle covers of D and let $hc(D)$ be the set of Hamiltonian cycle covers.

It is easy to see that $hc(D) \subseteq cc(D)$. Because among all the cycle covers of G , the Hamiltonian cycle covers are some particular cycle covers which consist of only one big cycle passing through all vertices of D . Let $cc(D) \setminus hc(D)$ be set of *non-Hamiltonian cycle covers*, i.e., $cc(D)/hc(D)$ contains all the cycle covers which have more than one small cycles. A Hamiltonian cycle cover of a direct graph can be simply written as a vertex order $(v_0, v_1, \dots, v_{n-1})$ (cf. Fig. 1).

Given a function $f : X \rightarrow Y$, f is *surjective* (or onto) if each element of Y can be obtained by applying f to some element of X . Let $f^{-1} : Y \rightarrow 2^X$ be the preimage of f , then $f^{-1}(b) = \{a \in X : f(a) = b\}$.

Then an important definition for *labeled cycle cover sum* will be given next. The name stems from the fact that every arc in cycle cover is labeled by a nonempty

Fig. 1 The direct graph with a non-Hamiltonian cycle cover $[(A, E, C), (B, D, F)]$ and a Hamiltonian cycle (A, E, F, B, D, C)

subset of a set of labels. It is important because the Hamiltonian path detection problem can be reduced to labeled cycle cover sum calculating problem.

Definition 4 Suppose $D = (V, E)$ is a directed graph, L is a label set, and f is a function on a ring R which takes an edge a in G and the a subset of labels in L as inputs. The *labeled cycle cover sum* for D is defined as

$$\Lambda(D, L, f) = \sum_{C \in cc(D)} \sum_{g: L \twoheadrightarrow C} \prod_{a \in C} f(a, g^{-1}(a)) \quad (5)$$

In above definition, all the cycles covers are summarized in the outer sum, and the inner sum is over all surjective function g from the label set L to the cycle cover set C with the two head arrow \twoheadrightarrow representing a surjective function.

4.4 Cycle Cover Cancelation in Characteristic Two

In Sect. 4.2, it has been mentioned that the basic idea is first counting too much and then canceling out every false contribution. Following this idea, since the cycle covers of the graph contains all the Hamiltonian paths, the objective is to cancel out all the non-Hamiltonian paths and hence keep the Hamiltonian cycle covers. Thus, this section first describes how the non-Hamiltonian cycle covers are canceled out in the labeled cycle cover sum over the ring R with characteristic two and then discusses how to keep the Hamiltonian cycle covers.

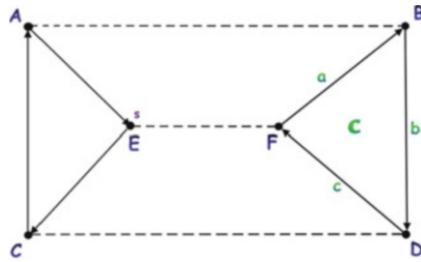

Before presenting the lemma, two definitions are necessary.

Definition 5

- A direct graph $G = (V, E)$ is *bidirected* if for every arc $uv \in E$, it has an arc $vu \in E$ in the opposite direction.
- For an arbitrarily chosen special vertex s , $f: A \times 2^L \setminus \{\emptyset\} \rightarrow R$ is an *s-oriented mirror function* if $f(uv, Z) = f(vu, Z)$ for all Z and all $u \neq s$ and $v \neq s$.

The next lemma proves that how the non-Hamiltonian cycle covers vanish, which also imply that the nonexistence of false positives in Björklund's randomized algorithm for detecting the Hamiltonian path.

Fig. 2 Considering Fig. 1 as a bidirected graph, this figure shows a cycle cover $[(AEC), (BDF)]$ which contains a labeled cycle $\mathbf{C} = (BDF)$ with the arcs along the cycle \mathbf{C} is to pair with the cycle cover in Fig. 3

Lemma 5 Given a bidirected graph $D = (V, E)$, a finite set L , and special vertex $s \in V$, let f be an s -oriented mirror function over a ring R of characteristic two. Then

$$\Lambda(D, L, f) = \sum_{H \in hc(D)} \sum_{g: L \rightarrow H} \prod_{a \in H} f(a, g^{-1}(a)) \quad (6)$$

Proof To cancel out all the labeled non-Hamiltonian cycle covers in the labeled cycle cover sum, a mapping M is created to partition all the non-Hamiltonian cycle covers into dual pairs such that both cycle covers in each pair contribute the same term to the sum. Since the ring R is of characteristic two, all these terms cancel.

Let $C \in cc(D)$ and \mathbf{C} be the first cycle of C not passing through s . Since all the non-Hamiltonian cycle cover consists of at least two cycles and all cycles are vertex disjoint, there must exist one such \mathbf{C} . There are two cases. In the general case, consider any fixed order of the cycles. Let $C' = C$ except for the cycle \mathbf{C} which is reversed in C' , i.e., every arc $uv \in \mathbf{C}$ is replaced by the arc in the opposite direction vu in C' . Since G is bidirected, this arc must exist. In the special case when \mathbf{C} contains only two arcs, C' is identical to C . The function g'^{-1} is identical to g^{-1} on $C \setminus \mathbf{C}$ and is defined by $g'^{-1}(uv) = g^{-1}(vu)$ for all arcs $uv \in \mathbf{C}$. Then the mapping is constructed by $M(C, g) = (C', g')$. And clearly, $(C, g) \neq M(C, g)$ and $(C, g) = M(M(C, g))$. Therefore, the mapping M uniquely pairs up the labeled non-Hamiltonian cycle covers. Figures 2 and 3 give an example.

From the known conditions of the lemma, f is an s -oriented mirror function. Thus, $f(uv, Z) = f(vu, Z)$ for all arcs uv not incident to s and all $Z \in 2^L \setminus \emptyset$. Also since F is a ring of characteristic two and (C, g) and $M(C, g)$ have same labels, the equality $\prod_{a \in C} f(a, g^{-1}(a)) = \prod_{a \in C'} f(a, g'^{-1}(a))$ satisfies. Therefore, the addition of the above tow products from (C, g) and $M(C, g)$ equals to 0. \square

The above lemma shows how the non-Hamiltonian cycle covers cancel out in labeled cycle cover sum if the function f meets some requirements. However, in order to detect the Hamiltonian cycle covers, at least one Hamiltonian cycle cover reserves is still needed. The technique used here is very similar to the

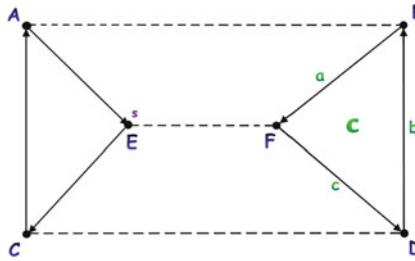

Fig. 3 This Figure is achieved by applying mapping M to Fig. 2. It has a cycle cover $[(AEC), (BFD)]$ which contains a labeled cycle $C = (BFD)$. The cycle (BDF) in Fig. 2 and the cycle (BFD) in this figure keep the same labeling and hence pair up to cancel out the label cycle cover sum

one used in the k -path problem. The labeled cycle cover sum are transformed into a multivariate polynomial such that it would have monomial with nonzero coefficient if Hamiltonian cycle exists. Moreover, it would not have monomials with nonzero coefficient resulting from non-Hamiltonian cycle covers, as a consequence of Lemma 5. Then Freivalds's fingerprint technique is employed to detect if the multivariate polynomial is identical to zero or not. If it is zero, the original direct graph does not contain Hamiltonian cycles, whereas if it is not zero, the original direct graph contains at least one Hamiltonian cycle.

A careful reader could discover that for the same Hamiltonian cycle in a bidirected graph, it has two opposite directions. If the two directions of the Hamiltonian cycle contribute the same terms to the sum, they would vanish in the labeled cycle cover sum. That is why the s -oriented mirror function is defined early in this section. In particular for the special vertex s and any $su, us \in E$, the above transformation ensures that $f(su, X)$ and $f(us, X)$ will not share variables. The details of the transformation will be discussed in Sect. 4.6.

4.5 Determinants and Inclusion-Exclusion

In this section, the readers would know how to compute labeled cycle cover sum efficiently. This technique can be found in Björklund's recent work [10]. In Sect. 2.2, it has been mentioned that for a matrix A over a ring of characteristic two, the result $\det(A) = \text{perm}(A)$ holds. Moreover, given a weighted direct graph $D = (V, E)$, let the weights of the edges be defined by a function $w : A \rightarrow R$ and define a $|V| \times |V|$ matrix with rows and columns representing the vertices V

$$\mathbf{A}_{i,j} = \begin{cases} w(ij) & : ij \in E \\ 0 & : \text{otherwise,} \end{cases}$$

then

$$\text{perm}(A) = \sum_{C \in cc(D)} \prod_{a \in C} w(a). \quad (7)$$

The above Eq. (7) holds because of two aspects. First, a cycle cover of the direct graph D is a collection of vertex-disjoint directed cycles that covers all nodes of D . Hence each vertex i in D has a unique successor $\sigma(i)$ in the cycle cover and σ is a permutation on $\{1, 2, \dots, n\}$ where n is the number of vertices in D . Then every cycle cover of D corresponds to a permutation σ on $\{1, 2, \dots, n\}$. Thus, according to the definition of permanent in Sect. 2.2, $\text{perm}(A) \geq \sum_{C \in cc(D)} \prod_{a \in C} w(a)$. On the other hand, any permutation σ on $\{1, 2, \dots, n\}$ corresponds to a possible cycle cover in which there is an edge from vertex i to vertex $\sigma(i)$ for each i in G . If there exists an edge created by the permutation σ which is not a right edge of D , the cycle cover created by the permutation σ is not a right cycle cover of D . Thus, the weight function w will make the contribution from this permutation zero. Thus, $\text{perm}(A) \leq \sum_{C \in cc(D)} \prod_{a \in C} w(a)$.

The remaining paragraphs describe how to compute labeled cycle cover sum through a sum of an exponential number of determinants. To this end the matrices $\mathbf{M}_f(Z)_{i,j}$ are defined as for every $Z \subseteq L$

$$\mathbf{M}_f(Z)_{i,j} = \begin{cases} f(ij, Z) & : ij \in E, Z \neq \emptyset \\ 0 & : \text{otherwise.} \end{cases} \quad (8)$$

Then the following polynomial $p(f, r)$ is introduced to compute an associated labeled cycle cover sum in characteristic two:

$$p(f, r) = \sum_{Y \subseteq L} \det \left(\sum_{Z \subseteq Y} r^{|Z|} \mathbf{M}_f(Z) \right) \quad (9)$$

It is easy to see that $p(f, r)$ consists of a sum of an exponential number of determinants in which r is indeterminate whose aim is to control the total rank of the subsets used as labels in the labeled cycle covers. The following lemma shows that the labeled cycle cover sum is identical to the coefficient of the monomial $r^{|L|}$ in $p(f, r)$. For a polynomial $q(r)$ in an indeterminate r , $[r^l]q(r)$ is the coefficient of monomial r^l in $q(r)$.

Lemma 6 *For a directed graph D , a set L of labels, and any $f : A \times 2^L \setminus \emptyset \rightarrow GF(2^k)$,*

$$[r^{|L|}]p(f, r) = \Lambda(D, L, f). \quad (10)$$

Proof Since the determinant is equivalent to the permanent in rings of characteristic two (Eq. 1) and the relationship between permanent and cycle covers,

$$\begin{aligned}
p(f, r) &= \sum_{Y \subseteq L} \text{perm} \left(\sum_{Z \subseteq Y} r^{|Z|} \mathbf{M}_f(Z) \right) \\
&= \sum_{Y \subseteq L} \sum_{C \in cc(D)} \prod_{a \in C} \left(\sum_{Z \subseteq Y} r^{|Z|} f(a, Z) \right).
\end{aligned}$$

After calculating the inner product,

$$p(f, r) = \sum_{Y \subseteq L} \sum_{C \in cc(D)} \sum_{q: C \rightarrow 2^Y \setminus \{\emptyset\}} \prod_{a \in C} r^{|q(a)|} f(a, q(a)).$$

Changing the order of summation,

$$p(f, r) = \sum_{C \in cc(D)} \sum_{q: C \rightarrow 2^L \setminus \{\emptyset\}} \sum_{\substack{\bigcup_{a \in C} q(a) \subseteq Y \\ Y \subseteq L}} \left(\prod_{a \in C} r^{|q(a)|} f(a, q(a)) \right). \quad (11)$$

Claim 1 In Eq.(11), all the terms from the functions $q : C \rightarrow 2^L \setminus \{\emptyset\}$ satisfied $\bigcup_{a \in C} q(a) \subset L$ cancel in rings of characteristic two.

From $\bigcup_{a \in C} q(a) \subset L$, the union of $q(a)$ over all the elements of C does not cover all of L , i.e., $L \setminus \bigcup_{a \in C} q(a) \neq \emptyset$. Then for each subset $T \subseteq L \setminus \bigcup_{a \in C} q(a)$, there is a term derived from T (let $Y = L \setminus T$) in the innermost summation. It is easy to see that for all the subsets of $L \setminus \bigcup_{a \in C} q(a)$, the terms derived from them are equal. And in total there are $2^{|L \setminus \bigcup_{a \in C} q(a)|}$ equal terms. Since the ring characteristic is two, these terms cancel.

Because of Claim 1, in Eq.(11),

$$p(f, r) = \sum_{C \in cc(D)} \sum_{\substack{q: C \rightarrow 2^L \setminus \{\emptyset\} \\ \bigcup_{a \in C} q(a) = L}} r^{\sum_{a \in C} |q(a)|} \left(\prod_{a \in C} f(a, q(a)) \right). \quad (12)$$

Since $\bigcup_{a \in C} q(a) = L$ and $\sum_{a \in C} |q(a)| = |L|$ implies $\forall a \neq b : q(a) \cap q(b) = \emptyset$, the coefficient of $r^{|L|}$ is

$$[r^{|L|}]p(f, r) = \sum_{C \in cc(D)} \sum_{\substack{q: C \rightarrow 2^L \setminus \{\emptyset\} \\ \bigcup_{a \in C} q(a) = L \\ \forall a \neq b : q(a) \cap q(b) = \emptyset}} \left(\prod_{a \in C} f(a, q(a)) \right).$$

Therefore, after inverting the function q , $[r^{|L|}]p(f, r)$ identifies the labeled cycle cover sum in Definition 4. \square

Based on the above lemma, the labeled cycle cover sum can be computed by calculating the coefficient of a polynomial. This is a typical algebrization which transforms a graph theoretical problem into a algebraic problem. The algebrization enables a relatively efficient algorithm for computing the labeled cycle cover sum. Before presenting the details of the algorithm, some definitions and a Lemma are given to compute the labeled cycle cover sum. These results are developed by Björklund et al. in [11]. For more information, please refer to their paper [11] and Yates' fast zeta transform [76].

Definition 6 Let N be a set of n elements with $n \geq 1$ and let us assume that $N = \{1, 2, \dots, n\}$. The set of all subsets of N is denoted by 2^N . Assume that R is an arbitrary ring. Let f be a function that associates with every subset $S \subseteq N$ an element $f(S)$ of the ring R . The Möbius transform of f is the function \hat{f} that associates with every $X \subseteq N$ the ring element

$$\hat{f}(X) = \sum_{S \subseteq X} f(S). \quad (13)$$

Given the Möbius transform \hat{f} , the original function f may be recovered via the Möbius inversion formula

$$f(S) = \sum_{X \subseteq S} (-1)^{|S \setminus X|} \hat{f}(X). \quad (14)$$

The *fast Möbius transform* [54, 76] is the following algorithm for computing the Möbius transform in $O(n2^n)$ ring operations.

Lemma 7 *There is an $O(n2^n)$ time algorithm to compute $\hat{f}(X)$ for all $X \subseteq N$.*

Proof To compute \hat{f} given f , let initially

$$\hat{f}_0(X) = f(X)$$

for all $X \subseteq N$ and then iterate for all $j = 1, 2, \dots, n$ and $X \subseteq N$ as follows:

$$\hat{f}_j(X) = \begin{cases} \hat{f}_{j-1}(X) & : \text{if } j \notin X, \\ \hat{f}_{j-1}(X \setminus \{j\}) + \hat{f}_{j-1}(X) & : \text{if } j \in X. \end{cases} \quad (15)$$

It is straightforward to verify by induction on j that this recurrence gives $\hat{f}_n(X) = \hat{f}(X)$ for all $X \subseteq N$ in $O(n^2 2^n)$ ring operations.

Let $N_j = \{1, 2, \dots, j\}$ and $N_0 = \emptyset$. Using induction on j , we can show that $\hat{f}_j(X) = \sum_{X_j \subseteq N_j \cap X} f(X_j \cup Y_j)$, where $Y_j = X - N_j$.

It is trivial for $j = 0$ since $\hat{f}_0(X) = f(X)$. Assume that $\hat{f}_j(X) = \sum_{X_j \subseteq N_j \cap X} f(X_j \cup Y_j)$.

It is easy to see that $\hat{f}_{j+1}(X) = \sum_{X_{j+1} \subseteq N_{j+1} \cap X} f(X_{j+1} \cup Y_{j+1})$ from the definition of $\hat{f}_{j+1}(X)$ and the hypothesis of induction. \square

Then the following lemma gives the details about computing the labeled cycle cover sum for a direct graph.

Lemma 8 *The labeled cycle cover sum $\Lambda(D, L, f)$ for a function f with codomain $GF(2^k)$ on a directed graph G on n vertices, and with $2^k > |L|n$, can be computed in $O(|L| + n)^{O(1)} 2^{|L|}$ arithmetic operations over $GF(2^k)$, where ω is the square matrix multiplication exponent.*

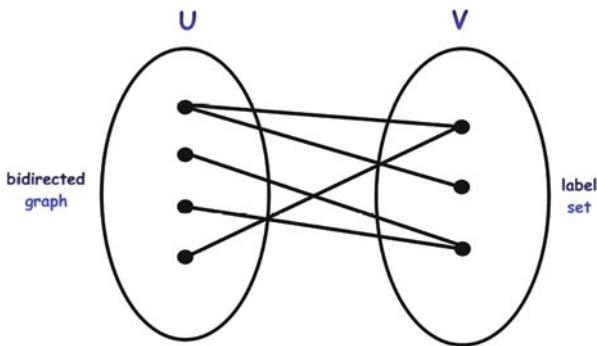

Proof The labeled cycle cover sum $\Lambda(D, L, f)$ can be computed by means of **Lemma 6**. It would be recognized that the runtime of the algorithm is exponential in the number of labels but polynomial in the size of the input graph. According to **Lemma 6**, for polynomial $p(f, r)$, the aim is to achieve the coefficient of $r^{|L|}$. It is easy to see from [Eq. \(12\)](#) that $p(f, r)$ is a polynomial of r with maximum degree $|L|n$. Thus, the polynomial for $|L|n$ choices of r is evaluated, and interpolation is used to solve for the sought coefficient. The condition $2^k > |L|n$ is required to make sure the interpolation has enough different points. Here, a generator g of the multiplicative group in $GF(2^k)$ is used to generate the interpolation point $r = g^0, g^1, \dots, g^{|L|n}$. To do interpolation, for instance, the $O(|L|^2 n^2)$ time Lagrange interpolation is one of the choices.

From the above analysis, it can be achieved that the second part of the runtime bound. However, the much more time-consuming procedures are matrixes tabulating and determinant calculating in formula ([Eq. 9](#)). Let $T(Y) = \sum_{Z \subseteq Y} r^{|Z|} M_f(Z)$: tabulating $T(Y)$ for all $Y \subseteq L$ can be done in $O(|L|2^{|L|})$ time using [Lemma 7](#). Moreover, for the determinant calculating of $p(f, r) = \sum_{Y \subseteq L} \det(T(Y))$, it can be done in $O(n^{O(1)} 2^{|L|})$ as the determinant of an $n \times n$ matrix can be computed in $O(n^{O(1)})$ time using any standard method such as Gauss elimination to convert the matrix of the determinant into a right triangular one. Since there are $|L|n$ values of r , the total runtime for the determinant calculating is bounded by $O((|L| + n)^{O(1)} 2^{|L|})$.

Therefore, by summing up all the time required by the matrix tabulating, the determinant calculating, and the Lagrange interpolation, the labeled cycle cover sum can be computed in $O((|L| + n)^{O(1)} 2^{|L|})$ time. \square

The complexity of the above lemma can be made as low as $O((|L|^2 n + |L|n^{1+\omega}) 2^{|L|} + |L|^2 n^2)$ as mentioned in [9] by using the algorithms of Bunch and Hopcroft [14] for computing determinant and the Coppersmith-Winograd square matrix multiplication exponent [22], where ω is the square matrix multiplication exponent.

Fig. 4 A bipartite graph contains two halves. To reduce the Hamiltonian path to the labeled cycle cover sum, the *left half* U is used as a bidirected graph and the *right half* V is a label set

4.6 Hamiltonicity in Undirected Graphs

In this section, an $O^*(1.657^n)$ time algorithm is introduced to detect Hamiltonian path for direct graphs. For the direct graphs $G = (V, E)$, the overall idea is to reduce Hamiltonian path to labeled cycle cover sum. In Björklund et al.'s paper, they first apply the reduction to bipartite graphs. It gives an $O^*(1.414^n)$ time algorithm for bipartite graphs.

Definition 7 A *bipartite graph* is a graph whose vertices can be divided into two disjoint sets V_1 and V_2 such that every edge connects a vertex in V_1 to one in V_2 .

For the bipartite graph, a smaller bidirected graph D is constructed on one of the halves, and the other half is used as labels in a labeled cycle cover sum on D . (cf. Fig. 4).

For the general direct graph, the core idea is same as the bipartite case. However, there are some slight differences. Compared with the bipartite case, the general graphs do not have the bipartite features. Hence, it seems impossible to partition the vertices into two equal parts of which the Hamiltonian cycle alternate vertices from one part to the other part. Then it is difficult to know which subset of the vertices could serve as labels. To solve this problem, a uniformly randomly chosen partition $V = V_1 \cup V_2$ with $|V_1| = |V_2|$ can be exploited. That is because the number of transitions along a fixed Hamiltonian cycle from a vertex in one part to a vertex in the other part is $n/2$ in expectation. Note that in the bipartite case it is n . So for random partition of the general graph, there still is a good chance that the transitions will happen along the fixed Hamiltonian cycle. The vertices in V_1 in the bipartite case were handled at a polynomial-time cost, whereas the vertices in V_2 case at a price of a factor 2 each in the runtime. In the same vein, the vertices in V_1 followed by a vertex in V_2 along a fixed Hamiltonian cycle in the general case will be computationally cheap. The alternation would not happen each time along the Hamiltonian cycle. Therefore, arcs need to be distinguished according to the partition.

The arcs connecting adjacent vertex pairs v_i, v_{i+1} along a Hamiltonian cycle H are called *unlabeled* by V_2 if both v_i and v_{i+1} belong to V_1 . The remaining arcs are referred to as *labeled* by V_2 . Then the arcs of H can be partitioned into two parts of which $\mathcal{L}(H)$ and $\mathcal{U}(H)$ represent the set of the labeled arcs and the set of the unlabeled arcs, respectively. Define $hc_{V_2}^m(G)$ as the subset of $hc(G)$ of Hamiltonian cycles H which have precisely m arcs unlabeled by V_2 along H .

A vertex s is fixed: two variables x_{uv} and x_{vu} are introduced for every edge $uv \in E$ such that $u \in V_2$ or $v \in V_2$ (or both). $x_{uv} = x_{vu}$ works except when $u = s$ or $v = s$.

For a complete bidirected graph $D = (V_1, F)$, F is the set of arcs connecting every two points u and v in V_1 such that there exists a path from u to v only through points in V_2 in G or edge $uv \in G[V_1]$.

V_2 contains some of the labels. In addition to V_2 , a set L_m contains m extra labels is added to handle arcs unlabeled by V_2 . For each edge uv in $G[V_1]$ and every element $d \in L_m$, new variables $x_{uv,d}$, $x_{vu,d}$ are introduced and set to $x_{uv,d} = x_{vu,d}$ except when $u = s$ or $v = s$. See Fig. 5 for an example.

For two vertices $u, v \in V$ and a nonempty subset $X \subseteq V$, $\mathcal{P}_{u,v}(X)$ is defined as the family of all simple paths in G from u to v passing through exactly the vertices in X (in addition to u and v). For $uv \in F$ and $\emptyset \subset X \subseteq V_2$,

$$f(uv, X) = \sum_{P \in \mathcal{P}_{u,v}(X)} \prod_{wz \in P} x_{wz}.$$

For every arc $uv \in F$ such that uv is an edge in $G[V_1]$, and every $d \in L_m$,

$$f(uv, d) = x_{uv,d}. \quad (16)$$

In all other points, f is set to zero. For simplicity, the general graphs with even number of vertices is considered.

Algorithm 2 Björklund's Algorithm for Hamiltonian Path

Input: A graph $G = (V_1, V_2, E)$ with vertex set v_1, v_2, \dots, v_n

Output: If G does not have a Hamiltonian path, the algorithm always outputs “No”; if G has a Hamiltonian path, the algorithm outputs “Yes” with probability no less than $1 - (1/2)^n$.

Steps:

- 1: Uniformly yield a partition $V_1 \cup V_2 = V$ at random, with $|V_1| = |V_2| = n/2$. Select k large enough such that $2^k > cn$ for some $c > 1$.
- 2: Let $m = 0$.
- 3: Transform the input graph G into a symbolic labeled cycle cover sum $\Lambda(D, V_2 \cup L_m, f)$ with D and f defined as above and the label set $L = V_2 \cup L_m$.
- 4: Pick a random point p from the field $GF(2^k)$ and evaluate $\Lambda(D, V_2 \cup L_m, f)$ in p over $GF(2^k)$ using the method from Lemmas 8 and 9.
- 5: Let $m = m + 1$. Repeat steps 3–5 until $m = m_{\max} = 0.205n$.
- 6: Repeat steps 2–5 for $r = n^{c20.024n}$ runs with constant c to be selected later.
- 7: If any result shows that $\Lambda(D, V_2, f)$ is a nonzero polynomial, output “Yes”; otherwise, output “No.”

End of Algorithm

Hamiltonian undirected graph $G = (V, E)$

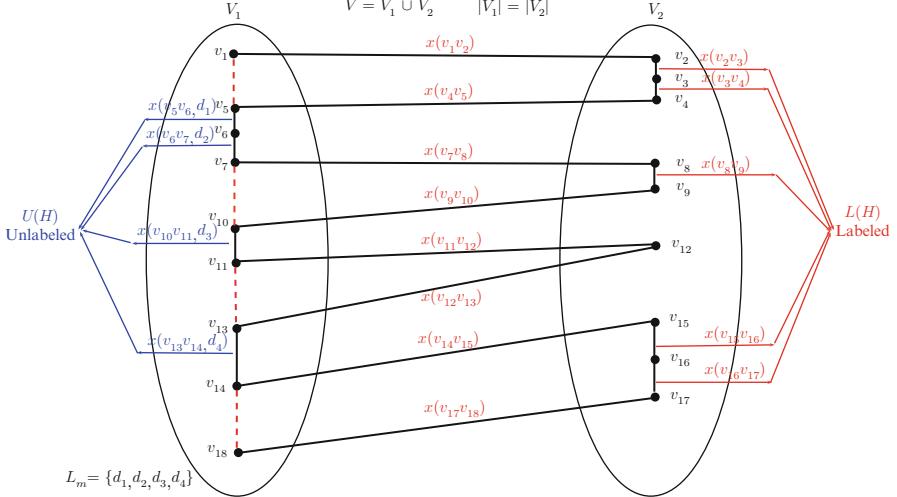

Fig. 5 The undirected graph $G = (V, E)$ with a Hamiltonian path is uniformly randomly partitioned into two equal parts V_1 and V_2 . Each part has nine vertices. The red variables show the labeled arcs, whereas the blue variables represent the unlabeled arcs. Here, for clearness of the figure, one unlabeled arc which is from v_{18} to v_1 is omit. Thus, the extra label set L_m has five elements handling arcs unlabeled by V_2 . This figure is very similar to the bipartite graph except that some unlabeled

The above algorithm has two loops. Since the partition yield randomly in step 1, the inner loop on m is to make sure all possible numbers of unlabeled arcs by V_2 can be evaluated. The algorithm runs for $r = n^{O(1)} 2^{0.024n}$ times to guarantee that the probability of the false negatives is exponentially small in n . Then the following lemma shows the relationship between labeled cycle cover sum $\Lambda(D, V_2 \cup L_m, f)$ and the Hamiltonian cycles of G . And Lemma 9 ensures the correctness of the algorithm for the general graphs.

Lemma 9 With $G, D, V_2, \mathcal{U}, \mathcal{V}, \mathcal{L}, m, L_m$, and f defined above,

1. $\Lambda(D, V_2 \cup L_m, f) = \sum_{H \in hc_{V_2}^m(G)} (\sum_{\sigma: \mathcal{U}(H) \rightarrow L_m} \prod_{uv \in \mathcal{U}(H)} x_{uv, \sigma(uv)}) (\prod_{uv \in \mathcal{L}(H)} x_{uv})$ with σ one to one.
2. $\Lambda(D, V_2 \cup L_m, f)$ is the zero polynomial iff $hc_{V_2}^m(G) = \emptyset$.

Proof (i) Since D is bidirected and f is an s -oriented mirror function, by Lemma 5

$$\Lambda(D, V_2 \cup L_m, f) = \sum_{H \in hc(D)} \sum_{g: V_2 \cup L_m \rightarrow H} \prod_{a \in H} f(a, g^{-1}(a)).$$

By omitting the vertices which belong to V_2 , it is easy to see that there is a mapping from a Hamiltonian cycle $H \in hc(G)$ to a Hamiltonian cycle

in D . Observing that the above equation is over all the Hamiltonian cycles in D , detecting the Hamiltonicity of G can be done in the backward way, to expand the Hamiltonian cycles in D into Hamiltonian cycles of G . Since previous works were first done on the Hamiltonian cycles in D , it is necessary to extend the definition of labeled and unlabeled arc which were defined before for Hamiltonian cycles in G only. For a Hamiltonian cycle $H \in hc(D)$ labeled by the function $g : V_2 \cup L_m \rightarrow H$, an arc $uv \in H$ is labeled by V_2 if $g^{-1}(uv) \subseteq V_2$ and unlabeled by V_2 if $g^{-1}(uv) \in L_m$. H_L and H_U are used to represent the labeled and unlabeled set of arcs, respectively.

According to the definition of the function f , the arcs of a Hamiltonian cycle in D in the labeled cycle cover sum either are labeled by an element of L_m or a nonempty subset of V_2 , since these are the only subsets of the labels for which f is nonzero. Moreover, the definition of f at Eq.(16) tells us that every arc unlabeled by V_2 along a Hamiltonian cycle consumes exactly one of the m labels in L_m , and all labels are used. Thus, only the Hamiltonian cycles in D with exactly m arcs unlabeled by V_2 leave a nonzero contribution. Note that there is another restriction that a cycle H leaves a nonzero result only if the m arcs unlabeled by V_2 along the cycle are also edges in G . Considering all the above restrictions on the inner summation in above formula,

$$\Lambda(D, V_2 \cup L_m, f) = \sum_{H \in hc(D)} \sum_{\substack{H_U \cup H_L = H \\ H_U \cap H_L = \emptyset \\ |H_U| = m \\ \forall a \in H_U : a \in E}} \Lambda_{H_U}(L_m) \Lambda_{H_L}(V_2)$$

with

$$\Lambda_{H_U}(L_m) = \left(\sum_{\sigma : H_U \rightarrow L_m} \prod_{a \in H_U} f(a, \sigma(a)) \right)$$

and

$$\Lambda_{H_L}(V_2) = \left(\sum_{g : V_2 \rightarrow H_L} \prod_{a \in H_L} f(a, g^{-1}(a)) \right).$$

Through analysis above, it is easy to see that the summation in $\Lambda_{H_U}(L_m)$ is over all functions σ which are one to one. Replacing f by its definition, the inner expressions is expanded to

$$\Lambda_{H_U}(L_m) = \left(\sum_{\sigma : H_U \rightarrow L_m} \prod_{uv \in H_U} x_{uv, \sigma(uv)} \right)$$

and

$$\Lambda_{H_L}(V_2) = \left(\sum_{g: V_2 \rightarrow H_L} \prod_{uv \in H_L} \sum_{P \in \mathcal{P}_{u,v}(g^{-1}(uv))} \prod_{wz \in P} x_{wz} \right).$$

Since every vertex in V_2 is mapped to by precisely one arc in F on a Hamiltonian cycle H in D , for arcs $a_1, a_2 \in H_L$ and $a_1 \neq a_2$, $g^{-1}(a_1) \cap g^{-1}(a_2) = \emptyset$. Thus, for every arc uv in the labeled set H_L , $\Lambda_{H_L}(V_2)$ exhausts all the possible simple paths from u to v passing through the vertices in X with $\emptyset \subset X \subseteq V_2$. Then through picking one simple path for each labeled arc in H_L , the combination of all the simple paths grouped with all the unlabeled arcs actually forms a Hamiltonian cycle in G . Therefore, rewriting the expression as a sum of Hamiltonian cycles in G , the result establishes as claimed:

$$\Lambda(D, V_2 \cup L_m, f) = \sum_{H \in hc_{V_2}^m(G)} \left(\sum_{\sigma: \mathcal{U}(H) \rightarrow L_m} \prod_{uv \in \mathcal{U}(H)} x_{uv, \sigma(uv)} \right) \left(\prod_{uv \in \mathcal{L}(H)} x_{uv} \right)$$

- (ii) If the graph G has no Hamiltonian cycles, the sum is clearly zero from above equation. Otherwise, if G has Hamiltonian cycles, then from the inner summation of the above equation, it is easy to see that each Hamiltonian cycle contributes a set of $m!$ different monomials per orientation of the cycle (one for each permutation of σ). Each edge of the cycle contributes a variable for the monomials. Since two different Hamiltonian cycles each has an edge and the other has not, monomials resulting from different Hamiltonian cycles are different. By the definition of s -oriented mirror function, the variables associated to the oppositely directed arcs incident to s are different. Thus, the monomials formed by oppositely oriented Hamiltonian cycles are unique in the sum.

□

Lemma 10 *There is an $O(n)$ time algorithm to randomly partition a set of (even) n elements into two equal parts with $n/2$ elements each.*

Proof Let V be a set of $n = 2m$ elements. Let V_1 be empty in the beginning. Select a random element from V , put it into V_1 , and remove the selected element from V . Repeat the above step until V_1 contains m elements. It is easy to see equal subset of size m of V has the same probability to be generated. Let U be a subset of m elements in V . With probability $\frac{m}{2m}$, the first selected is selected from U . Assume that the first i elements are all selected from U for some $i < m$. With probability $\frac{m-i}{2m-i}$, the $i+1$ -th element is selected from U . Thus, the probability that U is generated by the algorithm is

$$\frac{m}{2m} \cdot \frac{m-1}{2m-1} \cdots \frac{1}{m+1} = \frac{1}{\binom{2m}{m}}.$$

□

We need to follow probability amplification lemma for the randomized algorithm for Hamiltonian cycle problem. [Lemma 11](#) is a standard method in the randomized algorithm design.

Lemma 11 *Let A be an randomized algorithm for the Hamiltonian cycle problem such that for every $G = (V, E)$ without Hamiltonian cycle, it always returns “No” (zero false positive), and for every $G = (V, E)$ with a Hamiltonian cycle, it returns “Yes” with probability at least $\frac{1}{\alpha(n)}$ with $\alpha(n) > 1$. Then there is another algorithm A' by repeating A $n^{O(1)}\alpha(n)$ times such that for every $G = (V, E)$ without Hamiltonian cycle, it always returns “No,” and for every $G = (V, E)$ with a Hamiltonian cycle, it returns “Yes” with probability at least $1 - \frac{1}{2^n}$.*

Proof Let $r = n^c\alpha(n)$ with constant c to be determined later. The algorithm A is repeated r times. If one of the r times returns “Yes,” then the algorithm A' returns “Yes.” Otherwise, the algorithm A' returns “No.” It is easy to see that A' has a zero false positive. If the input graph $G = (V, E)$ has a Hamiltonian path, then with probability at most $(1 - \frac{1}{\alpha(n)})^r$, all of the r times execution of A returns “No.” Therefore, with probability at least $1 - (1 - \frac{1}{\alpha(n)})^r \geq 1 - \frac{1}{2^n}$, at least one of the r times of A executions returns “Yes” if constant c is selected to be large enough. \square

Theorem 4 ([10]) *There is a Monte Carlo algorithm detecting whether an undirected graph on n vertices is Hamiltonian or not running in $O^*(1.657^n)$ time, with no false positives and false negatives with probability exponentially small in n .*

Proof From [Lemma 9](#), the readers can realize the practicability of Björklund’s algorithm for the general graphs. The only thing left is to analyze the runtime and the probability of false negatives of our run results.

For the runtime, from the definition of $f(uv, X)$ for $\emptyset \subset X \subseteq V_2$, to evaluate the labeled cycle cover sum $\Lambda(D, V_2 \cup L_m, f)$, the function f needs to be tabulated for all subsets of V_2 . This can be achieved by running a variant of the Bellman-Held-Karp recursion. Formally, let $\hat{f} : (V \times V) \times 2^{V_2} \rightarrow GF(2^k)$ be defined for $u \neq v$ and $\emptyset \subset X \subseteq V_2$ by

$$\hat{f}(uv, X) = \sum_{P \in \mathcal{P}_{u,v}(X)} \prod_{w \in P} x_{wz}$$

then $f(uv, X) = \hat{f}(uv, X)$ for $uv \in F$ and $\emptyset \subset X \subseteq V_2$. For $|X| > 1$ the recursion

$$\hat{f}(uv, X) = \sum_{w \in X, uv \in E} x_{uw} \hat{f}(wv, X \setminus w)$$

can be used to tabulate $f(uv, X)$ for all $\emptyset \subset X \subseteq V_2$. Since V_2 has $n/2$ vertices, the tabulation for f can be done in $O^*(2^{n/2})$ time. After tabulation, $\Lambda(D, V_2 \cup L_m, f)$ can be evaluated by [Lemma 8](#). Then the runtime of the evaluation is close relevant

to the size of the label set $V_2 \cup L_m$. Since the size of V_2 is fixed to $n/2$, the only need is the analysis of the maximum size of L_m .

Let $G = (V, E)$ be a Hamiltonian undirected graph and $V_1 \cup V_2 = V$ with $|V_1| = |V_2|$. We will show

$$\Pr(|hc_{V_2}^m(G)| > 0) \geq \frac{\binom{n/2-1}{m-1}^2}{\binom{n}{n/2}} \in \Theta\left(\frac{m(\frac{1}{2} - \frac{m}{n})^{2m-n-1}}{(\frac{m}{n})^{2m} 4^n \sqrt{2\pi n^{1.5}}}\right). \quad (17)$$

To obtain the inequality in (Eq. 17), it is necessary to count the number of possibility that one fixed Hamiltonian cycle $H = (v_0, v_1, c \dots, v_{n-1})$ has exactly m arcs unlabeled by V_2 and moreover has $v_0 \in V_1$ and $v_{n-1} \in V_2$. For such a H , there are exactly $n/2 - m$ indices i such that $x_i \in V_1$ and $x_{i+1} \in V_2$, and just as many indices i where $x_i \in V_2$ and $x_{i+1} \in V_1$. Take Fig. 5 as an example, since $m = 5$, there are $n/2 - m = 4$ vertices $(v_1, v_7, v_{11}, v_{14})$ which satisfy $x_i \in V_1$ and $x_{i+1} \in V_2$. And similarly there are 4 vertices $(v_4, v_9, v_{12}, v_{17})$ which satisfy $x_i \in V_2$ and $x_{i+1} \in V_1$. The ordered list of these transition indices $i_1, i_2, \dots, i_{n-2m}$ uniquely describes the partition. In other words, any such list with $0 \leq i_1, \forall j : i_j < i_{j+1}$, and $i_{n-2m} = n-1$ corresponds to a unique partition. Set $i_0 = -1$ and define the positive integers $d_j = i_j - i_{j-1}$ for all $0 < j \leq n-2m$. Then $d_1, d_2, \dots, d_{n-2m-1}$ describes a partition of the vertices in V_1 in $n/2 - m$ groups. Analogously, $d_2, d_4, \dots, d_{n-2m}$ describes a partition of the vertices in V_2 in $n/2 - m$ groups. The number of ways to write a positive integer as a sum of k positive integers is $\binom{p-1}{k-1}$. Thus, by multiplying the number of ways to partition the vertices in V_1 with the number of ways for V_2 , and dividing with the total number of balanced partition $\binom{n}{n/2}$, the inequality in Eq. (17) is achieved.

The second bound is derived by replacing the binomial coefficients with their factorial definition and using Stirling's approximation for $n! \in \Theta((n/e)^n \sqrt{2\pi n})$.

Since $\Pr(\sum_{m=0}^{m_{\max}} |hc_{V_2}^m(G)| = 0) \leq 1 - \Pr(|hc_{V_2}^{m_{\max}}| > 0)$, to bring the probability of false negatives down to $\exp(-\Omega(n))$, the number of runs $r = n^{O(1)} \Pr^{-1}(|hc_{V_2}^{m_{\max}}| > 0)$ is needed by Lemma 11. Solving for the local minimum of the total runtime, using the inequality in (Eq. 17) to bound the probability, $m_{\max} = 0.205n$ and $r = n^{O(1)} 2^{0.024n}$ runs. Therefore, the total runtime is bounded by $O^*(1.657^n)$. \square

5 Minimum Common String Partition Problem

In this section, an application of the multilinear testing problem is presented to illustrate the practicability of algebrization. By means of multilinear testing for polynomials, a new exponential algorithm was recently developed by Fu et al. [33] to solve the minimum common string partition problem (MCSP). The problem MCSP has attracted a lot of attention, partly because of its applications in computational biology, text processing, and data compression. More specifically, MCSP has a close connection with the genome rearrangement problems such as edit

distance and sorting by reversals. In fact, MCSP was initially studied exactly as a problem on “edit distance with moves” [70].

Definition 8 Given a pair of strings S and S' , the common string partition problem is to find partitions for $S = S_1 \dots S_k$ and $S' = S'_1 \dots S'_k$ such that S'_1, \dots, S'_k is a rearrangement of S_1, \dots, S_k and k is the least.

Naturally, in the minimum common string partition problem, two strings X and Y of length n are given over an alphabet Σ . Let each symbol appear the same number of times in X and Y . This condition is certainly sufficient and necessary for us to compute a common string partition for X and Y . For example, two strings $X = beadcdb$ and $Y = abdebc$ have a common partition ($< b, e, ab, c, db >$, $< ab, db, e, b, c >$). There are several variants of MCSP. Restricted version is called where each letter occurs at most d times in each input string as d -MCSP. When the input strings are alphabet of size c , the corresponding problem is called $MCSP^c$.

5.1 A Brief History of MCSP

The problem d -MCSP has been well studied. 2-MCSP (and therefore MCSP) is NP-hard and APX-hard [37]. Several approximation algorithms have been proposed for MCSP problem [37, 59]. Chen et al. [18] studied the problem of computing signed reversal distance with duplicates (SRDD). They introduced the signed minimum common partition problem as a tool for dealing with SRDD and observed that for any two related signed strings X and Y , the size of a minimum common partition and the minimum number of reversal operations needed to transform X and Y are within a factor of 2. Kolman and Walen [60] devised an $O(d^2)$ -approximation algorithm running in $O(n)$ time for SRDD.

Chrobak et al. [21] analyzed the greedy algorithm for MCSP; they showed that for 2-MCSP the approximation ratio is exactly 3, for 4-MCSP the approximation ratio is $\Omega(\log n)$, and for the general MCSP, the approximation ratio is between $\Omega(n^{0.43})$ and $O(n^{0.67})$. Kaplan and Shafrir [50] improved the lower bound to $\Omega(n^{0.46})$ when the input strings are over an alphabet of size $O(\log n)$. Kolman [58] described a simple modification of the greedy algorithm; the approximation ratio of the modified algorithm is $O(p^2)$ for p -MCSP. Most recently, Goldstein and Lewenstein presented an greedy algorithm for MCSP [36].

In the framework of parameterized complexity, Damaschke first solved MCSP by an FPT algorithm with respect to parameters k (size of the optimum solution), r (the repetition number), and t (the distance ratio, depending on the shortest block in the optimum solution) [24]. Jiang et al. showed that both d -MCSP and $MCSP^c$ admit FPT algorithms when d and c are (constant) parameters [47]. However, it remains open whether MCSP admits any FPT algorithm parameterized only on k .

5.2 An $O(2^n n^{O(1)})$ Time Algorithm for General Cases

This section shows that algebrization, especially multilinear monomial testing, is a very useful tool by presenting an exact solution for the MCSP problem. The overall idea is to convert it into a detection of a multilinear monomial in the sum-product expansion of a multivariate polynomial.

Definition 9 Let $S = a_1 a_2 \cdots a_n$ be a string of length n ;

- For an integer $i \in [1, n]$, define $S[i] = a_i$.
- For an interval $[i, j] \subseteq [1, n]$, define $S[i, j]$ to be the substring $a_i a_{i+1} \cdots a_j$ of S .

The aim is to create a polynomial in which a multilinear monomial is used to encode a solution for the partition problem. Then the following theorem explains how to construct polynomial according to two given strings S and S' and gives the proof of the correctness of encoding.

Theorem 5 ([33]) *There is an $O(2^n n^{O(1)})$ time algorithm for the minimum common string partition problem.*

Proof Let S and S' be two input strings of length n . Let each position i of S' have a unique variable x_i to represent it. Define $P[a, b] = x_a x_{a+1} \cdots x_b$. For each interval $[s, t]$, define $G_{s,t} = \sum_{S'[s',t']=S[s,t]} P[s', t']$.

For each $i \leq n$, define a polynomial $F_{i,1} = G_{1,i}$. It represents all the substrings of S' that match $S[1, i]$. This is formally stated by Claim 2 below.

Claim 2 $S'[u, v]$ is a substring of S' with $S'[u, v] = S[1, i]$ if and only if there is a multilinear monomial $P[u, v]$ in $F_{i,1}$.

Let $F_{0,t} = 1$ for each $t \geq 1$. For each $i \leq n$, define

$$F_{i,t+1} = \sum_{1 \leq j \leq i} G_{j,i} \cdot F_{j-1,t}. \quad (18)$$

This polynomial has the property for encoding some partial common partition. It is stated in Claim 3.

Claim 3 Let i be an arbitrary integer parameter in the range $[1, n]$. Then there is a partition $S[i_1, j_1], \dots, S[i_t, j_t]$ for $S[1, i]$ such that $S[i_r, j_r] = S'[i'_r, j'_r]$ for some disjoint intervals $[i'_1, j'_1], \dots, [i'_t, j'_t]$ that are subset of $[1, n]$ if and only if there is a multilinear monomial Q in the sum of product expansion of $F_{i,t}$ with $Q = \prod_{r=1}^t P[i'_r, j'_r]$.

Proof Prove by induction. For the case $t = 1$, it follows from Claim 2. Assume that the claim is true for t .

Considering the case $t + 1$, the following two cases for the induction are needed to be analyzed:

- Assume that there is a partition $S[i_1, j_1], \dots, S[i_{t+1}, j_{t+1}]$ for $S[1, i]$ such that $1 = i_1 \leq j_1 = i_2 - 1 < j_2 = \dots = j_t = i_{t+1} - 1 < j_{t+1} = i$ and $S[i_r, j_r] = S'[i'_r, j'_r]$ for $r = 1, \dots, t + 1$ with some disjoint intervals $[i'_1, j'_1], \dots, [i'_{t+1}, j'_{t+1}]$. By our inductive hypothesis, there is a multilinear monomial $Q' = \prod_{r=1}^t P[i'_r, j'_r]$ that is in the sum of product expansion of $F_{j_r, t}$. By the definition of $G_{i_{t+1}, j_{t+1}}$, $G_{i_{t+1}, j_{t+1}}$ contains the multilinear monomial $P[i'_{t+1}, j'_{t+1}]$ in its sum of product expansion. By the definition of $F_{i, t+1}$ in Eq.(18), multilinear monomial $Q = Q' \cdot P[i'_{t+1}, j'_{t+1}]$ in the sum of expansion of $F_{i, t+1}$.
- Assume that there is multilinear monomial Q in $F_{i, t+1}$. By the definition of $F_{i, t+1}$ in Eq.(Eq. 18), there is an integer j and an interval $[i'_{t+1}, j'_{t+1}]$ such that $S[j, i] = S'[i'_{t+1}, j'_{t+1}]$, and there is a multilinear monomial Q' with $Q = P[i'_{t+1}, j'_{t+1}] \cdot Q'$.

By the inductive hypothesis, there is a partition $S[i_1, j_1], \dots, S[i_t, j_t]$ for $S[1, j - 1]$ such that for each $1 \leq r \leq t$, $S[i_r, j_r] = S'[i'_r, j'_r]$ for some disjoint intervals $[i'_1, j'_1], \dots, [i'_t, j'_t]$, and $Q' = \prod_{r=1}^t P[i'_r, j'_r]$. Since Q is a multilinear monomial, there is no intersection between $[i'_{t+1}, j'_{t+1}]$ and $\cup_{r=1}^t [i'_r, j'_r]$. \square

By Claim 3, it is easy to see that there is a partition of k segments if and only if there is a multilinear monomial $x_1 x_2 \cdots x_n$ in the sum of product expansion of $F_{n, k}$.

Then there is an $O(2^n n^{O(1)})$ time algorithm to find the multilinear monomial by evaluating $F_{n, k}$ from bottom-up. During the evaluation, only the multilinear monomials are kept in $F_{i, t}$. Since the total number of variables is n , the total number of multilinear monomials is at most 2^n . Note that $G_{j, i}$ has at most $O(n)$ monomials. Therefore, each multiplication $G_{j, i} F_{j-1, t}$ takes $O(2^n n^{O(1)})$ time. The arithmetic expression for $F_{n, k}$ involves $n^{O(1)}$ $+$ and \cdot operations. Therefore, the total time for generating all the multilinear monomials in the sum of product expansion of $F_{n, k}$ is $O(2^n n^{O(1)})$.

Testing the existence of multilinear monomial $x_1 x_2 \cdots x_n$ in the sum of product expansion over $F_{n, k}$ gives the existence of a common partition of at most k blocks. Tracing how the multilinear monomial $x_1 x_2 \cdots x_n$ is formed with a bottom-up approach to find all multilinear monomial in the sum of product expansion of $F_{n, k}$ shows how a common partition of at most k blocks is computed. This can be seen in the proof of Claim 3. \square

6 Algebraic FPT Algorithms for Channel Scheduling Problem

In this section, the algorithms for scheduling data retrieval in multichannel wireless data broadcast environments will be introduced. These algorithms are derived from the multilinear testing theory. Moreover, they also use algebraic method and randomized method to minimize the total time for channel scheduling. Generally, the Channel Scheduling Problem, which is also named the least time data retrieving (LTDR)

problem, is belong to wireless data broadcast. In many applications, such as stock quotes, flight schedules, and traffic news [1], the LTDR problem appears when people may want to download multiple data items at a time.

There are two major performance concerns with respect to wireless data broadcast, one is tuning time and the other is access time. The tuning time, defined as the amount of time a client spends on listening to the channels, is a performance criterium to evaluate the energy consumption, while the access time, defined as the time duration from the moment a client submits a query to the moment that all the required data are downloaded, reflects the response delay of queries. The LTDR problem is the problem of finding a schedule to download a set of required data, which are cyclically broadcasted via multiple broadcast channels, such that all the required data can be downloaded in a short time. The formal definition of the LTDR problem is as follows.

Definition 10 Given a query data set S and a broadcast program of k channels, find a valid schedule to download all the data items in S in some order so that the total access time is minimized.

In the following paragraphs, the related works about LTDR is first introduced. Then the algebraic FPT algorithms for LTDR will be presented in the next section. These works can be found in the recently accepted paper by Gao, Lu, Wu, and Fu [34].

6.1 A Brief History of LTDR

As it is talked about before, *access time* is one of the major factors with respect to the performance of the wireless data broadcast. Many works have been done to minimize the *access time* [42, 46, 71], etc. The LTDR problem, which is from the client point of view, is one of the optimization problems in the field of wireless data broadcast.

Under the assumption that the indices of all required data are already obtained, the LTDR problem focuses on developing efficient scheduling algorithms from the client point of view with the objective of minimizing the access time. Compared to the massive amount of works for scheduling the data retrieval process at the client side, there has been little work done on scheduling the data retrieval process at the client side. When there is only one broadcast channel, or the client requests single data item at a time, the data retrieval scheduling problem is straightforward. But in many cases, the clients may want to download multiple data per request [39–42, 48, 62, 71]. Juran et al. and Hurson et al. presented several data retrieval heuristics in [42, 48] to reduce the access time and the number of channel switchings. In [71], Shi et al. investigated how to schedule the downloading process at the client side by using multiple parallel processes. It is worthy to mention that the studies in [42, 48, 71] assume the data are partitioned over multiple channels without replications. This assumption simplifies the algorithm design, but there are many data allocation scheduling may result in the replicative data appearing on channels [1, 30, 41].

Here, the LTDR problem assumes that the data are allowed replicatively. Compared with the model studied in [42, 48, 71], this is more generalized assumption which fits all wireless data broadcast programs. Under this assumption, Du et al. give the complexity analysis and some approximation algorithms of the LTDR problem in their recently work [27].

6.2 Algebraic FPT Algorithms for LTDR

In this section, a fixed parameter tractable algorithm with computational time $O(2^t(nkh)^{O(1)})$ for the LTDR problem is introduced. Here, k is the number of channels, t is the least number of programs to be downloaded in a set of programs S , n is the maximal time slots, and h is the maximal number of channel switches.

A problem with input size n and parameter k has a fixed parameter tractable (FPT) algorithm if there is an algorithm that runs in an $O(f(k)n^{O(1)})$ time. Looking for FPT algorithms for NP-hard problems has been widely studied in the last two decades. Although it is unknown if the LTDR problem is NP-hard, it looks a challenging problem and hard to find the optimal solution.

Specifically, the LTDR problem can be described as the clients want to download a set S of m programs from k channels by a receiver. Each channel C_i is partitioned into many discrete time slots, and a program p_i takes integer $s_{i,j}$ of time slots in channel j . If the receiver switches from channel i at time t to channel j , it can start downloading the program in channel j at time $t+2$. As described before, the target is to minimize the total time and the number of switches among those channels.

Definition 11 A subset program $S' = \{x_{i_1}, \dots, x_{i_a}\} \subseteq S$ is (i, t, h) -downloadable if the receiver can download all programs in S' in time interval $[1, t]$, the total number of channel switches is at most h , and a program x_{i_j} is downloaded from channel i in the final time phase.

The following lemma transform the channel switches allowed LTDR problem to the monomial testing problem.

Lemma 12 *There is polynomial-time algorithm such that it constructs a circuit for a polynomial $F_{i,t,h,a}$ such that for each (i, t, h) -downloadable subset $S' = \{p_{i_1}, \dots, p_{i_a}\} \subseteq S$, the sum of product expansion of $F_{i,t,h,a}$ contains a multilinear monomial $(x_{i_1}, \dots, x_{i_a})Y$, where each variable x_i represents program p_i for $i = 1, \dots, m$, and Y is a multilinear monomial with only y variables.*

Proof For each program $p_i \in S$, let variable x_i represent it. A recursive way is used to define the polynomial $F_{i,t,h,a}$:

1. $F_{i,t,0,0} = 0$.
2. $F_{i,t,0,1} = \sum_{\substack{p_j \in S, \\ p_j \text{ is entirely in} \\ \text{the time interval} \\ [t_1, t_2] \text{ of channel } i}} x_j$.

$$3. F_{i,t,h+1,b+1} = y_{i,t,h+1,b+1,1} (\sum_{t_1 < t} F_{i,t_1,h+1,b} \cdot P_{i,t_1+1,t,1}) + y_{i,t,h+1,b+1,1} (\sum_{t_1 < t, j \neq i} F_{j,t_1-1,h,b} \cdot P_{i,t_1+1,t,1}).$$

In the recursion for $F_{i,t,h+1,b+1}$, it is based on the two cases. The first case, which corresponds to the term $(\sum_{t_1 < t} F_{i,t,h+1,b} \cdot P_{i,t_1+1,t,1})$, is that the second last program is still downloaded from channel i and so is the last program. The second case, which corresponds to the term $(\sum_{t_1 < t, j \neq i} F_{j,t_1-1,h,b} \cdot P_{i,t_1+1,t,1})$, is that the second last program is downloaded from another channel $j \neq i$ and the last program is downloaded from channel i . The switch needs one unit additional time than the case without channel switch. \square

If the clients just need to download a subset of t programs in set S , we have the following theorem to get an $O(2^t(nkh)^{O(1)})$ time randomized algorithm with two layers of randomization.

Theorem 6 ([34]) *There is an $O(2^t(nkh)^{O(1)})$ time randomized algorithm to determine if there is a scheduling to download t programs from S in at most n time slots and at most h channel switches.*

Proof By Lemma 12, let polynomial $H_{n,h,t} = \sum_{i=1}^k F_{i,n,h,t}$. It is easy to see that there is a scheduling for downloading at least t programs in time n and k channel switches if and only if the sum-product expansion of $H_{n,h,t}$ has a multilinear monomial $(x_{i_1}, \dots, x_{i_t})$, where each variable x_i represents program p_i for $i = 1, \dots, m$.

Replace each x_i with a vector $w_i = u_0^T + v_i^T$, where $u_0 = (0, \dots, 0)$ is the zero vector of dimension t and v_i is a random vector of dimension t .

Define the operation $(a_1, \dots, a_m)^T \cdot (b_1, \dots, b_m)^T = ((a_1 + b_1)(mod 2), \dots, (a_m + b_m)(mod 2))^T$. The replacement $x_i = w_i$, ($i = 1, \dots, m$) makes all monomials, which has non-multilinear monomial in its x part, be zero.

Assume that the sum of product expansion of $H_{n,h,t}$ has a multilinear monomial $(x_{i_1} \cdots x_{i_t})$. For a series of random vectors of dimension t : v_{j_1}, \dots, v_{j_t} , with probability at most $2^{t-1}/2^t = 1/2^{t-i+1}$, v_{j_i} is a linear combination of $v_{j_1}, \dots, v_{j_{i-1}}$. Therefore, with probability at most $\sum_{i=1}^t \frac{1}{2^{t-i+1}} \leq \frac{3}{4}$, v_{j_i} is a linear combination of $v_{j_1}, \dots, v_{j_{i-1}}$ for some $i \leq t$. When v_{i_1}, \dots, v_{i_t} are linearly independent, the product w_{i_1}, \dots, w_{i_t} is nonzero. Every monomial in the sum of product expansion has different product Y of its y variables since it is determined by a unique path forming the polynomial. Therefore, for those random vectors v_i , every multilinear monomial has a chance at least $1 - \frac{3}{4} = \frac{1}{4}$ be nonzero. There is solution if and only if with probability at least $\frac{1}{4}$, $H_{n,h,t}|_{x_i=w_i(i=1,\dots,m)}$ is not a zero polynomial in the field G_2 .

It is well known that there is randomized polynomial-time algorithm to check if a polynomial is identical to zero.

After the replacements, it generates 2^t terms since there are 2^t vectors of dimension t . The coefficient of each vector is kept as a polynomial size circuit. Therefore, the time is $O(2^t(nkh)^{O(1)})$. \square

7 The Complexity of Testing Monomials

Through the discussions of previous sections, the readers may have understood the motivation and necessity of the study about the monomial testing problem for multivariate polynomials. In this section, the question which asks whether a polynomial represented by certain economically compact structure has a multilinear monomial in its sum-product expansion will be discussed. The main results of this part come from the recent works by Chen and Fu [15]. The complexity aspects of this problem and its variants are investigated with twofolds of objectives. One is to understand how this problem relates to critical problems in complexity and if so to what extent. The other is to exploit possibilities of applying algebraic properties of polynomials to the study of those problems. The monomial testing problem is related to, and somehow complements with, the low-degree testing and the identity testing of polynomials. In addition to the k -path problem and the Hamiltonian path problem, applications has been found in genome sequencing [33] and wireless data broadcast [34]. Also it has been used to interpret the complexity of multivariate integration and derivative [26, 32]. In the following subsection, a brief history about the complexity of polynomials is first introduced. Then a series of results about $\prod \sum \prod$ and $\prod \sum$ polynomials are presented. These results are a part of the foundation of testing monomials in multivariate polynomials [15, 16, 20].

There has been a long history in complexity theory with heavy involvement of studies and applications of polynomials. More notably, low-degree polynomial testing or representing and polynomial identity testing have played invaluable roles in many major breakthroughs in complexity theory. For example, low-degree polynomial testing is involved in the proof of the PCP theorem, the cornerstone of the theory of computational hardness of approximation, and the culmination of a long line of research on IP and PCP [4, 29]. Polynomial identity testing has been extensively studied due to its role in various aspects of theoretical computer science (e.g., [17, 49]) and its application in various fundamental results such as Shamir's IP=PSPACE [69] and the AKS primality testing [63]. Low-degree polynomial representing [64] has been sought so as to prove important results in circuit complexity, complexity class separation, and subexponential time learning of boolean functions (e.g., [6, 31, 55]). These are a just few examples. A survey of the related literature is certainly beyond the scope of this chapter.

7.1 Notations and Definitions

Let $\mathcal{P} \in \{Z, Z_{\geq 0}\}$, where Z is the set of all integers $\{\dots, -2, -1, 0, 1, 2, \dots\}$ and $Z_{\geq 0}$ is the set of nonnegative integers $\{0, 1, 2, \dots\}$. For variables x_1, x_2, \dots, x_n , let $\mathcal{P}[x_1, \dots, x_n]$ denote the n -variate polynomials with coefficients from \mathcal{P} . For $1 \leq i_1 \leq \dots \leq i_k \leq n$, $\pi = x_{i_1}^{j_1} \cdots x_{i_k}^{j_k}$ is called a *monomial*. The degree of π , denoted by $\deg(\pi)$, is $\sum_{s=1}^k j_s$. π is multilinear, if $j_1 = \dots = j_k = 1$, i.e., π is linear in all

its variables x_{i_1}, \dots, x_{i_k} . For any given integer $c \neq 1$, π is called a c -monomial, if $1 \leq j_1, \dots, j_k < c$.

An arithmetic circuit, or circuit for short, is a direct acyclic graph with $+$ gates of unbounded fan-ins, \times gates of two fan-ins, and all terminals corresponding to variables. The size, denoted by $s(n)$, of a circuit with n variables is the number of gates in it. A circuit is called a formula, if the fan-out of every gate is at most one, i.e., the underlying direct acyclic graph is a tree.

By definition, any polynomial $p(x_1, \dots, x_n)$ can be expressed as a sum of a list of monomials, called the *sum-product expansion*. The degree of the polynomial is the largest degree of its monomials in the expansion. With this expression, it is trivial to see whether $p(x_1, \dots, x_n)$ has a multilinear monomial or a monomial with any given pattern. Unfortunately, this expression is essentially problematic with any given pattern. Unfortunately, this expression is essentially problematic and infeasible to realize, because a polynomial may often have exponentially many monomials in its expansion.

In general, a polynomial $p(x_1, \dots, x_n)$ can be represented by a circuit or some even simpler structure as defined in the following. This type of representation is simple and compact and may have a substantially smaller size, say, polynomially in n , in comparison with the number of all monomials in the sum-product expansion. The challenge is how to test whether $p(x_1, \dots, x_n)$ has a multilinear monomial or some needed monomial, efficiently without unfolding it into its sum-product expansion.

Definition 12 Let $p(x_1, \dots, x_n) \in \mathcal{P}[x_1, \dots, x_n]$ be any given polynomial. Let $m, s, t \geq 1$ be integers:

- $p(x_1, \dots, x_n)$ is said to be a $\prod_m \sum_s \prod_t$ polynomial, if $p(x_1, \dots, x_n) = \prod_{i=1}^m F_i$, $F_i = \sum_{j=1}^{r_i} X_{ij}$ and $1 \leq r_i \leq s$, and $\deg(X_{ij}) \leq t$. Each F_i is called a clause. Note that X_{ij} is not a monomial in the sum-product expansion of $p(x_1, \dots, x_n)$ unless $m = 1$. To differentiate this subtlety, X_{ij} is called a term.
- In particular, $p(x_1, \dots, x_n)$ is a $\prod_m \sum_s$ polynomial, if it is a $\prod_m \sum_s \prod_1$ polynomial. Here, each clause is a linear addition of single variables. In other word, each term has degree 1.
- When no confusing arises from the correct, $\prod \sum \prod$ and $\prod \sum$ is used to stand for $\prod_m \sum_s \prod_t$ and $\prod_m \sum_s$, respectively. Similarly, $\prod \sum_s \prod$ and $\prod \sum_s$ is used to stand for $\prod_m \sum_s \prod_t$ and $\prod_m \sum_s$, respectively, emphasizing that every clause in a polynomial has at most s terms or is a linear addition of at most s single variables.
- For any given integer $k > 1$, $p(x_1, \dots, x_n)$ is called a $k\text{-}\prod \sum \prod$ polynomial, if each of its terms has at most k distinct variables.
- $p(x_1, \dots, x_n)$ is called a $\prod \sum \prod \times \prod \sum$ polynomial, if $p(x_1, \dots, x_n) = p_1 p_2$ such that p_1 is a $\prod \sum \prod$ polynomial and p_2 is a $\prod \sum$ polynomial. Similarly, $p(x_1, \dots, x_n)$ is called a $k\text{-}\prod \sum \prod \times \prod \sum$ polynomial, if $p(x_1, \dots, x_n) = p_1 p_2$ such that p_1 is a $k\text{-}\prod \sum \prod$ polynomial and p_2 is a $\prod \sum$ polynomial.

On the surface, a $\prod_m \sum_s \prod_t$ polynomial “resembles” a 3SAT (2SAT) formula, especially when $t = 1$. Likewise, a $\prod_m \sum_3 \prod_t (\prod_m \sum_2 \prod_t)$ polynomial “resembles” a 3SAT (2SAT) formula, especially when $t = 1$. However, negated variables are not involved in a polynomials. Furthermore, as pointed out in the previous section, is not easy, if not impossible, to have some easy algebra to deal with the properties of $x^2 = x$ and $x \cdot \bar{x} = 0$ in a field, especially when the field is larger than Z_2 . Also, as pointed out before, the arithmetization technique is Shamir is not applicable to this case.

7.2 3SAT and Related NP-Complete Problems

In this section, we give the definition of 3SAT problem and its restricted version, which is called (3, 3)-SAT.

Definition 13

- A 3SAT instance is a conjunctive form $C_1 \cdot C_2 \cdots C_m$ such that each C_i is a disjunction of at most three literals.
- 3SAT is the language of those 3SAT instances that have satisfiable assignments.
- A (3, 3)-SAT instance is an instance G for 3SAT such that for each variable x , the total number of times of x and \bar{x} in G is at most 3, and the total number of times of \bar{x} in G is at most 1.
- (3, 3)-SAT is the language of those (3, 3)-SAT instances that have satisfiable assignments.

It is well known 3SAT is NP-complete. For example, $(x_1 + x_2 + x_3)(x_1 + \bar{x}_2)$ ($\bar{x}_1 + x_2$) is both 3SAT and (3, 3)-SAT instance, and also belongs to both 3SAT and (3, 3)-SAT. On the other hand, $(x_1 + x_2 + x_3)(\bar{x}_1 + \bar{x}_2)(\bar{x}_1 + x_2)$ is not a (3, 3)-SAT instance since \bar{x}_1 appears twice in the formula. The following lemma is similar to a result derived by Tovey [72].

Lemma 13 *There is a polynomial-time reduction from 3SAT to (3, 3)-SAT.*

Proof Let F be an instance for 3SAT. Let's focus on one variable x_i that appears m times in F . Introduce a series of new variables $y_{i,1}, \dots, y_{i,m}$ for x_i . Convert F to F' by changing the j -th occurrence of x_i in F to $y_{i,j}$ for $j = 1, \dots, m$. Define

$$\begin{aligned} G_{x_i} &= (x_i \rightarrow y_{i,1}) \cdot (y_{i,1} \rightarrow y_{i,2}) \cdot (y_{i,2} \rightarrow y_{i,3}) \cdot (y_{i,3} \rightarrow y_{i,4}) \cdots (y_{i,m-1} \rightarrow y_{i,m}) \cdot \\ &\quad (y_{i,m} \rightarrow x_i) \\ &= (\bar{x}_i + y_{i,1}) \cdot (\bar{y}_{i,1} + y_{i,2}) \cdot (\bar{y}_{i,2} + y_{i,3}) \cdot (\bar{y}_{i,3} + y_{i,4}) \cdots (\bar{y}_{i,m-1} + y_{i,m}) \cdot \\ &\quad (\bar{y}_{i,m} + x_i). \end{aligned}$$

Each logical formula $(x \rightarrow y)$ is equivalent to $(\bar{x} + y)$. If G_{x_i} is true, then $x_i, y_{i,1}, \dots, y_{i,m}$ are equivalent.

Convert F' into F'' such that $F'' = F'G_{x_1} \cdots G_{x_k}$, where x_1, \dots, x_k are all variables in F .

For each variable x in F'' with more than one \bar{x} , create a new variable y_x and replace each positive x of F by \bar{y}_x and each negative \bar{x} by y_x . Thus, F'' becomes F''' . It is easy to see that $F \in 3\text{SAT}$ iff F'' is satisfiable iff $F''' \in (3,3)\text{-SAT}$. \square

7.3 $\prod \sum \prod$ Polynomials

Given any $\prod_m \sum_s \prod_t$ polynomial $p(x_1, \dots, x_n) = p_1 \cdots p_m$, one can nondeterministically choose a term π_i from the clause p_i and then check whether $\pi_1 \cdots \pi_m$ is a multilinear monomial. So the problem of testing multilinear monomials in a $\prod \sum \prod$ polynomial is in NP. In the following, the reader will realize that this problem is also NP-hard.

Theorem 7 ([15]) *It is NP-hard to test whether a $2\text{-}\prod_m \sum_3 \prod_2$ polynomial has a multilinear monomial in its sum-product expansion.*

Proof By Lemma 13, $(3,3)\text{-SAT}$ is NP-complete. The $(3,3)\text{-SAT}$ problem can be reduced to the given problem. Let $f = f_1 \wedge \cdots \wedge f_m$ be a $(3,3)\text{-3SAT}$ instance. Every variable x_i in f appears at most three times, and if x_i appears three times, then x_i itself occurs twice and \bar{x}_i once.

Let x_i be any given variable in f ; new variables are introduced to replace it. If x_i appears only once, then the appearance of x_i (or \bar{x}_i) is replaced by a new variable y_{i1} . When x_i appears twice: if x_i occurs twice, then replace the first occurrence by a new variable y_{i1} and the second by y_{i2} . If both x_i and \bar{x}_i occur, then replace both occurrences by y_{i1} . When x_i occurs three times with x_i appearing twice and \bar{x}_i once, then replace the first x_i by y_{i1} and the second by y_{i2} , and replace \bar{x}_i by $y_{i1}y_{i2}$. This procedure of replacing all variables in f , negated or not, with new variables can be carried out easily in quadratic time.

Let $p = p_1 \cdots p_m$ be polynomial resulting from the above replacement process. Here, p_i corresponds to f_i with boolean literals being replaced. Clearly, p is a $2\text{-}\prod_m \sum_3 \prod_2$ polynomial.

Considering the sum-product expansion of $f = f_1 \cdots f_m$, it is easy to see that f is satisfiable iff its sum-product expansion has a product

$$\psi = \tilde{x}_{i_1} \cdots \tilde{x}_{i_m},$$

where the literal \tilde{x}_{i_j} is from the clause f_j and is either x_{i_j} or \bar{x}_{i_j} , $1 \leq j \leq m$. Furthermore, the negation of \tilde{x}_{i_j} must not occur in ψ .

Let $t(\tilde{x}_{i_j})$ denote the replacement of \tilde{x}_{i_j} by new variables $y_{i,j,1}$ and/or $y_{i,j,2}$ as described above to transform f to p . Then, $t(\tilde{x}_{i_j})$ is a term in the clause p_j . Hence,

$$t(\psi) = t(\tilde{x}_{i_1}) \cdots t(\tilde{x}_{i_m})$$

is a monomial in the sum-product expansion of p . Moreover, $t(\psi)$ is multilinear, because a variable and its negation cannot appear in ψ at the same time.

On the other hand, assume that

$$\pi = \pi_1 \cdots \pi_m$$

is a multilinear monomial in p with the term π_{i_j} in the clause p_j . Let $t^{-1}(\cdot)$ denote the reversal replacement of $t(\cdot)$. Then, by the procedure of the replacement above, $t^{-1}(\pi_{i_j})$ is a variable or the negation of a variable in f_j . Thus,

$$t^{-1}(\pi) = t^{-1}(\pi_1) \cdots t^{-1}(\pi_m)$$

is a product in the sum-product expansion of f . Since π is multilinear, a variable and its negation cannot appear in $t^{-1}(\pi)$ at the same time. This implies that f is satisfiable by an assignment of setting all the literals in $t^{-1}(\pi)$ true. \square

An example is given below to illustrate the variable replacement procedure given in the above proof. Given a 3SAT formula

$$f = (x_1 \vee \bar{x}_2 \vee x_3) \wedge (\bar{x}_1 \vee x_2 \vee x_4) \wedge (x_1 \vee x_2 \vee \bar{x}_3) \wedge (x_4 \vee x_5),$$

the polynomial for f after variable replacement is

$$p(f) = (y_{11} + y_{21}y_{22} + y_{31})(y_{11}y_{12} + y_{21} + y_{41})(y_{12} + y_{22} + y_{31})(y_{42} + y_{51}).$$

The truth assignment satisfying f as determined by the product $x_3 \cdot \bar{x}_1 \cdot x_2 \cdot x_4$ is one-to-one correspondent to the multilinear monomial $y_{31} \cdot y_{11}y_{12} \cdot y_{22} \cdot y_{42}$ in $p(f)$.

Two corollaries follow immediately from this theorem.

Corollary 1 ([15]) *It is NP-hard to test whether a $\prod \sum \prod$ polynomial has multilinear monomials in its sum-product expansion.*

7.4 Complexity for Coefficient of Monomial

In this section, it is shown that computing the coefficient of a multilinear monomial in a formula is #P-hard.

Theorem 8 ([16]) *It is #P-hard that given a formula of homogenous polynomial, compute the coefficient of any multilinear monomial.*

Proof It is well known that computing the number of perfect matchings in a bipartite graph is $\#P$ -hard. The counting of perfect matching problem can be reduced to this problem. Assume that $G = (V_1 \cup V_2, E)$ is a bipartite graph. A formula is constructed below.

Assume that $V_1 = \{v_1, \dots, v_n\}$ and $V_2 = \{u_1, \dots, u_m\}$. For each vertex $v_i \in V_1$, let x_i represent it. For each vertex $u_i \in V_2$, let y_i represent it.

For each vertex $v_i \in V_1$, define the polynomial $F_i = \sum_{(v_i, u_j) \in E} x_i y_j$. The formula F_G is $F_1 \cdot F_2 \cdots \cdot F_n$. The number of perfect matchings in G is equal to the coefficient of the multilinear monomial $x_1 x_2 \cdots x_n y_1 y_2 \cdots y_n$ in the sum of product expansion of F_G . \square

8 Hardness of Approximation of Integration and Differentiation

Integration and differentiation are basic operations in classical mathematics. Valiant showed that computing the high-dimensional integration and differentiation are both $\#P$ -hard via reducing permanent problem to them [73]. Valiant's results do not imply any inapproximability of the two problems since permanent has a polynomial-time approximation scheme [45]. Using the complexity theory of monomial testing, Fu [32] showed some hardness results for high-dimensional integration and differentiation of multivariate polynomials. This is an application of the complexity theory of testing monomial.

Let $Z_{\geq 0} = \{0, 1, 2, \dots\}$ be the set of all natural numbers. Let $Z_+ = \{1, 2, \dots\}$ be the set of all positive natural numbers.

Assume that function $r(n)$ is from $Z_{\geq 0}$ to Z^+ . For a functor $F(\cdot)$ that converts a multivariate polynomial into a real number, an algorithm $A(\cdot)$ gives an $r(n)$ -factor approximation to $F(f)$ if it satisfies the following conditions: if $F(f) \geq 0$, then $\frac{F(f)}{r(n)} \leq A(f) \leq r(n)F(f)$, and if $F(f) < 0$, then $r(n)F(f) \leq A(f) \leq \frac{F(f)}{r(n)}$, where n is the length of f .

8.1 Inapproximation of Integration

In this section, we show that it is NP-hard to approximate high-dimensional integration of multivariate polynomials.

Lemma 14 is our main technical lemma. It is used to convert a $(3, 3)$ -SAT instance into a $\prod \sum \prod_2$ polynomial.

Lemma 14 Let $g_1(x) = 30x^2 - 36x + 9$, $g_2(x) = -6x + 4$ and $f(x) = 2x$. They satisfy the following conditions:

1. $\int_0^1 g_1(x) dx$, $\int_0^1 g_2(x) dx$, $\int_0^1 f(x) dx$, and $\int_0^1 g_1(x)g_2(x) dx$ are all positive integers,
2. $\int_0^1 g_1(x)f(x) dx$, $\int_0^1 g_2(x)f(x) dx$, and $\int_0^1 g_1(x)g_2(x)f(x) dx$ are all equal to 0.

Proof For a polynomial $h(x) = a_n x^n + a_{n-1} x^{n-1} + \cdots + a_0$, we can compute its integration as $\int_0^1 h(x) dx = \frac{a_n}{n+1} + \frac{a_{n-1}}{n} + \cdots + a_0$. It is straightforward to verify the lemma with the concrete expressions for the three functions $g_1(x)$, $g_2(x)$ and $f(x)$. \square

Lemma 15 *There is a polynomial-time algorithm h such that given a $(3, 3)$ -SAT instance $s(x_1, \dots, x_d)$, it produces a $\prod \sum \prod_2$ polynomial $h(s(x_1, \dots, x_d)) = q(y_1, \dots, y_d)$ to satisfy the following two conditions:*

1. *If $s(x_1, \dots, x_d)$ is satisfiable, then $\int_{[0,1]^d} q(y_1, \dots, y_d) dy_1 \cdots dy_d$ is a positive integer; and*
2. *If $s(x_1, \dots, x_d)$ is not satisfiable, then $\int_{[0,1]^d} q(y_1, \dots, y_d) dy_1 \cdots dy_d$ is zero.*

Proof Let polynomials $g_1(y)$, $g_2(y)$, and $f(y)$ be defined according to those in Lemma 14.

For a $(3, 3)$ -SAT problem $s(x_1, \dots, x_d)$, let $q(y_1, \dots, y_d)$ be defined as follows:

- For the first positive literal x_i in $s(x_1, \dots, x_d)$, replace it with $g_1(y_i)$.
- For the second positive literal x_i in $s(x_1, \dots, x_d)$, replace it with $g_2(y_i)$.
- For the negative literal \bar{x}_i in $s(x_1, \dots, x_d)$, replace it with $f(y_i)$.

The formula $s(x_1, \dots, x_d)$ has a sum of product form. It is satisfiable if and only if one term does not contain both positive and negative literals for the same variable. If a term contains both x_i and \bar{x}_i , the corresponding term in the sum of product for $q(\cdot)$ contains both $g_j(y_i)$ and $f(y_i)$ for some $j \in \{1, 2\}$. This makes it zero after integration by Lemma 14. Therefore, $s(x_1, \dots, x_d)$ is satisfiable if and only if $\int_{[0,1]^d} q(y_1, \dots, y_d) dy_1 \cdots dy_d$ is not zero. Furthermore, it is satisfiable and the integration is a positive integer by Lemma 14. The computing time of h is clearly polynomial since we convert s to $h(s)$ by replacing each literal by a single variable function of degree at most 2. \square

Theorem 9 ([32]) *Let $a(n)$ be an arbitrary function from $Z_{\geq 0}$ to Z_+ . Then there is no polynomial-time $a(n)$ -factor approximation for the integration of a $\prod \sum \prod_2$ polynomial $p(x_1, \dots, x_d)$ in the region $[0, 1]^d$ unless $P = NP$.*

Proof Assume that $A(\cdot)$ is a polynomial-time $a(n)$ -factor approximation for the integration $\int_{[0,1]^d} p(y_1, \dots, y_d) dy_1 \cdots dy_d$ with $\prod \sum \prod_2$ polynomial $p(y_1, \dots, y_d)$. For a $(3, 3)$ -SAT instance $s(x_1, \dots, x_d)$, let $p(y_1, \dots, y_d) = h(s(x_1, \dots, x_d))$ according to Lemma 15. By Lemma 15, a $(3, 3)$ -SAT instance $s(x_1, \dots, x_d)$ is satisfiable if and only if the integration $J = \int_{[0,1]^d} p(y_1, \dots, y_d) dy_1 \cdots dy_d$ is not zero. Assume that $s(x_1, \dots, x_d)$ is not satisfiable, then we have $A(J) \in [J/a(n), J \cdot a(n)] = [0, 0]$ that implies $A(J) = 0$. Assume that $s(x_1, \dots, x_d)$ is satisfiable, then we have $A(J) \in [J/a(n), J \cdot a(n)] \subseteq (0, +\infty)$ that implies $A(J) > 0$. Thus, $s(x_1, \dots, x_d)$ is satisfiable if and only if $A(J) > 0$.

Therefore, there is a polynomial-time algorithm for solving $(3, 3)$ -SAT that is NP-complete by Lemma 13. So, $P = NP$. \square

8.2 Inapproximation of Differentiation

In this section, we study the hardness of high-dimensional differentiation. We derive the inapproximation results under both $\text{NP} \neq \text{P}$.

Definition 14 A monomial is an expression $x_1^{a_1} \cdots x_d^{a_d}$, and its degree is $a_1 + \cdots + a_d$. A monomial $x_1^{a_1} \cdots x_d^{a_d}$, in which x_1, \dots, x_d are different variables, is a *multilinear* if $a_1 = a_2 = \cdots = a_d = 1$.

For example, $(x_1x_3 + x_2^2)(x_2x_4 + x_3^2)$ is a $\prod \sum \prod_2$ polynomial. It has a multilinear monomial $x_1x_2x_3x_4$ in its sum of products expansion.

We give [Lemma 16](#) to convert an instance f for $(3, 3)$ -SAT into a $\prod \sum \prod_2$ polynomial. Its proof is similar to that of [Theorem 7](#).

Lemma 16 *Let $a(1^n)$ be a polynomial-time computable function from $Z_{\geq 0}$ to Z_+ . Then there is a polynomial-time algorithm A such that given a $(3, 3)$ -SAT instance $F(y_1, \dots, y_d)$, the algorithm returns a $\prod \sum \prod_2$ polynomial $G(x_1, \dots, x_d)$ such that:*

1. *If F is not satisfiable, then G does not have a multilinear monomial with a nonzero coefficient in its sum of product expansion.*
2. *If F is satisfiable, then G has the multilinear monomial $x_1 \cdots x_d$ with a positive integer coefficient at least $3a(1^n)^2$ in its sum of product expansion.*

Proof Let $(3, 3)$ -SAT instance F be $C_1C_2 \cdots C_k$. Each clause C_i has format $y_{i_1}^* + y_{i_2}^* + y_{i_3}^*$, where literal y_j^* is either y_j or its negation \bar{y}_j . Since F is a $(3, 3)$ -SAT instance, for each variable y_i in F , y_i and \bar{y}_i totally appear at most three times in F , and \bar{y}_i appears at most once in F .

For each variable y_i in F , create four new variables $z_{i,1}, z_{i,2}, u_{i,1}$, and $u_{i,2}$. Convert formula F into polynomial G_1 such that for each y_i in F , the first positive occurrence y_i is changed into $z_{i,1}u_{i,1}$, the second positive occurrence y_i is changed into $z_{i,2}u_{i,2}$, and the negative occurrence \bar{y}_i is changed to $z_{i,1}z_{i,2}$. After the conversion for all the variables, formula F is transformed into a polynomial G_1 . We have that F is satisfiable if and only if G_1 has a multilinear monomial with positive coefficient in its sum of products expansion. This is because a multilinear monomial in the sum of product expansion of G_1 corresponds a consistent conjunctive term, which does not contain both y_i and its negation \bar{y}_i for some variable y_i , in the sum of product expansion of F .

Let H_1 be the set of all variables in G_1 . Assume that d_1 is the degree of G_1 (it is easy to see that all monomials in the sum-product expansion of G_1 have the same degree d_1). Let m be the number of variables in H_1 . Let d be the number of boolean variables in F . Assume that no clause C_i in F contains a single literal (otherwise, we can force the literal to be true to simplify F). The number of clauses in F is at most $\frac{3d}{2}$ since each variable appears in F at most three times and each clause C_i of F contains at least two literals. The degree G_1 is at most $3d$ since each literal

of F is replaced by a product of two variables. The number of variables in G_1 is $m = 4d$ (we create four new variables for each variable in F), which is larger than the degree of G_1 .

Create new variables v_1, \dots, v_{m-d_1} . For $j = 1, \dots, m-d_1$, let $q_j = \sum_{x \in H_1} xv_j$. Finally, we get the polynomial $G = 3a(1^n)^2 \cdot G_1 \cdot q_1 \cdots q_{m-d_1}$, where $n = m + (m - d_1)$. Note that $3a(1^n)^2$ in the polynomial G is considered an integer constant which does not contain any variable. The degree of G is $n = d_1 + 2(m - d_1) = m + (m - d_1)$. Thus, the degree of G is the same as the total number of variables in g . We can show that f is satisfiable if and only if there is a multilinear monomial, which is the product of all variables in G , with positive coefficient of size at least $3a(1^n)^2$. \square

Theorem 10 ([32]) Assume that $r(n)$ is a function from $Z_{\geq 0}$ to Z_+ . If there is a polynomial-time algorithm A such that given a $\prod \sum \prod_2$ polynomial $g(x_1, \dots, x_d)$, it gives an $r(n)$ -factor approximation to $\frac{\partial g^{(n)}(x_1, \dots, x_d)}{\partial x_1 \cdots \partial x_d}$ at the origin point $(x_1, \dots, x_d) = (0, \dots, 0)$, then $P = NP$.

Proof Assume that $A(\cdot)$ is a polynomial-time $r(n)$ -approximation for computing $\frac{\partial g^{(n)}(x_1, \dots, x_n)}{\partial x_1 \cdots \partial x_n}$ at the origin point $(x_1, \dots, x_n) = (0, \dots, 0)$.

Assume that f is an arbitrary formula in a $(3, 3)$ -SAT problem. By Lemma 16, we can get a polynomial $g(x_1, \dots, x_n)$. The derivative $\frac{\partial g^{(n)}(0, \dots, 0)}{\partial x_1 \cdots \partial x_n}$ is equal to the coefficient of $x_1 \cdots x_n$ in the sum of product expansion of g .

If f is satisfiable, we have $A(g) > 0$, and if f is not satisfiable, we have $A(g) = 0$ since $A(\cdot)$ is a $r(n)$ -approximation and $r(n) \geq 1$. We can know if the coefficient of $x_1 \cdots x_n$ in the sum of product expansion of g is positive in polynomial time. Thus, $(3, 3)$ -SAT is solvable in polynomial time. Since $(3, 3)$ -SAT is NP-complete, we have $P = NP$. \square

9 Conclusion

The combination of randomization and polynomial brings efficient algorithm for the classical problems k -path and Hamiltonian path. The polynomial method has applications in the areas of wireless networking and bioinformatics. It can be seen that testing the existence of multilinear monomials in the sum-product expansion of a polynomial is NP-complete and computing the coefficient of a multilinear monomial in the sum-product expansion is #P-hard. These results shows the polynomial methods links to the central areas of computational complexity theory. This chapter explains some methods that are related to algorithm and computational complexity. It is expected to see the further development of the theory in the future.

Acknowledgements The authors would like to thank Dr. Dingzhu Du for his encouragements when writing this book chapter. We would also like to thank Zhixiang Chen, Yang Liu, and Robert Schweller for a wonderful experience of collaboration working in this area. Finally, we would like

to thank the reviewers for their helpful comments for an earlier version of this chapter. Bin Fu is supported in part by the National Science Foundation Early Career Award CCF-0845376.

Abstract

Domination in graph theory has many applications in the real world such as location problems. A dominating set of a graph $G = (V, E)$ is a subset D of V such that every vertex not in D is adjacent to at least one vertex in D . The domination problem is to determine the domination number $\gamma(G)$ of a graph G that is the minimum size of a dominating set of G . Although many theoretic theorems for domination and its variations have been established for a long time, the first algorithmic result on this topic was given by Cockayne, Goodman, and Hedetniemi in 1975. They gave a linear-time algorithm for the domination problem in trees by using a labeling method. On the other hand, at about the same time, Garey and John constructed the first (unpublished) proof that the domination problem is NP-complete. Since then, many algorithmic results are studied for variations of the domination problem in different classes of graphs. This chapter is to survey the development on this line during the past 36 years. Polynomial-time algorithms using labeling method, dynamic programming method, and primal-dual method are surveyed on trees, interval graphs, strongly chordal graphs, permutation graphs, cocomparability graphs, and distance-hereditary graphs. NP-completeness results on domination are also discussed.

1 Introduction

Graph theory was founded by Euler [88] in 1736 as a generalization of the solution to the famous problem of the Königsberg bridges. From 1736 to 1936, the same concept as graph, but under different names, was used in various scientific fields as models of real-world problems; see the historic book by Biggs et al. [22]. This chapter intends to survey the domination problem in graph theory from an algorithmic point of view.

Domination in graph theory is a natural model for many location problems in operations research. As an example, consider the following fire station problem. Suppose a county has decided to build some fire stations, which must serve all of the towns in the county. The fire stations are to be located in some towns so that every town either has a fire station or is a neighbor of a town which has a fire station. To save money, the county wants to build the minimum number of fire stations satisfying the above requirements.

Domination has many other applications in the real world. The recent book by Haynes et al. [112] illustrates many interesting examples, including dominating

		K		

queens, sets of representatives, school bus routing, computer communication networks, (r, d) -configurations, radio stations, social network theory, land surveying, and kernels of games.

Among them, the classical problems of covering chessboards by the minimum number of chess pieces are important in stimulating the study of domination, which commenced in the early 1970s. These problems certainly date back to De Jaenisch [83] and have been mentioned in the literature frequently since that time.

A simple example is to determine the minimum number of kings dominating the entire chessboard. The answer to an $m \times n$ chessboard is $\lceil \frac{m}{3} \rceil \lceil \frac{n}{3} \rceil$. In the Chinese chess game, a king only dominates the four neighbor cells which have common sides with the cell the king lies in. In this case, the Chinese king domination problem for an $m \times n$ chessboard is harder. Figure 1 shows optimal solutions to both cases for a 3×5 board.

The above problems can be abstracted into the concept of domination in terms of graphs as follows. A *dominating set* of a graph $G = (V, E)$ is a subset D of V such that every vertex not in D is adjacent to at least one vertex in D . The *domination number* $\gamma(G)$ of a graph G is the minimum size of a dominating set of G .

For the fire station problem, consider the graph G having all towns of the county as its vertices and a town is adjacent to its neighbor towns. The fire station problem is just the domination problem, as $\gamma(G)$ is the minimum number of fire stations needed.

For the king domination problem on an $m \times n$ chessboard, consider the king's graph G whose vertices correspond to the mn squares in the chessboard, and two vertices are adjacent if and only if their corresponding squares have a common point. For the Chinese king domination problem, the vertex set is the same, but two vertices are adjacent if and only if their corresponding squares have a common side. Figure 2 shows the corresponding graphs for the king and the Chinese king domination problems on a 3×5 chessboard. The king domination problem is just the domination problem, as $\gamma(G)$ is the minimum number of kings needed. Black vertices in the graph form a minimum dominating set.

Although many theoretic theorems for the domination problem have been established for a long time, the first algorithmic result on this topic was given by Cockayne et al. [56] in 1975. They gave a linear-time algorithm for the domination problem in trees by using a labeling method. On the other hand, at about the same time, Garey and Johnson (see [99]) constructed the first (unpublished) proof that the domination problem is NP-complete for general graphs. Since then, many

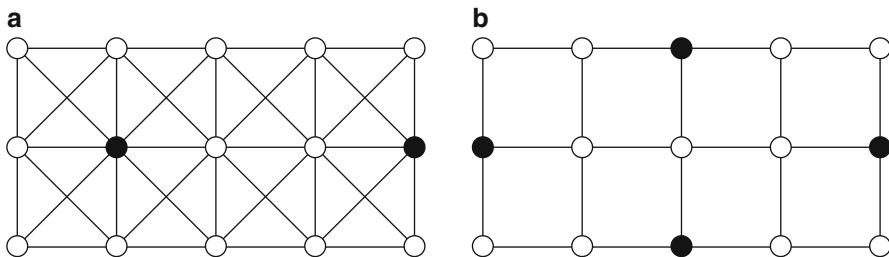

Fig. 2 King's graphs for the chess and the Chinese chess **(a)** For chess; **(b)** For Chinese chess

algorithmic results are studied for variations of the domination problem in different classes of graphs. The purpose of this chapter is to survey these results.

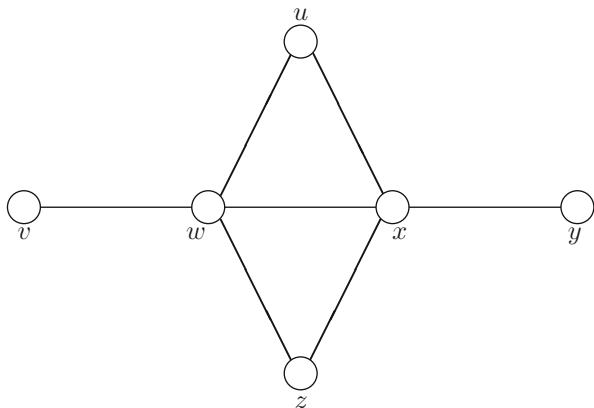

This chapter is organized as follows. [Section 2](#) gives basic definitions and notation. In particular, the classes of graphs surveyed in this chapter are introduced. Among them, trees and interval graphs are two basic classes in the study of domination. While a tree can be viewed as many paths starting from a center with different branches, an interval graph is a “thick path” in the sense that a vertex of a path is replaced by a group of vertices tied together. [Section 3](#) investigates different approaches for domination in trees, including labeling method, dynamic programming method, and primal–dual approach. These techniques are used not only for trees but also for many other classes of graphs in the study of domination as well as many other optimization problems. [Section 4](#) is for domination in interval graphs. It is in general not clear to which classes of graphs the results in trees and interval graphs can be extended. For some classes of graphs, the domination problem becomes NP-complete, while for some classes it is polynomially solvable. [Section 5](#) surveys NP-completeness results on domination, for which chordal graphs play an important role. The remaining sections are for classes of graphs in which the domination problem is solvable, including strongly chordal graphs, permutation graphs, cocomparability graphs, and distance-hereditary graphs.

2 Definitions and Notation

2.1 Graph Terminology

A *graph* is an ordered pair $G = (V, E)$ consisting of a finite nonempty set V of *vertices* and a set E of 2-subsets of V , whose elements are called *edges*. Sometimes $V(G)$ is used for the vertex set and $E(G)$ for the edge set of a graph G . A graph is *trivial* if it contains only one vertex. For any edge $e = \{u, v\}$, it is said that vertices u and v are *adjacent* and that vertex u (respectively, v) and edge e are *incident*. Two distinct edges are *adjacent* if they contain a common vertex. It is convenient to henceforth denote an edge by uv rather than $\{u, v\}$. Notice that uv and vu represent the same edge in a graph.

Fig. 3 A graph G with six vertices and seven edges

Two graphs $G = (V, E)$ and $H = (U, F)$ are *isomorphic* if there exists a bijection f from V to U such that $uv \in E$ if and only if $f(u)f(v) \in F$. Two isomorphic graphs are essentially the same as one can be obtained from the other by renaming vertices.

It is often useful to express a graph G diagrammatically. To do this, each vertex is represented by a point (or a small circle) in the plane and each edge by a curve joining the points (or small circles) corresponding to the two vertices incident to the edge. It is convenient to refer to such diagram of a graph as the graph itself. In Fig. 3, a graph G with vertex set $V = \{u, v, w, x, y, z\}$ and edge set $E = \{uw, ux, vw, wx, xy, wz, xz\}$ is shown.

Suppose A and B are two sets of vertices. The *neighborhood* $N_A(B)$ of B in A is the set of vertices in A that are adjacent to some vertex in B , that is,

$$N_A(B) = \{u \in A : uv \in E \text{ for some } v \in B\}.$$

The *closed neighborhood* $N_A[B]$ of B in A is $N_A(B) \cup B$. For simplicity, $N_A(v)$ stands for $N_A(\{v\})$, $N_A[v]$ for $N_A[\{v\}]$, $N(B)$ for $N_V(B)$, $N[B]$ for $N_V[B]$, $N(v)$ for $N_V(\{v\})$, and $N[v]$ for $N_V[\{v\}]$. The notion $u \sim v$ stands for $u \in N[v]$.

The *degree* $\deg(v)$ of a vertex v is the size of $N(v)$ or, equivalently, the number of edges incident to v . An *isolated vertex* is a vertex of degree zero. A *leaf* (or *end vertex*) is a vertex of degree one. The minimum degree of a graph G is denoted by $\delta(G)$ and the maximum degree by $\Delta(G)$. A graph G is r -regular if $\delta(G) = \Delta(G) = r$. A 3-regular graph is also called a *cubic graph*.

A graph $G' = (V', E')$ is a *subgraph* of another graph $G = (V, E)$ if $V' \subseteq V$ and $E' \subseteq E$. In the case of $V' = V$, G' is called a *spanning subgraph* of G . For any nonempty subset S of V , the (*vertex*) *induced subgraph* $G[S]$ is the graph with vertex set S and edge set

$$E[S] = \{uv \in E : u \in S \text{ and } v \in S\}.$$

A graph is *H-free* if it does not contain H as an induced subgraph. The *deletion* of S from $G = (V, E)$, denoted by $G - S$, is the graph $G[V \setminus S]$. $G - v$ is a short notation for $G - \{v\}$ when v is a vertex in G . The *deletion* of a subset F of E from $G = (V, E)$ is the graph $G - F = (V, E \setminus F)$. $G - e$ is a short notation for $G - \{e\}$ if e is an edge of G . The *complement* of a graph $G = (V, E)$ is the graph $\overline{G} = (V, \overline{E})$, where

$$\overline{E} = \{uv \notin E : u, v \in V \text{ and } u \neq v\}.$$

Suppose $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$ are two graphs with $V_1 \cap V_2 = \emptyset$. The *union* of G_1 and G_2 is the graph $G_1 \cup G_2 = (V_1 \cup V_2, E_1 \cup E_2)$. The *join* of G_1 and G_2 is the graph $G_1 + G_2 = (V_1 \cup V_2, E_+)$, where

$$E_+ = E_1 \cup E_2 \cup \{uv : u \in V_1 \text{ and } v \in V_2\}.$$

The *Cartesian product* of G_1 and G_2 is the graph $G_1 \square G_2 = (V_1 \times V_2, E_\square)$, where

$$V_1 \times V_2 = \{(v_1, v_2) : v_1 \in V_1 \text{ and } v_2 \in V_2\},$$

$$E_\square = \{(u_1, u_2)(v_1, v_2) : (u_1 = v_1, u_2 v_2 \in E_2) \text{ or } (u_1 v_1 \in E_1, u_2 = v_2)\}.$$

In a graph $G = (V, E)$, a *clique* is a set of pairwise adjacent vertices in V . An *i-clique* is a clique of size i . A 2-clique is just an edge. A 3-clique is called a *triangle*. A *stable* (or *independent*) set is a set of pairwise nonadjacent vertices in V .

For two vertices x and y of a graph, an *x-y walk* is a sequence $x = x_0, x_1, \dots, x_n = y$ such that $x_{i-1}x_i \in E$ for $1 \leq i \leq n$, where n is called the *length* of the walk. In a walk x_0, x_1, \dots, x_n , a *chord* is an edge $x_i x_j$ with $|i - j| \geq 2$. A *trail* (*path*) is a walk in which all edges (vertices) are distinct. A *cycle* is an $x-x$ walk in which all vertices are distinct except the first vertex is equal to the last. A graph is *acyclic* if it does not contain any cycle.

A graph is *connected* if for any two vertices x and y , there exists an $x-y$ walk. A graph is *disconnected* if it is not connected. A (*connected*) *component* of a graph is a maximal subgraph which is connected. A *cut-vertex* is a vertex whose deletion from the graph results in a disconnected graph. A *block* of a graph is a maximal connected graph which has no cut-vertices.

The *distance* $d(x, y)$ from a vertex x to another vertex y is the minimum length of an $x-y$ path; and $d(x, y) = \infty$ when there is no $x-y$ path.

Digraphs or *directed graphs* can be defined similar to graphs except that an edge (u, v) is now an ordered pair rather than a 2-subset. All terms in graphs can be defined for digraphs with suitable modifications by taking into account the directions of edges.

An *orientation* of a graph $G = (V, E)$ is a digraph (V, E') such that for each edge $\{u, v\}$ of E , exactly one of (u, v) and (v, u) is in E' and the edges in E' all come from this way.

2.2 Variations of Domination

Due to different requirements in the applications, people have studied many variations of the domination problem. For instance, in the queen's domination problem, one may ask the additional property that two queens do not dominate each other or any two queens must dominate each other. The following are most commonly studied variants of domination.

Recall that a dominating set of a graph $G = (V, E)$ is a subset D of V such that every vertex not in D is adjacent to at least one vertex in D . This is equivalent to that $N[x] \cap D \neq \emptyset$ for all $x \in V$ or $\cup_{y \in D} N[y] = V$.

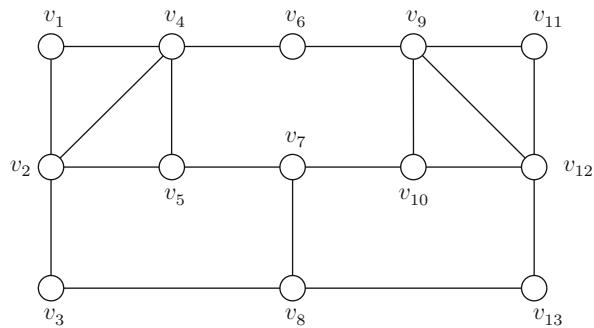

A dominating set D of a graph $G = (V, E)$ is *independent*, *connected*, *total*, or *perfect* (*efficient*) if $G[D]$ has no edge, $G[D]$ is connected, $G[D]$ has no isolated vertex, or $|N[v] \cap D| = 1$ for any $v \in V \setminus D$. An *independent* (respectively, *connected* or *total*) *perfect dominating set* is a perfect dominating set which is also independent (respectively, connected or total). A *dominating clique* (respectively, *cycle*) is a dominating set which is also a clique (respectively, cycle). For a fixed positive integer k , a k -*dominating set* of G is a subset D of V such that for every vertex v in V , there exists some vertex u in D with $d(u, v) \leq k$. An *edge dominating set* of $G = (V, E)$ is a subset F of E such that every edge in $E \setminus F$ is adjacent to some edge in F . For the above variations of domination, the corresponding *independent*, *connected*, *total*, *perfect*, *independent perfect*, *connected perfect*, *total perfect*, *clique*, *cycle*, and k - and *edge domination numbers* are denoted by $\gamma_i(G)$, $\gamma_c(G)$, $\gamma_t(G)$, $\gamma_{\text{per}}(G)$, $\gamma_{\text{iper}}(G)$, $\gamma_{\text{oper}}(G)$, $\gamma_{\text{tp}}(G)$, $\gamma_{\text{cl}}(G)$, $\gamma_{\text{cy}}(G)$, $\gamma_k(G)$, and $\gamma_e(G)$, respectively.

A dominating set D of a graph $G = (V, E)$ corresponds to a *dominating function* which is a function $f : V \rightarrow \{0, 1\}$ such that $\sum_{u \in N[v]} f(u) \geq 1$ for any $v \in V$. The *weight* of f is $w(f) = \sum_{v \in V} f(v)$. Then $\gamma(G)$ is equal to the minimum weight of a dominating function of G . Several variations of domination are defined in terms of functions as follows. A *signed dominating function* is a function $f : V \rightarrow \{+1, -1\}$ such that $\sum_{u \in N[v]} f(u) \geq 1$. The *signed domination number* $\gamma_s(G)$ of G is the minimum weight of a signed dominating function. A *Roman dominating function* is a function $f : V \rightarrow \{0, 1, 2\}$ such that any vertex v with $f(v) = 0$ is adjacent to some vertex u with $f(u) = 2$. The *Roman domination number* $\gamma_{\text{Rom}}(G)$ of G is the minimum weight of a Roman dominating function.

A set-valued variation of domination is as follows. For a fixed positive integer k , a k -*rainbow dominating function* is a function $f : V \rightarrow 2^{\{1, 2, \dots, k\}}$ such that $f(v) = \emptyset$ implies $\cup_{u \in N(v)} f(u) = \{1, 2, \dots, k\}$. The *weight* of f is $w(f) = \sum_{v \in V} |f(v)|$. The k -*rainbow domination number* $\gamma_{\text{krain}}(G)$ of G is the minimum weight of a k -rainbow dominating function. Notice that 1-rainbow domination is the same as the ordinary domination.

A quite different variation motivated from the power system monitoring is as follows. For a positive integer k , suppose D is a vertex subset of a graph $G = (V, E)$. The following two observation rules are applied iteratively:

Fig. 4 A graph G of 13 vertices and 19 edges

- **Observation rule 1 (OR1).** A vertex in D observes itself and all of its neighbors.
- **Observation rule 2 (OR2).** If an observed vertex is adjacent to at most k unobserved vertices, then these vertices become observed as well.

The set D is a k -power dominating set of G if all vertices of the graph are observed after repeatedly applying the above two observation rules. Alternatively, let $\mathcal{S}_0(D) = N[D]$ and

$$\mathcal{S}_{i+1}(D) = \cup\{N[v] : v \in \mathcal{S}_i(D), |N(v) \setminus \mathcal{S}_i(D)| \leq k\}$$

for $i \geq 0$. Notice that $\mathcal{S}_0(D) \subseteq \mathcal{S}_1(D) \subseteq \mathcal{S}_2(D) \subseteq \dots$ and there is a t such that $\mathcal{S}_t(D) = \mathcal{S}_i(D)$ for $i \geq t$. Using this notation, D is a k -power dominating set if and only if $\mathcal{S}_t(D) = V$. The k -power domination number $\gamma_{k\text{pow}}(G)$ of G is the minimum size of a k -power dominating set. For the case of $k = 1$, 1-power domination is called power domination.

Figure 4 shows a graph G of 13 vertices and 19 edges, whose values of $\gamma_\pi(G)$ for variations of domination and the corresponding optimal sets/functions are given below.

$\gamma(G)$	$= 3,$	$D^* = \{v_2, v_8, v_9\};$
$\gamma_i(G)$	$= 3,$	$D^* = \{v_2, v_8, v_9\};$
$\gamma_c(G)$	$= 6,$	$D^* = \{v_2, v_4, v_5, v_7, v_{10}, v_{12}\};$
$\gamma_t(G)$	$= 5,$	$D^* = \{v_2, v_4, v_7, v_{10}, v_{12}\};$
$\gamma_{\text{per}}(G)$	$= 4,$	$D^* = \{v_2, v_3, v_8, v_9\};$
$\gamma_{\text{iper}}(G)$	$= \infty,$	infeasible;
$\gamma_{\text{cp}}(G)$	$= 10,$	$D^* = \{v_1, v_2, v_4, v_5, v_6, v_7, v_9, v_{10}, v_{11}, v_{12}\};$
$\gamma_{\text{tp}}(G)$	$= 6,$	$D^* = \{v_1, v_2, v_4, v_5, v_{12}, v_{13}\};$
$\gamma_{\text{cl}}(G)$	$= \infty,$	infeasible;
$\gamma_{\text{cy}}(G)$	$= 8,$	$D^* = \{v_2, v_4, v_6, v_9, v_{12}, v_{10}, v_7, v_5\};$
$\gamma_2(G)$	$= 2,$	$D^* = \{v_6, v_7\};$
$\gamma_k(G)$	$= 1,$	$D^* = \{v_7\} \text{ for } k \geq 3;$
$\gamma_e(G)$	$= 3,$	$D^* = \{v_2v_4, v_9v_{12}, v_7v_8\};$
$\gamma_s(G)$	$= 5,$	$f^*(v_i) = -1 \text{ for } i = 1, 6, 8, 11 \text{ and } f^*(v_i) = +1 \text{ for other } i;$

$$\begin{aligned}
\gamma_{\text{Rom}}(G) &= 6, & f^*(v_i) &= 2 \text{ for } i = 2, 8, 9 \text{ and } f^*(v_i) = 0 \text{ for other } i; \\
\gamma_{1\text{rain}}(G) &= 3, & f^*(v_i) &= \{1\} \text{ for } i = 2, 8, 9 \text{ and } f^*(v_i) = \emptyset \text{ for other } i; \\
\gamma_{2\text{rain}}(G) &= 6, & f^*(v_i) &= \{1, 2\} \text{ for } i = 2, 8, 9 \text{ and } f^*(v_i) = \emptyset \text{ for other } i; \\
\gamma_{3\text{rain}}(G) &= 8, & f^*(v_i) &= \{1\} \text{ for } i = 3, 6, 8, 13, f^*(v_1) = f^*(v_{10}) = \{2\}, \\
&& f^*(v_5) &= f^*(v_{11}) = \{3\} \text{ and } f^*(v_i) = \emptyset \text{ for other } i; \\
\gamma_{4\text{rain}}(G) &= 10, & f^*(v_i) &= \{1\} \text{ for } i = 3, 6, 8, 13, f^*(v_1) = \{2\}, f^*(v_{10}) = \{2, 4\}, \\
&& f^*(v_5) &= \{3, 4\}, f^*(v_{11}) = \{3\} \text{ and } f^*(v_i) = \emptyset \text{ for other } i; \\
\gamma_{5\text{rain}}(G) &= 12, & f^*(v_i) &= \{1\} \text{ for } i = 3, 6, 8, 13, f^*(v_1) = \{2\}, f^*(v_{10}) = \\
&& &\{2, 4, 5\}, \\
&& f^*(v_5) &= \{3, 4, 5\}, f^*(v_{11}) = \{3\} \text{ and } f^*(v_i) = \emptyset \text{ for other } i; \\
\gamma_{k\text{rain}}(G) &= 13, & f^*(v_i) &= \{1\} \text{ for all } i \text{ for } k \geq 6; \\
\gamma_{k\text{pow}}(G) &= 1, & D^* &= \{v_2\} \text{ for } k \geq 1.
\end{aligned}$$

The (*vertex*-)*weighted* versions of all of the above vertex-subset variations of domination can also be considered. Now, every vertex v has a weight $w(v)$ of real number. The problem is to find a dominating set D in a suitable variation such that

$$w(D) = \sum_{v \in D} w(v)$$

is as small as possible. Denote this minimum value by $\gamma_\pi(G, w)$, where π stands for a variation of the domination problem. When $w(v) = 1$ for all vertices v , the weighted cases become the cardinality cases.

For some variations of domination, the vertex weights may assume to be nonnegative as the following lemma shows.

Lemma 1 Suppose $G = (V, E)$ is a graph in which every vertex is associated with a weight $w(v)$ of real number. If $w'(v) = \max\{w(v), 0\}$ for all vertices $v \in V$, then for any $\pi \in \{\emptyset, c, t, k, k\text{pow}\}$ we have

$$\gamma_\pi(G, w) = \gamma_\pi(G, w') + \sum_{w(v) < 0} w(v).$$

Proof Denote by A the set of all vertices v with $w(v) < 0$. Suppose D is a π -dominating set of G with $\sum_{v \in D} w(v) = \gamma_\pi(G, w)$. Then

$$\begin{aligned}
\gamma_\pi(G, w') &\leq \sum_{v \in D} w'(v) \\
&= \sum_{v \in D} w(v) - \sum_{v \in D \cap A} w(v) \\
&\leq \gamma_\pi(G, w) - \sum_{w(v) < 0} w(v).
\end{aligned}$$

On the other hand, for any π -dominating set D of G with $\sum_{v \in D} w'(v) = \gamma_\pi(G, w')$, $D \cup A$ is also a π -dominating set of G and so

$$\begin{aligned}
\gamma_\pi(G, w) &\leq \sum_{v \in D \cup A} w(v) \\
&= \sum_{v \in D} w'(v) + \sum_{v \in A} w(v) \\
&= \gamma_\pi(G, w') + \sum_{w(v) < 0} w(v).
\end{aligned}$$

The lemma then follows. \square

More generally, one may consider *vertex-edge-weighted* cases of the domination problems as follows. Now, besides the weights of vertices, each edge e has a weight $\bar{w}(e)$. The object is then to find a dominating set D in a suitable variation such that

$$\bar{w}(D) = \sum_{v \in D} w(v) + \sum_{u \in V \setminus D} \bar{w}(uu')$$

is as small as possible, where u' is a vertex in D that is adjacent to u . Note that there are many choices of u' except for the perfect domination and its three variations. Denote this minimum value by $\gamma_\pi(G, w, \bar{w})$, where π stands for a variation of domination. When $\bar{w}(e) = 0$ for all edges e , the vertex-edge-weighted cases become the vertex-weighted cases.

Another parameter related to domination is as follows. The *domatic number* $d(G)$ of a graph G is the maximum number r such that G has r pairwise disjoint dominating sets D_1, D_2, \dots, D_r . One can also define *independent*, *connected*, *total*, *perfect*, *independent perfect*, *connected perfect*, *total perfect*, *clique*, *cycle*, *k -edge*, *k -power domatic numbers* $d_l(G), d_c(G), d_t(G), d_{\text{per}}(G), d_{\text{iper}}(G), d_{\text{cper}}(G), d_{\text{tper}}(G), d_{\text{cl}}(G), d_{\text{cy}}(G), d_k(G), d_e(G)$, and $d_{k^{\text{pow}}}(G)$, respectively, according to above variations of domination in similar ways.

2.3 Special Classes of Graphs

In this subsection, special classes of graphs are introduced. They are not only important in the study of domination but also fundamental in graph theory.

A *complete graph* is a graph whose vertex set is a clique. The complete graph with n vertices is denoted by K_n . The complement \overline{K}_n of the complete graph K_n is then a graph with no edge.

The *n -path*, denoted by P_n , is a graph with n vertices that contains a chordless path of length n . The *n -cycle*, denoted by C_n , is a graph with n vertices that contains a chordless cycle of length n .

An *r -partite graph* is a graph whose vertex set can be partitioned into r stable sets, which are called its *partite sets*. A 2-partite graph is usually called a *bipartite* graph. A *complete r -partite graph* is an r -partite graph in which vertices in different partite sets are adjacent. A complete r -partite graph with partite sets having n_1, n_2, \dots, n_r vertices, respectively, is denoted by K_{n_1, n_2, \dots, n_r} .

A *tree* is a connected graph without any cycle. A *directed tree* is an orientation of a tree. A *rooted tree* is a directed tree in which there is a special vertex r , called the *root*, such that for every vertex v there is a directed $r-v$ path. Trees are probably the simplest structures in graph theory. Problems looking hard in general graphs are often investigated in trees first as a warm up. Domination in trees is introduced in Sect. 3. Many ideas for domination in trees are then generalized to other classes of graphs.

Suppose \mathcal{F} is a family of sets. The *intersection graph* of \mathcal{F} is the graph obtained by representing each set in \mathcal{F} as a vertex and joining two distinct vertices with an edge if their corresponding sets intersect. It is well known that any graph is the intersection graph of some family \mathcal{F} . The problem of characterizing the intersection graphs of families of sets having some specific topological or other pattern is often interesting and frequently has applications in the real world. A typical example is the class of interval graphs. An *interval graph* is the intersection graph of intervals in the real line. They play important roles in many applications. Domination in interval graphs is investigated in Sect. 4.

A graph is *chordal* (or *triangulated*) if every cycle of length greater than three has a chord. The class of chordal graphs is one of the classical classes in the *perfect graph theory*; see the book by Golumbic [101]. It turns out to be also very important in the domination theory. It is well known that a graph is chordal if and only if it is the intersection graph of some subtrees of a certain tree. If these subtrees are paths, this chordal graph is called an *undirected path graph*. If these subtrees are directed paths of a rooted tree, the graph is called a *directed path graph*. If these subtrees are paths in some n -path, the graph is just an interval graph.

Most variations of the domination problem are NP-complete even for chordal graphs; see Sect. 5. As an important subclass of chordal graphs, the class of strongly chordal graphs is a star of the domination theory. Strongly chordal graphs include directed path graphs, which in turn include trees and interval graphs. Domination in strongly chordal graphs is studied in Sect. 6.

A permutation diagram consists of n points on each of two parallel lines and n straight line segments matching the points. The intersection graph of the line segments is called a *permutation graph*. Domination in permutation graphs is introduced in Sect. 7.

A *comparability graph* is a graph $G = (V, E)$ that has a *transitive* orientation $G' = (V, E')$, that is, $uv \in E'$ and $vw \in E'$ imply $uw \in E'$. A *cocomparability graph* is the complement of a comparability graph. Cocomparability graphs are generalizations of permutation graphs and intervals graphs. Domination in cocomparability graphs is investigated in Sect. 8.

A graph is *distance hereditary* if the distance between any two vertices is the same in any connected induced subgraph containing them. Domination in distance-hereditary graphs is studied in Sect. 9.

For more detailed discussions of these classes of graphs, see the remaining sections of this chapter.

3 Trees

3.1 Basic Properties of Trees

Recall that a tree is an acyclic connected graph. The following characterizations are well known; see the textbook by West [193].

Theorem 1 *The following statements are equivalent for any graph $G = (V, E)$:*

- (1) G is a tree.
- (2) G is connected and $|V| = |E| + 1$.
- (3) G is acyclic and $|V| = |E| + 1$.
- (4) For any two vertices u and v , there is a unique u - v path.
- (5) The vertices of G have an ordering $[v_1, v_2, \dots, v_n]$ such that v_i is a leaf of $G_i = G[\{v_i, v_{i+1}, \dots, v_n\}]$ for $1 \leq i \leq n - 1$, or equivalently

for each $1 \leq i \leq n - 1$, v_i is adjacent to exactly one v_j with $j > i$. (TO)

The ordering in [Theorem 1](#) (5) is called a *tree ordering* of the tree, where the only neighbor v_j of v_i with $j > i$ is called the *parent* of v_i and v_i is a *child* of v_j . The tree ordering plays an important role in many algorithms dealing with trees. Many algorithms on trees process from leaves by passing information to their parents iteratively or, equivalently, doing a loop according to a tree ordering. From an algorithmic point of view, the testing of a tree and finding a tree ordering can be done in linear time. [Figure 5](#) shows a tree of 11 vertices and a tree ordering.

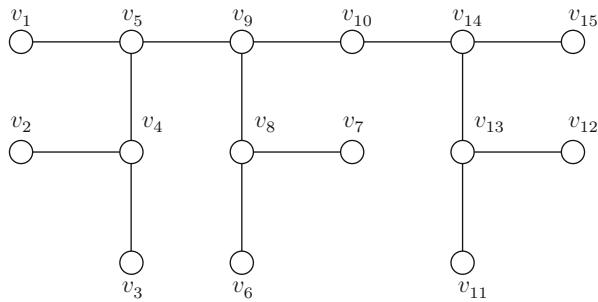

For some algorithms in trees, it is necessary to process simultaneously a group of leaves which is adjacent to a vertex with only one non-leaf neighbor. This corresponds to a tree ordering, which is called a *strong tree ordering*, with the property that all children of a vertex are consecutive in the ordering. The tree order $[v_2, v_3, v_1, v_4, v_6, v_7, v_5, v_8, v_9, v_{11}, v_{12}, v_{10}, v_{13}, v_{14}, v_{15}]$ is strong for the tree in [Fig. 5](#).

3.2 Labeling Algorithm for Trees

Cockayne et al. [56] gave the first linear-time algorithm for the domination problem in trees by a labeling method, which is a naive but useful approach.

The algorithm starts processing a leaf v of a tree T , which is adjacent to a unique vertex u . To dominate v , a minimum dominating set D of T must contain u or v . However, since $N[v] \subseteq N[u]$, it is better to have u in D rather than v in D . So one can keep an information “required” in u and delete v from T . At some iteration, if a “required” leaf v adjacent to u which is not labeled by “required” is processed, it is necessary to put v into D and delete it from T . But now, there is a vertex in D that dominates u , so u is labeled by “free.” For convenience, all vertices are labeled by “bound” initially.

Fig. 5 An example of the tree ordering

More precisely, suppose the vertex set of a graph $G = (V, E)$ is partitioned into three sets F , B , and R , where F consists of *free* vertices, B consists of *bound* vertices, and R consists of *required* vertices. A *mixed dominating set* of G (with respect to F , B , R) is a subset $D \subseteq V$ such that

$$R \subseteq D \text{ and every vertex in } B \setminus D \text{ is adjacent to some vertex in } D.$$

Free vertices need not be dominated by D but may be included in D in order to dominate bound vertices. The *mixed domination number* $\gamma^m(G)$ is the minimum size of a mixed dominating set in G , such a set is called an *md-set* of G . Note that mixed domination is the ordinary domination when $B = V$ and $F = R = \emptyset$.

The construction and correctness of the algorithm is based on the following theorem.

Theorem 2 Suppose T is a tree having free, bound, and required vertices F , B , and R , respectively. Let v be a leaf of T , which is adjacent to u . Then the following statements hold:

- (1) If $v \in F$, then $\gamma^m(T) = \gamma^m(T - v)$.
- (2) If $v \in B$ and T' is the tree which results from T by deleting v and relabeling u as “required,” then $\gamma^m(T) = \gamma^m(T')$.
- (3) If $v \in R$ and $u \in R$, then $\gamma^m(T) = \gamma^m(T - v) + 1$.
- (4) If $v \in R$, $u \notin R$ and T' is the tree which results from T by deleting v and relabeling u as “free”, then $\gamma^m(T) = \gamma^m(T') + 1$.

Proof (1) Since v is free, any md-set D' of $T - v$ is also a mixed dominating set of T . Thus, $\gamma^m(T) \leq |D'| = \gamma^m(T - v)$. On the other hand, suppose D is an md-set of T . If $v \notin D$, then D is also a mixed dominating set of $T - v$. If $v \in D$, then $(D \setminus \{v\}) \cup \{u\}$ is a mixed dominating set of $T - v$, whose size is at most $|D|$. Thus, in either case, $\gamma^m(T - v) \leq |D| = \gamma^m(T)$.

(2) Since u is required in T' , any md-set D' of T' always contains u and hence is also a mixed dominating set of T . Thus, $\gamma^m(T) \leq |D'| = \gamma^m(T')$. On the other hand, suppose D is an md-set of T . Since v is bound in T , either u or v is in D .

- In any case, $D' = (D \setminus \{v\}) \cup \{u\}$ is a mixed dominating set of T' , in which u is considered as a required vertex. So, $\gamma^m(T') \leq |D'| \leq |D| = \gamma^m(T)$.
- (3) If D' is an md-set of T' , then $D' \cup \{v\}$ is a mixed dominating set of T . Thus, $\gamma^m(T) \leq |D' \cup \{v\}| = \gamma^m(T') + 1$. On the other hand, any md-set D of T contains both u and v . Then $D \setminus \{v\}$ is a mixed dominating set of T' . So, $\gamma^m(T') \leq |D \setminus \{v\}| = \gamma^m(T) - 1$.
 - (4) If D' is an md-set of T' , then $D' \cup \{v\}$ is a mixed dominating set of T . Thus, $\gamma(T) \leq |D' \cup \{v\}| = \gamma^m(T') + 1$. On the other hand, any md-set D of T contains v . Since u is free in T' , $D \setminus \{v\}$ is a mixed dominating set in T' . So, $\gamma^m(T') \leq |D \setminus \{v\}| = \gamma^m(T) - 1$. \square

The above theorem then gives the following algorithm for the mixed domination problem in trees.

Algorithm DomTreeL. Find a minimum mixed dominating set of a tree.

Input. A tree T whose vertices are labeled by free, bound, or required. A tree ordering $[v_1, v_2, \dots, v_n]$ of T .

Output. A minimum mixed dominating set D of T .

Method.

```

 $D \leftarrow \phi;$ 
for  $i = 1$  to  $n - 1$  do
    let  $v_j$  be the parent of  $v_i$ ;
    if ( $v_i$  is bound) then
        relabel  $v_j$  as required;
    else if ( $v_i$  is required) then
         $D \leftarrow D \cup \{v_i\}$ ;
        if  $v_j$  is bound then relabel  $v_j$  as free;
        end if;
    end if;
end for;
if  $v_n$  is not free then  $D \leftarrow D \cup \{v_n\}$ .

```

Slater [183] generalized the above idea to solve the k -domination problem in trees. In fact he solved a slightly more general problem called R -domination. Now, each vertex v is associated with an ordered pair $R_v = (a_v, b_v)$, where a_v is a nonnegative integer and b_v a positive integer. The dominating set D is chosen so that each vertex v is within distance a_v from some vertex in D . The integer b_v indicates that there is a vertex in the current D that is at distance b_v from v . More precisely, an R -dominating set of $G = (V, E)$ is a vertex subset D such that for any vertex v in G , either there is some $u \in D$ with $d(u, v) \leq a_v$ or else there is some $u \in V$ with $b_u + d(u, v) \leq a_v$. The R -domination number $\gamma^R(G)$ of G is the minimum size of an R -dominating set. Notice that R -domination with each $R_v = (k, k + 1)$ is the same as the k -domination.

The construction and correctness of Slater's algorithm are based on the following theorem whose proof is omitted here.

Theorem 3 Suppose T is a tree in which each vertex v has a label $R_v = (a_v, b_v)$, where a_v is a nonnegative integer and b_v a positive integer. Let v be a leaf of T , which is adjacent to u . Then the following statements hold:

- (1) If $a_v \geq b_v$ and T' is the tree which results from T by deleting v and resetting b_u by $\min\{b_u, b_v + 1\}$, then $\gamma^R(T) = \gamma^R(T')$.
- (2) If $a_v = 0$ and T' is the tree which results from T by deleting v and resetting b_u by 1, then $\gamma^R(T) = \gamma^R(T') + 1$.
- (3) If $0 < a_v < b_v$ and T' is the tree which results from T by deleting v and resetting a_u by $\min\{a_u, a_v - 1\}$ and b_u by $\min\{b_u, b_v + 1\}$, then $\gamma^R(T) = \gamma^R(T')$.

This then gives the following algorithm for R -domination in trees.

Algorithm RDomTreeL. Find a minimum R -dominating set of a tree.

Input. A tree T with a tree ordering $[v_1, v_2, \dots, v_n]$, in which each vertex v has a label $R_v = (a_v, b_v)$, where $a_v \geq 0$ and $b_v > 0$ are integers.

Output. A minimum R -dominating set D of T .

Method.

```

 $D \leftarrow \phi;$ 
for  $i = 1$  to  $n - 1$  do
    let  $v_j$  be the parent of  $v_i$ ;
    if  $(a_{v_i} \geq b_{v_i})$  then
         $b_{v_j} \leftarrow \min\{b_{v_j}, b_{v_i} + 1\};$ 
    else if  $(a_{v_i} = 0)$  then
         $D \leftarrow D \cup \{v_i\};$ 
         $b_{v_j} \leftarrow 1;$ 
        end if;
    else if  $(0 < a_{v_i} < b_{v_i})$  then
         $a_{v_j} \leftarrow \min\{a_{v_j}, a_{v_i} - 1\};$ 
         $b_{v_j} \leftarrow \min\{b_{v_j}, b_{v_i} + 1\};$ 
        end if;
    end for;
if  $(a_{v_n} < b_{v_n})$  then  $D \leftarrow D \cup \{v_n\}.$ 

```

The labeling algorithm is also used for many variations of domination. For instance, Mitchell and Hedetniemi [162] and Yannakakis and Gavril [196] gave labeling algorithms for the edge domination problem in trees. Laskar et al. [149] gave a labeling algorithm for the total domination problem in trees.

Next, an example of labeling algorithm using strong tree orderings is demonstrated. Chang et al. [47] investigated the k -rainbow domination problem on trees. For technical reasons, they in fact dealt with a more general problem. A k -rainbow assignment is a mapping L that assigns each vertex v a label $L(v) = (a_v, b_v)$ with $a_v, b_v \in \{0, 1, \dots, k\}$. A k - L -rainbow dominating function is a function $f : V(G) \rightarrow 2^{\{1, 2, \dots, k\}}$ such that for every vertex v in G the following conditions hold:

- (L1) $|f(v)| \geq a_v$.
(L2) $|\cup_{u \in N(v)} f(u)| \geq b_v$ whenever $f(v) = \emptyset$.

The k -L-rainbow domination number $\gamma_{k\text{Rain}}(G)$ of G is the minimum weight of a k -L-rainbow dominating function. A k -L-rainbow dominating function f of G is *optimal* if $w(f) = \gamma_{k\text{Rain}}(G)$. Notice that k -rainbow domination is the same as k -L-rainbow domination if $L(v) = (0, k)$ for each $v \in V(G)$.

Theorem 4 Suppose v is a leaf adjacent to u in a graph G with a k -rainbow assignment L . Let $G' = G - v$ and L' be the restriction of L on $V(G')$, except that when $a_v > 0$ we let $b'_u = \max\{0, b_u - a_v\}$. Then the following hold:

- (1) If $a_v > 0$, then $\gamma_{k\text{Rain}}(G) = \gamma_{k\text{Rain}}(G') + a_v$.
- (2) If $a_v = 0$ and $a_u \geq b_v$, then $\gamma_{k\text{Rain}}(G) = \gamma_{k\text{Rain}}(G')$.

Theorem 5 Suppose $N(u) = \{z, v_1, v_2, \dots, v_s\}$ such that v_1, v_2, \dots, v_s are leaves in a graph G with a k -rainbow assignment L . Assume $a_{v_i} = 0$ for $1 \leq i \leq s$ and $b_{v_1} \geq b_{v_2} \geq \dots \geq b_{v_s} > a_u$. Let $b^* = \min\{b_{v_i} + i - 1 : 1 \leq i \leq s + 1\} = b_{v_{i^*}} + i^* - 1$, where $b_{v_{s+1}} = a_u$ and i^* is chosen as small as possible. If $G' = G - \{v_1, v_2, \dots, v_s\}$ and L' is the restriction of L on $V(G')$ with modifications that $a'_u = b_{v_{i^*}}$ and $b'_u = \max\{0, b_u - i^* + 1\}$, then $\gamma_{k\text{Rain}}(G) = \gamma_{k\text{Rain}}(G') + i^* - 1$.

Remark that for the case when the component of G containing u is a star, the vertex z does not exist. There is in fact no vertex v_{s+1} . The assignment of $b_{v_{s+1}} = a_u$ is for the purpose of convenience. In the case of $i^* = s + 1$, it just means that a'_u is the same as a_u .

The theorems above then give the following linear-time algorithm for the k -L-rainbow domination problem in trees.

Algorithm RainbowDomTreeL. Find the k -L-domination number of a tree.

Input. A tree $T = (V, E)$ in which each vertex v is labeled by $L(v) = (a_v, b_v)$.

Output. The minimum k -L-rainbow dominating number r of T .

Method.

```

 $r \leftarrow 0$ ;
get a breadth first search ordering  $x_1, x_2, \dots, x_n$  for the tree  $T$  rooted at  $x_1$ ;
for  $j = 1$  to  $n$  do  $s_j \leftarrow 0$ ; {number of children  $x_i$  with  $a_{x_i} = 0$  and  $b_{x_i} > a_{x_j}\}$ 
for  $j = n$  to  $2$  step by  $-1$  do
     $s \leftarrow s_j$ ;
     $v \leftarrow x_j$ ;
    if  $s > 0$  then {apply Theorem 5}
        let  $u = v$  and  $z, v_1, v_2, \dots, v_s, b^*, i^*$  be as described in Theorem 5;
         $r \leftarrow r + i^* - 1$ ;
         $a_u \leftarrow b_{v_{i^*}}$ ;
         $b_u \leftarrow \max\{0, b_u - i^* + 1\}$ ;
        end if;
    else {apply Theorem 4}
        let  $u = x_{j'}$  be the parent of  $v$ ;
        if  $a_v > 0$  then {  $b_u \leftarrow \max\{0, b_u - a_v\}$ ;  $r \leftarrow r + a_v$  };
    end if;
end if;

```

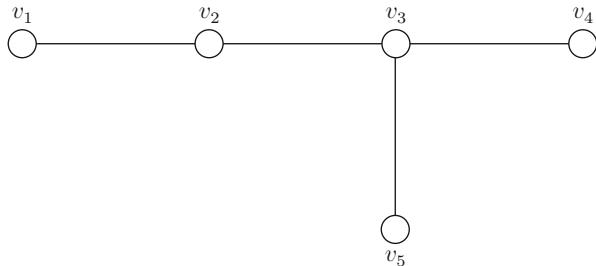

Fig. 6 A tree T with a unique minimum independent dominating set

```

else if  $a_u < b_v$  then  $s_{j'} \leftarrow s_{j'} + 1$ ;
end else;
end do;

```

As these algorithms suggest, the labeling algorithm may only work for problems whose solutions have “local property.” For an example of problem without local property, the independent domination problem in the tree T of Fig. 6 is considered. The only minimum independent dominating set of T is $\{v_1, v_3\}$. If the tree ordering $[v_1, v_2, v_4, v_3, v_5]$ is given, the algorithm must be clever enough to put the leaf v_1 into the solution at the first iteration. If another tree ordering $[v_5, v_4, v_3, v_2, v_1]$ is given, the algorithm must be clever enough not to put the leaf v_5 at the first iteration. So, the algorithm must be one that not only looks at a leaf and its only neighbor but also has some idea about the whole structure of the tree. This is the meaning that the solution does not have a “local property.”

3.3 Dynamic Programming for Trees

Dynamic programming is a powerful method for solving many discrete optimization problems; see the books by Bellman and Dreyfus [14], Dreyfus and Law [85], and Nemhauser [167]. The main idea of the dynamic programming approach for domination is to turn the “bottom-up” labeling method into “top-down.” Now a specific vertex u is chosen from G . A minimum dominating set D of G either contains or does not contain u . So it is useful to consider the following two domination problems which are the ordinary domination problem with boundary conditions:

$$\gamma^1(G, u) = \min\{|D| : D \text{ is a dominating set of } G \text{ and } u \in D\}.$$

$$\gamma^0(G, u) = \min\{|D| : D \text{ is a dominating set of } G \text{ and } u \notin D\}.$$

Lemma 2 $\gamma(G) = \min\{\gamma^1(G, u), \gamma^0(G, u)\}$ for any graph G with a specific vertex u .

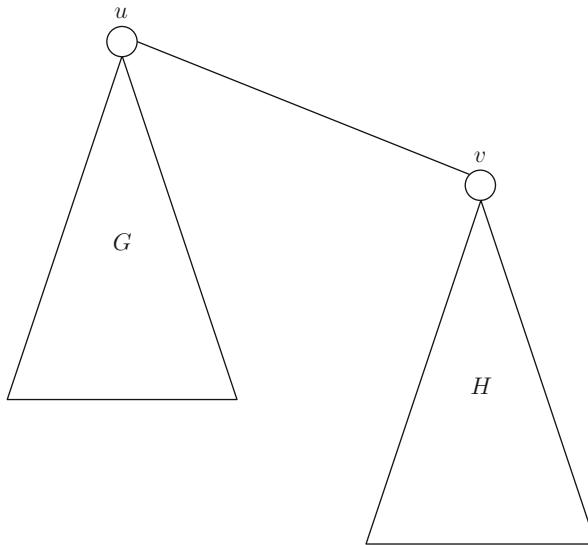

Fig. 7 The composition of two trees G and H

Suppose H is another graph with a specific vertex v . Let I be the graph with the specific vertex u , which is obtained from the disjoint union of G and H by joining a new edge uv ; see Fig. 7.

The aim is to use $\gamma^1(G, u)$, $\gamma^0(G, u)$, $\gamma^1(H, v)$, and $\gamma^0(H, v)$ to find $\gamma^1(I, u)$ and $\gamma^0(I, u)$. Suppose D is a dominating set of I with $u \in D$. Then $D = D' \cup D''$, where D' is a dominating set of G with $v \in D'$ and D'' is a subset of $V(H)$ which dominates $V(H) - \{v\}$. There are two cases. In the case of $v \in D''$, D'' is a dominating set of H . On the other hand, if $v \notin D''$, then D'' is a dominating set of $H - v$. In order to cover the latter case, the following new problem is introduced:

$$\gamma^{00}(G, u) = \min\{|D| : D \text{ is a dominating set of } G - u\}.$$

Note that $\gamma^{00}(G, u) \leq \gamma^0(G, u)$, since a dominating set D of G with $u \notin D$ is also a dominating set of $G - u$.

Theorem 6 Suppose G and H are graphs with specific vertices u and v , respectively. Let I be the graph with the specific vertex u , which is obtained from the disjoint union of G and H by joining a new edge uv . Then the following statements hold:

- (1) $\gamma^1(I, u) = \gamma^1(G, u) + \min\{\gamma^1(H, v), \gamma^{00}(H, v)\}.$
- (2) $\gamma^0(I, u) = \min\{\gamma^0(G, u) + \gamma^0(H, v), \gamma^{00}(G, u) + \gamma^1(H, v)\}.$
- (3) $\gamma^{00}(I, u) = \gamma^{00}(G, u) + \gamma^0(H) = \gamma^{00}(G, u) + \min\{\gamma^1(H, v), \gamma^0(H, v)\}.$

- Proof* (1) This follows from the fact that D is a dominating set of I with $u \in D$ if and only if $D = D' \cup D''$, where D' is a dominating set of G with $u \in D'$ and D'' is a dominating set of H with $v \in D''$ or a dominating set of $H - v$.
- (2) This follows from the fact that D is a dominating set of I with $u \notin D$ if and only if $D = D' \cup D''$, where either D' is a dominating set of G with $u \notin D'$ and D'' is a dominating set of H with $v \notin D''$ or D' is a dominating set of $G - u$ and D'' is a dominating set of H with $v \in D''$.
- (3) This follows from the fact that D is a dominating set of $I - u$ if and only if $D = D' \cup D''$, where D' is a dominating set of $G - u$ and D'' is a dominating set of H . \square

The lemma and the theorem above then give the following dynamic programming algorithm for the domination problem in trees.

Algorithm DomTreeD. Determine the domination number of a tree.

Input. A tree T with a tree ordering $[v_1, v_2, \dots, v_n]$.

Output. The domination number $\gamma(T)$ of T .

Method.

```

for  $i = 1$  to  $n$  do
     $\gamma^1(v_i) \leftarrow 1$ ;
     $\gamma^0(v_i) \leftarrow \infty$ ;
     $\gamma^{00}(v) \leftarrow 0$ ;
end do;
for  $i = 1$  to  $n - 1$  do
    let  $v_j$  be the parent of  $v_i$ ;
     $\gamma^1(v_j) \leftarrow \gamma^1(v_j) + \min\{\gamma^1(v_i), \gamma^{00}(v_i)\}$ ;
     $\gamma^0(v_j) \leftarrow \min\{\gamma^0(v_j) + \gamma^0(v_i), \gamma^{00}(v_j) + \gamma^1(v_i)\}$ ;
     $\gamma^{00}(v_j) \leftarrow \gamma^{00}(v_j) + \min\{\gamma^1(v_i), \gamma^0(v_i)\}$ ;
end do;
 $\gamma(T) \leftarrow \min\{\gamma^1(v_n), \gamma^0(v_n)\}.$ 

```

The advantage of the dynamic programming method is that it also works for problems whose solutions have no local property. As an example, Beyer et al. [21] solved the independent domination problem by this method. Moreover, the method can be used to solve the vertex-edge-weighted cases. The following derivation for the vertex-edge-weighted domination in trees is slightly different from that given by Natarajan and White [166]:

Define $\gamma^1(G, u, w, \bar{w})$, $\gamma^0(G, u, w, \bar{w})$, and $\gamma^{00}(G, u, w, \bar{w})$ in the same way as $\gamma^1(G, u)$, $\gamma^0(G, u)$, and $\gamma^{00}(G, u)$, except that $|D|$ is replaced by $\bar{w}(D)$.

Lemma 3 $\gamma(G, w, \bar{w}) = \min\{\gamma^1(G, u, w, \bar{w}), \gamma^0(G, u, w, \bar{w})\}$ for any graph G with a specific vertex u .

Theorem 7 Suppose G and H are graphs with specific vertices u and v , respectively. Let I be the graph with the specific vertex u , which is obtained from the

disjoint union of G and H by joining a new edge uv . The following statements hold:

- (1) $\gamma^1(I, u, w, \bar{w}) = \gamma^1(G, u, w, \bar{w}) + \min\{\gamma(H, v, w, \bar{w}), \bar{w}(uv) + \gamma^{00}(H, v, w, \bar{w})\}.$
- (2) $\gamma^0(I, u, w, \bar{w}) = \min\{\gamma^0(G, u, w, \bar{w}) + \gamma(H, w, \bar{w}), \gamma^{00}(G, u, w, \bar{w}) + \bar{w}(uv) + \gamma^1(H, v, w, \bar{w})\}.$
- (3) $\gamma^{00}(I, u, w, \bar{w}) = \gamma^{00}(G, u, w, \bar{w}) + \gamma(H, w, \bar{w}).$

The lemma and the theorem above then give the following algorithm for the vertex-edge-weighted domination problem in trees.

Algorithm VEWDomTreeD. Determine the vertex-edge-weighted domination number of a tree.

Input. A tree T with a tree ordering $[v_1, v_2, \dots, v_n]$, and each vertex v has a weight $w(v)$ and each edge e has a weight $\bar{w}(e)$.

Output. The vertex-edge-weighted domination number $\gamma(T, w, \bar{w})$ of T .

Method.

for $i = 1$ **to** n **do**

$\gamma(v_i) \leftarrow \gamma^1(v_i) \leftarrow w(v_i);$
 $\gamma^0(v_i) \leftarrow \infty;$
 $\gamma^{00}(v_i) \leftarrow 0;$

end do;

for $i = 1$ **to** $n - 1$ **do**

let v_j be the parent of v_i ;
 $\gamma^1(v_j) \leftarrow \gamma^1(v_j) + \min\{\gamma(v_i), \bar{w}(uv) + \gamma^{00}(v_i)\};$
 $\gamma^0(v_j) \leftarrow \min\{\gamma^0(v_j) + \gamma(v_i), \gamma^{00}(v_j) + \bar{w}(uv) + \gamma^1(v_i)\};$
 $\gamma^{00}(v_j) \leftarrow \gamma^{00}(v_j) + \gamma(v_i);$
 $\gamma(v_j) \leftarrow \min\{\gamma^1(v_j), \gamma^0(v_j)\};$

end do;

$\gamma(T, w, \bar{w}) \leftarrow \gamma(v_n).$

The dynamic programming method is also used in several papers for solving variations of the domination problems in trees; see [12, 96, 114, 122, 184, 201].

3.4 Primal–Dual Approach for Trees

The most beautiful method used in domination may be the primal–dual approach. In this method, besides the original domination problem, the following dual problem is also considered. In a graph $G = (V, E)$, a 2-stable set is a subset $S \subseteq V$ in which every two distinct vertices u and v have distance $d(u, v) > 2$. The 2-stability number $\alpha_2(G)$ of G is the maximum size of a 2-stable set in G . It is easy to see the following inequality.

Weak Duality Inequality: $\alpha_2(G) \leq \gamma(G)$ for any graph G .

Note that the above inequality can be strict, as shown by the n -cycle C_n that $\alpha_2(C_n) = \lfloor \frac{n}{3} \rfloor$ but $\gamma(C_n) = \lceil \frac{n}{3} \rceil$.

For a tree T , an algorithm which outputs a dominating set D^* and a 2-stable set S^* with $|D^*| \leq |S^*|$ is designed. Then

$$|S^*| \leq \alpha_2(T) \leq \gamma(T) \leq |D^*| \leq |S^*|,$$

which implies that all inequalities are equalities. Consequently, D^* is a minimum dominating set, S^* is a maximum 2-stable, and the *strong duality equality* $\alpha_2(T) = \gamma(T)$ holds.

The algorithm starts from a leaf v adjacent to u . It also uses the idea as in the labeling algorithm that u is more powerful than v since $N[v] \subseteq N[u]$. Instead of choosing v , u is put into D^* . Besides, v is also put into S^* . More precisely, the algorithm is as follows.

Algorithm DomTreePD. Find a minimum dominating set and a maximum 2-stable set of a tree.

Input. A tree T with a tree ordering $[v_1, v_2, \dots, v_n]$.

Output. A minimum dominating set D^* and a maximum 2-stable set S^* of T .

Method.

```

 $D^* \leftarrow \phi;$ 
 $S^* \leftarrow \phi;$ 
for  $i = 1$  to  $n$  do
    let  $v_j$  be the parent of  $v_i$ ;
    (assume  $v_j = v_n$  for  $v_i = v_n$ )
    if  $(N[v_i] \cap D^* = \phi)$  then
         $D^* \leftarrow D^* \cup \{v_j\};$ 
         $S^* \leftarrow S^* \cup \{v_i\};$ 
    end if:
end do.

```

To verify the algorithm, it is sufficient to prove that D^* is a dominating set, S^* is a 2-stable set, and $|D^*| \leq |S^*|$.

D^* is clearly a dominating set as the if-then statement does.

Suppose S^* is not a 2-stable set, that is, there exist v_i and $v_{i'}$ in S^* such that $i < i'$ but $d_T(v_i, v_{i'}) \leq 2$. Let $T_i = T[\{v_i, v_{i+1}, \dots, v_n\}]$. Then T_i contains v_i, v_j , and $v_{i'}$. Since $d(v_i, v_{i'}) \leq 2$, the unique v_i - $v_{i'}$ path in T (and also in T') is either $v_i, v_{i'}$ or $v_i, v_j, v_{i'}$. In any case, $v_j \in N[v_{i'}]$. Thus, at the end of iteration i , D^* contains v_j . When the algorithm processes $v_{i'}$, $N[v_{i'}] \cap D^* \neq \phi$ which causes that S^* does not contain $v_{i'}$, a contradiction.

$|D^*| \leq |S^*|$ follows from that when v_j is added into D^* , which may or may not already be in D^* , a new vertex v_i is always added into S^* .

Theorem 8 *Algorithm DomTreePD gives a minimum dominating set D^* and a maximum 2-stable set S^* of a tree T with $|D^*| = |S^*|$ in linear time.*

Theorem 9 (Strong Duality) $\alpha_2(T) = \gamma(T)$ for any tree T .

The primal–dual approach was in fact used by Farber [90] and Kolen [143] for the weighted domination problem in strongly chordal graphs. It was also used by Cheston et al. [55] for upper fraction domination in trees.

3.5 Power Domination in Trees

Power domination is a most different variation of domination. The observation rules make it so different from the ordinary domination as well as other variations. Haynes et al. [111] gave a linear-time algorithm for the power domination problem in trees. This subsection demonstrates a neat linear-time algorithm offered by Guo et al. [103].

Algorithm PowerDomTree. Find a minimum power dominating set of a tree.

Input. A tree T rooted at vertex r .

Output. A minimum power dominating set D of T .

Method.

sort the non-leaf vertices of T in a list L according to a post-order traversal of T ;

$D \leftarrow \emptyset$;

while $L \neq \{r\}$ **do**

$v \leftarrow$ the first vertex in L ;

$L \leftarrow L \setminus \{v\}$;

if v has at least two unobserved children **then**

$D \leftarrow D \cup \{v\}$;

exhaustively apply the two observation rules to T ;

end if;

end while;

if r is unobserved **then** $D \leftarrow D \cup \{r\}$.

Theorem 10 *Algorithm PowerDomTree gives a minimum power dominating set of a tree in linear time.*

Proof First is to prove that the output D of the algorithm is a power dominating set. The proof is based on an induction on the depth of the vertices u in T , denoted by $\text{depth}(u)$. Note that the proof works top-down, whereas the algorithm works bottom-up. For $\text{depth}(u) = 0$, it is clear that u , which is r , is observed due to the second “if”-condition of the algorithm. Suppose that all vertices u with $\text{depth}(u) < k$ with $k > 0$ are observed. Consider a vertex u with $\text{depth}(u) = k$, which is a child of the vertex v . If $v \in D$, then u is observed; otherwise, due to the induction hypothesis, v is observed. Moreover, if $\text{depth}(v) \geq 1$, then the parent of v is observed as well. Because of the first “if”-condition of the algorithm, v is not in D only if v has at most one unobserved child during the “while”-loop of the algorithm processing v . If vertex u is this only unobserved child, then it gets observed by applying OR2 to v , because v itself and all its neighbors (including the parent of v and its children)

with the only exception of u are observed by the vertices in D . In summary, it is concluded that all vertices in T are observed by D . \square

Next is to prove the optimality of D by showing a more general statement:

Claim Given a tree $T = (V, E)$ rooted at r , Algorithm PowerDomTree outputs a power dominating set D such that $|D \cap V_u| \leq |D' \cap V_u|$ for any minimum power dominating set D' of T and any tree vertex u , where V_u denotes the vertex set of the subtree of T rooted at u .

Proof of the Claim. Let $T_u = (V_u, E_u)$ denote the subtree of T rooted at vertex u . Let ℓ denote the depth of T , that is, $\ell := \max_{v \in V} \text{depth}(v)$. For each vertex $u \in V$, define $d_u := |D \cap V_u|$ and $d'_u := |D' \cap V_u|$. The claim is to be proved by an induction on the depth of tree vertices, starting with the maximum depth ℓ and proceeding to 0.

Since vertices u with $\text{depth}(u) = \ell$ are leaves and the algorithm adds no leaf to D , it is the case that $d_u = 0$ and so $d_u \leq d'_u$ for all u with $\text{depth}(u) = \ell$.

Suppose that $d_u \leq d'_u$ holds for all u with $\text{depth}(u) > k$ with $k < \ell$. Consider a vertex u with $\text{depth}(u) = k$. Let C_u denote the set of children of u . Then, for all $v \in C_u$, by the induction hypothesis, $d_v \leq d'_v$. In order to show $d_u \leq d'_u$, one only has to consider the case that

$$(a) u \in D, \quad (b) u \notin D', \quad \text{and (c)} \sum_{v \in C_u} d_v = \sum_{v \in C_u} d'_v. \quad (1)$$

In all other cases, $d_u \leq d'_u$ always holds. In the following, it will be shown that this case does not apply. Assume that $u \neq r$. The argument works also for $u = r$.

From (c) and that $d_v \leq d'_v$ for all $v \in C_u$ (induction hypothesis), $d_v = d'_v$ for all $v \in C_u$. Moreover, (a) is true only if u has two unobserved children v_1 and v_2 during the “while”-loop of the algorithm processing u (the first “if”-condition). In other words, this means that vertices v_1 and v_2 are not observed by the vertices in $(D \cap V_u) \setminus \{u\}$. In the following, it is shown that u has to be included in D' in order for D' to be a valid power dominating set. To this end, the following statement is needed:

$$\text{For all } x \in D' \cap V_{v_i} \text{ with } 1 \leq i \leq 2 \text{ there is some } x' \in W_{(v_i, x)} \cap D, \quad (2)$$

where $W_{(v_i, x)}$ denotes the path between v_i and x (including v_i and x).

Without loss of generality, consider only $i = 1$. Assume that statement (2) is not true for a vertex $x \in D' \cap V_{v_1}$. Since $x \notin D$, one can infer that $d_x < d'_x$. Since no vertex from $W_{(v_1, x)}$ is in D and, by induction hypothesis, $d_y \leq d'_y$ for all $y \in V_{v_1}$, it follows that $d_{x'} < d'_{x'}$ for all vertices $x' \in W_{(v_1, x)}$, in particular, $d_{v_1} < d'_{v_1}$. This contradicts the fact that $d_{v_i} = d'_{v_i}$ for all children v_i of u . Thus, statement (2) is true.

By statement (Eq. 2), for each vertex $x \in D' \cap V_{v_i}$ ($i \in \{1, 2\}$), there exists a vertex $x' \in D$ on the path $W_{(v_i, x)}$. Thus, if vertex v_i is observed by a vertex $x \in D' \cap V_{v_i}$, then there is a vertex $x' \in D \cap W_{(v_i, x)}$ that observes v_i . However, (a) in (Eq. 1) is true only if v_1 and v_2 are unobserved by the vertices in $D \cap V_{v_1}$ and $D \cap V_{v_2}$. Altogether, this implies that v_1 and v_2 cannot be observed by the vertices in $D' \cap V_{v_1}$ and $D' \cap V_{v_2}$. Since D' is a power dominating set of T , vertex u is taken into D' ; otherwise, u has two unobserved neighbors v_1 and v_2 . OR2 can never be applied to u whatever vertices from $V \setminus V_u$ are in D' . It concludes that the case that $u \in D, u \notin D'$, and $\sum_{v \in C_u} d_v = \sum_{v \in C_u} d'_v$ does not apply. This completes the proof of the claim. \square

Concerning the running time, the following explains how to implement the exhaustive applications of OR1 and OR2. Observe that if OR2 is applicable to a vertex u during the bottom-up process, then all vertices in T_u can be observed at the current stage of the bottom-up process. In particular, after adding vertex u to D , all vertices in T_u can be observed. Thus, exhaustive applications of OR1 and OR2 to the vertices of T_u can be implemented as pruning T_u from T which can be done in constant time. Next, consider the vertices in $V \setminus V_u$. After adding u to D , the only possible application of OR1 is that u observes its parent v . Moreover, the applicability of OR2 to the vertices x lying on the path from u to r is checked, in the order of their appearance, the first v , and the last r . As long as OR2 is applicable to a vertex x on this path, x is deleted from the list L that is defined in the first line of the algorithm and prune T_x from T .

The linear running time of the algorithm is then easy to see: The vertices to which OR2 is applied are removed from the list L immediately after the application of OR2 and are never processed by the instruction in the first line inside the “while”-loop of the algorithm. With proper data structures such as integer counters storing the number of observed neighbors of a vertex, the applications of the observation rules to a single vertex can be done in constant time. Post-order traversal of a rooted tree is clearly doable in linear time. \square

3.6 Tree Related Classes

Besides the methods demonstrated in the previous subsections, the “transformation method” sometimes is also used in the study of domination. Roughly speaking, the method transforms the domination problem in certain graphs to another well-known problem, which is solvable. As this method depends on the variation of domination and the type of graphs, it will be mentioned only when it is used in the problem surveyed in this chapter.

There are some classes of graphs which have treelike structures, including block graphs, (partial) k -trees, and cacti.

A *block graph* is a graph whose blocks are complete graphs. For results on variations of domination in block graphs, see [39, 43, 126, 130, 202].

A *cactus* is a graph whose blocks are cycles. Hedetniemi [118] gave a linear-time algorithm for the domination problem in cacti.

For a positive integer k , k -*trees* are defined recursively as follows: (a) A complete graph of $k + 1$ vertices is a k -tree; (b) the graph obtained from a k -tree by adding a new vertex adjacent to a clique of k vertices is a k -tree. *Partial k-trees* are subgraphs of k -trees. For results on variations of domination in k -trees and partial k -trees, see [3, 66, 95, 172, 180, 189, 190].

4 Interval Graphs

4.1 Interval Orderings of Interval Graphs

Recall that an interval graph is the intersection graph of a family of intervals in the real line.

In many papers, people design algorithms or prove theorems for interval graphs by using the interval models directly. This very often is accomplished by ordering the intervals according to some nondecreasing order of their right (or left) endpoints.

For instance, suppose $G = (V, E)$ is an interval graph with an interval model

$$\{I_i = [a_i, b_i] : 1 \leq i \leq n\},$$

where $b_1 \leq b_2 \leq \dots \leq b_n$. One can solve the domination problem for G by using exactly the same primal–dual algorithm for trees except replacing the 4th line of Algorithm DomTreePD by

let j be the largest index such that $v_j \in N[v_i]$.

In order to prove that the revised algorithm works for interval graphs, it is only necessary to show that S^* is a 2-stable set. Suppose to the contrary that S^* contains two vertices v_i and $v_{i'}$ with $i < i'$ and $d(v_i, v_{i'}) \leq 2$, say there is a vertex $v_k \in N[v_i] \cap N[v_{i'}]$. Consider the largest indexed vertex v_j of $N[v_i]$ as chosen in iteration i of the algorithm. Since $v_k \in N[v_i]$, $k \leq j$. Consider two cases:

Case 1. $j \leq i'$. In this case, $k \leq j \leq i'$. Then $b_k \leq b_j \leq b_{i'}$. Since $v_k \in N[v_{i'}]$, I_k intersects $I_{i'}$ and so $a_{i'} \leq b_k$. Therefore, $a_{i'} \leq b_j \leq b_{i'}$ and so I_j intersects $I_{i'}$.

Case 2. $i' < j$. In this case, $i < i' < j$. Then $b_i \leq b_{i'} \leq b_j$. Since $v_j \in N[v_i]$, I_i intersects I_j and so $a_j \leq b_i$. Therefore, $a_j \leq b_{i'} \leq b_j$ and so I_j intersects $I_{i'}$.

In any case, $v_j \in N[v_{i'}]$. As v_j is put into D^* in iteration i , when the algorithm processes $v_{i'}$, $N[v_{i'}] \cap D^* \neq \emptyset$ so that S^* does not contain $v_{i'}$, a contradiction. Therefore, S^* is a 2-stable set.

As one can see, the arguments in Cases 1 and 2 are quite similar. This is also true in many other proofs for interval graphs. One may expect that a unified property can be applied. This is in fact the so-called interval ordering in the following

theorem (see [175]). Notice that once property (IO) below holds, the conclusion $v_j \in N[v_i]$ above follows immediately.

Theorem 11 $G = (V, E)$ is an interval graph if and only if G has an interval ordering which is an ordering $[v_1, v_2, \dots, v_n]$ of V satisfying

$$i < j < k \text{ and } v_i v_k \in E \text{ imply } v_j v_k \in E. \quad (\text{IO})$$

Proof (\Rightarrow) Suppose G is the intersection graph of

$$\{I_i = [a_i, b_i] : 1 \leq i \leq n\}.$$

Without loss of generality, assume that $b_1 \leq b_2 \leq \dots \leq b_n$. Suppose $i < j < k$ and $v_i v_k \in E$. Then $b_i \leq b_j \leq b_k$. Since $v_i v_k \in E$, it is the case that $I_i \cap I_k \neq \emptyset$ which implies that $a_k \leq b_i$. Thus, $a_k \leq b_j \leq b_k$ and so $I_j \cap I_k \neq \emptyset$, that is, $v_j v_k \in E$.

(\Leftarrow) On the other hand, suppose (IO) holds. For any $v_i \in V$, let i^* be the minimum index such that $v_{i^*} \in N[v_i]$ and let interval $I_i = [i^*, i]$. If $v_i v_k \in E$ with $i < k$, then $k^* \leq i < k$ and so $I_i \cap I_k \neq \emptyset$. If $I_i \cap I_k \neq \emptyset$ with $i < k$, say $j \in I_i \cap I_k$, then $k^* \leq j \leq i < k$. Since $v_{k^*} v_k \in E$, by (IO), $v_i v_k \in E$. Therefore, G is an interval graph with

$$\{I_i = [i^*, i] : 1 \leq i \leq n\}$$

as an interval model. □

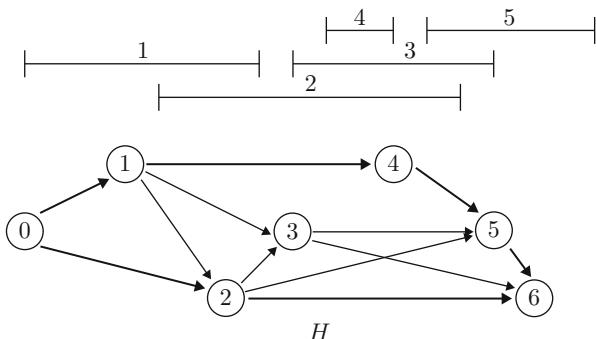

The problem of recognizing interval graphs and giving their interval ordering is a fundamental problem. Several linear-time recognition algorithms for interval graphs have been developed in the literature; see Booth and Leuker [26], Korte and Mohring [144], Hsu and his coauthors [123–125, 181], and Habib et al. [104], among many others. Note that a linear-time algorithm may not be easily implementable, and so there are still some efforts to search for new (simple) interval graph recognition algorithms and new ways to reconstruct an interval representation or just the interval ordering of a given interval graph. The 6-sweep LBFS algorithm by Corneil et al. [70] is a such one. It is believed that a 3-sweep LBFS algorithm is possible.

4.2 Domatic Numbers of Interval Graphs

Another interesting usage of the interval ordering is the following rewriting for the result on the domatic numbers of interval graphs obtained by Bertossi [24]. He transformed the domatic number problem on interval graphs to a network flow problem as follows. This is a typical example of the transformation method.

First, Bertossi's method is described as follows. Suppose $G = (V, E)$ is an interval graph, whose vertex set $V = \{1, 2, \dots, n\}$, with an interval model $\{[a_i, b_i] : 1 \leq i \leq n\}$. Without loss of generality, assume that

Fig. 8 The construction of H for an interval graph of domatic number 2

no two intervals share a common endpoint and $a_1 < a_2 < \dots < a_n$.

Two “dummy” vertices 0 and $n + 1$ are added to the graph with $b_0 < a_1$ and $b_n < a_{n+1}$. Then an acyclic directed network H is constructed as follows. The vertex set of H is $\{0, 1, 2, \dots, n, n + 1\}$, and there is a directed edge (i, j) in H if and only if $j \in P(i) \cup Q(i)$, where

$$P(i) = \{k : a_i < a_k < b_i < b_k\} \text{ and}$$

$$Q(i) = \{k : b_i < a_k \text{ and there is no } h \text{ with } b_i < a_h < b_h < a_k\}.$$

Figure 8 shows an example of H .

Bertossi then proved that any path from vertex 0 to vertex $n + 1$ in H corresponds to a proper dominating set of G and vice versa. His arguments have a flaw. In fact this statement is not true as $0, 2, 3, 5, 6$ is a path in the directed network H in Fig. 8, but its corresponding dominating set $\{2, 3, 5\}$ has a proper subset $\{2\}$ that is also a dominating set. To be precise, he only showed that

- (P1) a 0- $(n + 1)$ path in H corresponds to a dominating set of G , and
- (P2) a proper dominating set of G corresponds to a 0- $(n + 1)$ path in H .

Besides, the entire arguments can be treated in terms of the interval ordering as follows. Now assume that $[0, 1, 2, \dots, n, n + 1]$ is an interval ordering of the graph $G = (V, E)$ with two isolated vertices 0 and $n + 1$ added. Then construct a directed network H' with

vertex set $\{0, 1, 2, \dots, n, n + 1\}$ and

edge set $\{ij : i < j \text{ and } (i < h < j \text{ imply } ih \in E \text{ or } hj \in E)\}$.

Notice that H' is not the same as H . However, statements (P1) and (P2) remain true if H is replaced by H' . Also, there is a simpler proof using property (IO), which is different from their original proof using the endpoints of the intervals. The argument is as follows:

First, a 0- $(n + 1)$ path $P : 0 = i_0, i_1, \dots, i_r, i_{r+1} = n + 1$ in H certainly corresponds to a dominating set $D = \{i_0, i_1, \dots, i_r, i_{r+1}\}$ of G by the definition of the edge set of H' . This proves (P1). Conversely, for a proper dominating set D of G , consider the corresponding path P . For any $0 \leq s \leq r$, suppose $i_s < h < i_{s+1}$. Since D is a dominating set of G , there exists some $i_j \in D$ such that $hi_j \in E$.

Case 1. $j \leq s$. Then $i_s h \in E$ by (IO).

Case 2. $j = s + 1$. Then $hi_{s+1} \in E$.

Case 3. $j > s + 1$. If $N[i_{s+1}] \subseteq N[i_j]$, then $D \setminus \{v_{s+1}\}$ is a dominating set of G , violating that D is a proper dominating set. So, there is some vertex $k \in N[i_{s+1}] \setminus N[i_j]$. The case of $i_{s+1} < i_j < k$ or $h < k < i_j$ implies $k \in N[i_j]$ by (IO), a contraction. The case of $k < h < i_{s+1}$ implies $hi_{s+1} \in E$.

In any case, $i_s i_{s+1}$ is an arc in H . This proves (P2).

Primal–dual approaches were also used in [156, 187] to solve the domatic number problem in interval graphs. Manacher and Mankus [158] made it possible to get an $O(n)$ algorithm for the problem. Peng and Chang [168] used the primal–dual method to get a linear-time algorithm for the problem in strongly chordal graphs; see Sect. 6.3.

4.3 Weighted Independent Domination in Interval Graphs

There are many algorithms for variants of domination in interval graphs; see [16, 19, 48, 50, 53, 174, 175]. Among them, Ramalingam and Pandu Rangan [175] gave a unified approach to the weighted independent domination, the weighted domination, the weighted total domination, and the weighted connected domination problems in interval graphs by using the interval orderings. Their algorithms are demonstrated in this and the following subsections.

Now, suppose $G = (V, E)$ is an interval graph with vertex set $V = \{1, 2, \dots, n\}$, where $[1, 2, \dots, n]$ is an interval ordering of G . Assume that each vertex is associated with a real number as its weight. Notice that except for independent domination, according to Lemma 1, assume that the weights are nonnegative. Consider the following notation:

$V_i = \{1, 2, \dots, i\}$ and G_i denotes the subgraph $G[V_i]$ induced by V_i .

V_0 is the empty set.

$\text{low}(i) = \text{minimum element in } N[i]$.

$\text{maxlow}(i) = \max\{\text{low}(j) : \text{low}(i) \leq j \leq i\}$.

$L_i = \{\text{maxlow}(i), \text{maxlow}(i) + 1, \dots, i\}$.

$M_i = \{j : j > i \text{ and } j \text{ is adjacent to } i\}$.

For any family X of sets of vertices, $\min\{X\}$ denotes a minimum weighted set in X . If X is the empty set, then $\min\{X\}$ denotes a set of infinite weight.

Notice that the vertices in the set $\{1, 2, \dots, \text{low}(i) - 1\}$ are not adjacent to i and the vertices in $\{\text{low}(i), \text{low}(i) + 1, \dots, i\}$ are adjacent to i . The vertices in L_i form a maximal clique in the graph G_i . Let j be the vertex such that $\text{low}(i) \leq j \leq i$ and $\text{maxlow}(i) = \text{low}(j)$. Then, $\text{low}(i) \leq \text{low}(j) \leq j \leq i$. It can easily be seen that $N[j]$ is a subset of $L_i \cup M_i$. Furthermore, in G_i , j is adjacent only to the vertices in L_i .

Having all of these, it is ready to establish the solutions to weighted independent domination problem in interval graphs.

Let ID_i denote an independent dominating set of the graph G_i , and let MID_i denote the minimum weighted ID_i .

Notice that, in G_i , the set L_i is a maximal clique and that there is a vertex in L_i which is not adjacent to any vertex in $V_i \setminus L_i$. Hence, any ID_i contains exactly one vertex j in L_i . Furthermore, it is necessary and sufficient that $ID_i \setminus \{j\}$ dominates $V_{\text{low}(j)-1}$ and contains no vertex adjacent to j . Hence, $ID_i \setminus \{j\}$ is an independent dominating set of $G_{\text{low}(j)-1}$. In other words, a set is an ID_i if and only if it is of the form $ID_{\text{low}(j)-1} \cup \{j\}$ for some j in L_i .

These give the following lemma:

Lemma 4 (a) $MID_0 = \emptyset$. (b) For $1 \leq i \leq n$,

$$MID_i = \min\{MID_{\text{low}(j)-1} \cup \{j\} : j \in L_i\}.$$

A linear-time algorithm for the weighted independent domination problem in interval graphs then follows. The detailed description is omitted as it is easy. Similarly, in the following three subsections, only recursive formulas for variations of domination in interval graphs are presented.

4.4 Weighted Domination in Interval Graphs

Let D_i denote a subset of V that dominates V_i . Unlike independent domination, it is not necessary to restrict D_i as a subset of V_i . Let MD_i denote a minimum weighted D_i .

Since there is a vertex in L_i whose neighbors are all in $L_i \cup M_i$, the set D_i contains some vertex j in $L_i \cup M_i$. It is necessary and sufficient that the remaining set $D_i \setminus \{j\}$ dominates $V_{\text{low}(j)-1}$ since j dominates all vertices in $V_i \setminus V_{\text{low}(j)-1}$ and no vertex in $V_{\text{low}(j)-1}$. (Note that if $j \in L_i \cup M_i$, then $\text{low}(j) \leq i$). In other words, a set is a D_i if and only if it is of the form $D_{\text{low}(j)-1} \cup \{j\}$ for some j in $L_i \cup M_i$.

These give the following lemma:

Lemma 5 (a) $MD_0 = \emptyset$. (b) For $1 \leq i \leq n$,

$$MD_i = \min\{MD_{\text{low}(j)-1} \cup \{j\} : j \in L_i \cup M_i\}.$$

4.5 Weighted Total Domination in Interval Graphs

Let TD_i denote a subset of V that totally dominates V_i and let MTD_i be a minimum weighted TD_i . Let PD_i denote a subset of V that totally dominates $\{i\} \cup V_{\text{low}(i)-1}$, and let MPD_i be a minimum weighted PD_i .

As in domination, TD_i also includes some vertex j in $L_i \cup M_i$. If $j \in L_i$, then it is necessary and sufficient that the set $\text{TD}_i \setminus \{j\}$ totally dominates $V_{\text{low}(j)-1} \cup \{j\}$. If $j \in M_i$, then it is necessary and sufficient that the set $\text{TD}_i \setminus \{j\}$ totally dominates $V_{\text{low}(j)-1}$.

Similarly, any PD_i includes some vertex j adjacent to i . By the definition, $j \geq \text{low}(i)$. Hence, it is necessary and sufficient that the $\text{PD}_i \setminus \{j\}$ totally dominates $V_{\min\{\text{low}(i)-1, \text{low}(j)-1\}}$.

These give the following lemma:

Lemma 6 (a) $\text{MTD}_0 = \emptyset$. (b) For $1 \leq i \leq n$,

$$\text{MTD}_i = \min \left(\{ \text{MPD}_j \cup \{j\} : j \in L_i \} \bigcup \{ \text{MTD}_{\text{low}(j)-1} \cup \{j\} : j \in M_i \} \right).$$

$$\text{MPD}_i = \min \{ \text{MTD}_{\min\{\text{low}(j)-1, \text{low}(i)-1\}} \cup \{j\} : j \in N(i) \}.$$

Note that in the original paper by Ramalingam and Pandu Rangan [175], there is a typo that uses $j \in N[i]$ rather than $j \in N(i)$ in the formula for MPD_i .

4.6 Weighted Connected Domination in Interval Graphs

Let CD_i denote a connected dominating set of G_i that contains the vertex i , and let MCD_i denote a minimum weighted CD_i .

If $\text{low}(i) = 1$, then MCD_i is $\{i\}$ since all vertices have nonnegative weights. If $\text{low}(i) > 1$, then any CD_i contains vertices other than i and hence some vertex adjacent to i in G_i . Let j be the maximum vertex in $\text{CD}_i \setminus \{i\}$. Assume that $\text{low}(j) < \text{low}(i)$. Otherwise j is removed to get a CD_i of the same or lower weight. If $\text{low}(j) < \text{low}(i)$, then any other vertex of G_j adjacent to i is also adjacent to j . Thus, it is necessary and sufficient that $\text{CD}_i \setminus \{i\}$ is a CD_j .

These give the following lemma:

Lemma 7 (a) If $\text{low}(i) = 1$, then $\text{MCD}_i = \{i\}$. (b) For $\text{low}(i) > 1$,

$$\text{MCD}_i = \min \{ \text{MID}_j \cup \{i\} : j \in N[i] \text{ and } j < i \text{ and } \text{low}(j) < \text{low}(i) \}.$$

(c) $\min \{ \text{MCD}_n : i \in L_n \}$ is a minimum weighted connected dominating set of the graph G .

5 Chordal Graphs and NP-Completeness Results

5.1 Perfect Elimination Orderings of Chordal Graphs

It was seen in previous sections that the domination problem is well solved for trees and interval graphs. People then try to generalize the results for general graphs. However, the NP-completeness theory raised by Cook suggests that this is in general quite impossible. Garey and Johnson, in an unpublished paper (see [99]), pointed out that the dominating problem is NP-complete by transforming the vertex cover problem to it.

Vertex Cover

Instance: A graph $G = (V, E)$ and a positive integer $k \leq |V|$.

Question: Is there a subset $C \subseteq V$ of size at most k such that each edge xy of G has either $x \in C$ or $y \in C$?

Their idea can in fact be modified to prove many NP-complete results for the domination problem and its variations in many classes of graphs. Among these classes, the class of chordal graphs is most interesting in the study of many graph optimization problems. Chordal graphs are raised in the theory of perfect graphs; see [101]. It contains trees, interval graphs, directed path graphs, split graphs, undirected path graphs, etc., as subclasses.

Recall that a graph is chordal if every cycle of length at least four has a chord. The following property is an important characterization of chordal graphs. The proof presented here is from Theorem 4.3 in [102], except that the maximum cardinality search is not introduced explicitly.

Theorem 12 *A graph $G = (V, E)$ is chordal if and only if it has a perfect elimination ordering which is an ordering $[v_1, v_2, \dots, v_n]$ of V such that*

$$i < j < k \text{ and } v_i v_j, v_i v_k \in E \text{ imply } v_j v_k \in E. \quad (\text{PEO})$$

Proof (\Rightarrow) For any ordering $\sigma = [v_1, v_2, \dots, v_n]$, define the vector

$$d(\sigma) = (d_n, d_{n-1}, \dots, d_1),$$

where each $d_s = |\{t : t > s \text{ and } v_t \text{ is adjacent to } v_s\}|$. Choose an ordering σ such that $d(\sigma)$ is lexicographically largest.

Suppose $p < q < r$ and $v_r \in N(v_p) \setminus N(v_q)$. Consider the ordering σ' obtained from σ by interchanging v_p and v_q . Then $d'_s = d_s$ for all $s > q$ and

$$|\{t : t > q \text{ and } v_t \in N(v_p)\}| = d'_q \leq d_q = |\{t : t > q \text{ and } v_t \in N(v_q)\}|.$$

However, r is a vertex such that $r > q$ and $v_r \in N(v_p) \setminus N(v_q)$. Then, there exists some $s > q$ such that $v_s \in N(v_q) \setminus N(v_p)$. This gives

$p < q < r, v_r \in N(v_p) \setminus N(v_q)$ imply $v_s \in N(v_q) \setminus N(v_p)$ for some $s > q$. (*)

Next, (*) is used to prove the following claim:

Claim There does not exist any chordless path $P : v_{i_1}, v_{i_2}, \dots, v_{i_x}$ with $x \geq 3$ and $i_y < i_x < i_1$ for $1 < y < x$.

[Notice that the claim implies (PEO) as v_k, v_i, v_j is a chordless path with $i < j < k$ whenever $v_j v_k \notin E$.] Suppose to the contrary that such a path P exists. Choose one with a largest i_x . Since $i_2 < i_x < i_1$ and $v_{i_1} \in N(v_{i_2}) \setminus N(v_{i_x})$, by (*), there exists some $i_{x+1} > i_x$ such that $v_{i_{x+1}} \in N(v_{i_x}) \setminus N(v_{i_2})$. Let z be the minimum index such that $z \geq 2$ and $v_{i_{x+1}} v_z \in E$. Note that z exists and $z \geq 3$. For the case when $v_{i_1} v_{i_{x+1}} \notin E$, $P' : v_{i_1}, v_{i_2}, \dots, v_{i_{z-1}}, v_{i_z}, v_{i_{x+1}}$ (or its inverse) is a chordless path of length at least three with $i_y < i_{x+1} < i_1$ (or $i_y < i_1 < i_{x+1}$) for $1 < y \leq z$. In this case, $i_x < i_{x+1}$ is a contradiction to the choice of P . For the case when $v_{i_1} v_{i_{x+1}} \in E$, P' together with the edge $v_{i_1} v_{i_{x+1}}$ form a chordless cycle of length at least four, a contradiction to the fact that G is chordal.

(\Leftarrow) On the other hand, suppose (PEO) holds. For any cycle of length at least four, choose the vertex of the cycle with the least index. By (PEO), the two neighbors of this vertex in the cycle are adjacent. \square

5.2 NP-Completeness for Domination

This section first demonstrates Garey and Johnson's proof that the domination problem is NP-complete. The proof is adapted for split graphs, which are special chordal graphs. A *split graph* is a graph whose vertex set is the disjoint union of a clique C and a stable set S . Notice that a split graph is chordal as the ordering with the vertices in S first and the vertices in C next gives a perfect elimination ordering.

Theorem 13 *The domination problem is NP-complete for split graphs.*

Proof The proof is given by transforming the vertex cover problem in general graphs to the domination problem in split graphs. Given a graph $G = (V, E)$, construct the graph $G' = (V', E')$ with

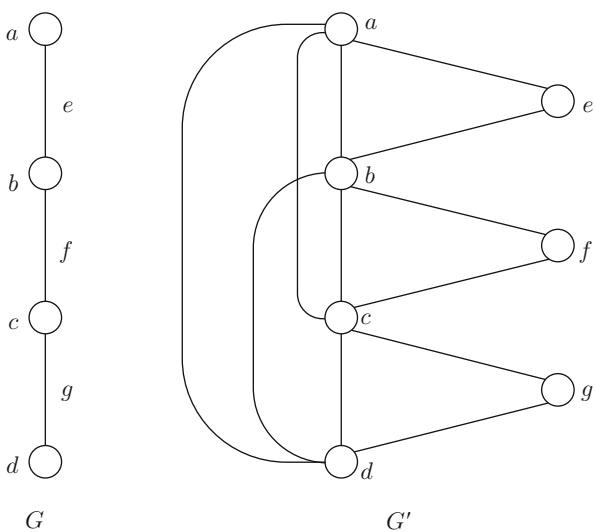

$$\text{vertex set } V' = V \cup E \text{ and}$$

$$\text{edge set } E' = \{v_1 v_2 : v_1 \neq v_2 \text{ in } V\} \cup \{ve : v \in e\}.$$

Notice that G' is a split graph whose vertex set V' is the disjoint union of the clique V and the stable set E (Fig. 9).

If G has a vertex cover C of size at most k , then C is a dominating set of G' of size at most k , by the definition of G' . On the other hand, suppose G' has a dominating set D of size at most k . If D contains any $e \in E$, say $e = uv$, then

Fig. 9 A transformation to a split graph

replace e with u to get a new dominating set of size at most k . In this way, assume that D is a subset of V . It is then clear that D is a vertex cover of G of size at most k .

Since the vertex cover problem is NP-complete, the domination problem is also NP-complete for split graphs. \square

Note that the dominating set of G' in the proof above in fact induces a connected subgraph.

Corollary 1 *The total and the connected domination problems are NP-complete for split graphs.*

In fact, the proof can be modified to get

Theorem 14 *The domination problem is NP-complete for bipartite graphs.*

Proof The vertex cover problem in general graphs is transformed to the domination problem in bipartite graphs as follows. Given a graph $G = (V, E)$, construct the graph $G' = (V', E')$ with

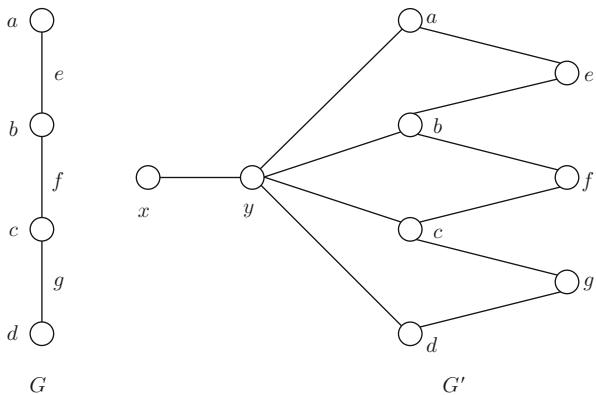

$$\text{vertex set } V' = \{x, y\} \cup V \cup E \text{ and}$$

$$\text{edge set } E' = \{xy\} \cup \{vv : v \in V\} \cup \{ve : v \in e\}.$$

Notice that G' is a bipartite graph whose vertex set V' is the disjoint union of two stable sets $\{x\} \cup V$ and $\{y\} \cup E$ (Fig. 10).

If G has a vertex cover C of size at most k , then $\{y\} \cup C$ is a dominating set of G' of size at most $k + 1$. On the other hand, suppose G' has a dominating set D of

Fig. 10 A transformation to a bipartite graph

size at most $k + 1$. Since $N_{G'}[x] = \{x, y\}$, D must contain x or y . One may assume that D contains y but not x , as $(D \setminus \{x\}) \cup \{y\}$ is also a dominating set of size at most $k + 1$. Since $y \in D$, if D contains any $e \in E$, say $e = uv$, one can replace e with u to get a new dominating set of size at most $k + 1$. In this way, one may assume that $D \setminus \{y\}$ is a subset of V . It is then clear that $D \setminus \{y\}$ is a vertex cover of G of size at most k .

Since the vertex cover problem is NP-complete, the domination problem is NP-complete for bipartite graphs. \square

Corollary 2 *The total and the connected domination problems are NP-complete for bipartite graphs.*

There are many other NP-complete results for variations of domination; see [12, 15, 25, 66, 76, 80, 96, 99, 114, 126, 131, 132, 165, 201, 202]. Most of the proofs are more or less similar to the above two. Only very few are proved by using different methods. As an example, Booth and Johnson [25] proved that the domination problem is NP-complete for undirected path graphs, which is another subclass of chordal graphs, by reducing the three-dimensional matching problem to it.

Theorem 15 *The domination problem is NP-complete for undirected path graphs.*

Proof Consider an instance of the three-dimensional matching problem, in which there are three disjoint sets W , X , and Y each of size q and a subset

$$M = \{m_i = (w_r, x_s, y_t) : w_r \in W, x_s \in X \text{ and } y_t \in Y \text{ for } 1 \leq i \leq p\}$$

of $W \times X \times Y$ having size p . The problem is to find a subset M' of M having size exactly q such that each $w_r \in W$, $x_s \in X$, and $y_t \in Y$ occurs in precisely one triple of M' .

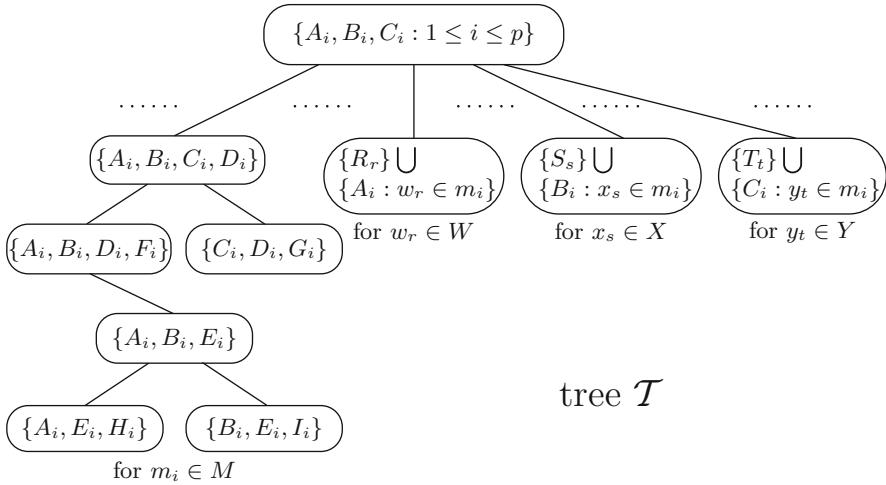

Fig. 11 A transformation to an undirected path graph

Given an instance of the three-dimensional matching problem, construct a tree \mathcal{T} having $6p + 3q + 1$ vertices from which an undirected path graph G is obtained. The vertices of the tree, which are represented by sets, are explained below.

For each triple $m_i \in M$, there are six vertices that depend only upon the triple itself and not upon the elements within the triple:

$$\begin{aligned}
 & \{A_i, B_i, C_i, D_i\} \\
 & \{A_i, B_i, D_i, F_i\} \\
 & \{C_i, D_i, G_i\} \\
 & \{A_i, B_i, E_i\} \\
 & \{A_i, E_i, H_i\} \\
 & \{B_i, E_i, I_i\} \quad \text{for } 1 \leq i \leq p.
 \end{aligned}$$

These six vertices form the subtree of \mathcal{T} corresponding to m_i , which is illustrated in Fig. 11. Next, there is a vertex for each element of W , X , and Y that depends upon the triples of M to which each respective element belongs:

$$\begin{aligned}
 & \{R_r\} \cup \{A_i : w_r \in m_i\} \quad \text{for } w_r \in W, \\
 & \{S_s\} \cup \{B_i : x_s \in m_i\} \quad \text{for } x_s \in X, \\
 & \{T_t\} \cup \{C_i : y_t \in m_i\} \quad \text{for } y_t \in Y.
 \end{aligned}$$

Finally, $\{A_i, B_i, C_i : 1 \leq i \leq p\}$ is the last vertex of \mathcal{T} . The arrangement of these vertices in the tree \mathcal{T} is shown in Fig. 11. This then results in an undirected path graph G with vertex set

$$\{A_i, B_i, C_i, D_i, E_i, F_i, G_i, H_i, I_i : 1 \leq i \leq p\} \cup \{R_j, S_j, T_j : 1 \leq j \leq q\}$$

of size $9p + 3q$, where the undirected path in \mathcal{T} corresponding to a vertex v of G consists of those vertices (sets) containing v in the tree \mathcal{T} .

The theorem then follows from the claim that G has a dominating set of size $2p + q$ if and only if the three-dimensional matching problem has a solution.

Suppose D is a dominating set of G of size $2p + q$. Observe that for any i , the only way to dominate the vertex set $\{A_i, B_i, C_i, D_i, E_i, F_i, G_i, H_i, I_i\}$ corresponding to m_i with two vertices is to choose D_i and E_i and that any larger dominating set might just as well consist of A_i, B_i , and C_i , since none of the other possible vertices dominate any vertex outside of the set. Consequently, D consists of A_i, B_i , and C_i for tm_i 's, and D_i and E_i for $p - t$ other m_i 's, and at least $\max\{3(q - t), 0\}$ R_r, S_s, T_t . Then,

$$2p + q = |D| \geq 3t + 2(p - t) + 3(q - t) = 2p + 3q - 2t$$

and so $t \geq q$. Picking q triples m_i for which A_i, B_i , and C_i are in D form a matching M' of size q .

Conversely, suppose the three-dimensional matching problem has a solution M' of size q . Let

$$D = \{A_i, B_i, C_i : m_i \in M'\} \cup \{D_i, E_i : m_i \in M \setminus M'\}.$$

It is straightforward to check that D is a dominating set of G of size $3q + 2(p - q) = 2p + q$. \square

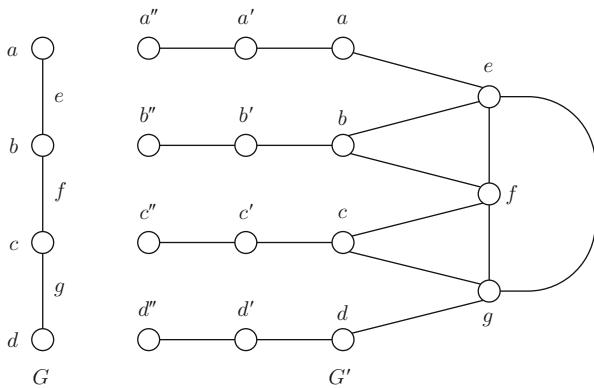

5.3 Independent Domination in Chordal Graphs

Farber [91] showed a surprising result that the independent domination problem is solvable by using a linear programming method. On the other hand, it is known [64] that the weighted independent domination problem is NP-complete. The proof has the same spirit of the proof of Theorem 13.

Theorem 16 *The weighted independent domination problem is NP-complete for chordal graphs.*

Proof The vertex cover problem in general graphs is transformed to the weighted independent domination problem in chordal graphs as follows. Given a graph $G = (V, E)$, construct the following chordal graph $G' = (V', E')$ with

Fig. 12 A transformation to a weighted chordal graph

vertex set $V' = \{v'', v' : v \in V\} \cup E$ and

edge set $E' = \{v''v', v'v : v \in V\} \cup \{ve : v \in e\} \cup \{e_1e_2 : e_1 \neq e_2 \text{ in } E\}$.

The weight of each $e \in E$ is $2|V| + 1$ and the weight of each vertex in V' is 1 (Fig. 12).

If G has a vertex cover C of size at most k , then $\{v'', v : v \in C\} \cup \{v' : v \in V \setminus C\}$ is an independent dominating set of G' with weight at most $|V| + k$. On the other hand, suppose G' has an independent dominating set D of weight at most $|V| + k$. As $k \leq |V|$, D contains no elements in E . Let $C = D \cap V$. It is clear that C is a vertex cover of G . Also, for each $v \in V$, the set D contains exactly one vertex in $\{v'', v'\}$. Thus, C is of size at most k .

Since the vertex cover problem is NP-complete, the weighted independent domination problem is NP-complete for chordal graphs. \square

Farber's algorithm for the independent domination problem in chordal graphs is by means of a linear programming method. Suppose $G = (V, E)$ is a chordal graph with a perfect elimination ordering $[v_1, v_2, \dots, v_n]$ and vertex weights w_1, w_2, \dots, w_n of real numbers. Write

$$i \sim j \text{ for } v_i \in N[v_j],$$

$$i \tilde{\sim} j \text{ for } i \sim j \text{ and } i \leq j,$$

$$i \tilde{\succ} j \text{ for } i \sim j \text{ and } i \geq j.$$

It follows from the definition of a perfect elimination ordering that each

$$C_j = \{v_i : i \tilde{\succ} j\}$$

is a clique. Thus, a set S of vertices is independent if and only if each C_j contains at most one vertex of S . Also, S is a dominating set if and only if for each j , S contains at least one vertex v_i with $i \sim j$. Consider the following linear problem:

$$\begin{aligned}
P_1(G, w) : \text{Minimize } & \sum_{i=1}^n w_i x_i, \\
\text{subject to } & \sum_{i \sim j} x_i \geq 1 \text{ for each } j, \\
& \sum_{i \sim j} x_i \leq 1 \text{ for each } j, \\
& x_i \geq 0 \quad \text{for each } i.
\end{aligned}$$

It follows from the above comments that there is a one-to-one correspondence between independent dominating sets of G and feasible 0–1 solutions to $P_1(G, w)$. Moreover, an optimal 0–1 solution to $P_1(G, w)$ corresponds to a minimum weighted independent dominating set in G . Notice that a set of vertices of G is an independent dominating set in G if and only if it is a maximal independent set in G . Consequently, there exist independent dominating sets, and $P_1(G, w)$ is a feasible linear program. It will follow from the algorithm presented below that if every vertex of G has a weight in $\{1, 0, -1, -2, \dots\}$, then $P_1(G, w)$ has an optimal 0–1 solution and that the following dual program has an integer optimal solution:

$$\begin{aligned}
D_1(G, w) : \text{Maximize } & \sum_{j=1}^n (y_j - z_j), \\
\text{subject to } & \sum_{j \sim i} y_j - \sum_{j \sim i} z_j \leq w_i \text{ for each } i, \\
& y_j, z_j \geq 0 \quad \text{for each } j.
\end{aligned}$$

If, however, not all vertex weights are in $\{1, 0, -1, -2, \dots\}$ (even though they are all integers), then it may be the case that neither $P_1(G, w)$ nor $D_1(G, w)$ has an integer solution. For the remainder of this section, assume that each vertex has a weight in $\{1, 0, -1, -2, \dots\}$.

First define two functions which simplify the presentation of the algorithm. For each i , let

$$\begin{aligned}
f(i) &= w_i + \sum_{j \sim i} z_j - \sum_{j \sim i} y_j, \\
g(i) &= w_i + \sum_{j \sim i} z_j - \sum_{j \sim i} y_j.
\end{aligned}$$

Note that $f(i)$ is the slack in the dual constraint associated with vertex v_i .

The algorithm to locate a minimum weighted dominating set in G has two stages. Stage 1 finds a feasible solution to $D_1(G, w)$ by scanning the vertices in the order v_1, v_2, \dots, v_n ; and stage 2 uses this solution to find a feasible 0–1 solution to $P_1(G, w)$ by scanning the vertices in the order v_n, v_{n-1}, \dots, v_1 . Initially, each $y_j = 0$, each $z_j = 0$, and each $x_i = 2$. (The interpretation of $x_i = 2$ is that x_i has not yet been assigned a value). If, at the time v_j is scanned in stage one, the dual constraint associated with v_j is violated, that is, if $f(j) < 0$, then add just enough to z_j to bring that constraint into feasible. Otherwise, add as much as possible to y_j without violating the dual constraint associated with v_j or with any previously scanned vertex. In stage two, if $x_i = 2$ and $g(i) = 0$ when v_i is scanned, then let $x_i = 1$ and let $x_j = 0$ for each v_j adjacent to v_i .

A formal description of the algorithm is given below.

Algorithm IndDomChordal. Determine $\gamma_i(G, w)$ for a chordal graph G with weights w_1, w_2, \dots, w_n in $\{1, 0, -1, -2, \dots\}$.

Input. A chordal graph G with a perfect elimination ordering $[v_1, v_2, \dots, v_n]$ and vertex weights w_1, w_2, \dots, w_n in $\{1, 0, -1, -2, \dots\}$.

Output. Optimal solutions to $P_1(G, w)$ and $D_1(G, w)$.

Method.

each $y_j \leftarrow 0$, each $z_j \leftarrow 0$ and each $x_i \leftarrow 2$;

Stage 1: **for** $j = 1$ **to** n **do**

if $f(j) < 0$ **then** $z_j \leftarrow -f(j)$
else $y_j \leftarrow \min\{f(k) : k \gtrsim j\}$;

Stage 2: **for** $i = n$ **to** 1 **by** -1 **do**

if $x_i = 2$ and $g(i) = 0$ **then**
 $x_i \leftarrow 1$;
 $x_j \leftarrow 0$ for each $v_j \in N(v_i)$;
end if.

The validity of the algorithm is established below.

Theorem 17 *Algorithm IndDomChordal finds a minimum weighted independent dominating set of a chordal graph with vertex weights in $\{1, 0, -1, -2, \dots\}$.*

Several lemmas are needed. Note that since the weights are integral, all $x_i, y_j, z_j, f(i), g(i)$ are integral at any time.

Lemma 8 *For each j , $f(j) \geq 0$ at all times after scanning v_j in stage 1.*

Proof The fact that $f(j) \geq 0$ immediately after scanning v_j in stage 1 follows from the choice of z_j and y_j . The fact that $f(j) \geq 0$ after scanning each v_k where $k > j$ follows from the choice of y_k . \square

Lemma 9 *At the end of stage one, $y_j \geq 0$ for any j .*

Proof This is an immediate consequence of Lemma 8. \square

Lemma 10 *At the end of stage 1, $0 \leq f(j) \leq g(j)$ for any j .*

Proof This follows from Lemmas 8 and 9. \square

Lemma 11 *At the end of stage 1, for each i , there is a $j \gtrsim i$ such that $g(j) = 0$.*

Proof According to Lemma 10, $g(i) \geq 0$. If $g(i) = 0$, then the lemma is true as j can be chosen to be i . Suppose $g(i) > 0$. Then $f(i)$ was positive immediately after scanning v_i , and so, by the choice of z_i and y_i , $z_i = 0$ and y_i was chosen to force $f(j)$ to be 0 for some $j \gtrsim i$. Thus, there is some $j \gtrsim i$ such that

$$\sum_{k \sim j, k \leq i} y_k - \sum_{k \sim j} z_j = w_j.$$

If $y_k = 0$ for each k such that $k \sim j$ and $k \leq i$, then $g(j) = 0$. Otherwise, choose k such that $y_k > 0$, $k \sim j$, and $k \leq i$. Then $i \sim k$ since $i \sim j$, $k \sim j$, and $[v_1, v_2, \dots, v_n]$ is a perfect elimination ordering. Hence, $k \sim i$ since $i \geq k$ and $i \sim k$. Since all vertex weights are integral, y_k is an integer. Thus, $y_k \geq w_i$, since $w_i \in \{1, 0, -1, -2, \dots\}$. Now, $g(i) > 0$, $y_k \geq w_i$, and $k \sim i$, and hence, there is some $\ell \sim i$ such that $z_\ell > 0$. By the choice of z_ℓ , it is the case that $g(\ell) = 0$. \square

Note that the proof of [Lemma 11](#) relies upon the fact that G has vertex weights in $\{1, 0, -1, -2, \dots\}$ to show that if $y_k > 0$, then $y_k \geq w_i$.

Lemma 12 *At the end of stage 2, for each j , if $g(j) = 0$, then $x_k = 1$ for some $k \sim j$.*

Proof It is clear from the instructions in stage two that, for each i , if $x_i = 1$ at any time during the algorithm, then $x_i = 1$ at the end of the algorithm. Suppose $g(j) = 0$. If x_j was 2 just prior to scanning v_j in stage two, then x_j was assigned the value of 1 when v_j was scanned, and hence, $x_j = 1$ at the end of the algorithm. In this case, choose $k = j$ as desired. Otherwise, x_j was 0 prior to scanning v_j . In that case, $x_j = 0$ by virtue of the fact that $x_k = 1$ for some previously scanned neighbor v_k of v_j , that is, $x_k = 1$ for some $k \sim j$. \square

Proof of Theorem 17. It is easy to see that Algorithm IndDomChordal halts after $O(|V| + |E|)$ operations. Next is to show that the final values of x_1, x_2, \dots, x_n and $y_1, y_2, \dots, y_n, z_1, z_2, \dots, z_n$ are feasible solutions to $P_1(G, w)$ and $D_1(G, w)$, respectively, and then to verify that these solutions satisfy the conditions of complementary slackness. It then follows that they are optimal.

- (i) **Feasibility of dual solution:** Clearly $z_j \geq 0$ for each j . By [Lemmas 8](#) and [9](#), $y_j \geq 0$ and $f(j) \geq 0$ for each j .
- (ii) **Feasibility of primal solution:** The instructions in stage two guarantee that if $x_i = x_j = 1$, then $v_i v_j \notin E$, and if $x_i = 0$, then $x_j = 1$ for some $j \sim i$. Since a 0–1 primal solution is feasible if and only if the set $\{v_j : x_j = 1\}$ is an independent dominating set in G , it suffices to show that each x_i is either 0 or 1. According to [Lemma 11](#), for each i , there is a $j \sim i$ such that $g(j) = 0$. According to [Lemma 12](#), there is a $k \sim j$ such that $x_k = 1$. Since $i \sim j$, $k \sim j$, and $[v_1, v_2, \dots, v_n]$ is a perfect elimination ordering, it follows that $i \sim k$. If $i = k$, then $x_i = 1$; otherwise $x_i = 0$.
- (iii) **Complementary slackness:** If $x_i > 0$, then $g(i) = 0$ by the choice of x_i , and hence, $f(i) = 0$, by [Lemma 10](#). Thus, $\sum_{j \sim i} y_j - \sum_{j \sim i} z_j = w_i$. If $z_j > 0$, then $g(j) = 0$ by the choice of z_j , and so $x_k = 1$ for some $k \sim j$, by [Lemma 12](#). Hence, $\sum_{i \sim j} x_i \geq 1$. Equality follows from the fact that the primal solution is feasible.

Suppose $y_j > 0$ but $x_i = x_k = 1$ for $i \sim j$ and $k \sim j$. Since $x_i = x_k = 1$, $g(i) = g(k) = 0$, and so $j \leq \min\{i, k\}$ by [Lemma 8](#), [Lemma 10](#), and the choice

of y_j . Thus, $i \tilde{>} j$ and $k \tilde{>} j$, which implies $i \sim k$ since $[v_1, v_2, \dots, v_n]$ is a perfect elimination ordering. On the other hand, $v_i v_k \notin E$ since $x_i = x_k = 1$. Consequently $i = k$. Hence, if $y_j > 0$, then $\sum_{i \sim j} x_i \leq 1$. Equality follows from the fact that the primal solution is feasible. \square

6 Strongly Chordal Graphs

6.1 Strong Elimination Orderings of Strongly Chordal Graphs

Strongly chordal graphs were introduced by several people [44, 93, 120] in the study of domination. In particular, most variations of the domination problem are solvable in this class of graphs. There are many equivalent ways to define them. This section adapts the notation from Farber's paper [93].

A graph $G = (V, E)$ is *strongly chordal* if it admits a *strong elimination ordering* which is an ordering $[v_1, v_2, \dots, v_n]$ of V such that the following two conditions hold:

- (a) If $i < j < k$ and $v_i v_j, v_i v_k \in E$, then $v_j v_k \in E$.
- (b) If $i < j < k < \ell$ and $v_i v_k, v_i v_\ell, v_j v_k \in E$, then $v_j v_\ell \in E$.

Notice that an ordering satisfying condition (a) is a perfect elimination ordering. Hence, every strong elimination ordering is a perfect elimination ordering, and every strongly chordal graph is chordal. The notion $i \sim j$ stands for $v_i \in N[v_j]$.

The following equivalent definition of the strong elimination ordering is more convenient in many arguments for strongly chordal graph.

Lemma 13 *An ordering $[v_1, v_2, \dots, v_n]$ of the vertices of G is a strong elimination ordering of G if and only if*

$$i \leq j, k \leq \ell, i \sim k, i \sim \ell \text{ and } j \sim k \text{ imply } j \sim \ell. \quad (\text{SEO})$$

Proof Suppose $[v_1, v_2, \dots, v_n]$ is a strong elimination ordering of G . Suppose that $i \leq j, k \leq \ell, i \sim k, i \sim \ell$, and $j \sim k$. If $i = j$ or $k = \ell$ or $j = \ell$, then clearly $j \sim \ell$. Suppose, on the other hand, that $i < j, k < \ell$, and $j \neq \ell$. By symmetry, assume that $i \leq k$. Now consider three cases:

- Case 1.* Suppose $j = k$. Then $i < j < \ell$ and $v_i v_j, v_i v_\ell \in E$, whence $v_j v_\ell \in E$, by (a) in the definition of a strong elimination ordering.
- Case 2.* Suppose $j < k$. Then $i < j < k < \ell$ and $v_i v_k, v_i v_\ell, v_j v_k \in E$, whence $v_j v_\ell \in E$, by (b) in the definition of a strong elimination ordering.
- Case 3.* Suppose $k < j$. If $i = k$, then $v_k v_\ell \in E$. Otherwise, $i < k < \ell$ and $v_i v_k, v_i v_\ell \in E$, whence $v_k v_\ell \in E$. Consequently, $v_k v_\ell, v_k v_j \in E$ and either $k < \ell < j$ or $k < j < \ell$. In either case, $v_j v_\ell \in E$.

This completes the proof of necessity. The proof of sufficiency is trivial and thus omitted. \square

6.2 Weighted Domination in Strongly Chordal Graphs

There are quite a few algorithms designed for variants of the domination problem in strongly chordal graphs; see [35, 38, 44, 45, 93, 120, 145, 194]. This section presents the linear algorithm, given by Farber [93], for locating a minimum weighted dominating set in a strongly chordal graph.

Let $G = (V, E)$ be a strongly chordal graph with a strong elimination ordering $[v_1, v_2, \dots, v_n]$ and vertex weights w_1, w_2, \dots, w_n . According to Lemma 1, assume that these vertex weights are nonnegative. Consider the following linear problem:

$$\begin{aligned} P_2(G, w) : & \text{Minimize } \sum_{i=1}^n w_i x_i, \\ & \text{subject to } \sum_{j \sim i} x_j \geq 1 \text{ for each } j, \\ & \quad x_i \geq 0 \quad \text{for each } i. \end{aligned}$$

By definition, a set S of vertices of G is a dominating set if and only if, for each j , S contains some vertex v_i such that $i \sim j$. Consequently, there is a one-to-one correspondence between feasible 0–1 solutions to $P_2(G, w)$ and dominating sets in G . Moreover, an optimal 0–1 solution to $P_2(G, w)$ corresponds to a minimum weighted dominating set in G . It follows from the algorithm below that $P_2(G, w)$ has an optimal 0–1 solution and that the following dual program has an optimal solution:

$$\begin{aligned} D_2(G, w) : & \text{Maximize } \sum_{j=1}^n y_j, \\ & \text{subject to } \sum_{j \sim i} y_j \leq w_i \text{ for each } i, \\ & \quad y_j \geq 0 \quad \text{for each } j. \end{aligned}$$

The algorithm presented below solves the linear programs $P_2(G, w)$ and $D_2(G, w)$. To simplify the presentation of the algorithm, define a function h and a family of sets. For each i , let

$$h(i) = w_i - \sum_{j \sim i} y_j \quad \text{and} \quad T_i = \{j : i \sim j \text{ and } y_j > 0\}.$$

Note that $h(i)$ is the slack in the dual constraint associated with vertex v_i , and T_i is the set of constraints in $P_2(G, w)$ containing x_i which must be at equality to satisfy the conditions of complementary slackness.

The algorithm has two stages. Stage 1 finds a feasible solution to $D_2(G, w)$ by scanning the vertices in the order v_1, v_2, \dots, v_n ; and stage 2 uses this solution to find a feasible 0–1 solution to $P_2(G, w)$ by scanning the vertices in the order v_n, v_{n-1}, \dots, v_1 . This algorithm uses a set T to assure that the conditions of complementary slackness are satisfied. Initially, $T = \{1, 2, \dots, n\}$, each $y_j = 0$, and each $x_i = 0$. When v_j is scanned in stage 1, y_j increases as much as possible without violating the dual constraint. In stage 2, if $h(i) = 0$ and $T_i \subseteq T$ when v_i is scanned, then let $x_i = 1$ and replace T by $T \setminus T_i$. Otherwise x_i remains 0. A more formal description of the algorithm follows.

Algorithm WDomSC. Determine $\gamma(G, w)$ for a strongly chordal graph G with nonnegative vertex weights w_1, w_2, \dots, w_n .

Input. A strongly chordal graph G with a strong elimination ordering $[v_1, v_2, \dots, v_n]$ and nonnegative vertex weights w_1, w_2, \dots, w_n .

Output. Optimal solutions to $P_2(G, w)$ and $D_2(G, w)$.

Method.

$T \leftarrow \{1, 2, \dots, n\}$; each $y_j \leftarrow 0$; each $x_i \leftarrow 0$;

Stage 1: **for** $j = 1$ **to** n **do**

$y_j \leftarrow \min\{h(k) : k \sim j\}$;

Stage 2: **for** $i = n$ **to** 1 **by** -1 **do**

if $(h(i) = 0 \text{ and } T_i \subseteq T)$ **then**

$x_i \leftarrow 1$;

$T \leftarrow T \setminus T_i$;

end if.

The algorithm is verified as follows.

Theorem 18 *Algorithm WDomSC finds a minimum weighted dominating set of a strongly chordal graph with nonnegative vertex weights in linear time provided that a strong elimination ordering is given.*

Proof It is easy to see that the algorithm halts after $O(|V| + |E|)$ operations. In order to show that the final values of x_1, x_2, \dots, x_n and $y_1, y_2, \dots, y_n, z_1, z_2, \dots, z_n$ are optimal solutions to $P_2(G, w)$ and $D_2(G, w)$, respectively, it suffices to show that these solutions are feasible and that they satisfy the conditions of complementary slackness.

- (i) **Feasibility of dual solution:** The instructions in stage 1 guarantee that $h(i) \geq 0$ for each i and $y_j \geq 0$ for each j .
- (ii) **Feasibility of primal solution:** Clearly, each x_i is either 0 or 1. Thus, it suffices to show that for each j , $x_i = 1$ for some $i \sim j$. By the choice of y_j , there is a $k \sim j$ such that $h(k) = 0$ and $\max T_k \leq j$. If $x_k = 1$, then the claim holds. Otherwise, by the algorithm, T_k was not contained in T when v_k was scanned in stage 2. Since, in stage 2, the vertices are scanned in the order v_n, v_{n-1}, \dots, v_1 , there is some $\ell > k$ such that $x_\ell = 1$ and $T_\ell \cap T_k \neq \emptyset$. Let $i \in T_\ell \cap T_k$. Then $i \leq j$ since $\max T_k \leq j$. Thus, $i \leq j$, $k < \ell$, $i \sim k$, $i \sim \ell$, and $j \sim k$, whence $\ell \sim j$ by Lemma 13, since $[v_1, v_2, \dots, v_n]$ is a strong elimination ordering. Hence, $\ell \sim j$ and $x_\ell = 1$. Consequently, the primal solution is feasible.
- (iii) **Complementary slackness:** If $x_i > 0$, then $x_1 = 1$ and so $h(i) = 0$, that is, $\sum_{j \sim i} y_j = w_i$.

Suppose $y_j > 0$. It is clear from the instructions that if $x_i = x_k = 1$, then $T_i \cap T_k = \emptyset$. Thus, $\sum_{i \sim j} x_i \leq 1$. Equality follows from the feasibility of the primal solution. \square

Farber in fact also gave an algorithm for the weighted independent domination problem with arbitrary real weights for strongly chordal graphs. The approach is similar to that for chordal graphs (with restricted weights) in Sect. 5.2. The only difference is that the function $g(i)$ is replaced by a set $S_i = \{j : i \sim j \text{ and } y_j > 0\}$ which is similar to T_i in this section. The development is similar to that in Sect. 5.2 and thus omitted.

6.3 Domatic Partition in Strongly Chordal Graphs

Peng and Chang [169] gave an elegant algorithm for the domatic partition problem in strongly chordal graphs.

Their algorithm uses a primal–dual approach. Suppose $[v_1, v_2, \dots, v_n]$ is a strong elimination ordering of $G = (V, E)$ with the minimum degree $\delta(G)$. Choose a vertex x of degree $\delta(G)$. As any dominating set D_i in a domatic partition of G contains at least one vertex v_i in $N[x]$ and two distinct D_i have different corresponding v_i , it is easy to see the following inequality.

Weak Duality Inequality: $d(G) \leq \delta(G) + 1$.

Their algorithm maintains $\delta(G) + 1$ disjoint sets. Initially, these sets are empty. The algorithm scans the vertices in the reverse order of the strong elimination ordering. A vertex is included in a set when it is scanned. When the algorithm terminates, these $\delta(G) + 1$ sets are dominating sets.

A vertex v is *completely dominated* if v is dominated by all of these $\delta(G) + 1$ dominating sets.

Algorithm DomaticSC. Determine a domatic partition of a strongly chordal graph G of size $\delta(G) + 1$.

Input. A strongly chordal graph $G = (V, E)$ with a strong elimination ordering $[v_1, v_2, \dots, v_n]$.

Output. A partition of V into $\delta(G) + 1$ disjoint dominating sets of G .

Method.

$S_i \leftarrow \emptyset$ for $1 \leq i \leq \delta(G) + 1$;

for $i = n$ **to** 1 **step** -1 **do**

find the largest $k \sim i$ such that v_k is not completely dominated;

let S_ℓ be a set that does not dominate v_k ;

$S_\ell \leftarrow \{v_i\} \cup S_\ell$;

if no such set exists then include v_i to an arbitrary S_ℓ ;

end do.

Before proving the correctness of the algorithm, two lemmas are needed.

Lemma 14 Assume $S_\ell \subseteq \{v_{i+1}, v_{i+2}, \dots, v_n\}$ and $k \sim i$, where $1 \leq i \leq n$. If S_ℓ does not dominate v_k , then S_ℓ does not dominate v_j for all $j \leq k$ with $j \sim i$.

Proof Suppose to the contrary that S_ℓ has a vertex v_p dominating v_j , that is, $i < p$ and $p \sim j$. Then $i < p$, $j \leq k$, $i \sim j$, $i \sim k$, and $p \sim j$ imply $p \sim k$ by (SEO), which contradicts that S_ℓ does not dominate v_k . \square

Let $r(v) = |\{x \in N[v] : x \text{ is not in any of the } \delta(G) + 1 \text{ sets}\}|$ and $\text{ndom}(v)$ be the number of sets that do not dominate v during the execution of Algorithm DomaticSC.

Lemma 15 *Algorithm DomaticSC maintains the following invariant:*

$$r(v_j) \geq \text{ndom}(v_j) \text{ for all } j \in \{1, 2, \dots, n\}.$$

Proof The lemma is proved by induction. Initially,

$$r(v_j) = \deg(v_j) + 1 \geq \delta(G) + 1 = \text{ndom}(v_j)$$

for all $v_j \in V$. During iteration i , only values of $r(v_j)$ and $\text{ndom}(v_j)$, where $j \sim i$, may be altered when v_i is included in a set S_ℓ . Notice that the algorithm determines the largest index $k \sim i$ such that v_k is not completely dominated. It then finds a set S_ℓ that does not dominate v_k (S_ℓ is chosen arbitrarily when v_k does not exist).

For any $j \sim i$ with $j \leq k$, by Lemma 14, v_j was not dominated by S_ℓ . Therefore, $r(v_j)$ and $\text{ndom}(v_j)$ are decremented by one after v_i is included in S_ℓ .

On the other hand, for any $j \sim i$ with $j > k$ (or nonexistence of such v_k), by the choice of the vertex v_k in the algorithm, vertex v_j is completely dominated, that is, $\text{ndom}(v_j) = 0$. Thus, the invariant is maintained. \square

Theorem 19 *Algorithm DomaticSC partitions the vertex set of a strongly chordal graph $G = (V, E)$ into $d(G) = \delta(G) + 1$ disjoint dominating sets in linear time provided that a strong elimination ordering is given.*

Proof Upon termination of the algorithm, $r(v_j) = 0$ for all $j \in \{1, 2, \dots, n\}$. According to Lemma 15, $\text{ndom}(v_j) = 0$ for all v_j in V . That is, these $\delta(G) + 1$ sets are dominating sets of G . The strong duality equality

$$d(G) = \delta(G) + 1$$

then follows from the weak duality inequality.

To implement that algorithm efficiently, each vertex v_i is associated with a variable $\text{ndom}(i)$ and an array $L(i)$ of size $\delta(G) + 1$. Initially, $\text{ndom}(i) = \delta(G) + 1$ and the values of entries in L_i are all zero. Thus, for each vertex it takes $O(d_i)$ time to test $\text{ndom}(i)$ to determine v_k , where d_i is the degree of v_i . It then takes

$O(\delta(G) + 1)$ time to decide which set v_i should go. Finally, for each $v_j \in N[v_i]$, it takes $O(1)$ time to update $\text{ndom}(j)$ and L_j . Therefore, the algorithm takes

$$O\left(\sum_{i=1}^n (d_i + \delta(G) + 1)\right) = O(|V| + |E|) \text{ time.} \quad \square$$

7 Permutation Graphs

Given a permutation $\pi = (\pi(1), \pi(2), \dots, \pi(n))$ on the set $I_n = \{1, 2, \dots, n\}$, the *permutation graph* of π is the graph $G(\pi) = (I_n, E(\pi))$ with

$$E(\pi) = \{jk : (j - k)(\pi^{-1}(j) - \pi^{-1}(k)) < 0\}.$$

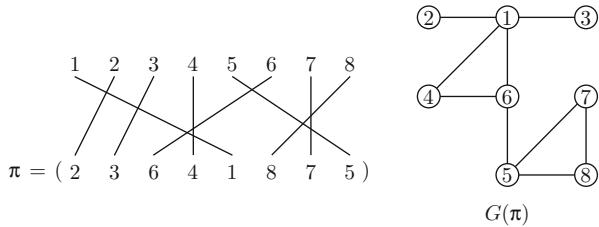

Note that $\pi^{-1}(j)$ is the position of j in the permutation π . [Figure 13](#) illustrates a permutation and its corresponding permutation graph. If a line between each integer i and its position in π is drawn, then n lines are created, each with an associated integer. In this way, two vertices j and k are adjacent in $G(\pi)$ if and only if their corresponding lines cross. That is, $G(\pi)$ is the intersection graph of these n lines. Notice that an independent set in $G(\pi)$ corresponds to an increasing subsequence of π , and a clique in $G(\pi)$ corresponds to a decreasing subsequence of π .

Permutation graphs were first introduced by Pnueli et al. in [87, 171]. Since that time quite a few polynomial-time algorithms have been constructed on permutation graphs. For example, Atallah et al. [8], Brandstädt and Kratsch [31]; Farber and Keil [94]; and Tsai and Hsu [191] have constructed polynomial domination and independent domination algorithms, Brandstädt and Kratsch [31] and Colbourn and Stewart [78] have constructed polynomial connected domination algorithms, and Brandstädt and Kratsch [31] and Corneil and Stewart [78] have constructed polynomial total domination algorithms.

This section presents a simple $O(n^2)$ -time algorithm, due to Brandstädt and Kratsch [32] for finding a minimum weighted independent dominating set in a permutation graph. Assume that the defining permutation π of the permutation graph is given as part of the input. Spinrad [186] has shown that π can be constructed in $O(n^2)$ time, given the graph G .

This algorithm takes advantage of the observation that a set is an independent dominating set if and only if it is a maximal independent set. Since maximal independent sets in permutation graphs correspond to maximal increasing subsequences in π , all that is necessary is to search for such a sequence in π of minimum weight. In particular, it determines, for every j , $1 \leq j < n$, the minimum weight $\gamma_i(j, w)$ of an independent dominating set in the subsequence $\pi(1), \pi(2), \dots, \pi(j)$, which contains $\pi(j)$ as the rightmost element. Let $w(j)$ denote the weight of vertex j .

Fig. 13 A permutation and its corresponding permutation graph

Algorithm WIndDomPer. Solve the weighted independent domination problem for permutation graphs.

Input. A permutation graph G with its corresponding permutation π on the set $\{1, 2, \dots, n\}$ and vertex weights $w(1), w(2), \dots, w(n)$ of real numbers.

Output. The weighted independent domination number $\gamma_i(G, w)$ of G .

Method.

```

for  $j = 1$  to  $n$  do
     $p(j) \leftarrow 0$ ;
     $\gamma_i(j) = w(\pi(j))$ ;
    end do;
for  $k = j - 1$  to  $1$  step  $-1$  do
    if  $(\pi(j) > \pi(k)$  and  $p(j) = 0)$  then
         $\gamma_i(j) \leftarrow w(\pi(j)) + \gamma_i(k)$ ;
         $p(j) \leftarrow \pi(k)$ ;
        end if;
    else if  $(\pi(j) > \pi(k) > p(j) > 0)$  then
         $\gamma_i(j) \leftarrow \min\{\gamma_i(j), w(\pi(j)) + \gamma_i(k)\}$ ;
         $p(j) \leftarrow \pi(k)$ ;
        end if
    end do;
 $m \leftarrow p(n)$ ;
 $\gamma_i(G, w) \leftarrow \gamma_i(n)$ ;
for  $j = n - 1$  to  $1$  step  $-1$  do
    if  $\pi(j) > m$  then
         $\gamma_i(G, w) \leftarrow \min\{\gamma_i(G, w), \gamma_i(j)\}$ ;
         $m \leftarrow \pi(j)$ ;
        end if.

```

The algorithm is illustrated by the permutation graph $G(\pi)$ in Fig. 13, where $\pi = (2 3 6 4 1 8 7 5)$ and all weights are equal to 1: $\gamma_i(j) = (1 2 3 3 1 2 2 2)$, and thus, the minimum size of an independent dominating set is 2, for example, the set $\{1, 5\}$.

8 Cocomparability Graphs

A graph $G = (V, E)$ is a *comparability graph* if G has an orientation $H = (V, F)$ such that $xy, yz \in F$ imply $xz \in F$. In other words, G has a *comparability ordering* which is an ordering $[v_1, v_2, \dots, v_n]$ of V satisfying

$$i < j < k \text{ and } v_i v_j, v_j v_k \in E \text{ imply } v_i v_k \in E. \quad (\text{CO})$$

A graph $G = (V, E)$ is a *cocomparability graph* if its complement \overline{G} is a comparability graph or, equivalently, G has a *cocomparability ordering* which is an ordering $[v_1, v_2, \dots, v_n]$ of V satisfying

$$i < j < k \text{ and } v_i v_k \in E \text{ imply } v_i v_j \in E \text{ or } v_j v_k \in E. \quad (\text{CCO})$$

There is an $O(n^{2.376})$ -time recognition algorithm for comparability graphs and thus for cocomparability graphs [186]. This has been improved by McConnell and Spinrad who gave an $O(n + m)$ -time algorithm constructing an orientation of any given graph G such that the orientation is a transitive orientation of G if and only if G has a transitive orientation [160]. Unfortunately, the best algorithm for testing whether the orientation is indeed transitive has running time $O(n^{2.376})$.

The class of cocomparability graphs is a well-studied superclass of the classes of interval graphs, permutation graphs, and trapezoid graphs. Domination problems on cocomparability graphs were considered for the first time by Kratsch and Stewart [148]. They obtained polynomial-time algorithms for the domination/total domination/connected domination and the weighted independent domination problems in cocomparability graphs. These algorithms are designed by dynamic programming using cocomparability orderings. Breu and Kirkpatrick [34] (see [4]) improved this by giving $O(nm^2)$ -time algorithms for the domination and the total domination problems and an $O(n^{2.376})$ -time algorithm for the weighted independent domination problem in cocomparability graphs.

On the other hand, the weighted domination, weighted total domination, and weighted connected domination problems are NP-complete in cocomparability graphs [49]. Also, the problem “Given a cocomparability graph G , does G have a dominating clique?” is NP-complete [148].

An $O(n^3)$ -time algorithm computing a minimum cardinality connected dominating set of a connected cocomparability graph has been given in [148]. The following is the algorithm for this problem given by Breu and Kirkpatrick [34] (see also [4]).

Let $[v_1, v_2, \dots, v_n]$ be a cocomparability ordering of a cocomparability graph $G = (V, E)$. For vertices $u, w \in V$, write $u < w$ if u appears before w in the ordering, that is, $u = v_i$ and $w = v_j$ implies $i < j$. For $i \leq j$ the set $\{v_k : i \leq k \leq j\}$ is denoted by $[v_i, v_j]$. Then $v_i v_j \in E$ implies that every vertex v_k with $i < k < j$ is adjacent to v_i or to v_j ; thus, $\{v_i, v_j\}$ dominates $[v_i, v_j]$. This can be generalized as follows: Let $S \subseteq V$ where $G[S]$ is connected. Then S dominates

$[\min(S), \max(S)]$ where $\min(S)$ (respectively, $\max(S)$) is the vertex of S with the smallest (respectively, largest) index in the ordering.

The following theorem and lemma are given in [148].

Theorem 20 *Any connected cocomparability graph G has a minimum connected dominating set S such that the induced subgraph $G[S]$ is a chordless path p_1, p_2, \dots, p_k .*

Lemma 16 *Suppose $S \subseteq V$ is a minimum connected dominating set of a cocomparability graph $G = (V, E)$ with a cocomparability ordering $[v_1, v_2, \dots, v_n]$. If $G[S]$ is a chordless path p_1, p_2, \dots, p_k , then every vertex $x < \min(S)$ is dominated by $\{p_1, p_2\}$ and every vertex $y > \max(S)$ is dominated by $\{p_{k-1}, p_k\}$.*

The following approach enables an elegant way of locating a chordless path of minimum size that dominates the cocomparability graph. A *source vertex* is a vertex v_i such that $v_k v_i \in E$ for all $k < i$, and a *sink vertex* is a vertex v_j such that $v_j v_k \in E$ for all $k > j$. Then $[v_1, v_2, \dots, v_n]$ is a *canonical cocomparability ordering* if $[v_1, v_2, \dots, v_r]$, $1 \leq r < n$, are the source vertices and v_s, v_{s+1}, \dots, v_n , $1 < s \leq n$, are the sink vertices. Note that every cocomparability graph G has a canonical cocomparability ordering. Furthermore, given any cocomparability ordering, a canonical one can be computed in time $O(n + m)$.

From now on, assume that $[v_1, v_2, \dots, v_n]$ is a canonical cocomparability ordering. Since the source vertices of G form a clique, any source vertex v_i dominates $[v_1, v_i]$. Analogously, since the sink vertices of G form a clique, any sink vertex v_j dominates $[v_j, v_n]$. Therefore, the vertex set of every path between a source vertex and a sink vertex is dominating.

The following theorem given in [34] enlightens the key property.

Theorem 21 *Every connected cocomparability graph $G = (V, E)$ satisfying $\gamma_c(G) \geq 3$ has a minimum connected dominating set which is the vertex set of a shortest path between a source and a sink vertex of G .*

Proof Let $[v_1, v_2, \dots, v_n]$ be a canonical cocomparability ordering of G . According to **Theorem 20**, there is a minimum connected dominating set S of G such that $G[S]$ is a chordless path $P : p_1, p_2, \dots, p_k$, $k \geq 3$. Construct below a chordless path P'' between a source vertex and a sink vertex of G that has the same number of vertices as the path P .

Let $p_1 = v_i$ and $p_2 = v_j$. First observe that $p_2 = v_j$ cannot be a source vertex, otherwise $N[p_2] \supseteq [v_1, v_j]$ implying that $\{p_2, p_3, \dots, p_k\}$ is also a connected dominating set of G , a contradiction. If p_1 is a source vertex, then P starts at a source vertex. In this case, proceed with the path $P' = P$ (possibly) rearranging p_{k-1}, p_k .

Suppose $p_1 = v_i$ is not a source vertex. Then there is a source vertex u of G with $u p_1 \notin E$. Since $[v_1, v_2, \dots, v_n]$ is a canonical cocomparability ordering and since

p_1 and p_2 are not source vertices, $u < p_1$ and $u < p_2$. Since $v_i v_j \in E$ and by Lemma 16, $\{v_i, v_j\}$ dominates $[1, \max\{v_i, v_j\}]$. Consequently $u p_2 \in E$.

Consider the set $S' = \{u, p_2, \dots, p_k\}$. Since $\{u, p_2\}$ dominates $[v_1, v_j]$, S' is a dominating set. Since $P : p_1, p_2, \dots, p_k$ is a chordless path, $t \geq 3$ implies $p_t u \notin E$. Thus, S' induces the chordless path $P' : u, p_2, \dots, p_k$.

Similarly, starting from P' the vertex p_k can be replaced, if necessary. Vertex p_{k-1} is not a sink vertex. If p_k is a sink vertex, then $S'' = S'$ and $P'' = P'$. Otherwise, replace p_k by a sink vertex v satisfying $v p_k \notin E$ to obtain S'' and P'' .

$G[S'']$ induces a chordless path between a sink and a source vertex. The vertex set of any path between a sink and a source vertex is a dominating set. By construction S'' is a minimum connected dominating set. Consequently S'' is the vertex set of a shortest path between a source vertex and a sink vertex of G . \square

According to Theorem 21, when $\gamma_c(G) \geq 3$, computing a minimum connected dominating set of a connected cocomparability graph G reduces to computing a shortest path between a source and a sink vertex of G .

Algorithm ConDomCC. Solve the connected domination problem in cocomparability graphs.

Input: A connected cocomparability graph $G = (V, E)$ and a canonical cocomparability ordering $[v_1, v_2, \dots, v_n]$ of G .

Output: A minimum connected dominating set of G .

Methods.

1. Check whether G has a minimum connected dominating set D of size at most 2. If so, output D and stop.
2. Construct a new graph G' by adding two new vertices s and t to G such that s is adjacent exactly to the source vertices of G and t is adjacent exactly to the sink vertices of G .
3. Compute a shortest path $P : s, p_1, p_2, \dots, p_k, t$ between s and t in G' by the breadth-first search.
4. Output $\{p_1, p_2, \dots, p_k\}$.

The correctness of Algorithm ConDomCC follows immediately from Theorem 21. The “almost linear” running time of the algorithm follows from the well-known fact that breadth-first search is a linear-time procedure.

Theorem 22 *For any connected cocomparability graph $G = (V, E)$ with a canonical cocomparability ordering $[v_1, v_2, \dots, v_n]$, Algorithm ConDomCC outputs a minimum connected dominating set of G in $O(nm)$ time. In fact, all parts of the algorithm except checking for a connected dominating set of size two can be done in time $O(n + m)$.*

It is clearly unsatisfactory that the straightforward test for a connected dominating set of size two dominates the overall running time. The crux is that there are even permutation graphs for which each minimum connected dominating set of size two contains neither a source nor a sink vertex (see [127, 142]). It seems that minimum

dominating sets of this type cannot be found by a shortest path approach. It is an open question whether step 1 of Algorithm ConDomCC can be implemented in a more efficient way.

Notice that the $O(n)$ -time algorithms computing a minimum connected dominating set for permutation graphs [127] and trapezoid graphs [142] both rely on [Theorem 21](#).

Corneil et al. have done a lot of research on asteroidal triple-free graphs, usually called AT-free graphs [72, 75]. They are defined as those graphs not containing an asteroidal triple, that is, a set of three vertices such that between any two of the vertices, there is a path avoiding the neighborhood of the third.

AT-free graphs form a superclass of the cocomparability graphs. They are a “large class of graphs” with nice structural properties, and some of them are related to domination. One of the major theorems on the structure of AT-free graphs states that every connected AT-free graph has a dominating pair, that is, a pair of vertices u, v such that the vertex set of each path between u and v is a dominating set.

An $O(n + m)$ algorithm computing a dominating pair for a given connected AT-free graph has been presented in [75]. This can be used to obtain an $O(n + m)$ algorithm computing a dominating path for connected AT-free graphs (see also [73]). An $O(n^3)$ algorithm computing a minimum connected dominating set for connected AT-free graphs is given in [10]. An $O(n + m)$ algorithm computing a minimum connected dominating set in connected AT-free graphs with diameter greater than three is given in [75].

9 Distance-Hereditary Graphs

9.1 Hangings of Distance-Hereditary Graphs

A graph is *distance hereditary* if every two vertices have the same distance in every connected induced subgraph. Distance-hereditary graphs were introduced by Howorka [121]. The characterization and recognition of distance-hereditary graphs have been studied in [11, 81, 82, 105, 121]. Distance-hereditary graphs are parity graphs [36] and include all cographs [68, 77].

The *hanging* h_u of a connected graph $G = (V, E)$ at a vertex $u \in V$ is the collection of sets $L_0(u), L_1(u), \dots, L_t(u)$ (or L_0, L_1, \dots, L_t if there is no ambiguity), where $t = \max_{v \in V} d_G(u, v)$ and

$$L_i(u) = \{v \in V : d_G(u, v) = i\}$$

for $0 \leq i \leq t$. For any $1 \leq i \leq t$ and any vertex $v \in L_i$, let $N'(v) = N(v) \cap L_{i-1}$. A vertex $v \in L_i$ with $1 \leq i \leq t$ is said to have a *minimal neighborhood* in L_{i-1} if $N'(x)$ is not a proper subset of $N'(v)$ for any $x \in L_i$. Such a vertex v certainly exists.

Theorem 23 ([11, 81, 82]) A connected graph $G = (V, E)$ is distance hereditary if and only if for every hanging $h_u = (L_0, L_1, \dots, L_t)$ of G and every pair of vertices $x, y \in L_i$ ($1 \leq i \leq t$) that are in the same component of $G - L_{i-1}$, we have $N'(x) = N'(y)$.

Theorem 24 ([11]) Suppose $h_u = (L_0, L_1, \dots, L_t)$ is a hanging of a connected distance-hereditary graph at u . For any two vertices $x, y \in L_i$ with $i \geq 1$, $N'(x) \cap N'(y) = \emptyset$ or $N'(x) \subseteq N'(y)$ or $N'(x) \supseteq N'(y)$.

Theorem 25 (Fact 3.4 in [105]) Suppose $h_u = (L_0, L_1, \dots, L_t)$ is a hanging of a connected distance-hereditary graph at u . If vertex $v \in L_i$ with $1 \leq i \leq t$ has a minimal neighborhood in L_{i-1} , then $N_{V \setminus N'(v)}(x) = N_{V \setminus N'(v)}(y)$ for every pair of vertices x and y in $N'(v)$.

9.2 Weighted Connected Domination

D'Atri and Moscarini [81] gave $O(|V||E|)$ algorithms for connected domination and Steiner tree problems in distance-hereditary graphs. Brandstädt and Dragan [29] presented a linear-time algorithm for the connected r -domination and Steiner tree problems in distance-hereditary graphs.

This section presents a linear-time algorithm given by Yeh and Chang [200] for finding a minimum weighted connected dominating set of a connected distance-hereditary graph $G = (V, E)$ in which each vertex v has a weight $w(v)$ that is a real number. According to Lemma 1, assume that the vertex weights are nonnegative.

Lemma 17 Suppose $h_u = \{L_0, L_1, \dots, L_t\}$ is a hanging of a connected distance-hereditary graph at u . For any connected dominating set D and $v \in L_i$ with $2 \leq i \leq t$, $D \cap N'(v) \neq \emptyset$.

Proof Choose a vertex y in D that dominates v . Then $y \in L_{i-1} \cup L_i \cup L_{i+1}$. If $y \in L_{i-1}$, then $y \in D \cap N'(v)$. So, assume that $y \in L_i \cup L_{i+1}$. Choose a vertex $x \in D \cap (L_0 \cup L_1)$ and an x - y path

$$P : x = v_1, v_2, \dots, v_m = y$$

using vertices only in D . Let j be the smallest index such that $\{v_j, v_{j+1}, \dots, v_m\} \subseteq L_i \cup L_{i+1} \cup \dots \cup L_t$. Then $v_j \in L_i$, $v_{j-1} \in N'(v_j)$, and v and v_j are in the same component of $G - L_{i-1}$. By Theorem 23, $N'(v) = N'(v_j)$ and so $v_{j-1} \in D \cap N'(v)$. In any case, $D \cap N'(v) \neq \emptyset$. \square

Theorem 26 Suppose $G = (V, E)$ is a connected distance-hereditary graph with a nonnegative weight function w on its vertices. Let $h_u = \{L_0, L_1, \dots, L_t\}$ be a hanging at a vertex u of minimum weight. Consider the set $\mathcal{A} = \{N'(v) : v \in L_i \text{ with } 2 \leq i \leq t \text{ and } v \text{ has a minimal neighborhood in } L_{i-1}\}$. For each $N'(v)$ in \mathcal{A} ,

choose one vertex v^* in $N'(v)$ of minimum weight, and let D be the set of all such v^* . Then D or $D \cup \{u\}$ or some $\{v\}$ with $v \in V$ is a minimum weighted connected dominating set of G .

Proof For any $x \in L_i$ with $2 \leq i \leq t$, by [Theorem 24](#), $N'(x)$ includes some $N'(v)$ in \mathcal{A} . This gives [Claim 1](#).

Claim 1 For any $x \in L_i$ with $2 \leq i \leq t$, $x \in N[L_{i-1} \cap D]$.

Claim 2 $D \cup \{u\}$ is a connected dominating set of G .

Proof of Claim 2. By [Claim 1](#) and $N[u] = L_1 \cup \{u\}$, $D \cup \{u\}$ is a dominating set of G . Also, by [Claim 1](#), for any vertex x in $D \cup \{u\}$, there exists an x - u path using vertices only in $D \cup \{u\}$, that is, $G[D \cup \{u\}]$ is connected. \square

Suppose M is a minimum weighted connected dominating set of G . According to [Lemma 17](#), $M \cap N'(v) \neq \emptyset$ for each $N'(v) \in \mathcal{A}$, say $v^{**} \in M \cap N'(v)$. Since any two sets in \mathcal{A} are disjoint, $|M| \geq |\mathcal{A}| = |D|$.

Case 1. $|M| = 1$. The theorem is obvious in this case.

Case 2. $|M| > |D|$. In this case, there is at least one vertex x in M that is not a v^{**} . Then

$$w(M) \geq \sum_{v^{**}} w(v^{**}) + w(x) \geq \sum_{v^*} w(v^*) + w(u) = w(D \cup \{u\}).$$

This together with [Claim 2](#) gives that $D \cup \{u\}$ is a minimum weighted connected dominating set of G .

Case 3. $|M| = |D| \geq 2$. Since \mathcal{A} contains pairwise disjoint sets, $M = \{v^{**} : N'(v) \in \mathcal{A}\}$. Then $w(M) = \sum_{v^{**}} w(v^{**}) \geq \sum_{v^*} w(v^*) = w(D)$.

For any two vertices x^* and y^* in D , x^{**} and y^{**} are in M . Since $G[M]$ is connected, there is an x^{**} - y^{**} path in $G[M]$:

$$x^{**} = v_0^{**}, v_1^{**}, \dots, v_n^{**} = y^{**}.$$

For any $1 \leq i \leq n$, since v_i^* and v_i^{**} are both in $N'(v_i) \in \mathcal{A}$, by [Theorem 25](#), $N_{V \setminus N'(v_i)}(v_i^*) = N_{V \setminus N'(v_i)}(v_i^{**})$. But $v_{i-1}^{**} \in N_{V \setminus N'(v_i)}(v_i^{**})$. Therefore, $v_{i-1}^{**} \in N_{V \setminus N'(v_i)}(v_i^*)$ and $v_i^* \in N_{V \setminus N'(v_{i-1})}(v_{i-1}^{**})$. Also, that v_{i-1}^* and v_{i-1}^{**} are both in $N'(v_{i-1}) \in \mathcal{A}$ implies that $N_{V \setminus N'(v_{i-1})}(v_{i-1}^*) = N_{V \setminus N'(v_{i-1})}(v_{i-1}^{**})$. Then $v_i^* \in N_{V \setminus N'(v_{i-1})}(v_{i-1}^*)$. This proves that v_{i-1}^* is adjacent to v_i^* for $1 \leq i \leq n$, and then

$$x^* = v_0^*, v_1^*, \dots, v_n^* = y^*$$

is an x^* - y^* path in $G[D]$, that is, $G[D]$ is connected.

For any x in V , since M is a dominating set, $x \in N[v^{**}]$ for some $N'(v) \in \mathcal{A}$. Note that v^{**} and v^* are both in $N'(v)$. According to [Theorem 25](#), $N_{V \setminus N'(v)}(v^{**}) = N_{V \setminus N'(v)}(v^*)$. In the case of $x \notin N'(v)$, $x \in N[v^{**}]$ implies $x \in N[v^*]$, that is, D

dominates x . In the case of $x \in N'(v)$, $N_{V \setminus N'(v)}(v^*) = N_{V \setminus N'(v)}(x)$. Since $G[D]$ is connected and $|D| \geq 2$, v^* is adjacent to some $y^* \in D \setminus N'(v)$. Then x is also adjacent to y^* , that is, D dominates x . In any case, D is a dominating set. Therefore, D is a minimum weighted connected dominating set of G . \square

Lemma 1 and **Theorem 26** together give an efficient algorithm for the weighted connected domination problem in distance-hereditary graphs as follows. To implement the algorithm efficiently, the set \mathcal{A} is not actually found. Instead, the following step is performed for each $2 \leq i \leq t$. Sort the vertices in L_i such that

$$|N'(x_1)| \leq |N'(x_2)| \leq \dots \leq |N'(x_j)|.$$

Then process $N'(x_k)$ for k from 1 to j . At iteration k , if $N'(x_k) \cap D = \emptyset$, then $N'(x_k)$ is in \mathcal{A} , and choose a vertex of minimum weight to put it into D ; otherwise, $N'(x_k) \notin \mathcal{A}$ and do nothing.

Algorithm WConDomDH. Find a minimum weighted connected dominating set of a connected distance-hereditary graph.

Input: A connected distance-hereditary graph $G = (V, E)$ and a weight $w(v)$ of real number for each $v \in V$.

Output: A minimum weighted connected dominating set D of graph G .

Method.

```

 $D \leftarrow \emptyset;$ 
let  $V' = \{v \in V : w(v) < 0\}$ ;
 $w(v) \leftarrow 0$  for each  $v \in V'$ ;
let  $u$  be a vertex of minimum weight in  $V$ ;
determine the hanging  $h_u = (L_0, L_1, \dots, L_t)$  of  $G$  at  $u$ ;
for  $i = 2$  to  $t$  do
    let  $L_i = \{x_1, x_2, \dots, x_j\}$ ;
    sort  $L_i$  such that  $|N'(x_{i_1})| \leq |N'(x_{i_2})| \leq \dots \leq |N'(x_{i_j})|$ ;
    for  $k = 1$  to  $j$  do
        if  $N'(x_{i_k}) \cap D = \emptyset$  then  $D \leftarrow D \cup \{y\}$  where  $y$  is a vertex
            of minimum weight in  $N'(x_{i_k})$ ;
    end do;
if not  $(L_1 \subseteq N[D]$  and  $G[D]$  is connected) then  $D \leftarrow D \cup \{u\}$ ;
for  $v \in V$  that dominates  $V$  do
    if  $w(v) < w(D)$  then  $D \leftarrow \{v\}$ ;
 $D \leftarrow D \cup V'$ .

```

Theorem 27 Algorithm WConDomDH gives a minimum weighted connected dominating set of a connected distance-hereditary graph in linear time.

Proof The correctness of the algorithm follows from **Lemma 1** and **Theorem 26**. For each i , sort L_i by using a bucket sort. Then the algorithm runs in $O(|V| + |E|)$ time. \square

Abstract

Combinatorial matrices are matrices that satisfy certain combinatorial properties and typically give rise to extremely challenging search problems with thousands of variables. In this chapter we present a survey of some recent algorithms to search for some kinds of combinatorial matrices, with an emphasis to algorithms within the realm of optimization and metaheuristics. It is to be noted that for most kinds of combinatorial matrices there are several known infinite classes

I.S. Kotsireas

Department of Physics and Computer Science, Wilfrid Laurier University, Waterloo, ON, Canada

in the literature, but these infinite classes do not suffice to cover the entire spectra of possible orders of these matrices, therefore it is necessary to resort to computational and meta-heuristic algorithms.

1 Introduction

The search for combinatorial matrices and their associated designs has been a fertile testing ground for algorithm designers for decades. These extremely challenging combinatorial problems have been tackled with algorithms using concepts and techniques from discrete mathematics, number theory, linear algebra, group theory, optimization, and metaheuristics. This chapter will survey some recent algorithms to search for combinatorial matrices, with an emphasis to algorithms within the realm of optimization and metaheuristics. The hope is that this chapter will arouse the interest of algorithm designers from various areas in order to invent new formalisms and new algorithms to search efficiently for combinatorial matrices. There are several open problems in the broad area of combinatorial matrices, and it is clear that new ideas are required to solve them. The existing algorithms continue to yield new results, especially in conjunction with the use of parallel programming techniques, but will still eventually reach a point of saturation, beyond which they will probably not be of much use. Therefore, cross-fertilization of research areas is necessary for producing new results in the search for new combinatorial matrices, at both the theoretical and the practical level.

Combinatorial matrices are defined as matrices that possess some combinatorial properties, such as prescribed row/column sums and special structure described in terms of circulant matrices. The research area of combinatorial matrices has been developed in a systematic manner over the last 50 years in the four books [10, 11, 48, 88]. It is worthwhile to point out that the unifying concept of combinatorial matrices includes well-known and widely studied categories of matrices, such as adjacency and incidence matrices of graphs, Hadamard matrices, and doubly stochastic matrices.

In addition, there is a number of more recent books that contain useful information and new developments in the area of combinatorial matrices and the closely related area of design theory. The book [52] (see also the update [53]) sheds considerable light in the cocyclic (i.e., group cohomological) aspects of certain kinds of combinatorial matrices and is the only systematic book-size treatment of this topic. The book [94] features a very readable exposition of design theory with emphasis on bent functions and coding theory aspects. The book [19] offers an alternative algebraic foundation of design theory. The book [54] places its emphasis on symmetric designs and their properties.

2 Preliminaries and Notations

A wide class of combinatorial matrices (or the relevant sequences) can be defined via the concepts of the periodic and aperiodic (or nonperiodic) autocorrelation functions associated to a finite sequence. These two concepts have been invented

and studied widely within the engineering community, and their importance has been recognized in the combinatorics community as well, especially in connection with several kinds of combinatorial matrices.

All sequences in this chapter will be finite and will have elements either from $\{-1, +1\}$ (binary sequences) or from $\{-1, 0, +1\}$ (ternary sequences).

Definition 1 The periodic autocorrelation function associated to a finite sequence $A = [a_1, \dots, a_n]$ of length n is defined as

$$P_A(i) = \sum_{k=1}^n a_k a_{k+i}, \quad i = 0, \dots, n-1,$$

where $k + i$ is taken modulo n , when $k + i > n$.

Definition 2 The aperiodic (or nonperiodic) autocorrelation function of a sequence $[a_1, \dots, a_n]$ of length n is defined as

$$N_A(i) = \sum_{k=1}^{n-i} a_k a_{k+i}, \quad i = 0, \dots, n-1,$$

where $k + i$ is taken modulo n , when $k + i > n$.

[Definitions 1](#) and [2](#) are best clarified with an example.

Example 1 For a finite sequence of length $n = 7$, $A = [a_1, \dots, a_7]$, we have

$$\begin{aligned} P_A(0) &= a_1^2 + a_2^2 + a_3^2 + a_4^2 + a_5^2 + a_6^2 + a_7^2 \\ P_A(1) &= a_1 a_2 + a_2 a_3 + a_3 a_4 + a_4 a_5 + a_5 a_6 + a_6 a_7 + a_7 a_1 \\ P_A(2) &= a_1 a_3 + a_2 a_4 + a_3 a_5 + a_4 a_6 + a_5 a_7 + a_6 a_1 + a_7 a_2 \\ P_A(3) &= a_1 a_4 + a_2 a_5 + a_3 a_6 + a_4 a_7 + a_5 a_1 + a_6 a_2 + a_7 a_3 \\ P_A(4) &= a_1 a_4 + a_2 a_5 + a_3 a_6 + a_4 a_7 + a_5 a_1 + a_6 a_2 + a_7 a_3 \\ P_A(5) &= a_1 a_3 + a_2 a_4 + a_3 a_5 + a_4 a_6 + a_5 a_7 + a_6 a_1 + a_7 a_2 \\ P_A(6) &= a_1 a_2 + a_2 a_3 + a_3 a_4 + a_4 a_5 + a_5 a_6 + a_6 a_7 + a_7 a_1 \\ N_A(0) &= a_1^2 + a_2^2 + a_3^2 + a_4^2 + a_5^2 + a_6^2 + a_7^2 \\ N_A(1) &= a_1 a_2 + a_2 a_3 + a_3 a_4 + a_4 a_5 + a_5 a_6 + a_6 a_7 \\ N_A(2) &= a_1 a_3 + a_2 a_4 + a_3 a_5 + a_4 a_6 + a_5 a_7 \\ N_A(3) &= a_1 a_4 + a_2 a_5 + a_3 a_6 + a_4 a_7 \\ N_A(4) &= a_1 a_5 + a_2 a_6 + a_3 a_7 \\ N_A(5) &= a_1 a_6 + a_2 a_7 \\ N_A(6) &= a_1 a_7. \end{aligned}$$

Definition 3 Two finite sequences $[a_1, \dots, a_n]$ and $[b_1, \dots, b_n]$ of length n each are said to have constant periodic autocorrelation if there is a constant c such that

$$P_A(i) + P_B(i) = c, \quad i = 1, \dots, n - 1.$$

Definition 4 Two sequences $[a_1, \dots, a_n]$ and $[b_1, \dots, b_n]$ of length n each are said to have constant aperiodic autocorrelation if there is a constant c such that

$$N_A(i) + N_B(i) = c, \quad i = 1, \dots, n - 1.$$

Note that the index $i = 0$ is omitted from [Definitions 3](#) and [4](#), because of the property $P_A(0) = N_A(0) = \sum_{j=1}^n a_j^2$. Also note that when writing out binary and ternary sequences, it is customary in the combinatorial literature to denote -1 by $-$, zero by 0 , and $+1$ by $+$, and this is the convention adopted in the current chapter. Also note that [Definitions 3](#) and [4](#) can be extended to more than two sequences. [Definitions 3](#) and [4](#) are best illustrated with an example.

Example 2 The following binary sequences with $n = 26$ have constant aperiodic autocorrelation with $c = 0$:

$$\begin{aligned} & + + + + - + + - - + - + - + - + + + - - + + + \\ & + + + + - + + - - + - + + + + + - + - - + + - - \end{aligned}$$

The following ternary sequences with $n = 30$ have constant aperiodic autocorrelation with $c = 0$:

$$\begin{aligned} & + + - - - - + - - 0000 + 0 + - + + + + - - + - + + \\ & + + - - - - - + - - + + - - 0 - 0000 - - + + - + - - \end{aligned}$$

The following properties of the periodic and aperiodic autocorrelation functions can be observed (and verified) in [Examples 1](#) and [2](#):

Property 1 (Symmetry)

$$P_A(i) = P_A(n - i), i = 0, 1, \dots, n.$$

Property 2 (Complementarity)

$$P_A(i) = N_A(i) + N_A(n - i), i = 0, 1, \dots, n.$$

Property 3 (Second Elementary Symmetric Function)

$$P_A(1) + \dots + P_A(n - 1) = 2 e_2(a_1, \dots, a_n)$$

$$N_A(1) + \dots + N_A(n - 1) = e_2(a_1, \dots, a_n)$$

where $e_2(a_1, \dots, a_n) = \sum_{1 \leq i < j \leq n} a_i a_j$ is the second elementary symmetric function in the n variables a_1, \dots, a_n .

The proof of the three properties stated above is a straightforward application of [Definitions 1](#) and [2](#) and is left to the reader.

The complementarity property of periodic and aperiodic autocorrelation functions implies that:

Property 4 If two sequences have constant aperiodic autocorrelation, then they must also have constant periodic autocorrelation.

Therefore, the two pairs of sequences in [Example 2](#) also have constant periodic autocorrelation with $c = 0$.

The converse of the above property does not hold, and counterexamples may be easily found.

The concept of a circulant matrix is also important in connection with several kinds of combinatorial matrices and sequences.

Definition 5 A $n \times n$ matrix $C(A)$ is called circulant if every row (except the first) is obtained by the previous row by a right cyclic shift by one. In particular,

$$C(A) = \begin{bmatrix} a_1 & a_2 & \dots & a_{n-1} & a_n \\ a_n & a_1 & \dots & a_{n-2} & a_{n-1} \\ \vdots & \vdots & \dots & \vdots & \vdots \\ a_3 & a_4 & \dots & a_1 & a_2 \\ a_2 & a_3 & \dots & a_n & a_1. \end{bmatrix}$$

The relationship between circulant matrices and periodic autocorrelation is described by the following property, whose proof is also a straightforward application of [Definitions 1](#) and [2](#).

Property 5 Consider a finite sequence $A = [a_1, \dots, a_n]$ of length n and the circulant matrix $C(A)$ whose first row is equal to A . Then $P_A(i)$ is the inner product of the first row of $C(A)$ and the $i + 1$ row of $C(A)$.

It turns out that the concepts of periodic and aperiodic autocorrelation can serve as the unifying concepts needed to define several kinds of combinatorial matrices and sequences simultaneously. We summarize some of these kinds of combinatorial matrices and sequences in the next table.

Note that in [Table 1](#), TCP stands for “ternary complementary pairs” and PCS stands for “periodic complementary sequences.” We refer the reader to the papers listed in [Table 1](#) for the complete definitions of these combinatorial objects.

In the remainder of this chapter, we focus on various kinds of algorithms that can be used to search efficiently for combinatorial matrices and sequences listed in [Table 1](#), as well as any other such combinatorial objects that can be defined via periodic and aperiodic autocorrelation. In fact, we will concentrate on general algorithmic schemes that are applicable to all such combinatorial objects and will provide high-level descriptions for these algorithmic schemes.

3 Cyclotomy Algorithms

Cyclotomy algorithms to search for combinatorial matrices and sequences are based on the premise that certain combinatorial concepts called “supplementary difference sets” (abbreviated as SDS) can be constructed by taking unions of cyclotomic classes (or cosets) or group action orbits of a suitable subgroup of the group of invertible elements of the ring of integers modulo n , where n is a parameter referring to the length of the sequences. This powerful theme has been exploited by several authors at the theoretical and practical level over more than two decades.

The crucial concept of an SDS has been introduced by Jennifer Seberry 40 years ago [101, 102].

Definition 6 Let n be a positive integer and let S_1, \dots, S_k be subsets of \mathbb{Z}_n with cardinalities n_1, \dots, n_k , respectively. Let $T_i = \{(s_1^i - s_2^i) \bmod n, (s_2^i - s_1^i) \bmod n, s_1^i, s_2^i \in S_i\}$ be the multiset of all pairwise differences (taken modulo n) of all elements in S_i , for $i = 1, \dots, k$. If the multiset $T_1 \cup \dots \cup T_k$ is equal to λ copies of $\{1, \dots, n-1\}$, then S_1, \dots, S_k form an SDS with parameters $k - \{n; n_1, \dots, n_k; \lambda\}$.

A simple counting argument shows that existence of an SDS with parameters $k - \{n; n_1, \dots, n_k; \lambda\}$ implies the following condition:

$$\sum_{i=1}^k n_i(n_i - 1) = \lambda(n - 1).$$

Here is a toy example, where the SDS property can be verified by hand.

Example 3 Let $n = 13$ and $t = 3$. Then there are 4 cyclotomic classes: $S_1 = [1, 3, 9]$, $S_2 = [2, 5, 6]$, $S_3 = [4, 10, 12]$ and $S_4 = [7, 8, 11]$. It turns out that S_1 and S_2 form an SDS with parameters $2 - \{13; 3, 3; 1\}$ because $(\text{mod } 13)$ we have

$$T_1 \cup T_2 = \{1-3, 1-9, 3-9, 3-1, 9-1, 9-3\} \cup \{2-5, 2-6, 5-6, 5-2, 6-2, 6-5\},$$

i.e.,

$$T_1 \cup T_2 = \{1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12\}.$$

Here is a non-toy example, where the SDS property needs to be verified by a computer program.

Example 4 Let $n = 323$ and $t = 3$. Then there are 4 cyclotomic classes C_1, C_2, C_3, C_4 with cardinalities $n_1 = 144$, $n_2 = 144$, $n_3 = 18$ and $n_4 = 16$. Then the sets $S_1 = C_1 \cup C_3$ and $S_2 = S_1$ form an SDS with parameters $2 - \{323; 162, 162; 162\}$.

The paper [103] states a general theorem that indicates conditions under which suitable unions of cyclotomic classes form an SDS with specific parameters. The paper [38] contains recent theoretical results and in particular gives two constructions of skew Hadamard difference sets in the additive groups of suitable finite fields by using unions of cyclotomic classes. The paper [39] gives two constructions of strongly regular Cayley graphs on finite fields by using unions of cyclotomic classes. The paper [97] explores the idea of blending a mathematical programming formalism with a cyclotomy-based approach; the resulting algorithm is quite promising and deserves further investigation. Chapter 3 of the PhD thesis [47] is a virtual treasure trove of cyclotomy-based algorithms and applications of such algorithms to several different kinds of combinatorial matrices and sequences. Some of the most spectacular successes of cyclotomy algorithms include the discovery of new orders of Hadamard and skew Hadamard matrices [21, 23–25] as well as D-optimal matrices [29]. These types of methods are bound to continue to produce new results.

4 String Sorting Algorithms

String sorting algorithms to search for combinatorial matrices and sequences are based on certain restrictions that the properties of constant periodic or aperiodic autocorrelation imply. These restrictions possess the important advantage that they

can be used to decouple the (quadratic) equations in [Definitions 3](#) and [4](#). In addition, one needs to carefully distinguish between periodic and aperiodic autocorrelation, because the corresponding restrictions are of a different nature.

4.1 Periodic Autocorrelation

The restrictions imposed by the constancy of periodic autocorrelation are described via the concept of power spectral density (PSD) associated to a finite sequence. We illustrate the main idea in the context of Hadamard matrices with two circulant cores, following [\[42, 63\]](#).

Let n be an odd positive integer and suppose that two binary sequences $A = [a_1, \dots, a_n]$ and $B = [b_1, \dots, b_n]$, both of length n , have constant periodic autocorrelation function -2 , i.e.,

$$P_A(s) + P_B(s) = -2, \text{ for } s = 1, \dots, \frac{n-1}{2}. \quad (1)$$

Definition 7 Let $\omega = e^{\frac{2\pi i}{n}}$ be a primitive n -th root of unity.

The discrete Fourier transform (DFT) of A is defined by

$$\text{DFT}_A(s) = \sum_{k=1}^n a_k \omega^{ks}, \text{ for } s = 0, \dots, n-1.$$

The power spectral density (PSD) of A is defined by

$$\text{PSD}_A(s) = |\text{DFT}_A(s)|^2, \text{ for } s = 0, \dots, n-1.$$

Therefore, the PSD values are the squared magnitudes of the DFT values, i.e., $\text{PSD}_A(s) = \text{Re}(\text{DFT}_A(s))^2 + \text{Im}(\text{DFT}_A(s))^2$. Note that the well-known properties $\omega^n = 1$ and $\text{DFT}_A(n-s) = \text{DFT}_A(s)$, $s = 0, 1, \dots, n-1$ are routinely used in order to perform DFT/PSD calculations efficiently.

It can be proved (see [\[42\]](#)) that property (Eq. 1) implies that

$$\text{PSD}_A(s) + \text{PSD}_B(s) = 2n + 2, \text{ for } s = 1, \dots, \frac{n-1}{2}. \quad (2)$$

Example 5 Let $n = 55$ and consider the two sequences from [\[13\]](#):

$$\begin{aligned} & -++-+++\cdots+-+--++-++-++-+--+--++-+--+--++-+--+--++-+--+-- \\ & +---++-+--+--++-+--+--++-+--+--++-+--+--++-+--+--++-+--+-- \end{aligned}$$

The above sequences have constant periodic autocorrelation -2 and can be used to construct a Hadamard matrix of order $2 \cdot 55 + 2 = 112$. The following table records the $\frac{55-1}{2} = 27$ PSD values for the above sequences, as well as their sums, which is equal to 112 for $s = 1, \dots, 27$ as expected.

Table 2 PSD values for binary sequences with $n = 55$

s	$\text{PSD}_A(s)$	$\text{PSD}_B(s)$	$\text{PSD}_A(s) + \text{PSD}_B(s)$

It is instructive to examine [Table 2](#) in order to see how [Eq. \(2\)](#) are materialized for the particular solution of [Example 5](#).

4.1.1 The PSD Criterion

[Equation \(2\)](#) can be used to derive the so-called PSD criterion by first remarking that since the PSD values are nonnegative, if for some $s \in \{1, \dots, \frac{n-1}{2}\}$ it turns out that $\text{PSD}_A(s) > 2n + 2$ or $\text{PSD}_B(s) > 2n + 2$, then the corresponding A or B candidate sequence can be safely discarded from the search.

4.1.2 A Subtle Point: Integer PSD Values

There is a subtle point regarding the computation of the PSD values that occur in string sorting algorithms, as well as other filtering-based algorithms to search for

sequences using the PSD criterion. The subtlety comes from the fact that although in the vast majority of cases the PSD values are (positive) floating point numbers, there exist cases when the PSD values are (positive) integers. A particular case when this phenomenon occurs is described in the following result proved in [64].

Lemma 1 *Let n be an odd integer such that $n \equiv 0 \pmod{3}$ and let $m = \frac{n}{3}$. Let $\omega = e^{\frac{2\pi i}{n}} = \cos\left(\frac{2\pi}{n}\right) + i \sin\left(\frac{2\pi}{n}\right)$ the principal n -th root of unity. Let $[a_1, \dots, a_n]$ be a sequence with elements from $\{-1, 0, +1\}$. Then we have that $\text{DFT}([a_1, \dots, a_n], m)$ can be evaluated explicitly in closed form and $\text{PSD}([a_1, \dots, a_n], m)$ is a nonnegative integer. The explicit evaluations are given by*

$$\begin{aligned}\text{DFT}([a_1, \dots, a_n], m) &= \left(A_1 - \frac{1}{2}A_2 - \frac{1}{2}A_3 \right) + \left(\frac{\sqrt{3}}{2}A_2 - \frac{\sqrt{3}}{2}A_3 \right) i \\ \text{PSD}([a_1, \dots, a_n], m) &= A_1^2 + A_2^2 + A_3^2 - A_1A_2 - A_1A_3 - A_2A_3\end{aligned}$$

where

$$A_1 = \sum_{i=0}^{m-1} a_{3i+1}, \quad A_2 = \sum_{i=0}^{m-1} a_{3i+2}, \quad A_3 = \sum_{i=0}^{m-1} a_{3i+3}.$$

It is important to carefully account for the phenomenon described by Lemma 1 in any implementation of string sorting algorithms in order not to miss any solutions due to numerical round-off error. One way of doing this is to omit the $n/3$ -th value from the construction of the string.

4.1.3 Bracelets and Necklaces

The symmetry property of periodic autocorrelation and PSD values under cyclic shifting must also be taken into account in order to avoid redundant computations for sequences that have the same periodic autocorrelation and PSD values. It turns out that the right combinatorial structures to deal with this symmetry property are bracelets and necklaces. The papers [89] and [90] and subsequent work by J. Sawada and his collaborators provide constant amortized time (CAT) algorithms to generate bracelets and necklaces, as well as extremely efficient C implementations of these algorithms.

4.2 Aperiodic Autocorrelation

The restrictions imposed by the constancy of periodic autocorrelation are described via the concept of a certain infinite class of functions associated to a finite sequence. We illustrate the main idea in the context of Turyn-type sequences, following [57].

Let n be an even positive integer and suppose that four binary sequences $X = [x_1, \dots, x_n]$ and $Y = [y_1, \dots, y_n]$, $Z = [z_1, \dots, z_n]$ and $W = [w_1, \dots, w_{n-1}]$ of

lengths $n, n, n, n - 1$ respectively, have constant aperiodic autocorrelation function in the sense that

$$N_X(s) + N_Y(s) + 2N_Z(s) + 2N_W(s) = 0, \text{ for } s = 1, \dots, n - 1. \quad (3)$$

The sequences X, Y, Z, W satisfying (3) are called Turyn type.

We associate to a binary sequence X of length n , the periodic (of period 2π) nonnegative function

$$f_X(\theta) = N_X(0) + 2 \sum_{j=1}^{n-1} N_X(j) \cos j\theta.$$

It can be proved (see [57]) that property (Eq. 3) implies that

$$f_X(\theta) + f_Y(\theta) + 2f_Z(\theta) + 2f_W(\theta) = 6n - 2, \quad \forall \theta. \quad (4)$$

4.2.1 Aperiodic Version of the PSD Criterion

Equation (4) can be used to derive the analog (an aperiodic version) of the PSD criterion in the aperiodic case. If for some value of θ it turns out that $f_X(\theta) > 6n - 2$ or $f_Y(\theta) > 6n - 2$, or $f_Z(\theta) > 3n - 1$ or $f_W(\theta) > 3n - 1$, then the corresponding X, Y, Z, W candidate sequence can be safely discarded from the search. In addition, if for some value of θ it turns out that $f_X(\theta) + f_Y(\theta) > 6n - 2$, then the corresponding pair (X, Y) of candidates sequences can be safely discarded from the search. Similar conditions can be derived for other partial sums of the four values $f_X(\theta), f_Y(\theta), f_Z(\theta), f_W(\theta)$ for arbitrary (but fixed) values of θ . The preprocessing of the sequences based on this aperiodic version of the PSD criterion is often carried out via a finite set of θ values, such as $\left\{ \frac{j\pi}{500}, j = 1, \dots, 500 \right\}$.

4.3 A General String Sorting Algorithmic Scheme

Based on the PSD criterion (periodic and aperiodic versions), a general string sorting algorithmic scheme can be defined as follows.

INPUT: lengths and types (binary/ternary) of two sequences A, B and the autocorrelation (periodic/aperiodic) property satisfied, value of PSD constant (or its aperiodic analog)

OUTPUT: sequences satisfying the input requirements (if any are found)

- Preprocess each one of the two sequences separately using the applicable version of the PSD criterion. In particular, discard all candidate sequences that violate the applicable version of the PSD criterion. If the set of all possible candidate sequences is too large to preprocess in its entirety, then use randomized methods to generate a representative part of this set.
- Encode candidate A -sequences by a string, namely, the concatenation of the integer parts of its PSD values, or the $f(\theta)$ values, for a small set of θ values.

Encode candidate B -sequences by a similar string, but taking the difference of the PSD (or $f(\theta)$ value) from the PSD constant (or its aperiodic analog).

- Sort the files containing the string encodings corresponding to each A -sequence and B -sequences separately. When the files containing the string encodings are too large to be sorted directly, this phase involves a distributed sorting algorithm.
- Look for identical strings in the two sorted files and output the corresponding solutions.

String sorting algorithms have been used in [?, 64] to compute several new weighing matrices of various weights constructed from two circulant cores, using the PSD criterion for periodic autocorrelation.

The ternary sequences with $n = 30$ in [Example 2](#) have been computed by the author using a C implementation of a string sorting algorithm and the aperiodic version of the PSD criterion.

5 Genetic Algorithms

Genetic algorithms (GAs) form a powerful metaheuristic method that exploits algorithmic analogs of concepts from Darwin's theory of evolution to design efficient search methods. The theory of genetic algorithms is presented in a extremely readable way in the classical book [44]. Among the more recent systematic treatments of GAs, one can consult [87]. Genetic algorithms have been applied successfully to tackle a wide range of difficult problems across many application areas. A central concept in the theory of GAs is the “objective function.” A judicious choice of an objective function is necessary in order to be able to apply GAs to solve a specific problem. Another important ingredient in the theory of GAs is the encoding of the solution space as a set of binary vectors. We will exemplify below how to formalize a problem of searching for combinatorial matrices as a GA problem, using binary sequences with constant periodic autocorrelation -2 as a case study, and following the exposition in [59].

Let n be an odd positive integer and suppose that two binary sequences $A = [a_1, \dots, a_n]$ and $B = [b_1, \dots, b_n]$, both of length n , have constant periodic autocorrelation function -2 , as in (1). Since the $m = \frac{n-1}{2}$ [Eq. \(1\)](#) must be satisfied simultaneously, one can consider the following two types of objective functions arising naturally:

$$OF_1 = | P_A(1) + P_B(1) + 2 | + \dots + | P_A(m) + P_B(m) + 2 |$$

and

$$OF_2 = (P_A(1) + P_B(1) + 2)^2 + \dots + (P_A(m) + P_B(m) + 2)^2.$$

There are two potentially important differences between the objective functions OF_1 OF_2 . First, OF_1 is not a continuous function, while OF_2 is. Second, OF_1 takes on smaller values than OF_2 . The GA will seek to minimize OF_1 and OF_2 , i.e., to find $2n$ $\{\pm 1\}$ values of the $2n$ variables $a_1, \dots, a_n, b_1, \dots, b_n$ such that OF_1 and OF_2

attain the value 0. Evidently, a set of $2n \{\pm 1\}$ values with this property is also a solution of the original problem of finding two binary sequences with constant periodic autocorrelation function -2 .

The GAs requirement of encoding the solution space as a set of binary vectors is inherent in the problem of searching for binary sequences with constant periodic/aperiodic autocorrelation function.

5.1 A General GAs Algorithmic Scheme

INPUT: k binary sequences A_1, \dots, A_k , all of length n , and the autocorrelation (periodic/aperiodic) property satisfied

OUTPUT: k -tuples of sequences satisfying the input requirements (if any are found)

- Specify an initial randomly chosen population (first generation) of binary sequences of length n .
- Encode the required periodic/aperiodic autocorrelation property in the form of OF_1 or OF_2 .
- Set current generation to be the first generation.
- Evolve the current generation to the next generation, using a set of genetic operators. Commonly used such operators include reproduction, crossover, and mutation.
- Examine the next generation to see whether it contains k binary sequences with the required periodic/aperiodic autocorrelation property. If yes, then output this solution and exit. If no, then set current generation to be the next generation and iterate the previous step.

Note that popular termination criteria for GAs include a predetermined number of generations to evolve or a predetermined amount of execution time.

There are several papers that use GAs to solve design-theoretic and combinatorial problems. In [1] the authors devise a GA to search for cocyclic Hadamard matrices. In [2] the author explains how to use genetic algorithms to solve three design-theoretic problems of graph-theoretic flavor. In [50] the authors apply GAs to construct D-optimal designs. In [68] the authors use so-called competent GAs to search efficiently for weighing matrices. In [17] the authors use SGA (simple genetic algorithm) to construct Hadamard matrices of various orders. The thesis [84] is concerned with the application of GAs to construct D-optimal experimental designs. The thesis [46] contains GAs to search for normal and near-Yang sequences.

6 Simulated Annealing

Simulated annealing (SA) was presented in [58] as a new approach to approximate solutions of difficult optimization problems. This approach is inspired from statistical mechanics and is motivated by an analogy to the behavior of physical systems in the presence of heat. In the words of Kirkpatrick et al.,

there is a deep and useful connection between statistical mechanics (the behavior of system with many degrees of freedom in thermal equilibrium at a finite temperature) and multivariate or combinatorial optimization (finding the minimum of a given function depending on many parameters).

In particular, they found that the Metropolis algorithm was well suited to approximate the observed behavior of solids when subjected to an annealing process. Recall that a local optimization method starts with some initial solution and, at each iteration, searches its neighbors for a better solution until no better solution can be found. A weakness of the local optimization method is that the program may get trapped at some local minima instead of detecting a global minimum. Simulated annealing addresses this issue by using randomization to improve on the local optimization search process, and in particular, occasional uphill moves (i.e., less than optimal solutions) are accepted with the hope that by doing so, a better solution will be obtainable later on. There are several parameters in the simulated annealing process which can significantly impact the actual performance, and there do not seem to be general rules on how to choose these parameters for the specific problem at hand.

In the annealing process, the physical system being optimized is first “melted” at a high temperature. The temperature is then decreased slowly until the system “freezes,” and no further physical changes occur. When the system’s structure is “frozen,” this correspond to a minimum energy configuration. The physical analogy for simulated annealing is often described using the annealing method for growing a crystal. The rate at which the temperature is reduced is vitally important to the annealing process. If the cooling is done too quickly, widespread irregularities will form and the trapped energy level will be higher than what one would find in a perfectly structured crystal. It can be shown that the states of this physical system correspond to the solutions of an optimization problem. The energy of a state in the physical world corresponds to the cost of a solution in the optimization world. The minimum energy configuration that is obtained when a system is frozen corresponds to an optimal solution in an optimization problem.

6.1 A General SA Algorithmic Scheme

The basic ingredients needed to formulate a problem in a manner amenable to SA algorithms are:

1. A finite set S . This is the set of all possible solutions.
2. An objective function OF defined on S .
3. The set S^* is the set of global minima (i.e., the desired solutions) using the OF .
It is assumed that $S^* \subset S$, a proper subset of S .
4. For each $i \in S$, we define a set $S(i) \subset S - \{i\}$ to be the set of *neighbors* of i .
5. A nonincreasing function $\alpha(t)$ called the *cooling schedule*, which controls how the temperature is lowered.

With the previous terminology in place, a general SA algorithmic scheme looks like:

```

Randomly select initial solution  $s_0$ ;
Select an initial temperature  $t_0 > 0$ ;
Select a temperature reduction function  $\alpha$ ;
Repeat
    Repeat
        Randomly select a neighbor,  $s$  of  $s_0$ ;
         $\delta = \text{OF}(s) - \text{OF}(s_0)$ ;
        if( $\delta < 0$ )
            then  $s_0 = s$ ;
        else
            generate random  $x$  uniformly in the range  $(0, 1)$ ;
            if( $x < e^{-\delta/t}$ )
                then  $s_0 = s$ ;
    Until  $\text{iteration\_count} = nrep$ 
    Set  $t = \alpha(t)$ ;
Until stopping condition = true
 $s_0$  is the approximation to the optimal solution

```

Recall that the goal of simulated annealing is to improve on the local search strategies by allowing some uphill moves in a controlled manner. The above SA scheme accepts a solution at each iteration if it is determined to be better than the current “best” solution. However, we also see how a less than optimal solution can be accepted and that it is accepted with probability $e^{-\delta/t}$. Also note that for the purposes of the OF required by SA, one can use OF_1 and OF_2 as defined previously for GAs. Commonly used cooling schedules include $\alpha(t) = \alpha t$, where $\alpha < 1$ and $\alpha(t) = \frac{t}{1 + \beta t}$ where β is small.

The papers [12, 55, 70, 72, 77] use SA techniques to tackle design theory problems.

7 Particle Swarm Optimization (PSO)

Particle swarm Optimization (PSO) is a population-based metaheuristic algorithm. It was introduced by R.C. Eberhart and J. Kennedy in 1995 [35] primarily for solving numerical optimization problems, as an alternative to evolutionary algorithms (EAs) [3]. Its verified efficiency in challenging optimization problems as well as its easy implementation rapidly placed PSO in a salient position among the state-of-the-art algorithms. Today, PSO counts a vast number of applications in diverse scientific fields [4, 5, 78], as well as an extensive bibliography [14, 37, 56, 83], and published scientific software [100].

Putting it formally, consider the n -dimensional global optimization problem:

$$\min_{x \in X \subset \mathbb{R}^n} f(x).$$

PSO probes the search space by using a *swarm*, namely, a set of search points:

$$S = \{x_1, x_2, \dots, x_N\}, \quad x_i \in X, \quad i \in I = \{1, 2, \dots, N\}.$$

Each search point of S constitutes a *particle*, i.e., a search vector:

$$x_i = (x_{i1}, x_{i2}, \dots, x_{in})^\top \in X, \quad i \in I,$$

which is randomly initialized in X and allowed to iteratively move within it. Its motion is based on stochastically adapted position shifts, called *velocity*, while it retains in memory the *best position* it has ever visited. These quantities are denoted as

$$v_i = (v_{i1}, v_{i2}, \dots, v_{in})^\top, \quad p_i = (p_{i1}, p_{i2}, \dots, p_{in})^\top, \quad i \in I,$$

respectively. Thus, if t denotes the current iteration of the algorithm, it holds that

$$p_i(t) = \arg \min_{q \in \{0, 1, \dots, t\}} \{f(x_i(q))\}, \quad i \in I.$$

The best positions constitute a sort of experience for the particles, guiding them towards the most promising regions of the search space, i.e., regions that possess lower function values.

In order to avoid the premature convergence of the particles on local minimizers, the concept of *neighborhood* was introduced [96]. A neighborhood of the i -th particle is defined as a set,

$$NB_{i,s} = \{j_1, j_2, \dots, j_s\} \subseteq I, \quad i \in NB_{i,s},$$

and consists of the indices of all the particles with which it can exchange information. Then, the neighborhood's best position

$$p_{g_i} = \arg \min_{j \in NB_{i,s}} \{f(p_j)\} \tag{5}$$

is used along with p_i to update the i -th particle's velocity at each iteration. The parameter s defines the *neighborhood size*. In the special case where $s = N$, the whole swarm constitutes the neighborhood. This case defines the so-called *global* PSO model (denoted as *gbest*), while strictly smaller neighborhoods correspond to the *local* PSO model (denoted as *lbest*). The schemes that are used for determining the particles that constitute each neighborhood are called *neighborhood topologies*, and they can have a crucial impact on PSO's performance. A popular scheme is the *ring* topology, where each particle assumes as neighbors of the particles with its

adjacent indices, assuming that indices recycle after N . Based on the definitions above, the iterative scheme of PSO is defined as follows [15]:

$$v_{ij}(t+1) = \chi \left[v_{ij}(t) + c_1 \mathcal{R}_1(p_{ij}(t) - x_{ij}(t)) + c_2 \mathcal{R}_2(p_{g_i,j}(t) - x_{ij}(t)) \right], \quad (6)$$

$$x_{ij}(t+1) = x_{ij}(t) + v_{ij}(t+1), \quad (7)$$

where $i = 1, 2, \dots, N$; $j = 1, 2, \dots, n$; the parameter χ is the *constriction coefficient*; acceleration constants c_1 and c_2 are called the *cognitive* and *social* parameter, respectively; and \mathcal{R}_1 and \mathcal{R}_2 , are random variables uniformly distributed in the range $[0, 1]$. It shall be noted that a different value of \mathcal{R}_1 and \mathcal{R}_2 is sampled for each i and j in (6) at each iteration. Also, the best position of each particle is updated at each iteration, as follows:

$$p_i(t+1) = \begin{cases} x_i(t+1), & \text{if } f(x_i(t+1)) < f(p_i(t)), \\ p_i(t), & \text{otherwise,} \end{cases} \quad i \in I. \quad (8)$$

The PSO variant described above was introduced by M. Clerc and J. Kennedy in [15], and it has gained increasing popularity, especially in interdisciplinary applications. This can be attributed to its simplicity, its efficiency, and its theoretical background.

Based on the stability analysis [15], the parameter set $\chi = 0.729$, $c_1 = c_2 = 2.05$, was determined as a satisfactory setting that produces a balanced convergence speed of the algorithm. Nevertheless, alternative settings have been introduced in relevant works [98]. Pseudocode of PSO is reported in [Algorithm 1](#).

Unified particle swarm optimization (UPSO) was proposed as a scheme that harnesses the lbest and gbest PSO models, combining their exploration and exploitation properties [79, 82]. Let $\mathcal{G}_i(t+1)$ be the gbest velocity update of x_i , while $\mathcal{L}_{ij}(t+1)$ be the corresponding lbest velocity update. Then, from [Eq. \(6\)](#), it holds that

$$\mathcal{G}_{ij}(t+1) = \chi \left[v_{ij}(t) + c_1 \mathcal{R}_1(p_{ij}(t) - x_{ij}(t)) + c_2 \mathcal{R}_2(p_{g_i,j}(t) - x_{ij}(t)) \right], \quad (9)$$

$$\mathcal{L}_{ij}(t+1) = \chi \left[v_{ij}(t) + c_1 \mathcal{R}_1(p_{ij}(t) - x_{ij}(t)) + c_2 \mathcal{R}_2(p_{g_i,j}(t) - x_{ij}(t)) \right], \quad (10)$$

where g denotes the overall best particle. The aggregation of these search directions defines the main UPSO scheme [79]:

$$\mathcal{U}_{ij}(t+1) = u \mathcal{G}_{ij}(t+1) + (1-u) \mathcal{L}_{ij}(t+1), \quad (11)$$

$$x_{ij}(t+1) = x_{ij}(t) + \mathcal{U}_{ij}(t+1). \quad (12)$$

The parameter $u \in [0, 1]$ is called the *unification factor* and determines the trade off between the two directions. Obviously, the standard gbest PSO is obtained by setting $u = 1$ in (11), while $u = 0$ corresponds to the standard lbest PSO. All intermediate

values of $u \in (0, 1)$ define composite UPSO variants that combine the exploration and exploitation properties of the global and local PSO variant.

Besides the basic UPSO scheme, a stochastic parameter can also be incorporated in Eq. (11) to enhance UPSO's exploration capabilities [79]. Thus, depending on which variant UPSO is mostly based, Eq. (11) becomes

$$\mathcal{U}_{ij}(t+1) = \mathcal{R}_3 u \mathcal{G}_{ij}(t+1) + (1-u) \mathcal{L}_{ij}(t+1), \quad (13)$$

which is mostly based on lbest, or,

$$\mathcal{U}_{ij}(t+1) = u \mathcal{G}_{ij}(t+1) + \mathcal{R}_3 (1-u) \mathcal{L}_{ij}(t+1), \quad (14)$$

which is mostly based on gbest. The random variable $\mathcal{R}_3 \sim \mathcal{N}(\mu, \sigma^2)$ is normally distributed, resembling the mutation operator in EAs. Yet, it is biased towards directions that are consistent with the PSO dynamic, instead of the pure random mutation used in EAs. Following the assumptions of Matyas [71], a proof of convergence in probability was derived for the UPSO variants of Eqs. (13) and (14) [79].

Although PSO and UPSO have been primarily designed for real-valued optimization problems, there are various applications also in problems with integer, mixed-integer, and binary variables (e.g., see Eqs. [62, 69, 80, 81, 85, 86]). The most common and easy way to achieve this is by rounding the corresponding variables to their nearest integers when evaluating the particles. Of course, problem-dependent techniques may be additionally needed to enhance performance.

8 Ant Colony Optimization (ACO)

Ant colony optimization (ACO) is a probabilistic algorithm, primarily for solving combinatorial optimization problems. The general algorithmic concept of ACO was introduced by M. Dorigo in 1992 [30], aiming at detecting optimal paths in graphs by imitating the foraging behavior of real ants. The first approaches proved to be very promising, leading to further developments and enhancements [7, 31, 33].

Today, there is a variety of ant-based algorithms. Perhaps the most popular variants are Ant System (AS) [34], Max–Min Ant System (MMAS) [95], and Ant Colony System (ACS) [32]. Setting aside some differences, most ant-based approaches follow the same procedure flow, which can be summarized in the following actions:

```

Procedure ACO
WHILE (termination condition is false)
Construct_Solutions()
Optional_Further_Actions()
Update_Pheromones()
END WHILE

```

Algorithm 1: Pseudocode of the standard PSO algorithm

Input : Objective function, $f : X \subset \mathbb{R}^n \rightarrow \mathbb{R}$; swarm size: N ; parameters: χ, c_1, c_2 .
Output: Best detected solution: $x^*, f(x^*)$.

```

1 // Initialization
2 t ← 0.
3 for i ← 1 to N do
4     Initialize  $x_i(t)$  and  $v_i(t)$ , randomly.
5      $p_i(t) \leftarrow x_i(t)$ . // Initialize best position
6     Evaluate  $f(x_i(t))$ . // Evaluate particle
7 end
8 // Main Iteration
9 while (termination criterion not met) do
10    // Position and Velocity Update
11    for i ← 1 to N do
12        Determine  $p_{gi}(t)$  from the  $i$ -th particle's neighborhood.
13        for j ← 1 to n do
14             $v_{ij}(t+1) \leftarrow \chi [v_{ij}(t) + c_1 \mathcal{R}_1(p_{ij}(t) - x_{ij}(t)) + c_2 \mathcal{R}_2(p_{gi,j}(t) - x_{ij}(t))]$ .
15             $x_{ij}(t+1) \leftarrow x_{ij}(t) + v_{ij}(t+1)$ .
16        end
17    end
18    // Best Positions Update
19    for i ← 1 to N do
20        Evaluate  $f(x_i(t+1))$ . // Evaluate new position
21         $p_i(t+1) \leftarrow \begin{cases} x_i(t+1), & \text{if } f(x_i(t+1)) < f(p_i(t)), \\ p_i(t), & \text{otherwise.} \end{cases}$ 
22    end
23    t ← t + 1.
24 end

```

In general, the algorithm assumes a number, K , of search agents, called the *ants*. Each ant constructs a solution component by component. The construction procedure is based on the probabilistic selection of each component's value from a discrete and finite set. For this purpose, a table of *pheromones* is retained and continuously updated. The pheromones play the role of quality weights, used for determining the corresponding selection probability of each possible value of a solution component.

Putting it formally, let

$$x = (x_1, x_2, \dots, x_n)^\top \in D,$$

be a candidate solution of the problem, with each component $x_i, i = 1, 2, \dots, n$, taking values from a discrete and finite set D_i . The construction of a solution begins from an initially empty partial solution, $x^p = \emptyset$. At each step, the next component of x^p is assigned one of the possible values from its corresponding discrete set. Naturally, the values assigned in previous components may affect the feasible set of

candidate values for the current one, prohibiting the use of some of them to retain feasibility. Assume that x^p is already built up to the $(i - 1)$ -th component, and let $D_i = \{d_{i1}, d_{i2}, \dots, d_{iM}\}$ be the set of candidate values for the i -th component. Each possible value d_{ij} is associated with a pheromone level τ_{ij} . The selection of a specific value for the i -th component is based on the probabilistic selection among the different candidate values, using the selection probabilities:

$$P(d_{ij} | x^p) = \frac{\tau_{ij}^a \eta(d_{ij})^b}{\sum_{d_{il} \in D_i} \tau_{il}^a \eta(d_{il})^b}, \quad j = 1, 2, \dots, M, \quad (15)$$

where $\eta(\cdot)$ is a *heuristic function* that offers a measure of the “desirability” of each component value in the solution (e.g., in TSP problems, it can be associated with the traveled distance). The parameters a and b are fixed, and they offer flexibility in tuning the trade off between pheromone and heuristic information.

Upon constructing a complete solution, it is evaluated with the objective value, and the pheromones are updated so that component values that appear in better solutions increase their pheromone levels and, consequently, their selection probabilities for subsequent iterations of the algorithm. Also, all pheromones undergo a standard reduction in their values, a procedure also known as *evaporation*. Thus, the pheromones are updated as follows:

$$\tau_{ij} = \begin{cases} (1 - \rho) \tau_{ij} + \rho \Delta\tau, & \text{if } d_{ij} \text{ appears in a good candidate solution,} \\ (1 - \rho) \tau_{ij}, & \text{otherwise,} \end{cases} \quad (16)$$

where $\rho \in (0, 1]$ is the *evaporation rate* and $\Delta\tau$ is an increment that can be either fixed or proportional to the quality of the corresponding candidate solution.

Different ant-based approaches can differ from the basic scheme described above. For example, in AS with K ants, the pheromone update takes place after all ants have constructed their solutions and they all contribute to the update:

$$\tau_{ij} = (1 - \rho) \tau_{ij} + \sum_{k=1}^K \Delta\tau_{ij}^{(k)},$$

where $\Delta\tau_{ij}^{(k)}$ is the contributed pheromone from the k -th ant and it is related to its quality. On the other hand, ACS uses a different rule for selecting component values, where the value of the i -th component is determined as

$$d_{ig} = \arg \max_{d_{ij} \in D_i} \left\{ \tau_{ij}^a \eta(d_{ij})^b \right\}, \quad \text{if } q \leq q_0,$$

where $q \in [0, 1]$ is a uniformly distributed random number and $q_0 \in [0, 1]$ is a user-defined parameter; otherwise, the scheme of Eq. (15) is used. Also, only the best ant contributes to the pheromones, instead of the whole swarm. Finally, MMAS employs pheromone bounds $[\tau_{\min}, \tau_{\max}]$. Each pheromone is initialized to

its maximum value and updated only from the best ant, either of the current iteration or overall.

There is a rich literature of applications of ant-based approaches in combinatorial optimization problems [7, 31, 33]. Recently, such approaches were used also for the solution of autocorrelation problems [69].

9 Combinatorial Optimization

Combinatorial optimization methods seem like a natural candidate of methods that should be employed to tackle extremely hard optimization problems such as the search for binary and ternary sequences that satisfy autocorrelation constraints. This is because combinatorial optimization methods routinely deal with problems featuring thousands of discrete variables. The missing link that allows one to formalize autocorrelation problems in a manner suitable for combinatorial optimization methods was provided in [66] and [61]. This formalism made it in fact possible to solve in [66] the entire Bömer-Antweiler diagram, which was proposed 20 years before, in [6]. This formalism is based on the fact that autocorrelation can be expressed in terms of certain symmetric matrices, which correspond to the matrices associated to autocorrelation viewed as *quadratic form*. We shall illustrate the formalism for D-optimal matrices, following the exposition in [61].

Let n be an odd positive integer and set $m = \frac{n-1}{2}$. D-optimal matrices correspond to two binary sequences of length n each, with constant periodic autocorrelation 2; see [61]. D-optimal matrices are $2n \times 2n \{-1, +1\}$ -matrices that attain Ehlich's determinant bound. See [29] for a state-of-the-art survey of existence questions for D-optimal matrices with $n < 200$. We reproduce the following definition and lemma from [66].

Definition 8 Let $a = [a_1, a_2, \dots, a_n]^T$ be a column $n \times 1$ vector, where $a_1, a_2, \dots, a_n \in \{-1, +1\}$ and consider the elements of the periodic autocorrelation function vector $P_A(1), \dots, P_A(m)$. Define the following m symmetric matrices (which are independent of the sequence a), for $i = 1, \dots, m$

$$M_i = (m_{jk}), \text{ s.t. } \begin{cases} m_{jk} = m_{kj} = \frac{1}{2}, & \text{when } a_j a_k \in P_A(i), \ j, k \in \{1, \dots, n\} \\ 0, & \text{otherwise} \end{cases}$$

Lemma The matrices M_i can be used to write equations involving autocorrelation in a matrix form:

- For n odd:

$$a^T M_i a = P_A(i), \quad i = 1, \dots, m.$$

- For n even:

$$a^T M_i a = P_A(i), \quad i = 1, \dots, m-1 \text{ and } a^T M_m a = \frac{1}{2} P_A(m).$$

Now one can formulate the D-optimal matrices problem as a binary feasibility problem.

Binary Feasibility version of the D-optimal matrices problem Find two sequences $a = [a_1, \dots, a_n]$, $b = [b_1, \dots, b_n]$, (viewed as $n \times 1$ column vectors) such that

$$a^T M_i a + b^T M_i b = 2, \quad i = 1, \dots, m,$$

where $a_i, b_i \in \{-1, +1\}$, $i = 1, \dots, n$.

It is now clear that one can use combinatorial optimization algorithms to search for D-optimal matrices, as well as several other combinatorial matrices and sequences referenced in [Table 1](#). [Definition 8](#) can easily be adapted for aperiodic autocorrelation as well.

Note that the D-optimal matrices problem also features certain Diophantine constraints, as proved in [\[61\]](#) and subsequently generalized in [\[29\]](#). It is not clear what is the right way to incorporate this kind of Diophantine constraints into the combinatorial optimization formalism described here, and this is certainly an issue that deserves to be investigated further.

The papers [\[73–76\]](#) demonstrate how to use various optimization techniques to find new designs.

10 Applications

There are several applications of combinatorial matrices and sequences described in [Table 1](#), in such areas as telecommunications, coding theory, and cryptography. The reader can consult [\[45\]](#) for applications in signal design for communications, radar, and cryptography applications. The book [\[53\]](#) describes applications in signal processing, coding theory, and cryptography. The book [\[104\]](#) describes applications in communications, signal processing, and image processing. The paper [\[99\]](#) discusses how partial Hadamard matrices (see [\[20\]](#)) are used in the area of compressed sensing. The paper [\[93\]](#) describes in detail several applications of Hadamard matrices on code division multiple access (CDMA) communication systems as well as in telecommunications. The 55-page paper [\[49\]](#) describes applications of Hadamard matrices in binary codes, information processing, maximum determinant problems, spectrometry, pattern recognition, and other areas. The papers [\[91\]](#) and [\[92\]](#) and the thesis [\[9\]](#) discuss cryptography applications of Hadamard matrices. Chapter 10 of the book [\[51\]](#) is devoted to several combinatorial problems that can be tackled with stochastic search methods.

11 Conclusion

Combinatorial matrices and the associated binary and ternary sequences provide a wide array of extremely challenging optimization problems that can be tackled with a variety of metaheuristic and combinatorial methods. We tried to summarize

some of these methods in the present chapter. Although there are no polynomial complexity algorithms to solve the problem of searching for such matrices and sequences, the combination of new insights, new algorithms, and new implementations will continue to produce new results. The second edition of the Handbook of Combinatorial Designs [16], edited by Charles J. Colbourn and Jeffrey H. Dinitz, is a very valuable resource regarding the state of the art on open cases for several types of such matrices and sequences. The on-line updated webpage maintained by the authors is also quite useful, as many open cases have been resolved since the publication of the handbook in 2007. We firmly believe that cross-fertilization of disciplines is a very important process, from which all involved disciplines benefit eventually. It seems reasonable to predict that the area of combinatorial matrices and their associated sequences will continue to experience strong interactions with other research areas, for many years to come.

Abstract

This chapter discusses advances in SAT algorithm design, including the use of SAT algorithms as theory drivers, classic implementations of SAT solvers, and some theoretical aspects of SAT. Some applications to which SAT solvers have been successfully applied are also presented. The intention is to assist someone interested in applying SAT technology in solving some stubborn class of combinatorial problems.

1 Introduction

The satisfiability problem (SAT) has gained considerable attention over the past decade for two reasons. First, the performance of competitive SAT solvers has improved enormously due to the implementation of new algorithmic concepts. Second, so many real-world problems that are not naturally expressed as instances of SAT can be transformed to SAT instances and solved relatively efficiently using one of the ever-improving SAT solvers or solvers based on SAT. This chapter attempts to clarify these successes by presenting the important advances in SAT algorithm design as well as the classic implementations of SAT solvers. Some applications to which SAT solvers have been successfully applied are also presented. Finally, for the sake of developing some intuition on the subject, some classic theoretical results are presented.

The next section of the chapter presents some logic background and notation that will be necessary to understand and express the algorithms presented. The third

section presents several representations for SAT instances in preparation for discussing the wide variety of SAT solver implementations that have been tried. The fourth section presents some applications of SAT. The next two sections present algorithms for SAT, including search and heuristic algorithms plus systems that use SAT to manage the logic of complex computations. The seventh section presents some theoretical results regarding k -SAT instances and relates these with the performance of practical SAT solvers. The last section summarizes the results of the chapter.

2 Logic

An instance of satisfiability is a propositional logic expression in conjunctive normal form (CNF), the meaning of which is described in the next few paragraphs. The most elementary object comprising a CNF expression is the Boolean variable, shortened to *variable* in the context of this chapter. A variable takes one of two values from the set $\{0, 1\}$. A variable v may be negated in which case it is denoted $\neg v$. The value of $\neg v$ is opposite that of v . A *literal* is either a variable or a negated variable. The term *positive literal* is used to refer to a variable and the term *negative literal* is used to refer to a negated variable. The *polarity* of a literal is positive or negative accordingly.

The building blocks of propositional expressions are binary Boolean operators. A *binary Boolean operator* is a function $\mathcal{O}_b : \{0, 1\} \times \{0, 1\} \mapsto \{0, 1\}$. Often, such functions are presented in tabular form, called *truth tables*, as illustrated in Fig. 10. There are 16 possible binary operators and the most common (and useful) are \vee (or), \wedge (and), \rightarrow (implies), \leftrightarrow (equivalent), and \oplus (xor, alternatively exclusive-or). Mappings defining the common operators are shown in Fig. 1. The only interesting *unary Boolean operator*, denoted \neg (negation), is a mapping from 0 to 1 and 1 to 0. If $\neg l$ is a literal, then $\neg\neg l$ is the same as l .

A *formula* is a propositional expression consisting of literals, parentheses, and operators which has some semantic content and whose syntax is described recursively as follows:

1. Any single variable is a formula.
2. If ψ is a formula, then so is $\neg\psi$.
3. If ψ_1 and ψ_2 are both formulas and \mathcal{O} is a Boolean binary operator, then $(\psi_1 \mathcal{O} \psi_2)$ is a formula, ψ_1 is called the *left operand* of \mathcal{O} , and ψ_2 is called the *right operand* of \mathcal{O} .

Formulas can be simplified by removing some or all parentheses. Parentheses around nestings involving the same associative operators such as \vee , \wedge , and \leftrightarrow may be removed. For example, $(\psi_1 \vee (\psi_2 \vee \psi_3))$, $((\psi_1 \vee \psi_2) \vee \psi_3)$, and $(\psi_1 \vee \psi_2 \vee \psi_3)$ are considered to be the same formula. In the case of non-associative operators such as \rightarrow , parentheses may be removed, but right associativity is then assumed. The following is an example of a simplified formula:

$$(\neg v_0 \vee v_1 \vee \neg v_7) \wedge (\neg v_2 \vee v_3) \wedge (v_0 \vee \neg v_6 \vee \neg v_7) \wedge (\neg v_4 \vee v_5 \vee v_9),$$

Fig. 1 A (0 ± 1) matrix representation and associated CNF formula where clauses are labeled c_0, c_1, \dots, c_7 , from left to right, top to bottom

$$\begin{array}{cccccccccc} v_0 & v_1 & v_2 & v_3 & v_4 & v_5 & v_6 & v_7 & v_8 & v_9 \\ \hline c_0 & \left(\begin{array}{cccccccccc} -1 & 1 & 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & -1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & -1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ -1 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 0 & -1 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & 1 & 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \end{array} \right) \\ c_1 & \\ c_2 & \\ c_3 & \\ c_4 & \\ c_5 & \\ c_6 & \\ c_7 & \end{array}$$

$$((\neg v_0 \vee v_1 \vee \neg v_7) \wedge (\neg v_1 \vee v_2) \wedge (\neg v_2 \vee v_3) \wedge (\neg v_0 \vee \neg v_3 \vee v_8) \wedge (v_0 \vee \neg v_6 \vee \neg v_7) \wedge (\neg v_5 \vee v_6) \wedge (\neg v_4 \vee v_5 \vee v_9) \wedge (v_0 \vee v_4))$$

Table 1 The most common binary Boolean operators and their mappings

Operator	Symbol	Mapping
Or	\vee	$\{00 \mapsto 0; 10, 01, 11 \mapsto 1\}$
And	\wedge	$\{00, 01, 10 \mapsto 0; 11 \mapsto 1\}$
Implies	\rightarrow	$\{10 \mapsto 0; 00, 01, 11 \mapsto 1\}$
Equivalent	\leftrightarrow	$\{01, 10 \mapsto 0; 00, 11 \mapsto 1\}$
XOR	\oplus	$\{00, 11 \mapsto 0; 01, 10 \mapsto 1\}$

A useful parameter associated with a formula is depth. The *depth* of a formula is determined as follows:

1. The depth of a formula consisting of a single variable is 0.
2. The depth of a formula $\neg \psi$ is the depth of ψ plus 1.
3. The depth of a formula $(\psi_1 \mathcal{O} \psi_2)$ is the maximum of the depth of ψ_1 and the depth of ψ_2 plus 1.

A truth assignment or *assignment* is a set of variables all of whom have value 1. If M is an assignment and V is a set of variables, then, if $v \in V$ and $v \notin M$, v has value 0. Any assignment of values to the variables of a formula induces a value on the formula. A formula is evaluated from innermost \neg or parentheses out using mappings associated with the Boolean operators that are found in [Table 1](#).

Many algorithms that will be considered later iteratively build assignments, and it will be necessary to distinguish variables that have been assigned a value from those that have not been. In such cases, a variable will be allowed to hold a third value, denoted \perp , which means the variable is unassigned. This requires that the evaluation of operations be augmented to account for \perp as shown in [Table 2](#). If M is an assignment of values to a set of variables where at least one variable has value \perp , then M is said to be a *partial assignment*.

Formulas that are dealt with in this chapter often have many components of the same type which are called clauses. Two common special types of clauses are disjunctive and conjunctive clauses. A *disjunctive clause* is a formula consisting only of literals and the operator \vee . If all the literals of a clause are negative (positive), then the clause is called a *negative clause* (respectively, *positive clause*).

Table 2 Boolean operator mappings with \perp . Symbol? means 1 or 0

Operator	Symbol	Mapping
Or	\vee	$\{00 \mapsto 0; 10, 01, 11, 1\perp, \perp 1 \mapsto 1; 0\perp, \perp 0, \perp\perp \mapsto \perp\}$
And	\wedge	$\{00, 01, 10 \mapsto 0; 11 \mapsto 1; ?\perp, \perp?, \perp\perp \mapsto \perp\}$
Implies	\rightarrow	$\{10 \mapsto 0; 00, 01, 11, 0\perp \mapsto 1; 1\perp, \perp? \mapsto \perp\}$
Equivalent	\leftrightarrow	$\{01, 10 \mapsto 0; 00, 11 \mapsto 1; ?\perp, \perp?, \perp\perp \mapsto \perp\}$
XOR	\oplus	$\{00, 11 \mapsto 0; 01, 10 \mapsto 1; ?\perp, \perp?, \perp\perp \mapsto \perp\}$
Negate	\neg	$\{0 \mapsto 1; 1 \mapsto 0, \perp \mapsto \perp\}$

In this chapter disjunctive clauses will usually be represented as sets of literals. When it is understood that an object is a disjunctive clause, it will be referred to simply as a *clause*. The following two lines show the same formula of four clauses expressed, above, in conventional logic notation and, below, as a set of sets of literals:

$$(\neg v_0 \vee v_1 \vee \neg v_7) \wedge (\neg v_2 \vee v_3) \wedge (v_0 \vee \neg v_6 \vee \neg v_7) \wedge (\neg v_4 \vee v_5 \vee v_9)$$

$$\{\{\neg v_0, v_1, \neg v_7\}, \{\neg v_2, v_3\}, \{v_0, \neg v_6, \neg v_7\}, \{\neg v_4, v_5, v_9\}\}.$$

A *conjunctive clause* is a formula consisting only of literals and the operator \wedge . A conjunctive clause will also usually be represented as a set of literals and called a clause when it is unambiguous to do so. The number of literals in any clause is referred to as the *width* of the clause.

Often, formulas are expressed in some normal form. Four of the most frequently arising forms are defined as follows:

A *CNF formula* is a formula consisting of a conjunction of two or more disjunctive clauses.

Given CNF formula ψ and L_ψ , the set of all literals in ψ , a literal l is said to be a *pure literal* in ψ if $l \in L_\psi$ but $\neg l \notin L_\psi$. A clause $c \in \psi$ is said to be a *unit clause* if c has exactly one literal.

A k -*CNF formula*, k fixed, is a CNF formula restricted so that the width of each clause is exactly k .

A *Horn formula* is a CNF formula with the restriction that all clauses contain at most one positive literal. Observe that a clause $(\neg a \vee \neg b \vee \neg c \vee g)$ is functionally the same as $(a \wedge b \wedge c \rightarrow g)$, so Horn formulas are closely related to logic programming. In fact, logic programming was originally the study of Horn formulas.

A *DNF formula* is a formula consisting of a disjunction of two or more conjunctive clauses.

When discussing a CNF or DNF formula ψ , V_ψ is used to denote its variable set and C_ψ is used to denote its clause set. The subscripts are dropped when the context is clear.

As mentioned earlier, evaluation of a formula is from innermost parentheses out using the truth tables for each operator encountered and a given truth assignment. If the formula evaluates to 1, then the assignment is called a *satisfying assignment*, *model*, or a *solution*.

There are 2^n ways to assign values to n Boolean variables. Any subset of those assignments is a Boolean function on n variables. Thus, the number of such functions is 2^{2^n} . Any Boolean function f on n variables can be expressed as a CNF formula ψ where the set of assignments for which f has value 1 is identical to the set of assignments satisfying ψ [129]. However, k -CNF formulas express only a proper subset of Boolean functions: for example, since a width k clause eliminates the fraction 2^{-k} of potential models, any Boolean function comprising more than $2^n(1 - 2^{-k})$ assignments cannot be represented by a k -CNF formula. Similarly, all Boolean functions can be expressed by DNF formulas but not by k -DNF formulas [129].

The partial evaluation of a given formula ψ is possible when a subset of its variables are assigned values. A partial evaluation usually results in the replacement of ψ by a new formula which expresses exactly those assignments satisfying ψ under the given partial assignment. Write $\psi|_{v=1}$ to denote the formula resulting from the partial evaluation of ψ due to assigning value 1 to variable v . An obvious similar statement is used to express the partial evaluation of ψ when v is assigned value 0 or when some subset of variables is assigned values. For example,

$$(v_1 \vee \neg v_2) \wedge (\neg v_1 \vee v_3) \wedge (\neg v_2 \vee \neg v_3)|_{v_1=1} = (v_3) \wedge (\neg v_2 \vee \neg v_3)$$

since $(v_3) \wedge (\neg v_2 \vee \neg v_3)$ expresses all solutions to $(v_1 \vee \neg v_2) \wedge (\neg v_1 \vee v_3) \wedge (\neg v_2 \vee \neg v_3)$ given v_1 has value 1.

If an assignment M is such that all the literals of a disjunctive (conjunctive) clause have value 0 (respectively, 1) under M , then the clause is said to be *falsified* (respectively, *satisfied*) by M . If M is such that at least one literal of a disjunctive (conjunctive) clause has value 1 (respectively, 0) under M , then the clause is said to be *satisfied* (respectively, *falsified*) by M . If a clause evaluates to \perp , then it is neither satisfied nor falsified.

A formula ψ is *satisfiable* if there exists at least one assignment under which ψ has value 1. In particular, a CNF formula is *satisfiable* if there exists a truth assignment to its variables which satisfies all its clauses. Otherwise, the formula is *unsatisfiable*. Every nonempty DNF formula is satisfiable, but a DNF formula that is satisfied by *every* truth assignment to its variables is called a *tautology*. The negation of a DNF tautology is an unsatisfiable CNF formula.

Several assignments may satisfy a given formula. Any satisfying assignment containing the smallest number of variables of value 1 among all satisfying assignments is called a *minimal model* with respect to 1. Thus, consistent with our definition of model as a set of variables of value 1, a minimal model is a set of variables of least cardinality. The usual semantics for Horn formula logic programming is the minimal model semantics: the only model considered is the (unique) minimal one.¹

¹Each satisfiable set of Horn clauses has a unique minimal model with respect to 1, which can be computed in linear time by a well-known algorithm [53, 78] which is discussed in Sect. 6.2. Implications of the minimal model semantics may be found in Sect. 6.5, among others.

If a CNF formula is unsatisfiable but removal of any clause makes it satisfiable, then the formula is said to be *minimally unsatisfiable*. Minimally unsatisfiable formulas play an important role in understanding the difference between *easy* and *hard* formulas.

This section ends with a discussion of formula equivalence. Three types of equivalence are defined along with symbols that are used to represent them as follows:

1. *Equality of formulas* ($\psi_1 = \psi_2$): two formulas are *equal* if they are the same string of symbols. Also “=” is used for equality of Boolean values, for example, $v = 1$.
2. *Logical equivalence* ($\psi_1 \Leftrightarrow \psi_2$): two formulas ψ_1 and ψ_2 are said to be logically equivalent if, for every assignment M to the variables of ψ_1 and ψ_2 , M satisfies ψ_1 if and only if M satisfies ψ_2 . For example, in the following expression, the two leftmost clauses on each side of “ \Leftrightarrow ” force v_1 and v_3 to have the same value so $(v_2 \vee v_3)$ may be substituted for $(v_1 \vee v_2)$. Therefore, the expression on the left of “ \Leftrightarrow ” is logically equivalent to the expression on the right.

$$(\neg v_1 \vee v_3) \wedge (v_1 \vee \neg v_3) \wedge (v_1 \wedge v_2) \Leftrightarrow (\neg v_1 \vee v_3) \wedge (v_1 \vee \neg v_3) \wedge (v_2 \wedge v_3).$$

Another example is

$$(v_1 \vee \neg v_2) \wedge (\neg v_1 \vee v_3) \wedge (\neg v_2 \vee \neg v_3) |_{v_1=1} \Leftrightarrow (v_3) \wedge (\neg v_2 \vee \neg v_3).$$

In the second example, assigning $v_1 = 1$ has the effect of eliminating the leftmost clause and the literal $\neg v_1$. After doing so, equivalence is clearly established.

It is important to point out the difference between $\psi_1 \Leftrightarrow \psi_2$ and $\psi_1 \Rightarrow \psi_2$. The former is an assertion that ψ_1 and ψ_2 are logically equivalent. The latter is just a formula of formal logic upon which one can ask whether there exists a satisfying assignment. The symbol “ \Leftrightarrow ” may not be included in a formula, and it makes no sense to ask whether a given assignment satisfies $\psi_1 \Leftrightarrow \psi_2$. It is easy to show that $\psi_1 \Leftrightarrow \psi_2$ if and only if $\psi_1 \Rightarrow \psi_2$ is a tautology (i.e., it is satisfied by every assignment to the variables of ψ_1 and ψ_2).

Similarly, define ψ_1 logically implies ψ_2 ($\psi_1 \Rightarrow \psi_2$): for every assignment M to the variables in ψ_1 and ψ_2 , if M satisfies ψ_1 , then M also satisfies ψ_2 . Thus, $\psi_1 \Leftrightarrow \psi_2$ if and only if $\psi_1 \Rightarrow \psi_2$ and $\psi_2 \Rightarrow \psi_1$. Also, $\psi_1 \Rightarrow \psi_2$ if and only if $\psi_1 \rightarrow \psi_2$ is a tautology.

3. *Functional equivalence* ($\psi_1 \Leftarrow_V \psi_2$): two formulas ψ_1 and ψ_2 , with variable sets V_{ψ_1} and V_{ψ_2} , respectively, are said to be functionally equivalent with respect to *variable base set* $V \subseteq V_{\psi_1} \cap V_{\psi_2}$ if, for every assignment M_V to just the variables of V , either:
 - a. There is an assignment M_1 to $V_{\psi_1} \setminus V$ and an assignment M_2 to $V_{\psi_2} \setminus V$ such that $M_V \cup M_1$ satisfies ψ_1 and $M_V \cup M_2$ satisfies ψ_2 or
 - b. There is no assignment to $V_{\psi_1} \cup V_{\psi_2}$ which contains M_V as a subset and satisfies either ψ_1 or ψ_2 .

The assignments $M_V \cup M_1$ and $M_V \cup M_2$ are called *extensions* to the assignment M_V .

The notation $\psi_1 \leftrightharpoons_V \psi_2$ is used to represent the functional equivalence of formulas ψ_1 and ψ_2 with respect to base set V . The notation $\psi_1 \leftrightharpoons \psi_2$ is used if $V = V_{\psi_1} \cap V_{\psi_2}$. In this case logical equivalence and functional equivalence are the same.

For example, $(\neg a) \wedge (a \vee b) \leftrightharpoons_{\{\neg a\}} (\neg a) \wedge (a \vee c)$ because $\exists b : (\neg a) \wedge (a \vee b)$ if and only if $\exists c : (\neg a) \wedge (a \vee c)$. But $(\neg a) \wedge (a \vee b) \neq (\neg a) \wedge (a \vee c)$ since $a = 0, b = 1, c = 0$ satisfies $(\neg a) \wedge (a \vee b)$ but falsifies $(\neg a) \wedge (a \vee c)$.

Functional equivalence is useful when transforming a formula to a more useful formula. For example, consider the Tseitin transformation [139] (Sect. 5.3) which extends resolution: for CNF formula ψ containing variables from set V_ψ , any pair of variables $x, y \in V_\psi$, and variable $z \notin V_\psi$,

$$\psi \leftrightharpoons_{V_\psi} \psi \wedge (z \vee x) \wedge (z \vee y) \wedge (\neg z \vee \neg x \vee \neg y).$$

The term *functional equivalence* is somewhat of a misnomer. For any set V of variables, \leftrightharpoons_V is an equivalence relation but \leftrightharpoons is not transitive: for example, $a \vee c \leftrightharpoons a \vee b$ and $a \vee b \leftrightharpoons a \vee \neg c$ but $a \vee c \not\leftrightharpoons a \vee \neg c$.

The foundational problem considered in this chapter is the satisfiability problem, commonly called SAT. It is stated as follows:

Satisfiability (SAT)

Given: A Boolean formula ψ .

Question: Determine whether ψ is satisfied by some truth assignment to the variables of ψ .

For the class of CNF, even 3-CNF, formulas, SAT is \mathcal{NP} -hard. However, for the class of CNF formulas of maximum width 2, SAT can be solved in linear time using Algorithm 19 of Sect. 6.1. For the class of Horn formulas, SAT can be solved in linear time using Algorithm 20 of Sect. 6.2. If ψ is a CNF formula such that reversing the polarity of some subset of its variables results in a Horn formula, then ψ is *renamable Horn*. Satisfiability of a renamable Horn formula can be determined in linear time by Algorithm 21 of Sect. 6.4.

The problem of determining the satisfiability of k -CNF formulas is referred to as k -SAT. In that context, input formulas are said to be instances of k -SAT or k -SAT formulas.

A second problem of interest is a generalization of the common problem of determining a minimal model for a given formula. The question of minimal models is considered in Sect. 6.2.

Variable-Weighted Satisfiability

Given: A CNF formula ψ and a function $w : V \mapsto \mathbb{Z}^+$ where $w(v)$ is the weight of variable v .

Question: Determine whether ψ is satisfied by some truth assignment and, if so, determine the assignment M such that

$$\sum_{v \in M} w(v) \text{ is minimized.}$$

A third problem of interest is the fundamental optimization version of SAT. This problem is probably more important in terms of practical use than even SAT.

Maximum Satisfiability (MAX-SAT)

Given: A CNF formula ψ .

Question: Determine the assignment M that satisfies the maximum number of clauses in ψ .

The following is an important variant of MAX-SAT:

Weighted Maximum Satisfiability (Weighted MAX-SAT)

Given: A CNF formula ψ and a function $w : C_\psi \mapsto \mathbb{Z}^+$ where $w(c)$ is the weight of clause $c \in C_\psi$.

Question: Determine the assignment M such that

$$\sum_{c \in \psi} w(c) \cdot s_M(c) \text{ is maximized,}$$

where $s_M(c)$ is 1 if clause c is satisfied by M and is 0 otherwise.

3 Representations and Structures

Algorithmic concepts are usually easier to specify and understand if a formula or a particular part of a formula is suitably represented. Many representations are possible for Boolean formulas, particularly when expressed as CNF or DNF formulas. As mentioned earlier, CNF and DNF formulas will often be represented as sets of clauses and clauses as sets of literals. In this section additional representations are presented; these will later be used to express algorithms and explain algorithmic behavior. Some of these representations involve only a part of a given formula.

3.1 (0 ± 1) Matrix

A CNF formula of m clauses and n variables may be represented as an $m \times n$ (0 ± 1) -matrix \mathcal{M} where the rows are indexed on the clauses, the columns are indexed on the variables, and a cell $\mathcal{M}(i, j)$ has the value $+1$ if clause i contains variable j as a positive literal, the value -1 if clause i contains variable j as a negative literal, and the value 0 if clause i does not contain variable j as a positive or negative literal. [Figure 1](#) shows an example of a CNF formula and its (0 ± 1) matrix representation.

It is well known that the question of satisfiability of a given CNF formula ψ can be cast as an integer program as follows:

$$\mathcal{M}_\psi \alpha + b \geq \mathbf{Z}, \quad (1)$$

$$\alpha_i \in \{0, 1\}, \text{ for all } 0 \leq i < n,$$

where \mathcal{M}_ψ is the (0 ± 1) matrix representation of ψ , \mathbf{b} is an integer vector with b_i equal to the number of -1 entries in row i of \mathcal{M}_ψ , and \mathbf{Z} is a vector of 1s. A solution to this system of inequalities certifies ψ is satisfiable. In this case a model can be obtained directly from α as α_i is the value of variable v_i . If there is no solution to the system, then ψ is unsatisfiable.

In addition to the well-known matrix operations, two matrix operations that are relevant to SAT algorithms on (0 ± 1) matrix representations are applied in this chapter. The first is column scaling: a column may be multiplied or *scaled* by -1 which has the effect of reversing the polarity of a single variable. Every solution before scaling corresponds to a solution after scaling; the difference is that the values of variables associated with scaled columns are reversed. The second is row and column reordering: rows and columns may be *permuted* with the effect on a solution being only a possible relabeling of variables taking value 1.

3.2 Binary Decision Diagrams

Binary decision diagrams [6, 103] are a general, graphical representation for arbitrary Boolean functions. Various forms have been put into use, especially for solving VLSI design and verification problems. A canonical form [27, 28] has been shown to be quite useful for representing some particular, commonly occurring, Boolean functions. An important advantage of BDDs is that the complexity of binary and unary operations such as existential quantification, logical or, and logical and, among others, is efficient with respect to the size of the BDD operands. Typically, a given formula ψ is represented as a large collection of BDDs and operations such as those stated above are applied repeatedly to create a single BDD which expresses the models, if any, of ψ . Intermediate BDDs are created in the process. Unfortunately, the size of intermediate BDDs may become extraordinarily and impractically large even if the final BDD is small. So in some applications BDDs are useful and in some they are not.

A *binary decision diagram* (BDD) is a rooted, directed acyclic graph. A BDD is used to compactly represent the truth table, and therefore complete functional description, of a Boolean function. Vertices of a BDD are called *terminal* if they have no outgoing edges and are called *internal* otherwise. There is one internal vertex, called the *root*, which has no incoming edge. There is at least one terminal vertex, labeled 1, and at most two terminal vertices, labeled 0 and 1. Internal vertices are labeled to represent the variables of the corresponding Boolean function. An internal vertex has exactly two outgoing edges, labeled 1 and 0. The vertices incident to edges outgoing from vertex v are called *then*(v) and *else*(v), respectively. Associated with any internal vertex v is an attribute called *index*(v) which satisfies the properties $\text{index}(v) < \min\{\text{index}(\text{then}(v)), \text{index}(\text{else}(v))\}$ and $\text{index}(v) = \text{index}(w)$ if and only if vertices v and w have the same labeling (i.e., correspond to the same variable). Thus, the *index* attribute imposes a linear ordering on the variables of a BDD. An example of a formula and one of its BDD representations is given in Fig. 2.

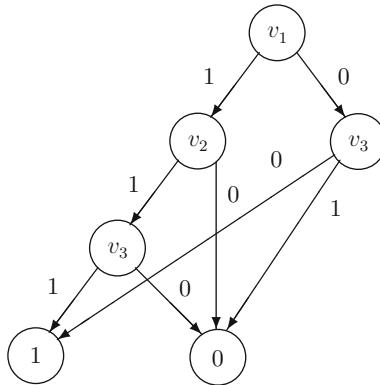

Fig. 2 The formula $(v_1 \vee \neg v_3) \wedge (\neg v_1 \vee v_2) \wedge (\neg v_1 \vee \neg v_2 \vee v_3)$ represented as a BDD. The topmost vertex is the root. The two bottom vertices are terminal vertices. Edges are directed from upper vertices to lower vertices. Vertex labels (variable names) are shown inside the vertices. The 0 branch out of a vertex labeled v means v takes the value 0. The 1 branch out of a vertex labeled v means v takes the value 1. The *index* of a vertex is, in this case, the subscript of the variable labeling that vertex

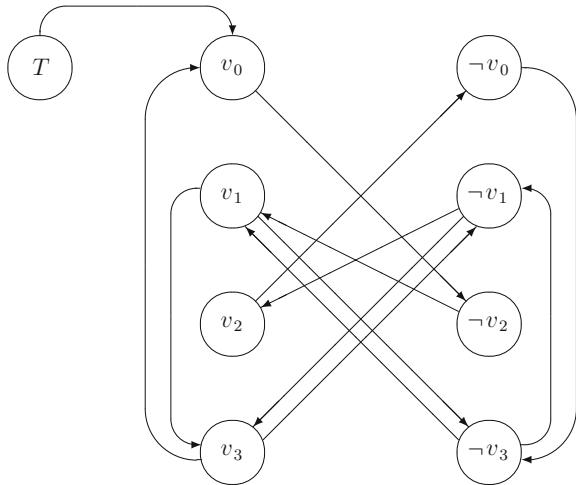

Clearly, there is no unique BDD for a given formula. In fact, for the same formula, one BDD might be extraordinarily large and another might be rather compact. It is usually advantageous to use the smallest BDD possible. At least one canonical form of BDD, called *reduced ordered BDD*, does this [27, 28]. The idea is to order the variables of a formula and construct a BDD such that (1) variables contained in a path from the root to any leaf respect that ordering and (2) each vertex is the root of a BDD that represents a Boolean function that is unique with respect to all other vertices. Two Boolean functions are equivalent if their reduced ordered BDDs are isomorphic. A more detailed explanation is given in Sect. 5.9.

3.3 Implication Graph

An *implication graph* of a CNF formula ψ is a directed graph $\vec{G}_\psi(V, \vec{E})$ where V consists of one special vertex T which corresponds to the value 1, other vertices which correspond to the literals of ψ , and the edge set \vec{E} such that there is an edge $\langle v_i, v_j \rangle \in \vec{E}$ if and only if there is a clause $(\neg v_i \vee v_j)$ in ψ and an edge $\langle T, v_i \rangle \in \vec{E}$ ($\langle T, \neg v_i \rangle \in \vec{E}$) if and only if there is a unit clause (v_i) (respectively, $(\neg v_i)$) in ψ . Figure 3 shows an example of an implication graph for a particular 2-CNF formula.

Implication graphs are most useful for, but not restricted to, 2-CNF formulas. In this role the meaning of an edge $\langle v_i, v_j \rangle$ is as follows: *if variable v_i is assigned the value 1 then variable v_j is inferred to have value 1, or else the clause $(\neg v_i \vee v_j)$ will be falsified.*

Fig. 3 An implication graph and associated 2-CNF formula

$$((v_0) \wedge (\neg v_0 \vee \neg v_2) \wedge (v_1 \vee v_2) \wedge (\neg v_1 \vee \neg v_3) \wedge \\ (\neg v_1 \vee v_3) \wedge (v_1 \vee v_3) \wedge (v_0 \vee \neg v_3))$$

3.4 Propositional Connection Graph

A *propositional connection graph* for a CNF formula ψ is an undirected graph $G_\psi(V, E)$ whose vertex set corresponds to the clauses of ψ and whose edge set is such that there is an edge $\{c_i, c_j\} \in E$ if and only if the clause in ψ represented by vertex c_i has a literal that appears negated in the clause represented by vertex c_j , and there is no other literal in c_i 's clause that appears negated in c_j 's clause. An example of a connection graph for a particular CNF formula is given in Fig. 4. Propositional connection graphs are a specialization of the first-order connection graphs developed by Kowalski [102].

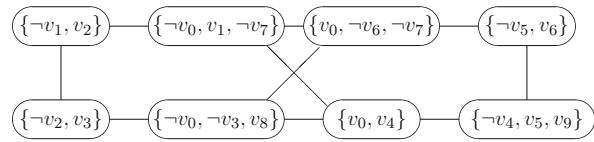

3.5 Variable-Clause Matching Graph

A *variable-clause matching graph* for a CNF formula is an undirected bipartite graph $G = (V_1, V_2, E)$ where V_1 vertices correspond to clauses and V_2 vertices correspond to variables and whose edge set contains an edge $\{v_i, v_j\}$ if and only if $v_i \in V_1$ corresponds to a variable that exists, either as positive or negative literal, in clause $v_j \in V_2$. An example of a variable-clause matching graph is shown in Fig. 5.

3.6 Formula Digraph

Formulas are defined recursively on Page 313. Any Boolean formula can be adapted to fit this definition with the suitable addition of parentheses, and its structure

Fig. 4 A propositional connection graph and associated CNF formula

$$((\neg v_0 \vee v_1 \vee \neg v_7) \wedge (\neg v_1 \vee v_2) \wedge (\neg v_2 \vee v_3) \wedge (\neg v_0 \vee \neg v_3 \vee v_8) \wedge \\ (v_0 \vee \neg v_6 \vee \neg v_7) \wedge (\neg v_5 \vee v_6) \wedge (\neg v_4 \vee v_5 \vee v_9) \wedge (v_0 \vee v_4))$$

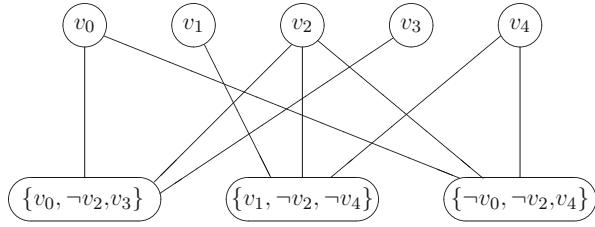

Fig. 5 A variable-clause matching graph and associated CNF formula

$$((v_0 \vee \neg v_2 \vee v_3) \wedge (v_1 \vee \neg v_2 \vee \neg v_4) \wedge (\neg v_0 \vee \neg v_2 \vee v_4))$$

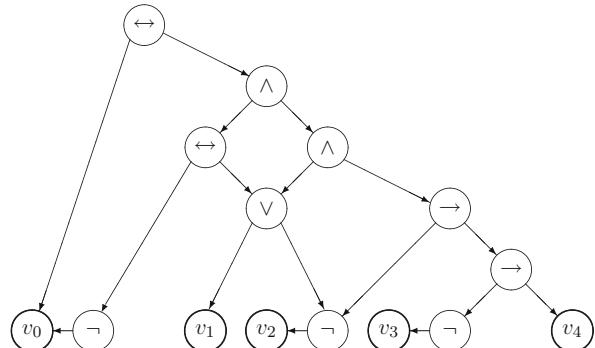

Fig. 6 A formula digraph and associated formula

$$v_0 \leftrightarrow ((\neg v_0 \leftrightarrow (v_1 \vee \neg v_2)) \wedge (v_1 \vee \neg v_2) \wedge (\neg v_2 \rightarrow \neg v_3 \rightarrow v_4))$$

(as opposed to its functionality) can be represented by a binary rooted acyclic digraph. In such a digraph, each internal vertex corresponds to a binary operator or a unary operator \neg that occurs in the formula. A vertex corresponding to a binary operator has two outward-oriented edges: the left edge corresponds to the left subformula and the right edge to the right subformula operated on. A vertex corresponding to \neg has one outward directed edge. The root represents the operator applied at top level. The leaves are variables. Call such a representation a *wff digraph*. An example is given in Fig. 6. An efficient algorithm for constructing a wff digraph is given in Sect. 5.1.

3.7 Satisfiability Index

Let ψ be a CNF formula and let \mathcal{M}_ψ be its (0 ± 1) matrix representation. Let $\alpha = (\alpha_0, \alpha_1, \dots, \alpha_{n-1})$ be an n -dimensional vector of real variables. Let z be a real variable and let $Z = (z, z, \dots, z)$ be an m dimensional vector where every component is the variable z . Finally, let $b = (b_0, b_1, \dots, b_{m-1})$ be an m dimensional vector such that for all $0 \leq i < m$, b_i is the number of negative literals in clause c_i . Form the system of inequalities

$$\mathcal{M}_\psi \alpha + b \leq Z, \quad (2)$$

$$0 \leq \alpha_i \leq 1 \text{ for all } 0 \leq i < n.$$

The satisfiability index of ψ is the minimum z for which no constraints of the system are violated. For example, the CNF formula

$$((v_1 \vee \neg v_2) \wedge (v_2 \vee \neg v_3 \vee v_5) \wedge (v_3 \vee \neg v_4 \vee \neg v_5) \wedge (v_4 \vee \neg v_1))$$

has satisfiability index of 5/4.

3.8 And/Inverter Graphs

An AIG is a directed acyclic graph where all *gate* vertices have in-degree 2, all *input* vertices have in-degree 0, all *output* vertices have in-degree 1, and edges are labeled as either *negated* or *not negated*. Any combinational circuit can be equivalently implemented as a circuit involving only 2-input *and* gates and *not* gates. Such a circuit has an AIG representation: *gate* vertices correspond directly to the *and* gates, negated edges correspond directly to the *not* gates, and inputs and outputs represent themselves directly. Negated edges are typically labeled by overlaying a white circle on the edge: this distinguishes them from non-negated edges which are unlabeled. Examples are shown in Fig. 7.

4 Applications

This section presents a sample of real-world problems that may be viewed as, or transformed to, instances of SAT. Of primary interest is to explore the thinking process required for setting up logic problems and gauging the complexity of the resulting systems. Since it is infeasible to meet this objective and thoroughly discuss a large number of known applications, a small but varied and interesting collection of problems are discussed.

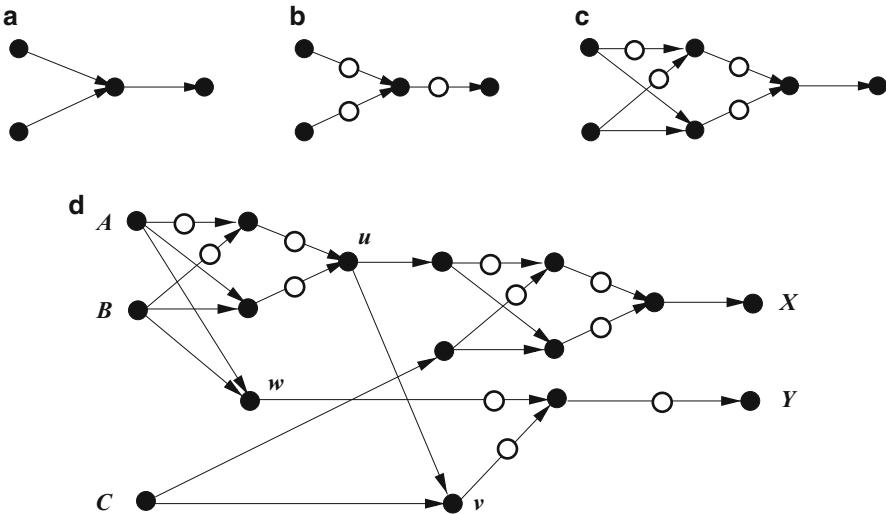

Fig. 7 Examples of AIGs. Edges with white circles are negated. Edges without a white circle are not negated. (a) and gate. (b) or gate. (c) xor gate. (d) 1-bit add circuit of Fig. 9

4.1 Consistency Analysis in Scenario Projects

This application, taken from the area of scenario management [8, 54, 63], is contributed by Feldmann and Sensen [57] of Burkhard Monien's old PC² group at Universität Paderborn, Germany. A *scenario* consists of (i) a progression of events from a known base situation to a possible terminal future situation and (ii) a means to evaluate its likelihood. Scenarios are used by managers and politicians to strategically plan the use of resources needed for solutions to environmental, social, economic, and other such problems.

A systematic approach to scenario management due to Gausemeier, Fink, and Schlake [62] involves the realization of *scenario projects* with the following properties:

1. There is a set S of *key factors*. Let the number of key factors be n .
2. For each key factor $s_i \in S$, there is a set $D_i = \{d_{i,1}, d_{i,2}, \dots, d_{i,m_i}\}$ of m_i possible *future developments*. In the language of databases, key factors are *attributes* and future developments are attribute *values*.
3. For all $1 \leq i \leq n$, $1 \leq k \leq m_i$, denote by $(s_i, d_{i,k})$ a feasible *projection* of development $d_{i,k} \in D_i$ from key factor s_i . For each pair of projections $(s_i, d_{i,k}), (s_j, d_{j,l})$, a *consistency value*, usually an integer ranging from 0 to 4, is defined. A consistency value of 0 typically means two projections are completely inconsistent, a value of 4 typically means the two projections support each other strongly, and the other values account for intermediate levels of support.

Consistency values may be organized in a $\sum_{i=1}^n m_i \times \sum_{i=1}^n m_i$ matrix with rows and columns indexed on projections.

4. Projections for all key factors may be *bundled* into a vector $x = (x_{s_1}, \dots, x_{s_n})$ where x_{s_i} is a future development of key factor s_i , $i = 1, 2, \dots, n$. In the language of databases, a bundle is a *tuple* which describes an assignment of values to each attribute.
5. The *consistency* of bundle x is the sum of the consistency values of all pairs $(s_i, x_{s_i}), (s_j, x_{s_j})$ of projections represented by x if no pair has consistency value of 0, and is 0 otherwise.

Bundles with greatest (positive) consistency are determined and clustered. Each cluster is a scenario.

To illustrate, consider a simplified example from [57] which is intended to develop likely scenarios for the German school system over the next 20 years. It was felt by experts that 20 key factors are needed for such forecasts; to keep the example small, only the first 10 are shown. The first five key factors and their associated future developments are as follows: $[s_1]$ *continuing education* ($[d_{1.1}]$ lifelong learning), $[s_2]$ *importance of education* ($[d_{2.1}]$ important, $[d_{2.2}]$ unimportant), $[s_3]$ *methods of learning* ($[d_{3.1}]$ distance learning, $[d_{3.2}]$ classroom learning), $[s_4]$ *organization and policies of universities* ($[d_{4.1}]$ enrollment selectivity, $[d_{4.2}]$ semester schedules), and $[s_5]$ *adequacy of trained people* ($[d_{5.1}]$ sufficiently many, $[d_{5.2}]$ not enough).

The table in Fig. 8, called a *consistency matrix*, shows the consistency values for all possible pairs of future developments. The s_i, s_j cell of the matrix shows the consistency values of pairs $\{(s_i, d_{i,x}), (s_j, d_{j,y}) : 1 \leq x \leq m_i, 1 \leq y \leq m_j\}$, with all pairs which include $(s_i, d_{i,x})$ on the x th row of the cell. For example, $|D_5| = 2$ and $|D_2| = 2$, so there are 4 numbers in cell s_5, s_2 and the consistency value of $(s_5, d_{5.2}), (s_2, d_{2.2})$ is the bottom right number of that cell. That number is 0 because experts have decided the combination of there being too few trained people ($d_{5.2}$) at the same time education is considered unimportant ($d_{2.2}$) is unlikely.

It is relatively easy to compute the consistency of a given bundle from this table. One possible bundle of future developments is $\{(s_i, d_{i,1}) : 1 \leq i \leq 10\}$. Since the consistency value of $\{(s_5, d_{5,1}), (s_2, d_{2,1})\}$ is 0, this bundle is inconsistent. Another possible bundle is

$$\begin{aligned} &\{(s_1, d_{1,1}), (s_2, d_{2,1}), (s_3, d_{3,1}), (s_4, d_{4,1}), (s_5, d_{5,2}), \\ &(s_6, d_{6,3}), (s_7, d_{7,1}), (s_8, d_{8,2}), (s_9, d_{9,1}), (s_{10}, d_{10,2})\}. \end{aligned}$$

Its consistency value is 120 (the sum of the 45 relevant consistency values from the table).

Finding good scenarios from a given consistency matrix requires efficient answers to the following questions:

1. Does a consistent bundle exist?
2. How many consistent bundles exist?
3. What is the bundle having the greatest consistency?

Fig. 8 A consistency matrix for a scenario project**Table 3** Formula to determine existence of a consistent bundle

Clause of $\psi^{S,D}$	Subscript range	Meaning
$(\neg v_{i,j} \vee \neg v_{i,k})$	$1 \leq i \leq n, 1 \leq j < k \leq m_i$	≤ 1 development/key factor
$(v_{i,1} \vee \dots \vee v_{i,m_i})$	$1 \leq i \leq n$	≥ 1 development/key factor
$(\neg v_{i,k} \vee \neg v_{j,l})$	$i, j, k, l : C_{i,k,j,l} = 0$	Consistent developments only

Finding answers to these questions is \mathcal{NP} -hard [57]. But transforming to CNF formulas, in some cases with weights on proposition letters, and solving a variant of SAT are sometimes reasonable ways to tackle such problems. This context provides the opportunity to use our vast knowledge of SAT structures and analysis to apply an algorithm that has a reasonable chance of solving the consistency problems efficiently. It is next shown how to construct representative formulas so that, often, a large subset of clauses is polynomial-time solvable and the whole formula is relatively easy to solve.

Consider, first, the question whether a consistent bundle exists for a given consistency matrix of n key factors with m_i projections for factor i , $1 \leq i \leq n$. Let $C_{i,k,j,l}$ denote the consistency of the pair $(s_i, d_{i,k})(s_j, d_{j,l})$ and let $D = \cup_{i=1}^n D_i$. For each future development $d_{i,j}$, define variable $v_{i,j}$ which is intended to take the value 1 if and only if $d_{i,j}$ is a future development for key attribute s_i . The CNF formula $\psi^{S,D}$ with the clauses described in Table 3 then says that there is a consistent bundle. That is, the formula is satisfiable if and only if there is a consistent bundle.

The second question to be considered is how many consistent bundles exist for a given consistency matrix? This is the same as asking how many satisfying truth assignments there are for $\psi^{S,D}$. A simple inclusion-exclusion algorithm exhibits very good performance for some actual problems of this sort [57].

The third question is which bundle has the greatest consistency value? This question can be transformed to an instance of the variable-weighted satisfiability problem (defined on Page 318). The transformed formula consists of $\psi^{S,D}$ plus some additional clauses as follows. For each pair $(s_i, d_{i,k})(s_j, d_{j,l})$, $i \neq j$, of projections such that $C_{i,k,j,l} > 0$, create a new Boolean variable $p_{i,k,j,l}$ of weight $C_{i,k,j,l}$ and add the following subexpression to $\psi^{S,D}$:

$$(\neg v_{i,k} \vee \neg v_{j,l} \vee p_{i,k,j,l}) \wedge (v_{i,k} \vee \neg p_{i,k,j,l}) \wedge (v_{j,l} \vee \neg p_{i,k,j,l}).$$

Observe that a satisfying assignment requires $p_{i,j,k,l}$ to have value 1 if and only if $v_{i,k}$ and $v_{j,l}$ both have value 1, that is, if and only if the consistency value of $\{(s_i, d_{i,k}), (s_j, d_{j,l})\}$ is included in the calculation of the consistency value of the bundle.

If weight 0 is assigned to all variables other than the $p_{i,k,j,l}$'s, a maximum weight solution specifies a maximum consistency bundle. It should be pointed out that, although the number of clauses added to $\psi^{S,D}$ might be significant compared to the number of clauses originally in $\psi^{S,D}$, the total number of clauses will be linearly related to the size of the consistency matrix. Moreover, the set of additional clauses is a Horn subformula.² A maximum weight solution can be found by means of a branch-and-bound algorithm such as that discussed in Sect. 5.11.

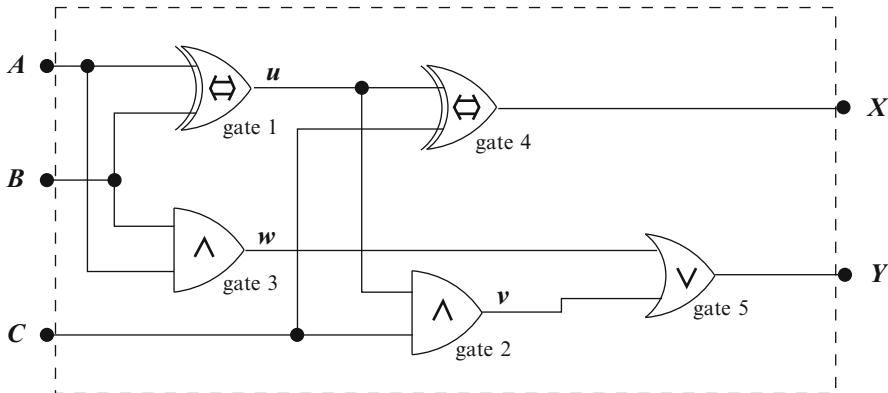

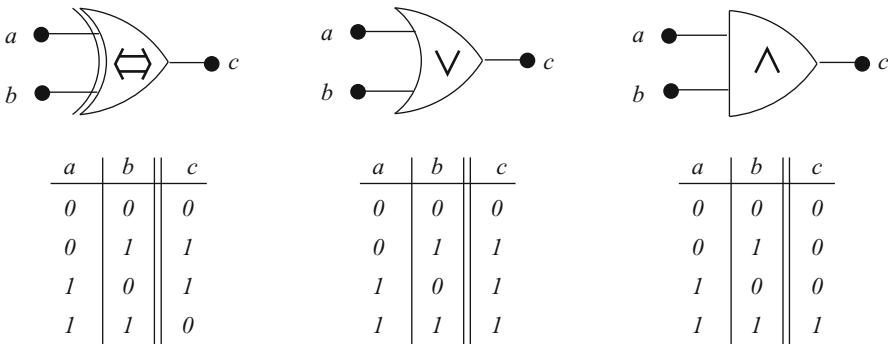

4.2 Testing of VLSI Circuits

A classic application is the design of test vectors for VLSI circuits. At the specification level, a combinational VLSI circuit is regarded to be a function mapping n 0-1 inputs to m 0-1 outputs.³ At the design level, the interconnection of numerous 0-1 logic gates are required to implement the function. Each connection entails an actual interconnect point that can fail during or soon after manufacture. Failure of an interconnect point usually causes the point to become *stuck-at* value 0 or 1.

Traditionally, VLSI circuit testing includes testing all interconnect points for stuck-at faults. This task is difficult because interconnect points are encased in plastic and are therefore inaccessible directly. The solution is to apply an input pattern to the circuit which excites the point under test *and* sensitizes a path through the circuit from the test point to some output so that the correct value at the test point can be determined at the output.

²Horn formulas are solved efficiently (see Sect. 6.2).

³Actual circuit voltage levels are abstracted to the values 0 and 1.

**Fig. 9** A 1-bit full adder circuit**Fig. 10** Truth tables for logic elements of a 1-bit full adder

The following example illustrates how such an input pattern and output is found for one internal point of a *1-bit full adder*: an elementary but ubiquitous functional hardware block that is depicted in Fig. 9. For the sake of discussion, assume a given circuit will have at most one stuck-at failure. The 1-bit full adder uses logic gates that behave according to the truth tables in Fig. 10 where a and b are gate inputs and c is a gate output. Suppose none of the interconnect points enclosed by the dashed line of Fig. 9 are directly accessible, and suppose it is desired to develop a test pattern to determine whether point w is stuck at 0. Then inputs must be set to give point w the value 1. This is accomplished by means of the Boolean expression $\psi_1 = (A \wedge B)$. The value of point w can only be observed at output Y . But this requires point v be set to 0. This can be accomplished if either the value of C is 0 or u is 0, and u is 0 if and only if A and B have the same value. Therefore, the Boolean expression representing sensitization of a path from w to Y is $\psi_2 = (\neg C \vee (A \wedge B) \vee (\neg A \wedge \neg B))$. The conjunction $\psi_1 \wedge \psi_2$ is the CNF expression $(A \wedge B)$. This expression is satisfied if and only if A and B are set to 1. Such an

input will cause output Y to have value 1 if w is not stuck at 0 and value 0 if w is stuck at 0, assuming no other interconnect point is stuck at some value.

Test patterns must be generated for all internal interconnect points of a VLSI circuit. There could be millions of these and the corresponding expressions could be considerably more complex than that of the example above. Moreover, testing is complicated by the fact that most circuits are not combinational: that is, they contain feedback loops. This last case is mitigated by adding circuitry for testing purposes only. The magnitude of the testing problem, although seemingly daunting, is not great enough to cause major concern at this time because it seems that SAT problems arising in this domain are usually easy. Thus, at the moment, the VLSI testing problem is considered to be under control. However, this may change in the near future since the number of internal points in a dense circuit is expected to continue to increase dramatically.

4.3 Diagnosis of Circuit Faults

A natural extension of the test design discussed in Sect. 4.2 is finding a way to automate the diagnosis of, say, bad chips, starting with descriptions of their bad outputs. How can one reason backwards to identify likely causes of the malfunction? Also, given knowledge that some components are more likely to fail than others, how can the diagnosis system be tailored to suggest the most likely causes first? The first of these questions is discussed in this section.

The first step is to write the Boolean expression representing both the normal and abnormal behavior of the analyzed circuit. This is illustrated using the circuit of Fig. 9. The expression is assembled in stages, one for each gate, starting with gate 3 of Fig. 9, which is an *and* gate. The behavior of a correctly functioning *and* gate is specified in the right-hand truth table in Fig. 10. The following formula expresses the truth table:

$$(a \wedge b \wedge c) \vee (\neg a \wedge \neg b \wedge c) \vee (\neg a \wedge b \wedge \neg c) \vee (\neg a \wedge \neg b \wedge \neg c).$$

If gate 3 is possibly stuck at 0, its functionality can be described by adding variable Ab_3 (for *gate 3 is abnormal*) and substituting A, B , and w for a, b , and c , to get the following abnormality expression:

$$\begin{aligned} & (A \wedge B \wedge w \wedge \neg Ab_3) \vee (\neg A \wedge \neg B \wedge w \wedge \neg Ab_3) \vee \\ & (\neg A \wedge B \wedge \neg w \wedge \neg Ab_3) \vee (\neg A \wedge \neg B \wedge \neg w \wedge \neg Ab_3) \vee (\neg w \wedge Ab_3) \end{aligned}$$

which has value 1 if and only if gate 3 is functioning normally for inputs A and B or it is functioning abnormally and w is stuck at 0. The extra variable may be regarded as a switch which allows toggling between abnormal and normal states for gate 3. Similarly, switches Ab_1, Ab_2, Ab_4 , and Ab_5 may be added for all the other gates in

Table 4 Possible stuck-at-0 failures of 1-bit adder gates (see Fig. 9) assuming given inputs are $A = 0$ and $B, C = 1$ and observed outputs are $X, Y = 0$. This is the list of assignments to Δ which satisfy the abnormality predicates for the 1-bit adder. A “1” in the column for Ab_i means gate i is stuck at 0

IDs	Ab_1	Ab_2	Ab_3	Ab_4	Ab_5
1–16	*	*	*	*	1
17–24	*	1	*	*	0
25–26	1	0	*	1	0

The symbol “*” means either “0” or “1”

the circuit, and corresponding expressions may be constructed using those switches. Then the set

$$\Delta = \{Ab_1, Ab_2, Ab_3, Ab_4, Ab_5\}$$

represents all possible explanations for stuck-at-0 malfunctions. The list of assignments to the variables of Δ which satisfy the collection of abnormality expressions, given particular inputs and observations, determines all possible combinations of stuck-at-0 failures in the circuit. The next task is to choose the most likely failure combination from the list. This requires some assumptions which are motivated by the following examples.

Suppose that, during some test, inputs are set to $A = 0$ and $B, C = 1$ and the observed output values are $Y = 0$ and $X = 1$ whereas $Y = 1$ and $X = 0$ are the correct outputs. One can reason backwards to try to determine which gates are stuck at 0. Gate 4 cannot be stuck at 0 since its output is 1. Suppose gate 4 is working correctly. Since the only gate that gate 4 depends on is gate 1, that gate must be stuck. One cannot tell whether gates 2, 3, and 5 are functioning; normally it would be assumed that they are functioning correctly until evidence to the contrary is obtained. Thus, the natural diagnosis is gate 1 is defective (only Ab_1 has value 1).

Alternatively, suppose under the same inputs it is observed that $X, Y = 0$. Possibly, gates 5 and 4 are malfunctioning. If so, all other combinations of gate outputs will lead to the same observable outputs. If gate 5 is defective but gate 4 is good, then $u = 1$ so gate 1 is good, and any possible combinations of w and v lead to the same observable outputs. If gate 5 is good and gate 4 is defective, the bad Y value may be caused by a defective gate 2. In that case gates 1 and 3 conditions do not affect the observed outputs. But if gate 2 is not defective, the culprit must be gate 1. If gates 4 and 5 are good, then $u = 1$ so gate 2 is defective. Nothing can be determined about the condition of gate 3 through this test. The results of this paragraph lead to 26 abnormal Δ values that witness the observed outputs: these are summarized in Table 4, grouped into three cases. In the first two of these cases, the minimum number of gates stuck at 0 is 1.

As before, it is assumed that the set of malfunctioning gates is as small as possible, so only those two diagnoses are considered: that is, either (i) gate 5 or (ii) gate 2 is defective. In general, it is argued, common sense leads us to consider

only *minimal* sets of abnormalities: sets, like gate 2 above, where no proper subset is consistent with the observations. This is Reiter's *principle of parsimony* [117]:

A diagnosis is a conjecture that some minimal set of components are faulty.

This sort of inference is called *non-monotonic* because it is inferred, above, that gate 3 was functioning correctly, since there is no evidence it was not. Later evidence may cause that inference to be withdrawn.

Yet a further feature of non-monotonic logic may be figured into such systems; the following illustrates the idea. Suppose it is known that one component, say, gate 5, is the least likely to fail. Then, if there are any diagnoses in which gate 5 does not fail, it will report only such diagnoses. If gate 5 fails in all diagnoses, then it will report all the diagnoses. Essentially, this reflects a kind of preference relationship among diagnoses.

There is now software which automates this diagnosis process (e.g., [66]). Although worst-case performance of such systems is provably bad, such a system can be useful in many circumstances. Unfortunately, implementations of non-monotonic inference are new enough that there is not yet a sufficiently large body of standard benchmark examples.

4.4 Functional Verification of Hardware Design

Proving correctness of the design of a given block of hardware has become a major concern due to the complexity of present day hardware systems and the economics of product delivery time. Prototyping is no longer feasible since it takes too much time and fabrication costs are high. Breadboarding no longer gives reliable results because of the electrical differences between integrated circuits and discrete components. Simulation-based methodologies are generally fast but do not completely validate a design since there are many cases left unconsidered. Formal verification methods can give better results, where applicable, since they will catch design errors that may go undetected by a simulation.

Formal verification methods are used to check correctness by detecting errors in translation between abstract levels of the design hierarchy. Design hierarchies are used because it is impractical to design a VLSI circuit involving millions of components at the substrate, or lowest, level of abstraction. Instead, it is more reasonable to design at the specification or highest level of abstraction and use software tools to translate the design, through some intermediate stages such as the logic-gate level, to the substrate level. The functionality between a pair of levels may be compared. In this case, the more abstract level of the pair is said to be the *specification* and the other level is the *implementation* level of the pair. If functionality is equivalent between all adjacent pairs of levels, the design is said to be *verified*.

Determining functional equivalence (defined on Page 317) between levels amounts to proving a theorem of the form *implementation I realizes specification S* in a particular, suitable formal proof system. For illustration purposes only, consider the 1-bit full adder of Fig. 9. Inputs *A* and *B* represent a particular bit position of

two different binary addends. Input C is the carry due to the addition at the next lower valued bit position. Output X is the value of the same bit position of the sum and output Y is the carry to the next higher valued bit position. The output X must have value 1 if and only if all inputs have value 1 or exactly one input has value 1. The output Y has value 1 if and only if at least two out of three inputs have value 1. Therefore, the following simple Boolean expression offers a reasonable specification of any 1-bit full adder:

$$(X \Leftrightarrow (A \wedge \neg B \wedge \neg C) \vee (\neg A \wedge B \wedge \neg C) \vee (\neg A \wedge \neg B \wedge C) \vee (A \wedge B \wedge C)) \wedge \\ (Y \Leftrightarrow (A \wedge B) \vee (A \wedge C) \vee (B \wedge C)).$$

A proposed implementation of this specification is given in the dotted region of Fig. 9. Its behavior may be described by a Boolean expression that equates each gate output to the corresponding logical function applied to its inputs. The following is such an expression:

$$(u \Leftrightarrow (A \wedge \neg B) \vee (\neg A \wedge B)) \wedge \\ (v \Leftrightarrow u \wedge C) \wedge \\ (w \Leftrightarrow A \wedge B) \wedge \\ (X \Leftrightarrow (u \wedge \neg C) \vee (\neg u \wedge C)) \wedge \\ (Y \Leftrightarrow w \vee v).$$

Designate these formulas $\psi_S(A, B, C, X, Y)$ and $\psi_I(A, B, C, X, Y, u, v, w)$, respectively. The adder correctly implements the specification if, for all possible inputs $A, B, C \in \{0, 1\}$, the output of the adder matches the specified output. For any individual inputs, A, B, C , that entails checking whether $\psi_I(A, B, C, X, Y, u, v, w)$ has value 1 for the appropriate u, v, w ,

$$\psi_S(A, B, C, X, Y) \Leftrightarrow \exists u, v, w \psi_I(A, B, C, X, Y, u, v, w),$$

where the quantification $\exists u, v, w$ is over *Boolean values* u, v, w . For *specific* A, B, C , the problem is a satisfiability problem: can values for u, v, w which make the formula have value 1 be found? (Of course, it is an easy satisfiability problem in this case.) Thus, the question of whether the adder correctly implements the specification for all 32 possible input sequences is answered using the formula:

$$\forall A, B, C, X, Y (\psi_S(A, B, C, X, Y) \Leftrightarrow \exists u, v, w \psi_I(A, B, C, X, Y, u, v, w)),$$

which has a second level of Boolean quantification. Such formulas are called *quantified Boolean formulas*.

The example of the 1-bit full adder shows how combinational circuits can be verified. A characteristic of combinational circuits is that output behavior is strictly a function of the current values of inputs and does not depend on past history.

Table 5 The operators of temporal logic

Op. name	$(S, s_i) \models$	If and only if
	p (p a variable)	$s_i(p) = 1$
<i>Not</i>	$\neg\psi_1$	$(S, s_i) \not\models \psi_1$
<i>And</i>	$\psi_1 \wedge \psi_2$	$(S, s_i) \models \psi_1$ and $(S, s_i) \models \psi_2$
<i>Or</i>	$\psi_1 \vee \psi_2$	$(S, s_i) \models \psi_1$ or $(S, s_i) \models \psi_2$
<i>Henceforth</i>	$\Box\psi_1$	$(S, s_j) \models \psi_1$ for all states s_j , $j \geq i$
<i>Eventually</i>	$\Diamond\psi_1$	$(S, s_j) \models \psi_1$ for some state s_j , $j \geq i$
<i>Next</i>	$\circ\psi_1$	$(S, s_{i+1}) \models \psi_1$
		For some $j \geq i$,
<i>Until</i>	$\psi_1 \mathcal{U} \psi_2$	$(S, s_i), (S, s_{i+1}), \dots, (S, s_{j-1}) \models \psi_1$, and $(S, s_j) \models \psi_2$

However, circuits frequently contain components, such as registers, which exhibit some form of time dependency. Such effects may be modeled by some form of *propositional temporal logic*.

Systems of temporal logic have been applied successfully to the verification of some sequential circuits including microprocessors. One may think of a sequential circuit as possessing one of a finite number of valid *states* at any one time. The current state of such a circuit embodies the complete electrical signal history of the circuit beginning with some distinguished initial state. A change in the electrical properties of a sequential circuit at a particular moment in time is represented as a fully deterministic movement from one state to another based on the current state and a change in some subset of input values only. Such a change in state is accompanied by a change in output values.

A description of several temporal logics can be found in [149]. For illustrative purposes, one of these is discussed below, namely, the linear time temporal logic (LTTL). LTTL formulas take value 1 with respect to an infinite sequence of states $S = \{s_0, s_1, s_2, \dots\}$. States of S obey the following: state s_0 is a *legal* initial state of the system, state s_i is a *legal* state of the system at time step i , and every pair s_i, s_{i+1} must be a *legal* pair of states. Legal pairs of states are forced by some of the components of the formula itself (the latch example at the end of this section illustrates this). Each state is just an interpretation of an assignment of values to a set of Boolean variables.

LTTL is an extension of the propositional calculus that adds one binary and three unary *temporal* operators which are described below and whose semantics are outlined in Table 5 along with the standard propositional operators \neg , \wedge , and \vee (the definition of $(S, s_i) \models$ is given below). The syntax of LTTL formulas is the same as for propositional logic except for the additional operators.

Let ψ be a LTTL expression that includes a component representing satisfaction of some desired property in a given circuit. An example of a property for a potential JK flip-flop might be that *it is eventually possible to have a value of 1 for output Q while input J has value 1* which has a corresponding formula $\Diamond(J \wedge Q)$. The event that ψ has value 1 for state s_i in S is denoted by

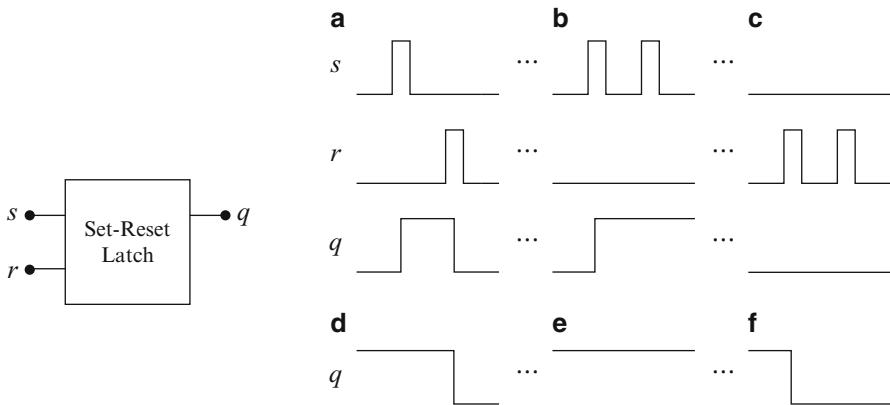

Fig. 11 A set-reset latch and complete description of signal behavior. Inputs are s and r , output is q . The horizontal axis represents time. The vertical axis represents signal value for both inputs and output. Values of all signals are assumed to be either 0 (low) or 1 (high) at any particular time. Two rows for q values are used to differentiate between the cases where the initial value of q is 0 or 1

$$(S, s_i) \models \psi.$$

Also, say

$$S \models \psi \text{ if and only if } (S, s_0) \models \psi.$$

Finally, two LTTL formulas ψ_1 and ψ_2 are *equivalent* if, for all sequences S ,

$$S \models \psi_1 \text{ if and only if } S \models \psi_2.$$

Our example concerns a hardware device of two inputs and one output called a *set-reset latch*. The electrical behavior of such a device is depicted in Fig. 11 as a set of six waveforms which show the value of the output q in terms of the history of the values of inputs r and s . For example, consider waveform (a) in the Fig. 11. This shows the value of the output q , as a function of time, if initially q , r , and s have value 0 and then s is *pulsed* or raised to value 1 then some time later dropped to value 0. The waveform shows the value of q rises to 1 some time after s does and stays at value 1 after the value of s drops. The waveform (a) also shows that if q has value 1 and r and s have value 0 and then r is pulsed, the value of q drops to 0. Observe the two cases where (i) r and s have value 1 at the same moment and (ii) q changes value *after* s or r pulses are not allowed. The six waveforms are enough to specify the behavior of the latch because the device is simple enough that only *recent* history matters.

The specification of this behavior is given by the LTTL formula of Table 6. Observe that the first three expressions of Table 6 represent assumptions needed for the latch to work correctly and do not necessarily reflect requirements that can

Table 6 Temporal logic formula for a set-reset latch

Expressions	Comments
$\square \neg(s \wedge r)$	No two inputs have value 1 simultaneously
$\square((s \wedge \neg q) \rightarrow ((s \mathcal{U} q) \vee \square s))$	Input s cannot change if s is 1 and q is 0
$\square((r \wedge q) \rightarrow ((r \mathcal{U} \neg q) \vee \square r))$	Input r cannot change if r is 1 and q is 1
$\square(s \rightarrow \diamond q)$	If s is 1, q will eventually be 1
$\square(r \rightarrow \diamond \neg q)$	If r is 1, q will eventually be 0
$\square((\neg q \rightarrow ((\neg q \mathcal{U} s) \vee \square \neg q)))$	Output q rises to 1 only if s becomes 1
$\square((q \rightarrow ((q \mathcal{U} r) \vee \square q)))$	Output q drops to 0 only if r becomes 1

be realized within the circuitry of the latch itself. Care must be taken to insure that the circuitry in which a latch is placed meets those requirements.

Latch states are triples representing values of s , r , and q , respectively. Some examples, corresponding to state sequences depicted by waveforms (a)–(f) in Fig. 11, that satisfy the formula of Table 6 are as follows:

$$\begin{aligned} S_a &: (\langle 000 \rangle, \langle 100 \rangle, \langle 101 \rangle, \langle 001 \rangle, \langle 011 \rangle, \langle 010 \rangle, \langle 000 \rangle, \dots) \\ S_b &: (\langle 000 \rangle, \langle 100 \rangle, \langle 101 \rangle, \langle 001 \rangle, \langle 101 \rangle, \langle 001 \rangle, \dots) \\ S_c &: (\langle 000 \rangle, \langle 010 \rangle, \langle 000 \rangle, \langle 010 \rangle, \langle 000 \rangle, \dots) \\ S_d &: (\langle 001 \rangle, \langle 101 \rangle, \langle 001 \rangle, \langle 011 \rangle, \langle 010 \rangle, \langle 000 \rangle, \dots) \\ S_e &: (\langle 001 \rangle, \langle 101 \rangle, \langle 001 \rangle, \langle 101 \rangle, \langle 001 \rangle, \dots) \\ S_f &: (\langle 001 \rangle, \langle 011 \rangle, \langle 010 \rangle, \langle 000 \rangle, \langle 010 \rangle, \langle 000 \rangle, \dots) \end{aligned}$$

Clearly, infinitely many sequences satisfy the formula of Table 6, so the problem of verifying functionality for sequential circuits appears daunting. However, by means of careful algorithm design, it is sometimes possible to produce such verifications and successes have been reported. In addition, other successful temporal logic systems such as computation tree logic and interval temporal logic have been introduced, along with algorithms for proving theorems in these logics. The reader is referred to [149], ►Combinatorial Optimization Techniques for Network-Based Data Mining for details and citations.

4.5 Bounded Model Checking

Section 4.4 considered solving verification problems of the form $S \models \psi_1 \equiv S \models \psi_2$. If it is desired instead to determine whether there exists an S such that $S \models \psi$ temporal operators can be traded for Boolean variables, the sentence can be expressed as a propositional formula, and a SAT solver applied. The propositional formula must have the following parts:

1. Components which force the property or properties of the time-dependent expression to hold
2. Components which establish the starting state

3. Components which force legal state transitions to occur

In order for the Boolean expression to remain of reasonable size, it is generally necessary to bound the number of time steps in which the time-dependent expression is to be verified, thus the name *bounded model checking*.

As an example, consider a simple 2-bit counter whose outputs are represented by variables v_1 (LSB) and v_2 (MSB). Introduce variables v_1^i and v_2^i whose values are intended to be the same as those of variables v_1 and v_2 , respectively, on the i th time step. Suppose the starting state is the case where both v_1^0 and v_2^0 have value 0. The transition relation is

Current output		Next output
00	:	01
01	:	10
10	:	11
11	:	00

the i th line of which can be expressed as the following Boolean function:

$$(v_1^{i+1} \leftrightarrow \neg v_1^i) \wedge (v_2^{i+1} \leftrightarrow v_1^i \oplus v_2^i).$$

Suppose the time-dependent expression to be proved is as follows:

Can the two-bit counter reach a count of 11 in exactly three time steps?

Assemble the propositional formula having value 1 if and only if the above query holds as the conjunction of the following three parts:

1. *Force the property to hold:*

$$(\neg(v_1^0 \wedge v_2^0) \wedge \neg(v_1^1 \wedge v_2^1) \wedge \neg(v_1^2 \wedge v_2^2) \wedge (v_1^3 \wedge v_2^3)).$$

2. *Express the starting state:*

$$(\neg v_1^0 \wedge \neg v_2^0).$$

3. *Force legal transitions (repetitions of the transition relation):*

$$\begin{aligned} & (v_1^1 \leftrightarrow \neg v_1^0) \wedge (v_2^1 \leftrightarrow v_1^0 \oplus v_2^0) \wedge \\ & (v_1^2 \leftrightarrow \neg v_1^1) \wedge (v_2^2 \leftrightarrow v_1^1 \oplus v_2^1) \wedge \\ & (v_1^3 \leftrightarrow \neg v_1^2) \wedge (v_2^3 \leftrightarrow v_1^2 \oplus v_2^2). \end{aligned}$$

Since $(a \leftrightarrow b) \Leftrightarrow (a \vee \neg b) \wedge (\neg a \vee b)$, the last expression can be directly turned into a CNF expression. Therefore, the entire formula can be turned into a CNF expression and solved with an off-the-shelf SAT solver.

The reader may check that the following assignment satisfies the above expressions:

$$v_1^0 = 0, v_2^0 = 0, v_1^1 = 1, v_2^1 = 0, v_1^2 = 0, v_2^2 = 1, v_1^3 = 1, v_2^3 = 1.$$

It may also be verified that no other assignment of values to v_1^i and v_2^i , $0 \leq i \leq 3$, satisfies the above expressions. Information on the use and success of bounded model checking may be found in [18, 36].

4.6 Combinational Equivalence Checking

The power of bounded model checking is not needed to solve the combinational equivalence checking (CEC) problem which is to verify that two given *combinational circuit* implementations are functionally equivalent. CEC problems are easier, in general, because they carry no time dependency and there are no feedback loops in combinational circuits. It has recently been discovered that CEC can be solved very efficiently, in general [92, 94, 95], by incrementally building a single-output and/inverter graph (AIG), representing the miter [26] of both input circuits, and checking whether the output has value 0 for all combinations of input values. The AIG is built one vertex at a time, working from input to output. Vertices are merged if they are found to be *functionally equivalent*. Vertices can be found functionally equivalent in two ways: (1) candidates are determined by random simulation [26, 93] and then checked by a SAT solver for functional equivalence, and (2) candidates are hashed to the same location in the data structure representing vertices of the AIG (for the address of a vertex to represent function, it must depend solely on the opposite endpoints of the vertex's incident edges, and therefore, an address change typically takes place on a merge). AIG construction continues until all vertices have been placed into the AIG and no merging is possible. The technique exploits the fact that checking the equivalence of two *topologically similar* circuits is relatively easy [65] and avoids testing all possible input-output combinations, which is CoNP -hard.

In CEC the AIG is incrementally developed from gate level representations. For example, Fig. 7a shows the AIG for an *and* gate, Fig. 7b shows the AIG for an *or* gate, Fig. 7c shows the AIG for *exclusive-or*, and Fig. 7d shows the AIG for the adder circuit of Fig. 9. Vertices may take 0-1 values. Values are assigned independently to input vertices. The value of a gate vertex (a dependent vertex) is the product $x_1 x_2$ where x_i is either the value of the non-arrow side endpoint of incoming edge i , $1 \leq i \leq 2$, if the edge is not negated or 1 minus the value of the endpoint if it is negated.

CEC begins with the construction of the AIG for one of the circuits as exemplified in Fig. 12a which shows an AIG and a circuit it is to be compared against. Working from input to output, a node of the circuit is determined to be functionally equivalent to an AIG vertex and is merged with the vertex. The output lines from the merged node become AIG edges outgoing from the vertex involved in the merge. Figure 12b shows the first two nodes of the circuit being merged with the AIG and Fig. 12c shows the completed AIG.

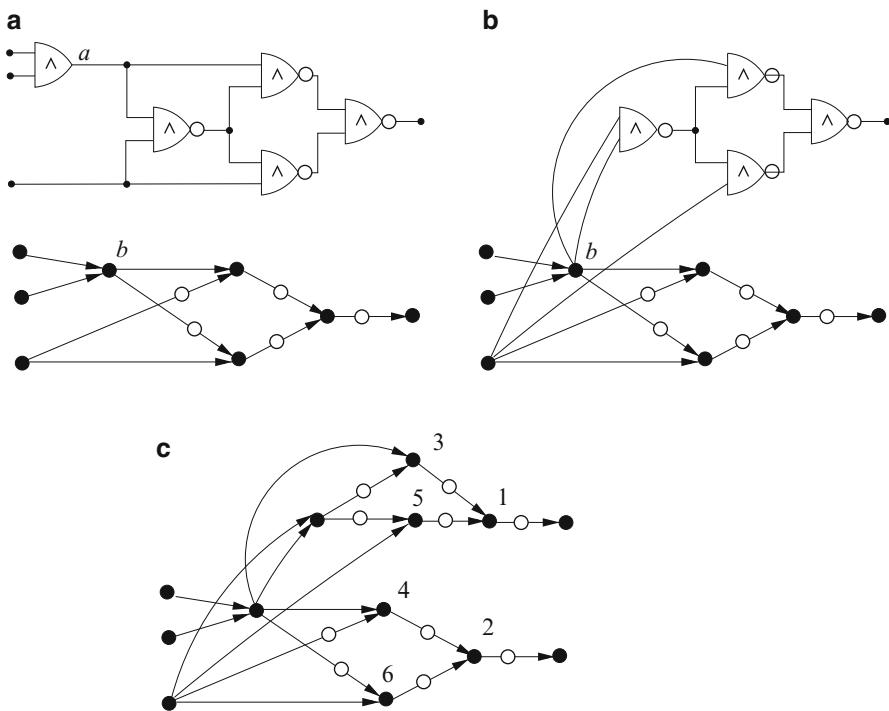

Fig. 12 Creating the AIG. (a) The beginning of the equivalency check – one circuit has been transformed to an AIG. (b) Node a of the circuit (Fig. 12a) has been merged with vertex b of the AIG. (c) The completed AIG

CEC proceeds with the application of many random input vectors to the input vertices of the AIG for the purpose of partitioning the vertices into potential equivalence classes (two vertices are in the same equivalence class if they take the same value under all random input vectors). In the case of Fig. 12c, suppose the potential equivalence classes are $\{1, 2\}$, $\{3, 4\}$, and $\{5, 6\}$.

The next step is to use a SAT solver to verify that the equivalences actually hold. Those that do are merged, resulting in a smaller AIG. The cycle repeats until merging is no longer possible. If the output vertices hash to the same address, the circuits are equivalent. Alternatively, the circuits are equivalent if the AIG is augmented by adding a vertex corresponding to an xor gate with incident edges connecting to the two output vertices of the AIG, and the resulting graph represents an unsatisfiable formula, determined by using a SAT solver.

Above, CEC has been shown to check the equivalence of two combinational circuits, but it can also be used for checking a specification against a circuit implementation or for reverse engineering a circuit.

4.7 Transformations to Satisfiability

It is routine in the operations research community to transform a given optimization problem into another, solve the new problem, and use the solution to construct a solution or an approximately optimal solution for the given problem. Usual targets of transformations are linear programming and network flows. In some cases, where the given problem is \mathcal{NP} -complete, it may be more efficient to obtain a solution or approximate solution by transformation to a satisfiability problem than by solving directly. However, care must be taken to choose a transformation that keeps running time down *and* supports low error rates. In this section a successful transformation from network Steiner tree problems to weighted MAX-SAT problems is considered (taken from [87]).

The network Steiner tree problem originates from the following important network cost problem (see, e.g., [4]). Suppose a potential provider of communications services wants to offer private intercity service for all of its customers. Each customer specifies a collection of cities it needs to have connected in its own private network. Exploiting the extraordinary bandwidth of fiber-optic cables, the provider intends to save cable costs by *piggy-backing* the traffic of several customers on single cables when possible. Assume there is no practical limit on the number of customers piggybacked to a single cable. The provider wants an answer to the following question: *Through what cities should the cables be laid to meet all customer connectivity requirements and minimize total cabling cost?*

This problem can be formalized as follows. Let $G(V, E)$ be a graph whose vertex set $V = \{c_1, c_2, c_3, \dots\}$ represents all cities and whose edge set E represents all possible connections between pairs of cities. Let $w : E \mapsto \mathbb{Z}^+$ be such that $w(\{c_i, c_j\})$ is the cost of laying fiber-optic cable between cities c_i and c_j . Let R be a given set of vertex-pairs $\{c_i, c_j\}$ representing pairs of cities that must be able to communicate with each other due to at least one customer's requirement. The problem is to find a minimum total weight subgraph of G such that there is a path between every vertex-pair of R .

Consider the special case of this problem in which the set T of all vertices occurring in at least one vertex-pair of R is a proper subset of all vertices of G (i.e., the provider has the freedom to use as connection points cities not containing customers' offices) and R requires that all vertices of T be connected. This is known as the network Steiner tree problem. An example and its optimal solution are given in Fig. 13. This problem is one of the first shown to be \mathcal{NP} -complete [85]. The problem appears in many applications and has been extensively studied. Many enumeration algorithms, heuristics, and approximation algorithms are known (see [4] for a list of examples).

A feasible solution to an instance (G, T, w) of the network Steiner tree problem is a tree spanning all vertices of a subgraph of G which includes T . Such a subgraph is called a *Steiner tree*. A *transformation from (G, T, w) to an instance of satisfiability* is a uniform method of encoding of G , T , and w by a CNF formula ψ with nonnegative weights on its clauses. A necessary (feasibility) property of any transformation is that a truth assignment to the variables of ψ which maximizes

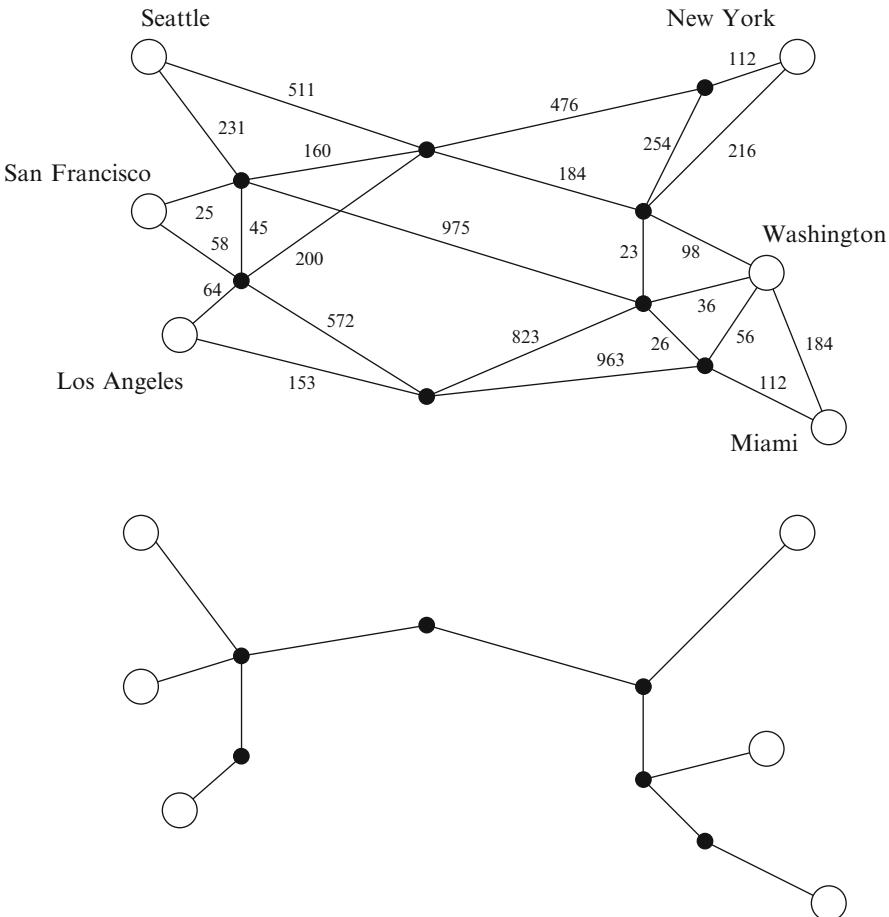

Fig. 13 An example of a network Steiner tree problem (*top*) and its optimal solution (*bottom*). The white nodes are terminals and the numbers represent hypothetical costs of laying fiber-optic cables between pairs of cities

the total weight of all satisfied clauses specifies a feasible solution for (G, T, w) . A desired (optimality) property is, in addition, that feasible solution have minimum total weight. Unfortunately, known transformations that satisfy both properties produce formulas of size that is superlinearly related to the number of edges and vertices in G . Such encodings are useless for large graphs. More practical linear transformations satisfying the feasibility property are possible but these do not satisfy the optimality property. However, it has been demonstrated that, using a carefully defined linear transformation, one can achieve close to optimal results.

As an example, consider the linear transformation introduced in [87]. This transformation has a positive integer parameter k which controls the quality of the

approximation. Without losing any interesting cases, assume that G is connected. It is also assumed that no two paths in G between the same nodes of T have the same weight; this can be made true, if necessary, by making very small adjustments to the weights of the edges.

Preprocessing

1. Define an auxiliary weighted graph $((T, E'), w')$ as follows:
Graph $G' = (T, E')$ is the complete graph on all vertices in T .
For edge $e' = \{c_i, c_j\}$ of G' , let $w'(e')$ be the total cost of the minimum cost path between c_i and c_j in G . (This can be found, e.g., by Dijkstra's algorithm).
2. Let W be a minimum-cost spanning tree of (G', w') . It is intended to choose, for each edge $\{c_i, c_j\}$ of W , (all the edges on) one entire path in (G, w) between c_i and c_j to be included in the Steiner tree. This will produce a Steiner tree for T, G , although perhaps not a minimum-cost tree, as long as no cycles in G are included.

For some prespecified, fixed k : Find the k minimum-cost paths in G between c_i and c_j (again, e.g., by a variation of Dijkstra's algorithm); call them $P_{i,j,1}, \dots, P_{i,j,k}$. Thus, the algorithm will choose one of these k paths between each pair of elements of W .

The Formula

The output of the preprocessing step is a tree W spanning all vertices of T . Each edge $\{c_i, c_j\} \in W$ represents one of the paths $P_{i,j,1}, \dots, P_{i,j,k}$ in G . The tree W , the list of edges in G , the lists of edges comprising each of the k shortest paths between pairs of vertices of W , and the number k are input to the transformation step. The path weights are not needed by the transformation step and are therefore not provided as an input. The transformation is then carried out as shown in [Table 7](#). In the table, E is the set of edges of G and I is any number greater than the sum of the weights of all edges of G .

A maximum weight solution to a formula of [Table 7](#) must satisfy all non-unit clauses because the weights assigned to those clauses are so high. Satisfying those clauses corresponds to choosing all the edges of at least one path between pairs of vertices in the list. Therefore, since the list represents a spanning tree of G' , a maximum weight solution specifies a connected subgraph of G which includes all vertices of T .

On the other hand, the subgraph must be a tree. If there is a cycle in the subgraph, then there is more than one path from a T vertex u to a non- T vertex v , so there is a shorter path that may be substituted for one of the paths going from u through v to some T vertex. Choosing a shorter path is always possible because it will still be one of the k shortest. Doing so removes at least one edge and cycle. This process may be repeated until all cycles are broken and the number of edges remaining is minimal for all T vertices to be connected. Due to the unit clauses, all edge variables whose values are not set to 1 by an assignment add their edge weights to that of the formula. Therefore, the maximum weight solution contains only edges forced by p variables and must specify a Steiner tree.

Table 7 Transformation from an instance of the network Steiner tree problem to a CNF formula. The instance has already been preprocessed to spanning tree W plus lists of k shortest paths $P_{i,j,x}$, $1 \leq x \leq k$, corresponding to edges $\{c_i, c_j\}$ of W . The edges of the original graph are given as set E . Boolean variables created expressly for the transformation are defined at the top and clauses are constructed according to the middle chart. Weights are assigned to clauses as shown at the bottom. The number I is chosen to be greater than the sum of all weights of edges in E

Variable	Subscript range	Meaning
$e_{i,j}$	Edge $\{c_i, c_j\} \in E$	$\{c_i, c_j\} \in$ the Steiner tree
$p_{i,j,l}$	$\{c_i, c_j\} \in W, 1 \leq l \leq k$	$P_{i,j,l} \subseteq$ the Steiner tree
Clause	Subscript range	Meaning
$(\neg e_{i,j})$	$\{c_i, c_j\} \in E$	$e_{i,j} \notin$ Steiner tree
$(p_{i,j,1} \vee \dots \vee p_{i,j,k})$	$\{c_i, c_j\} \in W$	Include at least one of k shortest paths between c_i, c_j
$(\neg p_{i,j,l} \vee e_{m,n})$	$\{c_m, c_n\} \in P_{i,j,l}$	Include all edges of that path
Clause	Weight	Significance
$(\neg e_{i,j})$	$w(\{i, j\})$	Maximize weights of edges <i>not</i> included
$(p_{i,j,1} \vee \dots \vee p_{i,j,k})$	I	Force connected subgraph of G containing all vertices of T
$(\neg p_{i,j,l} \vee e_{m,n})$	I	Force connected subgraph of G containing all vertices of T

A maximum weight solution specifies an optimal Steiner tree only if k is sufficiently large to admit all the shortest paths in an optimal solution. Generally this is not practical since too large a k will cause the transformation to be too large. However, good results can be obtained even with k values up to 30.

Once the transformation to satisfiability is made, an incomplete algorithm such as Walksat (see Sect. 5.8.1) or even a branch-and-bound variant (see Sect. 5.11) can be applied to obtain a solution. The reader is referred to [87] for empirical results showing speed and approximation quality.

4.8 Boolean Data Mining

The field of *data mining* is concerned with discovering *hidden* structural information in databases; it is a form of (or variant of) *machine learning*. In particular, it is concerned with finding hidden correlations among apparently weakly related data. For example, a credit card company might look for patterns of charging purchases that are frequently correlated with using stolen credit card numbers. Using this data, the company can look more closely at suspicious patterns in an attempt to discover thefts before they are reported by the card owners.

Many of the methods for data mining involve essentially numerical calculations. However, others work on Boolean data. Typically, the relevant part of the database consists of a set B of m Boolean n -tuples (plus keys to distinguish tuples, which presumably are unimportant here). Each of these n attributes might be the results of some monitoring equipment or experts' answers to questions.

Some of the tuples in B are known to have some property; the others are known not to have the property. Thus, what is known is a partially defined Boolean function f_B of the n variables. An important problem is to predict whether tuples to be added later will have the same property. This amounts to finding a completely defined Boolean function f which agrees with f_B at every value for which it is defined. Frequently, the goal is also to find such an f with, in some sense, a simple definition: such a definition, it is hoped, will reveal some interesting structural property or explanation of the data points.

For example, binary vectors of dimension two describing the condition of an automobile might have the following interpretation:

Vector	Value	Overheating	Coolant level
00	0	No	Low
01	0	No	Normal
10	0	Yes	Low
11	1	Yes	Normal

where the value associated with each vector is 1 if and only if the automobile's thermostat is defective.

One basic method is to search for such a function f with a relatively short disjunctive normal form (DNF) definition. An example formula in DNF is

$$(v_1 \wedge v_2 \wedge \neg v_3) \vee (\neg v_1 \wedge v_4) \vee (v_3 \wedge v_4 \wedge v_5 \wedge v_6) \vee (\neg v_3).$$

DNF formulas have the same form as that of CNF formulas except that the positions of the \wedge 's and the \vee 's are reversed. In this case the formula is in 4-DNF since each disjunct contains at most 4 conjuncts. Each *term*, for example, $(v_1 \wedge v_2 \wedge \neg v_3)$ is an *implicant*: whenever it is true, the property holds.

There is extensive research upon the circumstances under which, when some random sample points f_B from an actual Boolean function f are supplied, a program can, with high probability, *learn* a good approximation to f within reasonable time (e.g., [140]). Of course, if certain additional properties of f are known or assumed, more such functions f can be determined.

Applications are driving interest in the field. The problem has become more interesting due to the use of binarization which allows nonbinary data sets to be transformed to binary data sets [25]. Such transformations allow the application of special binary tools for cause-effect analysis that would otherwise be unavailable and may even sharpen *explainability*. For example, for a set of 290 data points containing 9 attributes related to Chinese labor productivity, it was observed in [24] that the short clause

Not in the northwest region *and* time **is later than 1987**,

where *time* ranges over the years 1985–1994, explains all the data and the clause

SOE is at least 71.44% and time is earlier than 1988,

where SOE means *state-owned enterprises*, explains 94 % of the data. The technique of logical analysis of data has been successfully applied to inherently nonbinary problems of oil exploration, psychometric analysis, and economics, among others.

5 General Algorithms

In this section some algorithms for solving various SAT problems are presented. Most of these algorithms operate on CNF formulas. Therefore, the following efficient transformation to CNF formulas is needed to demonstrate the general applicability of these algorithms.

5.1 Efficient Transformation to CNF Formulas

An algorithm due to Tseitin [139] efficiently transforms an arbitrary Boolean formula ϕ to a CNF formula ψ such that ψ has a model if and only if ϕ has a model and if a model for ψ exists, it is a model for ϕ . The transformation is important because it supports the general use of many of the algorithms which are described in following sections and require CNF formulas as input.

The transformation can best be visualized graphically. As discussed in Sect. 3.6, any Boolean formula ϕ can be represented as a binary rooted acyclic digraph W_ϕ where each internal vertex represents some operation on one or two operands (an example is given in Fig. 6). Associate with each internal vertex x of W_ϕ a new variable v_x not occurring in ϕ . If x represents a binary operator \mathcal{O}_x , let v_l and v_r be the variables associated with the left and right endpoints, respectively, of the two outward-oriented edges of x (v_l and v_r may be variables labeling internal or leaf vertices). If x represents the operator \neg , then call the endpoint of the outward-oriented edge v_g . For each internal vertex x of W_ϕ , write

$$\begin{aligned} v_x &\Leftrightarrow (v_l \mathcal{O}_x v_r) && \text{if } \mathcal{O}_x \text{ is binary or} \\ v_x &\Leftrightarrow \neg v_g && \text{if vertex } x \text{ represents } \neg. \end{aligned}$$

For each equivalence there is a short, functionally equivalent CNF expression. The table of Fig. 14 shows the equivalent CNF expression for all 16 possible binary operators where each bit pattern in the left column expresses the functionality of an operator for each of four assignments to v_l and v_r , in increasing order, from 00 to 11. The equivalent CNF expression for \neg is $(v_g \vee v_x) \wedge (\neg v_g \vee \neg v_x)$.

The target of the transformation is a CNF formula consisting of all clauses in every CNF expression from Fig. 14 that corresponds to an equivalence expressed at a non-leaf vertex of W_ϕ plus a unit clause that forces the root expression to evaluate to 1. For example, the expression of Fig. 6, namely,

$$v_0 \Leftrightarrow ((\neg v_0 \Leftrightarrow (v_1 \vee \neg v_2)) \wedge (v_1 \vee \neg v_2) \wedge (\neg v_2 \rightarrow \neg v_3 \rightarrow v_4)),$$

\mathcal{O}_x	Equivalent CNF Expression	Comment
0000	$(\neg v_x)$	$v_x \Leftrightarrow 0$
1111	(v_x)	$v_x \Leftrightarrow 1$
0011	$(v_l \vee \neg v_x) \wedge (\neg v_l \vee v_x)$	
1100	$(v_l \vee v_x) \wedge (\neg v_l \vee \neg v_x)$	$v_x \Leftrightarrow \neg v_l$
0101	$(v_r \vee \neg v_x) \wedge (\neg v_r \vee v_x)$	
1010	$(v_r \vee v_x) \wedge (\neg v_r \vee \neg v_x)$	
0001	$(v_l \vee \neg v_x) \wedge (v_r \vee \neg v_x) \wedge (\neg v_l \vee \neg v_r \vee v_x)$	$v_x \Leftrightarrow (v_l \wedge v_r)$
1110	$(v_l \vee v_x) \wedge (v_r \vee v_x) \wedge (\neg v_l \vee \neg v_r \vee \neg v_x)$	$v_x \Leftrightarrow (\neg v_l \vee \neg v_r)$
0010	$(\neg v_l \vee \neg v_x) \wedge (v_r \vee \neg v_x) \wedge (v_l \vee \neg v_r \vee v_x)$	
1101	$(v_l \vee v_x) \wedge (\neg v_r \vee v_x) \wedge (\neg v_l \vee v_r \vee \neg v_x)$	$v_x \Leftrightarrow (v_l \rightarrow v_r)$
0100	$(v_l \vee \neg v_x) \wedge (\neg v_r \vee \neg v_x) \wedge (\neg v_l \vee v_r \vee v_x)$	
1011	$(\neg v_l \vee v_x) \wedge (v_r \vee v_x) \wedge (v_l \vee \neg v_r \vee \neg v_x)$	$v_x \Leftrightarrow (v_l \leftarrow v_r)$
1000	$(\neg v_l \vee \neg v_x) \wedge (\neg v_r \vee \neg v_x) \wedge (v_l \vee v_r \vee v_x)$	$v_x \Leftrightarrow (\neg v_l \wedge \neg v_r)$
0111	$(\neg v_l \vee v_x) \wedge (\neg v_r \vee v_x) \wedge (v_l \vee v_r \vee \neg v_x)$	$v_x \Leftrightarrow (v_l \vee v_r)$
1001	$(v_l \vee \neg v_r \vee \neg v_x) \wedge (\neg v_l \vee v_r \vee \neg v_x) \wedge$ $(\neg v_l \vee \neg v_r \vee v_x) \wedge (v_l \vee v_r \vee v_x)$	$v_x \Leftrightarrow (v_l \leftrightarrow v_r)$

 & (v_0 \vee v_{x_1}) \wedge (\neg v_0 \vee \neg v_{x_1}) \wedge \\
 & (v_2 \vee v_{x_2}) \wedge (\neg v_2 \vee \neg v_{x_2}) \wedge \\
 & (v_3 \vee v_{x_3}) \wedge (\neg v_3 \vee \neg v_{x_3}) \wedge \\
 & (\neg v_1 \vee v_{x_4}) \wedge (\neg v_{x_2} \vee v_{x_4}) \wedge (v_1 \vee v_{x_2} \vee \neg v_{x_4}) \wedge \\
 & (v_{x_3} \vee v_{x_5}) \wedge (\neg v_4 \vee v_{x_5}) \wedge (\neg v_{x_3} \vee v_4 \vee \neg v_{x_5}) \wedge \\
 & (v_{x_1} \vee \neg v_{x_4} \vee \neg v_{x_6}) \wedge (\neg v_{x_1} \vee v_{x_4} \vee \neg v_{x_6}) \wedge (\neg v_{x_1} \vee \neg v_{x_4} \vee v_{x_6}) \wedge \\
 & (v_{x_1} \vee v_{x_4} \vee v_{x_6}) \wedge (v_{x_2} \vee v_{x_7}) \wedge (\neg v_{x_5} \vee v_{x_7}) \wedge (\neg v_{x_2} \vee v_{x_5} \vee \neg v_{x_7}) \wedge \\
 & (v_{x_4} \vee \neg v_{x_8}) \wedge (v_{x_7} \vee \neg v_{x_8}) \wedge (\neg v_{x_4} \vee \neg v_{x_7} \vee v_{x_8}) \wedge \\
 & (v_{x_6} \vee \neg v_{x_9}) \wedge (v_{x_8} \vee \neg v_{x_9}) \wedge (\neg v_{x_6} \vee \neg v_{x_8} \vee v_{x_9}) \wedge \\
 & (v_0 \vee \neg v_{x_9} \vee \neg v_{x_{10}}) \wedge (\neg v_0 \vee v_{x_9} \vee \neg v_{x_{10}}) \wedge (\neg v_0 \vee \neg v_{x_9} \vee v_{x_{10}}) \wedge \\
 & (v_0 \vee v_{x_9} \vee v_{x_{10}}) \wedge (v_{x_{10}}).
 \end{aligned}$$

where each line except the last corresponds to an internal vertex x_i of W_ϕ of Fig. 6, i increasing from 1 in left-to-right and bottom-to-top order, and the new variables labeling those vertices are $v_{x_1}, \dots, v_{x_{10}}$ correspondingly. The last line forces the root expression to evaluate to 1. The algorithm of Fig. 15 expresses these ideas formally.

Algorithm 1.**Transformation to CNF (ϕ)**

```

/* Input  $\phi$ : formula consistent with syntax described on Page 2 */ 
/* Output  $\psi$ : CNF expression functionally equivalent to  $\phi$  */ 
/* Assume variables of  $\phi$  are labeled  $v_0, v_1, \dots, v_{n-1}$  */ 
/* Additional variables  $v_n, v_{n+1}, v_{n+2}, \dots$  are created as needed */ 
/* Locals: stack  $S$ , integer  $i$ , quoted expression  $\phi^q$ , set of clauses  $\phi^c$  */ 

Set  $\phi^q \leftarrow \text{"} \phi \text{"}.$ 
Next  $s \leftarrow \phi^q$ .
Repeat the following while  $\phi^q \neq \emptyset$ :
  If  $s$  is a variable and the symbol at the top of  $S$  is  $\neg$ ,
    Set  $i \leftarrow i + 1$ . // Evaluate ' $\neg s$ '.
    Replace the top of  $S$  with  $v_i$ .
    Append  $L \leftarrow \text{"} v_i \Leftrightarrow \neg s \text{"}$ .
    Next  $s \leftarrow \phi^q$ .
  Otherwise, if  $s$  is ')',
    Pop  $w \leftarrow S$ . // Evaluate '( $v \mathcal{O} w$ )'
    Pop  $\mathcal{O} \leftarrow S$ .
    Pop  $v \leftarrow S$ .
    Pop  $S$ .
    Set  $i \leftarrow i + 1$ .
    Append  $L \leftarrow \text{"} v_i \Leftrightarrow (v \mathcal{O} w) \text{"}$ .
    Set  $s \leftarrow v_i$ .
  Otherwise, // Push an operator, positive variable, or '(' onto  $S$ 
    Push  $S \leftarrow s$ .
    Next  $s \leftarrow \phi^q$ .
Set  $\psi \leftarrow \{\{\text{Pop } S\}\}$ 
Repeat the following while  $L \neq \emptyset$ :
  Pop  $\psi^q \leftarrow L$ .
  If  $\psi^q$  equals " $v_j \Leftrightarrow \neg v_g$ " for some  $v_j$  and  $v_g$ ,
    Set  $\psi \leftarrow \psi \cup \{\{v_j, v_g\}, \{\neg v_j, \neg v_g\}\}$ .
  Otherwise,  $\psi^q$  equals " $v_j \Leftrightarrow (v_l \mathcal{O} v_r)$ " so do the following:
    Build  $\phi^c$  based on  $\mathcal{O}$ ,  $v_j$ ,  $v_l$ ,  $v_r$  using the table of Figure 14.
    Set  $\psi \leftarrow \psi \cup \phi^c$ .
Output  $\psi$ .

```

□

Fig. 15 Algorithm for transforming a formula to a functionally equivalent CNF formula

For simplicity, it is assumed that the input is a formula with syntax consistent with that described on Page 313.

The next lemma and theorems show that the algorithm correctly transforms a given expression to a CNF formula and the size of the target formula is linearly related to the size of the original expression.

Lemma 1 Let \mathcal{O} be any binary Boolean operator except the two trivial ones that evaluate to 0 or 1 regardless of the value of their operands. Given formulas ψ_1 and ψ_2 , variables $v_1 \in V_{\psi_1} \setminus V_{\psi_2}$ and $v_2 \in V_{\psi_2} \setminus V_{\psi_1}$, and some base set V such that $\psi_1|_{v_1=1} \leftrightharpoons_V \psi_1|_{v_1=0}$ and $\psi_2|_{v_2=1} \leftrightharpoons_V \psi_2|_{v_2=0}$,

$$(v_1 \mathcal{O} v_2) \wedge \psi_1 \wedge \psi_2 \leftrightharpoons_V \neg(v_1 \mathcal{O} v_2) \wedge \psi_1 \wedge \psi_2.$$

Proof It must be shown that for every truth assignment M_V to V (1) if there is an extension that satisfies ψ_1 , ψ_2 , and $(v_1 \mathcal{O} v_2)$, then there is an extension that satisfies ψ_1 , ψ_2 , and $\neg(v_1 \mathcal{O} v_2)$ and (2) if there is an extension that satisfies ψ_1 , ψ_2 , and $\neg(v_1 \mathcal{O} v_2)$, then there is an extension that satisfies ψ_1 , ψ_2 , and $(v_1 \mathcal{O} v_2)$. It is only necessary to take care of (1) since a similar argument applies for (2).

Assume there is an extension M_1 that satisfies ψ_1 , ψ_2 , and $(v_1 \mathcal{O} v_2)$. From $\psi_1|_{v_1=1} \leftrightharpoons_V \psi_1|_{v_1=0}$ and $\psi_2|_{v_2=1} \leftrightharpoons_V \psi_2|_{v_2=0}$ and the fact that M_1 satisfies both ψ_1 and ψ_2 , all four extensions identical to M_1 except in v_1 and v_2 will satisfy ψ_1 and ψ_2 . One of those will also satisfy $\neg(v_1 \mathcal{O} v_2)$ since \mathcal{O} is nontrivial. Hence, if there is an extension to M_V that satisfies ψ_1 , ψ_2 , and $(v_1 \mathcal{O} v_2)$, there is also an extension that satisfies ψ_1 , ψ_2 , and $\neg(v_1 \mathcal{O} v_2)$. \square

Theorem 1 Let ϕ be a formula and $V_\phi = \{v_0, v_1, \dots, v_{n-1}\}$ the set of n variables contained in it. The output of [Algorithm 1](#) on input ϕ represents a CNF formula ψ , written (v_0) if ϕ has no operators and otherwise written $(v_i) \wedge \psi_\phi$, $n \leq i$, where clause (v_i) is due to the line “Set $\psi \leftarrow \{\{\text{Pop } S\}\}$ ” and ψ_ϕ is such that $\psi_\phi|_{v_i=1} \leftrightharpoons_{V_\phi} \psi_\phi|_{v_i=0}$.⁴ In addition, $\psi \leftrightharpoons_{V_\phi} \phi$. That is, any truth assignment $M_{V_\phi} \subset V_\phi$ is a model for ϕ if and only if there is a truth assignment $M_1 \subset \{v_n, v_{n+1}, \dots, v_i\}$ such that $M_{V_\phi} \cup M_1$ is a model for ψ .

Proof The output is a set of sets of variables and therefore represents a CNF formula. The line “Set $\psi \leftarrow \{\{\text{Pop } S\}\}$ ” is reached after all input symbols are read. This happens only after either the “Evaluate ‘ $\neg s$ ’” block or the “Push $S \leftarrow s$ ” line. In the former case, v_i is left at the top of the stack. In the latter case, s must be v_0 , in the case of no operators, or v_i from execution of the “Evaluate ‘ $(v \mathcal{O} w)$ ’” block immediately preceding execution of the “Push $S \leftarrow s$ ” line (otherwise, the input is not a formula). Therefore, either v_0 or v_i is the top symbol of S when “Set $\psi \leftarrow \{\{\text{Pop } S\}\}$ ” is executed so $\{v_0\}$ or $\{v_i\}$ is a clause of ψ .

Formulas ψ' and ψ may be shown to have the stated properties by induction on the depth of the input formula ϕ . For improved clarity, \leftrightharpoons is used instead of $\leftrightharpoons_{V_{\phi'}}$ below.

The base case is depth 0. In this case ϕ is the single variable v_0 and $n = 1$. The line “Push $S \leftarrow s$ ” is executed in the first Repeat block, then the line “Set $\psi \leftarrow \{\{\text{Pop } S\}\}$ ” is executed so $\psi = \{\{v_0\}\}$. Since $L = \emptyset$, execution terminates. Obviously, $\psi = \phi$ so both hypotheses are satisfied.

⁴The meaning of \leftrightharpoons is given on Page [318](#).

For the induction step, suppose ϕ is a formula of positive depth $k + 1$ and the hypotheses hold for all formulas of depth k or less. It is next shown that they also hold for ϕ . Consider first the case $\phi = \neg\phi'$ (ϕ' has depth k). [Algorithm 1](#) stacks \neg in the line “Push $S \leftarrow s$ ” and then, due to the very next line, proceeds as though it were operating on ϕ' . The algorithm reaches the same point it would have if ϕ' were input. However, in this case, \neg and a variable are on the stack. This requires one pass through the “Evaluate ‘ $\neg s$ ’” block which adds “ $v_i \Leftrightarrow \neg s$ ” to L and leaves v_i as the only symbol in S . Thus, upon termination,

$$\psi = (v_i) \wedge \psi_\phi = (v_i) \wedge (v_{i-1} \vee v_i) \wedge (\neg v_{i-1} \vee \neg v_i) \wedge \psi_{\phi'}$$

and v_i is not in $\psi_{\phi'}$. Hence,

$$\begin{aligned} \psi_\phi |_{v_i=1} &= ((v_{i-1} \vee v_i) \wedge (\neg v_{i-1} \vee \neg v_i)) |_{v_i=1} \wedge \psi_{\phi'} \\ &= (\neg v_{i-1}) \wedge \psi_{\phi'} \\ &\stackrel{\text{(by the induction hypothesis and Lemma 1, Page 348)}}{=} (v_{i-1}) \wedge \psi_{\phi'} \\ &= ((v_{i-1} \vee v_i) \wedge (\neg v_{i-1} \vee \neg v_i)) |_{v_i=0} \wedge \psi_{\phi'} \\ &= \psi_\phi |_{v_i=0}. \end{aligned}$$

Next, it is shown that $\psi \Leftarrow \phi$ for this case. The expression $(v_i) \wedge \psi_\phi$ can evaluate to 1 only when the value of v_i is 1. Therefore,

$$\begin{aligned} \psi &= (v_i) \wedge \psi_\phi \Leftarrow \psi_\phi |_{v_i=1} \\ &= (\neg v_{i-1}) \wedge \psi_{\phi'} \\ &\stackrel{\text{(from above)}}{=} (v_{i-1}) \wedge \psi_{\phi'} \\ &\stackrel{\text{(by } \psi \Leftarrow \phi \text{ induction hypothesis)}}{=} \phi' \\ &\stackrel{\text{defn}}{=} \phi. \end{aligned}$$

Finally, consider the case that $\phi = (\phi_l \mathcal{O} \phi_r)$ (ϕ_l and ϕ_r have depth at most k). The algorithm stacks a “(” then, by the inductive hypothesis and the recursive definition of a formula, completes operations on ϕ_a which results in ψ_{ϕ_l} in L . The line “Set $\psi \leftarrow \{\{\text{Pop } S\}\}$ ” is avoided because there are still unread input symbols. Thus, there are two symbols on the stack at this point: a “(” which was put there initially and a variable. The symbol \mathcal{O} is read next and pushed on S by the line “Push $S \leftarrow s$.” Then ψ_{ϕ_r} is put in L , but again the line “Set $\psi \leftarrow \{\{\text{Pop } S\}\}$ ” is avoided because there is still a “)” to be read. Thus, the stack now contains “(;” a variable, say, v_l ; an operator symbol \mathcal{O} ; and another variable, say, v_r . The final “)” is read and the “Evaluate ‘($v_l \mathcal{O} v_r$)’” section causes the stack to be popped, $v \Leftarrow (v_l \mathcal{O} v_r)$ to be added to L , and variable v_i to be put on S (in the final iteration of the first loop). Therefore, upon termination,

$$\psi = (v_i) \wedge \psi_\phi = (v_i) \wedge (v_i \Leftrightarrow (v_l \mathcal{O} v_r)) \wedge \psi_{\phi_l} \wedge \psi_{\phi_r},$$

where $(v_l) \wedge \psi_{\phi_l}$ is what the algorithm output represents on input ϕ_l and $(v_r) \wedge \psi_{\phi_r}$ is represented by the output on input ϕ_r (some clauses may be duplicated to exist both in ψ_{ϕ_l} and ψ_{ϕ_r}). Then,

$$\begin{aligned}\psi_\phi|_{v_i=1} &= (v_i \Leftrightarrow (v_l \mathcal{O} v_r))|_{v_i=1} \wedge \psi_{\phi_l} \wedge \psi_{\phi_r} \\ &= (v_l \mathcal{O} v_r) \wedge \psi_{\phi_l} \wedge \psi_{\phi_r} \\ &\Leftarrow \neg(v_l \mathcal{O} v_r) \wedge \psi_{\phi_l} \wedge \psi_{\phi_r} \quad (\text{induction hypothesis and Lemma 1}) \\ &= (v_i \Leftrightarrow (v_l \mathcal{O} v_r))|_{v_i=0} \wedge \psi_{\phi_l} \wedge \psi_{\phi_r} \\ &= \psi_\phi|_{v_i=0}.\end{aligned}$$

It remains to show $\psi \Leftarrow \phi$ for this case. By the induction hypothesis, $\psi_{\phi_l}|_{v_l=1} \Leftarrow \psi_{\phi_l}|_{v_l=0}$. Therefore, for a given truth assignment M_{ψ_ϕ} , if there is an extension such that v_l has value 1 (0) and ψ_{ϕ_l} has value 0, then there is always an extension such that v_l has value 0 (1), respectively, and ψ_{ϕ_l} has value 1. Since, by the induction hypothesis, $\phi_l \Leftarrow (v_l) \wedge \psi_{\phi_l}$, there is always an extension such that ψ_{ϕ_l} has value 1 and v_l has the same value as ϕ_l . The same holds for v_r and ϕ_r . Therefore,

$$\begin{aligned}\psi &= (v_i) \wedge \psi_\phi \Leftarrow \psi_\phi|_{v_i=1} \\ &= ((v_i) \wedge (v_i \Leftrightarrow (v_l \mathcal{O} v_r)))|_{v_i=1} \wedge \psi_{\phi_l} \wedge \psi_{\phi_r} \\ &\Leftarrow (v_l \mathcal{O} v_r) \wedge \psi_{\phi_l} \wedge \psi_{\phi_r} \\ &\Leftarrow (\phi_l \mathcal{O} \phi_r) \Leftarrow \phi.\end{aligned}$$

□

Theorem 2 *Algorithm 1* produces a representation using a number of symbols that is no greater than a constant times the number of symbols the input formula has if there are no double negations in the input formula.

Proof Each binary operator in the input string accounts for a pair of parentheses in the input string plus itself plus a literal. Hence, if there are m binary operators, the string has at least $4m$ symbols.

If there are m binary operators in the input string, m new variables associated with those operators will exist in ψ due to the Append of the “Evaluate ‘ $(v \mathcal{O} w)$ ’” block. For each, at most 12 symbols involving literals, 12 involving operators (both \wedge and \vee represented as “,”), and 8 involving parentheses (represented as “{” “}”) are added to ψ (see Fig. 14), for a total of at most $32m$ symbols. At most $m + n$ new variables associated with negations are added to ψ (both original variables and new variables can be negated) due to the Append of the “Evaluate ‘ $\neg s$ ’” block. For each, at most 4 literals, 4 operators, and 4 parentheses are added to ψ (from $\{v_i, v_j\}, \{\neg v_i, \neg v_j\}$), for a total of $12(m+n)$ symbols. Therefore, the formula output by *Algorithm 1* has at most $44m + 12n$ symbols.

Since $n - 1 \leq m$, $44m + 12n \leq 56m + 12$. Therefore, the ratio of symbols of ψ to ϕ is not greater than $(56m + 12)/4m = 14 + 3/m < 17$. \square

The next result shows that the transformation is computed efficiently.

Theorem 3 *Algorithm 1* has $O(m)$ worst-case complexity if input formulas do not have double negations, where m is the number of operators, and one symbol is used per parenthesis, operator, and variable.

Proof Consider the first Repeat block. Every right parenthesis is read once from the input, is never stacked, and results in an extra loop of the Repeat block due to the line “Set $s \leftarrow v_i$ ” in the first Otherwise block. Since all other symbols are read once during an iteration of the Repeat block, the number of iterations of this block is the number of input symbols plus the number of right parentheses. Since the number of operators (m) must be at least one fifth of the number of input symbols, the number of iterations of the Repeat block is no greater than $10m$. Since all lines of the Repeat block require unit time, the complexity of the block is $O(m)$.

The second Repeat block checks items in L , in order, and for each makes one of a fixed number of substitutions in which the number of variables is bounded by a constant. An item is appended to L every time a \neg or right parenthesis is encountered, and there is one right parenthesis for every binary operator. Thus, there are m items in L and the complexity of the second Repeat block is $O(m)$. Therefore, the complexity of the algorithm is $O(m)$. \square

If ϕ contains duplicate subformulas, the output will consist of more variables and CNF blocks than are needed to represent a CNF formula equivalent to ϕ . This is easily remedied by implementing L as a balanced binary search tree keyed on v_l , v_r , and \mathcal{O} and changing the Append to a tree insertion operation. If, before insertion in the “Evaluate ‘ $(v\mathcal{O}w)$ ’” block, it is discovered that “ $v_j \Leftrightarrow (v\mathcal{O}w)$ ” already exists in L for some v_j , then s can be set to v_j , i need not be incremented, and the insertion can be avoided. A similar change can be made for the “Evaluate ‘ $\neg s$ ’” block. With L implemented as a balanced binary search tree, each query and each insertion would take at most $\log(m)$ time since L will contain no more than m items. Hence, the complexity of the algorithm with the improved data structure would be $O(m \log(m))$.

As a final remark, there is no comparable, efficient transformation from a formula to a DNF formula.

5.2 Resolution

Resolution is a general procedure that is primarily used to certify that a given CNF formula is unsatisfiable, but can also be used to find a model, if one exists. The idea originated as *consensus* in [20] and [129] (ca. 1937) and was applied to DNF formulas in a form exemplified by the following:

$$(x \wedge y) \vee (\neg x \wedge z) \Leftrightarrow (x \wedge y) \vee (\neg x \wedge z) \vee (y \wedge z).$$

Consensus in DNF was rediscovered in [120] and [116] (ca. 1954) where it was given its name. A few years later its dual, as resolution in propositional logic, was applied to CNF (M. Davis and H. Putnam, 1958, Computational methods in the propositional calculus, unpublished report), for example,

$$(x \vee y) \wedge (\neg x \vee z) \Leftrightarrow (x \vee y) \wedge (\neg x \vee z) \wedge (y \vee z).$$

The famous contribution of Robinson [118] in 1965 was to lift resolution to first-order logic.

Let c_1 and c_2 be disjunctive clauses such that there is exactly one variable v that occurs negated in one clause and unnegated in the other. Then, the *resolvent* of c_1 and c_2 , denoted by $\mathcal{R}_{c_2}^{c_1}$, is a disjunctive clause which contains all the literals of c_1 and all the literals of c_2 except for v or its complement. The variable v is called a *pivot* variable. If c_1 and c_2 are treated as sets, their resolvent is $\{l : l \in c_1 \cup c_2 \setminus \{v, \neg v\}\}$.

The usefulness of resolvents derives from the following Lemma.

Lemma 2 *Let ψ be a CNF formula represented as a set of sets. Suppose there exists a pair $c_1, c_2 \in \psi$ of clauses such that $\mathcal{R}_{c_2}^{c_1} \notin \psi$ exists. Then $\psi \Leftrightarrow \psi \cup \{\mathcal{R}_{c_2}^{c_1}\}$.*

Proof Clearly, any assignment that does not satisfy CNF formula ψ cannot satisfy a CNF formula which includes a subset of clauses equal to ψ . Therefore, no satisfying assignment for ψ implies none for $\psi \cup \{\mathcal{R}_{c_2}^{c_1}\}$.

Now suppose M is a model for ψ . Let v be the pivot variable for c_1 and c_2 . Suppose $v \in M$. One of c_1 or c_2 contains $\neg v$. That clause must also contain a literal that has value 1 under M or else it is falsified by M . But that literal exists in the resolvent $\mathcal{R}_{c_2}^{c_1}$, by definition. Therefore, $\mathcal{R}_{c_2}^{c_1}$ is satisfied by M and so is $\psi \cup \{\mathcal{R}_{c_2}^{c_1}\}$. A similar argument applies if $v \notin M$. \square

The *resolution* method makes use of [Lemma 2](#) and the fact that a clause containing no literals cannot be satisfied by any truth assignment. A resolution algorithm for CNF formulas is presented in [Fig. 16](#). It uses the notion of pure literal (Page 315) to help find a model, if one exists. Recall, a literal is pure in formula ψ if it occurs in ψ , but its complement does not occur in ψ . If the algorithm outputs *unsatisfiable*, then the set of all resolvents generated by the algorithm is a *resolution refutation* for the input formula.

Theorem 4 *Let ψ be a CNF formula represented as a set of sets. The output of [Algorithm 2](#) on input ψ is unsatisfiable, if and only if ψ is unsatisfiable. If the output is a set of variables, then it is a model for ψ .*

Proof If the algorithm returns *unsatisfiable*, one resolvent is the empty clause. From [Lemma 2](#) and the fact that an empty clause cannot be satisfied, ψ is unsatisfiable.

If the algorithm does not return “unsatisfiable” the Otherwise block is entered because new resolvents cannot be generated from ψ . Next, a Repeat block to

Algorithm 2.**Resolution (ψ)**

```

/* Input  $\psi$  is a set of sets of literals representing a CNF formula */
/* Output is either “unsatisfiable” or a model for  $\psi$  */
/* Locals: set of variables  $M$  */
Set  $M \leftarrow \emptyset$ .
Repeat the following until some statement below outputs a value:
  If  $\emptyset \in \psi$ , Output “unsatisfiable.”
  If there are two clauses  $c_1, c_2 \in \psi$  such that  $\mathcal{R}_{c_2}^{c_1} \notin \psi$  exists,
    Set  $\psi \leftarrow \psi \cup \{\mathcal{R}_{c_2}^{c_1}\}$ .
  Otherwise,
    Repeat the following while there is a pure literal  $l$  in  $\psi$ :
      If  $l$  is a positive literal, Set  $M \leftarrow M \cup \{l\}$ .
      Set  $\psi \leftarrow \{c : c \in \psi, l \notin c\}$ .
    Arbitrarily index all variables in  $V_\psi$  as  $v_1, v_2, \dots, v_n$ .
    Repeat the following for  $i$  from 1 to  $n$ :
      If  $M_{1:i}$  falsifies some clause in  $\psi$ , Set  $M \leftarrow M \cup \{v_i\}$ .
    Output  $M$ .

```

□

Fig. 16 Resolution algorithm for CNF formulas

remove clauses containing pure literals is executed, followed by a final **Repeat** block which adds some variables to M .

Consider the result of the **Repeat** block on pure literals. All the clauses removed in this block are satisfied by M because all variables associated with negative pure literals are absent from M and all variables associated with positive pure literals are in M . Call the set of clauses remaining after this **Repeat** block ψ' . Now, consider the final **Repeat** block. If $\psi' = \emptyset$, then all clauses are satisfied by M from the previous **Repeat** block, and $M_{1:i}$ will never falsify a clause for any i . In that case M is returned and is a model for ψ . So suppose $\psi' \neq \emptyset$. The only way a clause can be falsified by $M_{1:i}$ is if it is $\{v_i\}$. In that case, the line “Set $M \leftarrow M \cup \{v_i\}$ ” changes M to satisfy that clause. The clause $\{\neg v_1\} \notin \psi'$ because otherwise it would have resolved with $\{v_1\}$ to give $\emptyset \in \psi$ which violates the hypothesis that the pure literal **Repeat** block was entered. Therefore, no clauses are falsified by $M_{1:i}$ at the beginning of the second iteration of the **Repeat** block when $M_{1:2}$ is considered.

Assume the general case that no clause is falsified for $M_{1:i-1}$ at the beginning of the i th iteration of the final **Repeat** block. A clause c_1 will be falsified by $M_{1:i}$ but not by $M_{1:i-1}$ if it contains literal v_i , which cannot be a pure literal that was processed in the previous **Repeat** block. Then, the line “Set $M \leftarrow M \cup \{v_i\}$ ” changes M to satisfy c_1 without affecting any previously satisfied clauses. However, it is possible that a clause that was not previously satisfied becomes falsified by the change. If there were such a clause c_2 , it must contain literal $\neg v_i$ and no other literal in c_2 would have a complement in c_1 ; otherwise, it would already have been satisfied by $M_{1:i-1}$. That means ψ , before the pure literal **Repeat** block, would contain $\mathcal{R}_{c_2}^{c_1}$. Moreover, $\mathcal{R}_{c_2}^{c_1}$ could not be satisfied by $M_{1:i-1}$ because such an assignment

would have satisfied c_1 and c_2 . But then $\mathcal{R}_{c_2}^{c_1}$ must be falsified by $M_{1:i-1}$ because it contains literals associated only with variables v_1, \dots, v_{i-1} . But this is impossible by the inductive hypothesis. It follows that the line “Set $M \leftarrow M \cup \{v_i\}$ ” does not cause any clauses to be falsified and that no clause is falsified for $M_{1:i}$. Since no clause is falsified by $M_{1:n}$, all clauses must be satisfied by M which is then a model. The statement of the theorem follows. \square

Resolution is a powerful tool for mechanizing the solution to variants of SAT. However, in the case of an unsatisfiable input formula, since the resolution algorithm offers complete freedom to choose which pair of clauses to resolve next, it can be difficult to control the total number of clauses resolved and therefore the running time of the algorithm. The situation in the case of satisfiable input formulas is far worse since the total number of resolvents generated can be quite large even when a certificate of satisfiability can be generated quite quickly using other methods.

It is easy to find examples of formulas on which the resolution algorithm may perform poorly or well, depending on the order of resolvents, and one infinite family is presented here. Let there be n *normal* variables $\{v_0, v_1, \dots, v_{n-1}\}$ and $n - 1$ *selector* variables $\{z_1, z_2, \dots, z_{n-1}\}$. Let each clause contain one normal variable and one or two selector variables. For each $0 \leq i \leq n - 1$, let there be one clause with v_i and one with $\neg v_i$. The selector variables allow the clauses to be *chained* together by resolution to form any n -literal clause consisting of normal variables. Therefore, the number of resolvents generated could be as high as $2^{O(n)}$ although the input length is $O(n)$. The family of input formulas is specified as follows:

$$\begin{aligned} & \{\{v_0, \neg z_1\}, \{z_1, v_1, \neg z_2\}, \{z_2, v_2, \neg z_3\}, \dots, \{z_{n-2}, v_{n-2}, \neg z_{n-1}\}, \{z_{n-1}, v_{n-1}\}, \\ & \{\neg v_0, \neg z_1\}, \{z_1, \neg v_1, \neg z_2\}, \dots, \{z_{n-2}, \neg v_{n-2}, \neg z_{n-1}\}, \{z_{n-1}, \neg v_{n-1}\}\}. \end{aligned}$$

The number of resolvents generated by the resolution algorithm greatly depends on the order in which clauses are chosen to be resolved. Resolving vertically, the 0th column adds resolvent $\{\neg z_1\}$. This resolves with the clauses of column 1 to add $\{v_1, \neg z_2\}$ and $\{\neg v_1, \neg z_2\}$, and these two add resolvent $\{\neg z_2\}$. Continuing, resolvents $\{\neg z_3\}, \dots, \{\neg z_{n-1}\}$ are added. Finally, $\{\neg z_{n-1}\}$ resolves with the two clauses of column $n - 1$ to generate resolvent \emptyset showing that the formula is unsatisfiable. The total number of resolutions executed is $O(n)$ in this case. On the other hand, resolving horizontally (resolve one clause of column 0 with a clause of column 1, then resolve the resolvent with a clause from column 2, and so on), all 2^n n -literal clauses of *normal* variables can be generated before \emptyset is.

The number of resolution steps executed on a satisfiable formula can be outrageous. Remove column $n - 1$ from the above formulas. They are then satisfiable. But that is not known until $2^{O(n)}$ resolutions fail to generate \emptyset .

This example may suggest that something is wrong with resolution and that it should be abandoned in favor of faster algorithms. While this is reasonable for satisfiable formulas, it may not be for unsatisfiable formulas. As illustrated by [Theorem 5](#), in the case of providing a certificate of unsatisfiability, the resolution algorithm can always *simulate* the operation of many other algorithms in time

bounded by a polynomial on input length. So the crucial problem for the resolution algorithm, when applied to unsatisfiable formulas, is determining the order in which clauses should be resolved to keep the number of resolvents generated at a minimum. A significant portion of this chapter deals with this question. However, first consider an extension to resolution that has shown improved ability to admit short refutations.

5.3 Extended Resolution

In the previous section it was shown that the size of a resolution refutation can vary enormously depending on the order in which resolvents are formed. That is, for at least one family of formulas, there are both exponentially long and linearly long refutations. But for some families of formulas, nothing shorter than exponential size resolution refutations is possible. However, the simple idea of *extended resolution* can sometimes yield short refutations in such cases.

Extended resolution is based on a result of Tseitin [139] who showed that, for any pair of variables v, w in a given CNF formula ψ , the following expression may be appended to ψ :

$$(z \vee v) \wedge (z \vee w) \wedge (\neg z \vee \neg v \vee \neg w), \quad (3)$$

where z is a variable that is not in ψ . From Fig. 14 this is equivalent to

$$z \leftrightarrow (\neg v \vee \neg w),$$

which means either v and w both have value 1 (then $z = 0$) or at least one of v or w has value 0 (then $z = 1$). Observe that as long as z is never used again, any of the expressions of Fig. 14 can be used in place of or in addition to (3). More generally,

$$z \leftrightarrow f(v_1, v_2, \dots, v_k)$$

can be used as well where f is any Boolean function of arbitrary arity. Judicious use of such extensions can result in polynomial size refutations for problems that have no polynomial size refutations without extension, a notable example being the pigeonhole formulas.

By adding variables not in ψ , one obtains, in linear time, a satisfiability-preserving translation from any propositional expression to CNF with at most a constant factor blowup in expression size as shown in Sect. 5.1.

5.4 Davis-Putnam Resolution

The Davis-Putnam procedure (DPP) [51] is presented here mainly for historical reasons. In DPP, a variable v is chosen and then all resolvents with v as pivot are

generated. When no more such resolvents can be generated, all clauses containing v or $\neg v$ are removed and the cycle of choosing a variable, generating resolvents, and eliminating clauses is repeated to exhaustion. The fact that it works is due to the following result.

Lemma 3 *Let ψ be a CNF formula. Perform the following operations:*

$$\psi_1 \leftarrow \psi.$$

Choose any variable v from ψ_1 .

Repeat the following until no new resolvents with v as pivot can be added to ψ_1 :

If there is a pair of clauses $c_1, c_2 \in \psi_1$ such that $\mathcal{R}_{c_2}^{c_1}$ with v as pivot exists and $\mathcal{R}_{c_2}^{c_1} \notin \psi_1$,

$$\psi_1 \leftarrow \psi_1 \cup \{\mathcal{R}_{c_2}^{c_1}\}.$$

$$\psi_2 \leftarrow \psi_1.$$

Repeat the following while there is a clause $c \in \psi_2$ such that $v \in c$ or $\neg v \in c$:

$$\psi_2 \leftarrow \psi_2 \setminus \{c\}.$$

Then ψ is satisfiable if and only if ψ_2 is satisfiable.

Proof By Lemma 2 ψ_1 is functionally equivalent to ψ . Since removing clauses cannot make a satisfiable formula unsatisfiable, if ψ and therefore ψ_1 is satisfiable, then so is ψ_2 .

Now, suppose ψ is unsatisfiable. Consider any pair of assignments M (without v) and $M \cup \{v\}$. Either both assignments falsify some clause not containing v or $\neg v$ or else all clauses not containing v or $\neg v$ are satisfied by both M and $M \cup \{v\}$. In the former case, some clause common to ψ and ψ_2 is falsified by M , so both formulas are falsified by M . In the latter case, M must falsify a clause $c_1 \in \psi$ containing v , and $M \cup \{v\}$ must falsify a clause containing $\neg v$. Then the resolvent $\mathcal{R}_{c_2}^{c_1} \in \psi_2$ is falsified by M . Therefore, since every assignment falsifies ψ , ψ_2 is unsatisfiable. \square

Despite the apparent improvement in the management of clauses over the resolution algorithm, DPP is not considered practical. However, it has spawned some other commonly used variants, especially the next algorithm to be discussed.

5.5 Davis-Putnam Loveland Logemann Resolution

Here a reasonable implementation of the key algorithmic idea in DPP is presented. The idea is to repeat the following: choose a variable, take care of all resolutions due to that variable, and then erase clauses containing it. The algorithm, called DPLL [52], is shown in Fig. 17. It was developed when Loveland and Logemann attempted to implement DPP but found that it used too much RAM. So they changed the way variables are eliminated by employing the splitting rule: assignments are

Algorithm 3.

```

DPLL ( $\psi$ )
/* Input  $\psi$  is a set of sets of literals representing a CNF formula */ 
/* Output is either “unsatisfiable” or a model for  $\psi$  */ 
/* Locals: integer  $d$ , variable stack  $V_P$ , list of formulas  $\psi_0, \psi_1, \dots$  */ 
/*           partial assignments  $M_{1:d}$ . */ 

Set  $d \leftarrow 0$ ; Set  $M_{1:0} \leftarrow \emptyset$ ; Set  $\psi_0 \leftarrow \psi$ ; Set  $V_P \leftarrow \emptyset$ .
Repeat the following until some statement outputs a value:
  If  $\psi_d = \emptyset$ , Output  $M_{1:d}$ .
  If  $\emptyset \in \psi_d$ ,
    Repeat the following until  $l$  is “tagged.” 
      If  $V_P = \emptyset$ , Output “unsatisfiable.”
      Pop  $l \leftarrow V_P$ .
      Set  $d \leftarrow d - 1$ .
      Push  $V_P \leftarrow \neg l$ . /*  $l$  and  $\neg l$  are not tagged */
      If  $l$  is a negative literal then  $M_{1:d+1} \leftarrow M_{1:d} \cup \{\neg l\}$ .
      Otherwise,  $M_{1:d+1} \leftarrow M_{1:d}$ .
      Set  $\psi_{d+1} \leftarrow \{c - \{\neg l\} : c \in \psi_d, l \notin c\}$ .
      Set  $d \leftarrow d + 1$ .
    Otherwise,
      If there exists a pure literal in  $\psi_d$ ,
        Choose a pure literal  $l$ .
      Otherwise, if there is a unit clause in  $\psi_d$ ,
        Choose a literal  $l$  in a unit clause and “tag”  $l$ .
      Otherwise,
        Choose a literal  $l$  in  $\psi_d$  and “tag”  $l$ .
      Push  $V_P \leftarrow l$ .
      If  $l$  is a positive literal,  $M_{1:d+1} \leftarrow M_{1:d} \cup \{l\}$ .
      Otherwise,  $M_{1:d+1} \leftarrow M_{1:d}$ .
      Set  $\psi_{d+1} \leftarrow \{c - \{\neg l\} : c \in \psi_d, l \notin c\}$ .
      Set  $d \leftarrow d + 1$ .

```

□

Fig. 17 DPLL algorithm for CNF formulas

recursively extended by one variable in both possible ways, looking for a satisfying assignment. Thus, DPLL is of the divide-and-conquer family of algorithms.

The DPLL algorithm of Fig. 17 is written iteratively instead of recursively for better comparison with other algorithms to be discussed later. Omitted is a formal proof of the fact that the output of DPLL on input ψ is *unsatisfiable* if and only if ψ is unsatisfiable, and if the output is a set of variables, then it is a model for ψ . The reader may consult [52] for details.

A common visualization of the flow of control of DPLL and similar algorithms involves a graph structure known as a search tree. Since search trees will be used several times in this chapter to assist in making some difficult points clear, this concept is explained here. A *search tree* is a rooted acyclic digraph where each

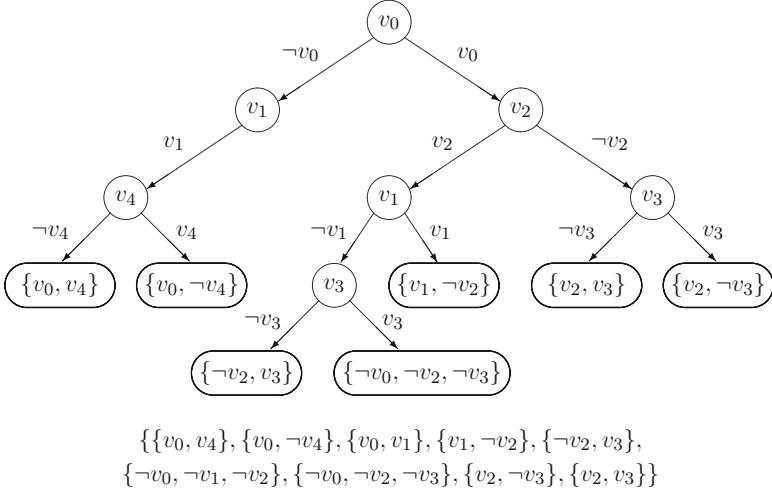

Fig. 18 A DPLL refutation tree for the above CNF formula

vertex has out-degree at most 2 and in-degree 1 except for the root. Each internal vertex represents some Boolean variable and each leaf may represent a clause or may have no affiliation. If an internal vertex represents variable v and it has two outward-oriented edges, then one is labeled v and the other is labeled $\neg v$; if it has one outward-oriented edge, that edge is labeled either v or $\neg v$. All vertices encountered on a path from root to a leaf represent distinct variables. The labels of edges on such a path represent a truth assignment to those variables: $\neg v$ means set the value of v to 0 and v means set the value of v to 1.

The remaining details are specific to a particular CNF formula ψ which is input to the algorithm modeled by the search tree. A leaf is such that the partial truth assignment represented by the path from the root either minimally satisfies all clauses of ψ or minimally falsifies at least one clause of ψ . In the latter case, one of the clauses falsified becomes the label for the leaf. If ψ is unsatisfiable, all leaves are labeled and the search tree is a *refutation tree*. A fully labeled refutation tree modeling one possible run of DPLL on a particular unsatisfiable CNF formula is shown in Fig. 18. With reference to Fig. 17, a path from the root to any vertex represents the state of V_P at some point in the run. For a vertex with out-degree 2, the left edge label is a *tagged literal*. For vertices with out-degree 1, the single edge label is a *pure literal*.

The DPLL algorithm is a performance compromise. Its strong point is that sets of resolvents are constructed incrementally, allowing some sets of clauses and resolvents to be entirely removed from consideration long before the algorithm terminates. But this is offset by the weakness that some freedom in choosing the order of forming resolvents is lost, so more resolvents may have to be generated. Applied to a satisfiable formula, DPLL can be a huge winner over the resolution

algorithm: if the right choices for variable elimination are made, models may be found in $O(n)$ time. However, for an unsatisfiable formula it is not completely clear which algorithm performs best generally. [Theorem 5](#) below shows that if there is a short DPLL refutation for a given unsatisfiable formula, then there must be a short resolution refutation for the same formula.⁵ But, in [7] a family of formulas for which a shortest resolution proof is exponentially smaller than the smallest DPLL refutation is presented. These facts seem to give the edge to resolution. On the other hand, it may actually be relatively easy to find a reasonably short DPLL refutation but very hard to produce an equally short or shorter resolution refutation. An important determining factor is the order in which variables or resolutions are chosen, and the best order is often sensitive to structural properties of the given formula. For this reason, quite a number of choice heuristics have been studied and some results on these are presented later in this chapter.

Many modern SAT solvers augment DPLL with other features such as restarts and conflict-driven clause learning. The refutation complexity of a solver so modified is then theoretically similar to that of resolution. More will be said about this in subsequent sections.

This section concludes with the following classic result.

Theorem 5 *Suppose DPLL is applied to a given unsatisfiable CNF formula ψ and suppose the two lines “Set $\psi_{d+1} \leftarrow \{c - \{\neg l\} : c \in \psi_d, l \notin c\}$ ” are together executed p times. Then there is a resolution refutation in which no more than $p/2$ resolvents are generated.*

Proof Run DPLL on ψ and, in parallel, generate resolvents from clauses of ψ and other resolvents. At most one resolvent will be generated every time the test “If $V_P = \emptyset$ ” succeeds or the line “Pop $l \leftarrow V_P$ ” is executed and l is neither tagged nor a pure literal. But this is at most half the number of times ψ_{d+1} is set. Hence, when DPLL terminates on an unsatisfiable formula, at most $p/2$ resolvents will be generated. Next, it is shown how to generate resolvents and show that \emptyset is a resolvent of two of them.

The idea can be visualized as a series of destructive operations on a DPLL refutation tree. Assume clauses in ψ label leaves as discussed on [Page 358](#). Repeat the following: if there are two leaf siblings, replace the subtree of the two siblings and their parent either with the resolvent of the leaf clauses, if they resolve, or with the leaf clause that is falsified by the assignment represented by the path from root to the parent (there must be one if ψ is unsatisfiable); otherwise, there is a pair of vertices consisting of one leaf and a parent, so replace this pair with the leaf. Replacement entails setting the edge originally pointing to the parent to point to the replacement vertex. Eventually, the tree consists of a root only and its label is the empty clause.

⁵See [39] for other results along these lines.

This visualization is implemented as follows. Define a stack S and set $S \leftarrow \emptyset$. The stack will hold clauses of ψ and resolvents. Run DPLL on ψ . In parallel, manipulate S as follows:

1. The test “If $\emptyset \in \psi_d$ ”:

Whenever this test succeeds, there is a clause $c \in \psi$ whose literals can only be complements of those in V_P so push $S \leftarrow c$.

2. The line “Pop $l \leftarrow V_P$ ”:

Immediately after execution of this line, if l is not *tagged* and is not a pure literal, then do the following. Pop $c_1 \leftarrow S$ and pop $c_2 \leftarrow S$. If c_1 and c_2 can resolve, push $S \leftarrow \mathcal{R}_{c_2}^{c_1}$; otherwise, at least one of c_1 or c_2 , say, c_1 , does not contain l or $\neg l$, so push $S \leftarrow c_1$.

3. The line “If $V_P = \emptyset$, Output ‘unsatisfiable.’”:

The algorithm terminates so pop $c_1 \leftarrow S$, pop $c_2 \leftarrow S$, and form the resolvent $c_t = \mathcal{R}_{c_2}^{c_1}$.

We claim that, when the algorithm terminates, $c_t = \emptyset$.

To prove this claim, it is shown that when c_1 and c_2 are popped in Step 2, c_2 contains literals that are only complementary to those of a subset of $V_P \cup \{l\}$ and c_1 contains literals that are only complementary to those of a subset of $V_P \cup \{\neg l\}$, and if l is a pure literal in the same step, then c_1 contains literals complementary to those of a subset of V_P . Since $V_P = \emptyset$ when c_1 and c_2 are popped to form the final resolvent, c_t , it follows that $c_t = \emptyset$.

By induction on the maximum depth of stacking of c_2 and c_1 . The base case has c_2 and c_1 as clauses of ψ . This can happen only if c_2 had been stacked in Step 1 then Step 2 was executed and then c_1 was stacked soon after in Step 1. It is straightforward to check that the hypothesis is satisfied in this case.

Suppose the hypothesis holds for maximum depth up to k and consider a situation where the maximum depth of stacking is $k + 1$. There are two cases. First, suppose l is a pure literal. Then neither l nor $\neg l$ can be in c_1 so, by the induction hypothesis, all of the literals of c_1 must be complementary to literals of V_P . Second, suppose l is not *tagged* and not a pure literal. Then c_1 and c_2 are popped. By the induction hypothesis, c_1 contains only literals complementary to some in $V_P \cup \{\neg l\}$ and c_2 contains only literals complementary to some in $V_P \cup \{l\}$. Therefore, if they resolve, the pivot must be l and the resolvent contains only literals complementary to some in V_P . If they do not resolve, by the induction hypothesis, one must not contain l or $\neg l$. That one has literals only complementary to those of V_P , so the hypothesis holds in this case. \square

5.6 Conflict-Driven Clause Learning

Early SAT solvers used refinements and enhancements to DPLL to solve SAT instances. Recently, these refinements and enhancements have been standardized and developed into a parameterized algorithm. This algorithm is far enough removed from DPLL that it is commonly referred to as conflict-driven clause learning (CDCL) [119, 130, 131].

The reasons for the increased solving power and efficiency of modern SAT solvers lie in specialized CDCL techniques tailored to support core CDCL operations such as binary constraint propagation (BCP) and heuristic computation. Each technique on its own is not very impressive but, when all of these techniques are fitted together in the DPLL framework, orders of magnitude improvement can be seen. For example, conflict clause learning helps to create a dynamic search space that is DAG-like instead of treelike as was the case for early DPLL-based algorithms [16]. This technique, when used in conjunction with dynamic restarts, is as strong as general resolution and exponentially more powerful than DPLL [16]. The combination of such techniques has allowed SAT solvers to be used practically in a wide range of fields such as bioinformatics [107], cryptography [110, 132], and planning [46, 151] as well as on many hard combinatorial problems such as van der Waerden numbers [100, 101]. Also, the recent integration of SAT-based techniques with theory solvers (this technology is named SMT [126] – details are given in Sect. 5.7) is enabling push-button solutions to industrial strength problems that previously required expert human interaction to solve (e.g., see [77]).

Two chapters in the Handbook of Satisfiability [19] cover CDCL extensively. The reader is referred to [50] and [131] for details. The remainder of this section highlights the main points.

5.6.1 Conflict Analysis

DPLL explores both sides of a choicepoint before backtracking over it. This is called *chronological backtracking* and is not generally conducive to good SAT solving because it is often the case that the same conflict exists on both sides of a choicepoint. Analyzing the conflict on one side may prevent re-computation of the same conflict on the other side, in which case the choicepoint can be *backjumped* over. Performing conflict analysis in the framework of DPLL enables nonchronological backtracking, which, in effect, works to counteract bad decisions made by the search heuristic.

Conflict analysis is often depicted in terms of an implication graph, though, in practice, the implication graph is not actually built. In modern SAT solvers, new clauses are generated by resolution steps ordered by the current search tree path. Specifically, a conflict is reached when two asserting clauses infer opposing literals during BCP. These two clauses can be resolved together to create a new clause called a *conflict clause*. This clause will either be the empty clause (in which case the formula is unsatisfiable) or it will, if evaluated under the current partial assignment, be falsified. Consider the most recently assigned literal in the conflict clause. If the literal was assigned by an asserting clause, the conflict clause and the asserting clause are resolved, creating a new conflict clause, and the process is repeated. If the literal was assigned by a choicepoint, the current search tree up to the literal is undone and the value assigned by the choicepoint is flipped. All new conflict clauses may be safely added to the original CNF formula (i.e., learned) because they are logical consequences of the original formula [130]. Learning conflict clauses helps to prune the search space by preventing re-exploration of shared search structure, especially when used in conjunction with restarts. Also, prior to adding

newly learned clauses, it may be beneficial to attempt to minimize the clauses by performing a restricted version of resolution with other asserting clauses [15, 143].

There is at least one special case to consider when learning conflict clauses. If a conflict clause contains only one literal at the current decision level, called a unique implication point (UIP), the search state can backjump to the second most recently assigned literal in the clause. This will cause the UIP literal to be naturally inferred via BCP [112] and has the effect of promoting those parts of the search tree relevant to the current conflict.

Conflict analysis is also used to generate resolution proofs of unsatisfiable instances. In the same way that an assignment to a satisfiable instance acts as a polynomial-time checkable certificate that an instance is satisfiable, a resolution proof acts as a certificate of unsatisfiability, checkable in linear time and space on the number of learned clauses (though the number of learned clauses can be exponential on the number of variables in the best case). More information on this topic can be found in [15, 150], and [142].

5.6.2 Conflict Clause Memory Management

Not all derived conflict clauses can be stored. Too many conflict clauses increase the overhead of finding an applicable one, and too few conflict clauses reduce the chance that a good one can be found to prune the search space. Therefore, the size of the conflict clause database, what goes into it, and how long entries should stay there have been well studied. The number of conceivable schemes is quite large. A good one was recently discovered and reported in [11]. In that paper the learned clause measure LBD (for literals blocks distance) is defined to be the number of different levels at which literals of a clause were assigned values as choicepoints up to the current assignment. A small LBD suggests a learned clause that was useful in generating a long sequence of unit resolutions. It was found in experiments on all SAT-Race '06 benchmarks that 40 % of unit resolutions occur in clauses of $LBD = 2$ versus 20 % on 2-literal clauses, and generally, the lower the LBD, the more significant the contribution to BCP. Due to this, the following *cleaning strategy* was proposed: remove half of the learned clauses, not including a class of easy discovered clauses of least LBD, every $20000 + 500 * x$ conflicts, where x is the number of times this operation has been performed before on the current input. Adding this strategy to existing solvers resulted in a significant improvement in performance.

Many other ideas for determining the life of conflict clauses have been proposed and tried. Several of these are mentioned in [131] near the end of the chapter.

5.6.3 Lazy Structures

An important aspect of CDCL associated with performance has to do with maintaining data structures that store solver state. The degree to which these structures are managed lazily has an impact on the optimal choice of other solver mechanisms. For example, lazy structures result in faster backtracking, so “the authors of Chaff proposed to always stop clause learning at the first UIP” and “always take the backtrack step” [131]. In addition, the implementation of BCP and conflict analysis

is influenced by the implementation of lazy structures. Using lazy structures, the fact that a clause becomes satisfied by a state change may not be reported to solver mechanisms immediately or even at all. This presents potential savings by preventing some unnecessary computation and does not affect the correctness of the solver. Next, in this section the classic notion of watched literals [112] is used to illustrate this point.

Suppose a clause is stored as a sequence of literals and suppose the number of literals is at least 2. For each clause, assign two pointers each pointing to one of the literals but both pointing to different literals of the clause. The literals pointed to are called *watched literals* and are distinguished in name as the *first* and *second* watched literal. The following properties are maintained always:

1. A clause is satisfied if and only if its first watched literal has value 1.
2. A clause is falsified if and only if its first and second watched literals have value 0.
3. A clause is *unit* if and only if one watched literal is unassigned and the other has value 0.
4. A clause is unassigned and not *unit* if and only if both watched literals are unassigned.

Initially, a clause is unassigned and the pointers are pointing to arbitrary literals. If a clause is unassigned, not *unit*, and a literal other than the second watched literal takes value 1, then that literal becomes the first watched literal. If the literal taking value 1 is the second watched literal, the first and second watched literals are swapped. If both watched literals are unassigned and one of them takes value 0, a check must be made to determine whether the clause has another unassigned literal. If it does not, the clause becomes a unit clause and the single unassigned literal takes value 1 and becomes the first watched literal swapping title, if necessary, with the watched literal of value 0. Otherwise, the pointer referencing the recently assigned watched literal gets set to point to the unassigned literal that was found during the check. The search for an unassigned literal can proceed in any direction among the literals of the clause. Observe that the watched literal pointers do not have to be reset on backtrack. Further savings are obtained by associating a *level* and *value* field with every literal: when a clause is satisfied or falsified, it is the level and value of the first watched literal that is set. Since watched literals do not change during backtrack, this information represents clause status as well. Earlier schemes for managing clause status during backtrack associate level and value fields with clauses and require searching the literals of a clause to determine status. Thus, implementing the watched literal concept results in much less backtracking overhead and significantly increases the number of backtracks handled per second.

As can be observed from the above discussion, watched literals are useful in reacting to single-variable inferences. But more advanced techniques look at multivariable inferences, for example, two-variable equivalence. Watched literals cannot help in this case. Additional clause references, of course, may be used to support these advances [141] at added expense. Another idea [106] is to maintain an order of assigned literals in a clause by nondecreasing level, while the unassigned literals remain watched as above. As a variable is assigned a value, it is *sifted* into

its proper place in the ordered list. The problem with this idea is that all literals in the ordered list may need to be visited on a backtrack.

5.6.4 CDCL Heuristics

Lazy data structures can drastically increase the speed of BCP, but since the current state of the search is not readily available, traditional heuristics such as MOMs (see [60] for a complete discussion), Jeroslow-Wang [80], and Johnson [81] cannot be used. The first CDCL heuristic is the variable state independent decaying sum (VSIDS) [112] heuristic. VSIDS maintains one counter per literal in the SAT instance, initialized to the number of clauses each literal occurs in. VSIDS branches on the literal with the highest count, though this requires sorting the counters, which is expensive, and so is only done periodically. When a new clause is learned, the counts for each literal in the clause are incremented. Also periodically, the counters are halved. This heuristic and many similar variants efficiently glean information from learned clauses to guide the solver towards unsatisfiable cores, enabling modern solvers to solve large SAT instances (millions of variables and clauses) that have small resolution proofs.

5.6.5 Restarts

Conflict-directed heuristics can sometimes cause a solver to focus too heavily on one particular region of the search space, leading to heavy-tailed runtime distribution (where progress seems to exponentially decrease the longer a solver runs). One way to positively modify this behavior [68] is to restart. A *dynamic restart* [76, 88] clears a solver’s current partial assignment; heuristic information and learned clauses are kept, and a short preprocessing phase where the learned clause database is garbage collected may typically follow a restart. As reported empirically in the literature, “it is advantageous to restart often” [50].

5.7 Satisfiability Modulo Theories

Despite highly significant and broad advances to SAT solver design, there are still many problems for which DPLL and CDCL variants are a challenge. For example, it is well known that verifying correctness of arithmetic circuits is generally difficult for SAT solvers. The problem is that datapath operations are over a fixed bit-width and, beyond modular arithmetic, some operations such as multiplication are not linear and particularly vexing for SAT solvers. An accepted method, called *bit-blasting*, for dealing with small bit-widths is to describe operations as propositional formulas over vectors of Boolean variables, convert to CNF using the results of Sect. 5.1, and solve with a SAT solver. But it is doubtful that bit-blasting is going to be universally practical for 64-bit or even 32-bit logic. As another, more universally occurring example, SAT solvers have a difficult time handling cardinality constraints and, more generally, constraints comparing numeric expressions. To mitigate these and other problems, a significant body of research has studied the use of a SAT solver to manage a collection of special purpose solvers for first order theories,

including bit-vector arithmetic. This extension of SAT has found applications in hardware verification, software model checking and testing, and vulnerability detection, among other applications, and is called *Satisfiability Modulo Theories* or SMT.

A formal specification of SMT is not given here; the reader is invited to check [12] for the syntax and semantics of SMT-LIB, the official documented language of SMT solvers. Most importantly, with respect to SAT, an instance of SMT is a formula in first-order logic where uninterpreted functions are admitted and Boolean variables are used to tie predicates from disparate theories and allow a SAT solver to decide the consistency of the constraints of the instance. The scope of SMT is made apparent through the SMT examples shown in Figs. 19 and 20. The examples are expressed in a lisp-like language that is native to YICES [55], one of the leading available SMT solvers, and may actually be input to YICES.

In Fig. 19, f and g are uninterpreted functions: note that only their signatures, namely, a single `int` as input and an `int` as output, are defined in the second and third lines. However, the fifth and sixth lines force $f(x) = x$, $g(y) = x$, and $g(x) = y$ for all integers. This is inconsistent with the seventh line which requires, for any integer a , that $g(f(g(a)))$, which is $g(g(a))$ and therefore a from the above, is not equal to a . On this input YICES returns `unsat`. If $/=$ (not equal) is changed to $=$, YICES returns `unknown` with the following interpretation: $a = 2$, $g(2) = 1$, $f(1) = 1$, $g(1) = a2$. The first and eighth lines are YICES-specific directives.

Figure 20 shows constraints expressed in terms of bit-vector operations. This instance is satisfied by 8-bit numbers $b1$ and $v2$ such that multiplying $b1$ by 17, shifting right by 2 bits, and adding $v2$ result in 39.

YICES output on this example is as follows:

```
sat
(= v1 0b00100111)
(= b1 0b01110110)
(= b2 0b11010110)
(= v2 0b11110010)
```

That is, $b1$ is 118 and $v2$ is 242, which is one of many possible solutions.

Clearly, admitting bit-vector operations is important as it makes circuit design and verification problems easier to express and solve: trying to express the constraints of such problems as a CNF formula is unnatural and time-and-space consuming. A special solver for the theory of bit-vector arithmetic and logic may be developed to handle bit-vector predicates such as those in Fig. 20. Other theory solvers may be designed to handle other problems that are difficult for CNF solvers. Examples of such theories, including the theory of bit-vectors, are as follows:

1. *Linear arithmetic (LA)*: constraints are equations or inequalities involving addition and subtraction over rational variables, constants, or constants times variables.
2. *Uninterpreted functions (UF)*: all uninterpreted function, constant, and predicate symbols together with Leibniz's law that allows substitution of equals for equals.
3. *Difference arithmetic*: this is linear arithmetic restricted to equations or inequalities of the form $x - y \leq c$ where x and y are variables and c is a constant.
4. *Nonlinear arithmetic*: constraints are like linear arithmetic except that variables may be multiplied by other variables.
5. *Arrays*: array constraints ensure that the value of a memory location does not change unless a specific *write* operation on that location with a different value is executed and that a value written to a location may be accessed by a read operation. Symbols of this theory might be *select* and *store* with semantics given by the following:

```
select(store(v, i, e), j) = if  $i = j$  then  $e$  else select( $v, j$ )
store( $v, i, \text{select}(v, i)$ ) =  $v$ 
store(store( $v, i, e$ ),  $i, f$ ) = store( $v, i, f$ )
 $i \neq j \Rightarrow \text{store}(\text{store}(v, i, e), j, f) = \text{store}(\text{store}(v, j, f), i, e)$ ,
```

where *select*(v, j) means read the j th value from array v and *store*(v, i, e) means store the value e into the i th element of array v .

6. *Lists*: symbols of this theory might be *car*, *cdr*, *cons*, and *atom* with semantics given by the following:

```
car(cons( $x, y$ )) =  $x$ 
cdr(cons( $x, y$ )) =  $y$ 
\neg atom( $x$ ) \Rightarrow cons(car( $x$ ), cdr( $x$ )) =  $x$ 
\neg atom(cons( $x, y$ ))
```

7. *Fixed-width bit-vectors*: the main reason for including a bit-vector theory is to remove the burden of solving bit-level formulas from the SAT solver. As seen in Fig. 20, constraints are expressed at word level and may involve any machine-level operations on words.
8. *Recursive data types*: this is an abstraction for common data structures that may be defined recursively such as linked lists and for common data types that may be defined recursively such as a tree or the natural numbers.

It is not within the scope of this chapter to discuss the construction of decision procedures for theories. The interested reader may begin a search for such information by consulting [13]. The remainder of this section will show how a SAT solver can be made to interact with constraints from several theories.

Some definitions are given now to make the procedures to be discussed later easier to express and analyze. A *first-order formula* is an expression consisting of a set V of variables and symbols $(,)$, \neg , \vee , \wedge , \rightarrow , \exists , \forall ; a set \mathcal{P} of predicate symbols; a set \mathcal{F} of function symbols, each with associated positive arity; and a set $C \subset \mathcal{F}$ of constant symbols which are just 0-arity function symbols, for example, x or f . A *signature*, denoted Σ , is a subset of $\mathcal{F} \cup \mathcal{P}$. A *first-order structure* \mathcal{A} specifies a semantics for the above: that is, a domain A of elements, mappings of every n -ary function symbol $f \in \Sigma$ to a total function $f^{\mathcal{A}} : A^n \mapsto A$ and mappings of every n -ary predicate symbol $p \in \Sigma$ to a relation $p^{\mathcal{A}} \subseteq A^n$. The symbols \exists and \forall are quantifiers and the scope of one of these is the entire formula. A *sentence* is a formula all of whose variables are bound by a quantifier (i.e., the formula has no free variables) and therefore evaluates either to *true* or *false*, depending on the structure it is evaluated over. A formula is a *ground formula* if it has no variables. Observe that $x + 1 \leq y$ has no variables because x and y are constants in the theory of linear arithmetic and is therefore a ground formula. Denote $(\mathcal{A}, \alpha) \models \phi$ to mean the sentence ϕ evaluates to *true* in structure \mathcal{A} under variable assignment $\alpha : V \mapsto A^{|V|}$. Sentence ϕ is said to be *satisfiable* in \mathcal{A} if $(\mathcal{A}, \alpha) \models \phi$ for some α . Sentence ϕ is said to be *valid* in \mathcal{A} if $(\mathcal{A}, \alpha) \models \phi$ for every α . If \mathcal{A} is finite, the question $(\mathcal{A}, \alpha) \models \phi$ for some α and given ϕ is decidable. However, for infinite structures, the question may be undecidable.

A *theory* T is a set of first-order sentences expressed in the language of some signature Σ . Equality is implicit in the theories mentioned earlier so their signatures do not contain the symbol $=$. A *model* of T is a structure \mathcal{A} in which every sentence of T is valid. Denote by $T \models \phi$ the condition where \mathcal{A} is a model for T and $(\mathcal{A}, \alpha) \models \phi$ for all α . Then ϕ is said to be *T -valid*. Let \perp denote a formula that is not satisfied by any structure. Then ϕ is said to be *T -satisfiable* if $T \cup \{\phi\} \not\models \perp$, also written $T, \phi \not\models \perp$. T -validity and T -satisfiability are seen as dual concepts since $T, \neg\phi \models \perp$ if and only if $T \models \phi$.

One is generally interested in combining theories: that is, proving that statements with terms from more than one theory are valid over those combined theories. Suppose, for two theories T_1 of Σ_1 and T_2 of Σ_2 , there exist procedures P_1 and P_2 that determine whether a given formula ϕ_1 expressed in the language of Σ_1 is T_1 -valid and whether a given formula ϕ_2 expressed in the language of Σ_2 is T_2 -valid,

respectively. It is generally not possible to solve the problem of determining whether $\{\phi_1\} \cup \{\phi_2\}$ in the language of $\Sigma_1 \cup \Sigma_2$ is $(T_1 \cup T_2)$ -valid with P_1 and P_2 . However, it can be under some modest restrictions that usually do not get in the way in practice. These restrictions will be assumed for the rest of this section and are as follows: theories T_1 and T_2 are decidable, $\Sigma_1 \cap \Sigma_2 = \emptyset$, and T_1 and T_2 are stably infinite – let C be an infinite set of constants not in signature Σ and define a theory T of Σ to be *stably infinite* if every T -satisfiable ground formula of signature $\Sigma \cup C$ is satisfiable in a model of T with an infinite domain of elements.

By the duality noted above, the validity problem can be treated as a satisfiability problem where it is more conveniently solved. Suppose ϕ is a formula that is logically equivalent to a DNF formula with m conjuncts $\phi_{i,1} \wedge \phi_{i,2}$, $i \in \{1, 2, \dots, m\}$, where $\phi_{i,1}$ and $\phi_{i,2}$ are expressed in the language of $\Sigma_1 \cup C$ and $\Sigma_2 \cup C$, respectively, and C is a set of constants that are shared by $\phi_{i,1}$ and $\phi_{i,2}$. Terms $\phi_{i,1} \wedge \phi_{i,2}$ are said to be in pure form. Clearly, ϕ is $(T_1 \cup T_2)$ -unsatisfiable if and only if for all $i \in \{1, 2, \dots, m\}$, $\phi_{i,1} \wedge \phi_{i,2}$ is $(T_1 \cup T_2)$ -unsatisfiable. It is desirable to use P_1 and P_2 individually to determine this. By Craig's interpolation lemma [45], a pure-form term $\phi_{i,1} \wedge \phi_{i,2}$ is $(T_1 \cup T_2)$ -unsatisfiable if and only if there is a formula ψ , called an *interpolant*, whose free variables are a subset of the free variables contained in both $\phi_{i,1}$ and $\phi_{i,2}$ such that $T_1, \phi_{i,1} \models \psi$ and $T_2, \phi_{i,2}, \psi \models \perp$. Finding an interpolant is a primary goal of an SMT solver and the subject of much of the remainder of this section, the exposition of which is strongly influenced by Klaedtke [90]. Although combining only two theories is considered here, the process generalizes to more than two theories.

The first step in combining theories is to produce a pure-form formula from ϕ . This is accomplished by introducing variables to C which remove the dependence on objects from an *alien* theory through substitution. More specifically, suppose function $f \in \Sigma_1$ and one of its arguments t is a term, possibly a constant, expressed in Σ_2 . Then create a new w , set $C = C \cup \{w\}$, add a new constraint $w = t$, and replace t by w in the argument list of f . Similarly, for predicates $p \in \Sigma_1$, $p \in \Sigma_2$ and function $f \in \Sigma_2$. If there is a constraint $s = t$ where $s \in \Sigma_1$ and $t \in \Sigma_2$, then create a new w , and replace the constraint with $w = s$ and $w = t$. If there is a constraint $s \neq t$, then add a new w_1 and new w_2 and replace the constraint with $w_1 = s$, $w_2 = t$, and $w_1 \neq w_2$. For example, consider

$$\phi = \{x \leq y, y \leq x + \text{car}(\text{cons}(0, x)), p(h(x) - h(y)), \neg p(0)\},$$

which mixes uninterpreted functions, linear arithmetic, and lists. For this ϕ , $C = \{x, y\}$. The constraint on the left need not be touched because it only contains symbols from linear arithmetic. The subterm $h(x) - h(y)$ is mixed, so create new constants $g_1 = h(x)$ and $g_2 = h(y)$ and substitute $g_1 - g_2$ for $h(x) - h(y)$. The term $p(g_1 - g_2)$ is mixed, so create constant $g_3 = g_1 - g_2$ and substitute. The remaining term $p(g_3)$ has no *alien* subterms. The symbol 0 is alien to the theory of uninterpreted functions. Hence, create $g_4 = 0$ and substitute making the rightmost constraint $\neg p(g_4)$, and changing the list theory subterm to $\text{car}(\text{cons}(g_4, x))$, both

of which may be left alone. However, the second constraint from the left is still mixed, so create $g_5 = \text{car}(\text{cons}(g_4, x))$ and substitute. This leaves

$$\begin{aligned} C &= \{x, y, g_1, g_2, g_3, g_4, g_5\}, && (\text{Shared constants}) \\ \phi_1 &= \{x \leq y, y \leq x + g_5, g_3 = g_1 - g_2, g_4 = 0\}, && (\text{LA}) \\ \phi_2 &= \{g_1 = h(x), g_2 = h(y), p(g_4) = \text{false}, p(g_3) = \text{true}\}, && (\text{UF}) \\ \phi_3 &= \{g_5 = \text{car}(\text{cons}(g_4, x))\}, && (\text{Lists}) \end{aligned}$$

so ϕ has become a pure formula whose constraints are partitioned according to the theories of linear arithmetic, uninterpreted functions, and lists and are tied by newly created constants and equality constraints.

The next step is to propagate inferred equalities between the partitioned sections. First, this is illustrated using the above example, then a general procedure for propagation is presented. By the first axiom of the theory of lists, the constraint $g_5 = \text{car}(\text{cons}(g_4, x))$ infers $g_4 = g_5$. This propagates to section LA where $g_5 = 0$ is inferred. Then $y \leq x$ is inferred and $x = y$ is inferred from $x \leq y$ and $y \leq x$. The inferred constraint $x = y$ propagates to section UF where $g_1 = g_2$ is inferred. Propagating back to LA infers $g_3 = 0$ and finally $g_3 = g_4$. But this contradicts UF constraints which say $p(g_3) = \text{true}$ and $p(g_4) = \text{false}$. Hence, the conclusion is that ϕ is unsatisfiable in the combined theories of linear arithmetic, lists, and uninterpreted functions. Observe that ϕ_1 , ϕ_2 , and ϕ_3 are all satisfiable in their respective theories.

[Figure 21](#) shows an algorithm for determining satisfiability of a formula $\phi_1 \wedge \phi_2$ that is in pure form with ϕ_1 of signature $\Sigma_1 \cup C$, ϕ_2 of signature $\Sigma_2 \cup C$, C a set of shared constants, and $\Sigma_1 \cap \Sigma_2 = \emptyset$ and assumes there exist decision procedures P_1 and P_2 for theories T_1 and T_2 over Σ_1 and Σ_2 , respectively. It is straightforward to generalize this to any number of theories; it is also possible to use the generalized algorithm to decide any mixed theory formula by converting to DNF in pure form and applying the algorithm to the conjuncts separately. Step 1 applies decision procedures P_1 and P_2 to ϕ_1 and ϕ_2 . Both P_1 and P_2 not only decide whether their respective theories are consistent but also infer the maximum number of equalities from ϕ_1 and ϕ_2 within their respective theories. If no inconsistencies are found, these inferences are propagated out of their theories and the step is repeated; otherwise, *unsatisfiable* is returned. Step 2 does a case split in case a disjunction of equalities is inferred by one of the partitioned sets of constraints. Step 3 returns “satisfiable” if nothing else can be inferred and no inconsistencies between current sets ϕ_1 and ϕ_2 have been discovered. The algorithm always terminates since the number of shared constants is finite and the number of equalities added is directly related to that number. The algorithm closely follows the algorithm of the original Nelson-Oppen paper [113].

Completeness of [Algorithm 4](#) is not difficult to see. Soundness is proved by observing that the algorithm produces an interpolant for ϕ_1 and ϕ_2 : namely, the residue of $\phi_1 \wedge \phi_2$. The residue of a formula ϕ , denoted $\text{Res}(\phi)$, is the strongest collection of equalities between constants that are inferred by the formula. The important property of residues is that if ϕ_1 and ϕ_2 are formulas whose signatures

Algorithm 4.

```

CTSolver ( $\phi_1, \phi_2, P_1, P_2$ )
/* Input: formulas  $\phi_1$  over  $\Sigma_1 \cup C$ ,  $\phi_2$  over  $\Sigma_2 \cup C$ ,
   where  $\Sigma_1 \cap \Sigma_2 = \emptyset$ , and decision procedures
    $P_1, P_2$  for theories  $T_1$  over  $\Sigma_1$  and  $T_2$  over  $\Sigma_2$  */
/* Output: satisfiable if  $\phi_1 \wedge \phi_2$  is  $(T_1 \cup T_2)$ -satisfiable,
   otherwise unsatisfiable */

```

1. Apply P_1 to ϕ_1 , and apply P_2 to ϕ_2 collecting all inferences of equality made within T_1 and T_2 . If ϕ_1 or ϕ_2 is unsatisfiable, return unsatisfiable. Otherwise, if there is an inferred equality between constants $u = v$ that is not inferred by one of ϕ_1 or ϕ_2 , then add $u = v$ to the set that does not infer it and repeat this step.
2. If ϕ_1 or ϕ_2 infers a disjunction of equalities between constants without inferring any of the equalities alone, then, for every such equality $u = v$ inferred by ϕ_1 , call **CTSolver**($\phi_1, \phi_2 \cup \{u = v\}, P_1, P_2$) and for every such equality $u = v$ inferred by ϕ_2 , call **CTSolver**($\phi_1 \cup \{u = v\}, \phi_2, P_1, P_2$). If, for every inferred equality both calls to **CTSolver** return unsatisfiable, then return unsatisfiable, otherwise return satisfiable.
3. If neither ϕ_1 nor ϕ_2 infers an equality or a disjunction of equalities, then return satisfiable.

□

Fig. 21 Combined theory solver for two theories

overlap only in constants, then $\text{Res}(\phi_1 \wedge \phi_2)$ is logically equivalent to $\text{Res}(\phi_1) \wedge \text{Res}(\phi_2)$. Thus, the residue of the conjunction of all formulas derived within each theory is the conjunction of the residues of formulas for each theory. The algorithm returns “satisfiable” only if all theories are consistent and no additional equalities of constants can be inferred. In this case the residues of all theories are satisfiable. It may be observed that the conjunction of the residues is therefore satisfiable. Hence, the residue of the conjunction of theories is satisfiable. This means if the algorithm returns satisfiable, then $\phi_1 \wedge \phi_2$ is satisfiable.

The purpose of this section is to acquaint the reader with procedures that comprise SMT solver implementations. As such, much has been left out. This chapter has not considered elimination of the purification step by shifting the burden of handling alien terms to the theory solvers themselves, application of theory specific rewrites, Shostak’s theories and method, and how to lift the requirement of stably infinite theories for completeness by propagating cardinality constraints in addition to equalities. Nelson-Oppen only works for quantifier free formulas, but there are some techniques for allowing quantifiers which are not discussed here. For more information about these topics, the reader may start by consulting [13].

5.8 Stochastic Local Search

In DPLL and CDCL variants, a search for a satisfying assignment proceeds by extending a partial assignment as long as no constraint is falsified. In stochastic local search (SLS), there is a “current” complete assignment at every point in the search: if some clauses are not satisfied by the current assignment, one of a set of functions, each designed to create a new assignment from the given formula and current assignment, is applied according to some probability schedule to determine a new current assignment. This process continues until either all clauses are satisfied or until some function determines it is time to give up. Thus, SLS algorithms are generally *incomplete* and are not typically designed to provide a certificate for an unsatisfiable formula. A main strength of SLS algorithms is that they admit “long jumps” through the search space and thereby avoid the condition of becoming mired in an unnecessarily long exploration of a search subspace, particularly that for which all search trajectories lead to a local minimum number of satisfied clauses: deterministic solvers must take special measures to avoid that condition. On the other hand, it is difficult for SLS solvers to use the systematic tabulation and learning techniques that have made the deterministic variants successful.

5.8.1 Walksat

A successful early implementation of SLS for SAT is Walksat [127]. The Walksat algorithm is shown in Fig. 22. It is safe to assume that all clauses in the input formula ψ have at least two literals since elementary and prudent preprocessing of ψ would have assigned a value to any variable in a unit clause to satisfy that clause and would have propagated the effect of that change to the remainder of ψ .

This algorithm has a few interesting features worth pointing out. One is the probability p which is used to choose a variable whose value should be reversed (from now on the word *flipped* is used to mean just this): whether a random literal or the one whose flipped value results in the minimum number of satisfied clauses that become falsified. Experiments suggest the optimal value for p depends on and is sensitive to the particular class of problem the algorithm is applied to [89]. For example, it has been found that $p = 0.57$ is best for random 3-SAT formulas⁶ and this point sits at the minimum of an upward facing, cup-shaped curve with steeply increasing slopes on either side of the minimum. A second interesting feature is that a flip is chosen randomly *only if* there is not a variable in c which does not *break* any satisfied clauses. Thus, emphasizing positive movement to the goal of satisfying the most clauses as early as possible, Walksat has weakened some of the protection against loop stagnation that random flips provide. A third feature is the parameter mf which limits exploration of a local search space: if significant progress is not being made for a while, then exploration of this local space terminates and a long jump to a different local search space is made and search resumed. This *restart*

⁶Random 3-SAT formulas are defined in Sect. 7, Page 440.

Algorithm 5.

```

Walksat ( $\psi, mt, mf, p$ )
/* Input:  $\psi$  is a set of sets of literals representing a CNF formula, */
/*          mt is the maximum number of solution attempts,           */
/*          mf is the maximum number of assignment changes,         */
/*          p is a probability                                     */
/* Output is either a model for  $\psi$  or “give up”            */

    Repeat the following  $mt$  times:
        Set  $M \leftarrow$  a random truth assignment for  $\psi$ .
        Repeat the following  $mf$  times:
            If  $M$  is a model for  $\psi$ , Output  $M$ .
            Set  $c \leftarrow$  a random falsified clause of  $\psi$ .
            If  $\exists l \in c$  such that flipping  $var(l)$  does not
                falsify a satisfied clause, Set  $v \leftarrow var(l)$ .
            Otherwise, Set  $v \leftarrow var(l)$  where, with probability  $p$ ,  $l$  is
                chosen randomly from  $c$ ; and otherwise is the literal  $l \in c$ 
                for which the number of satisfied clauses that become
                falsified by flipping  $var(l)$  is minimum.
            Flip  $v$ .
        Output “give up”
    □

```

Fig. 22 Walksat

mechanism compensates for the possible problem nonrandom flips may get into as mentioned above. Walksat may be applied to MAX-SAT problems. A version for weighted MAX-SAT problems is available [86].

5.8.2 Novelty Family

Novelty [109] is a variant of Walksat that uses a more sophisticated variable selection algorithm. Once a falsified clause c is chosen, a score is computed for each variable v represented in c , based on the total number of satisfied clauses that would result if v were flipped. If the variable with highest score is not the variable that was most recently flipped, it is flipped now. Otherwise, it becomes the flipped variable with probability $1 - p$ or the second highest scoring variable becomes the flipped variable with probability p .

Although Novelty is an improvement over Walksat in many empirical cases, it has the problem that its inner loop may not terminate for a given M [73]. Novelty+ is a slight modification that eliminates this problem by introducing a second probability wp : a variable is randomly selected from c and flipped with probability wp and otherwise the Novelty flip heuristic is applied. It is reported that $wp = 0.01$ is sufficient to eliminate the non-termination problem [75] (i.e., a solution will be found with arbitrarily high probability, if one exists, even if $mt = 1$, as long as mf is set arbitrarily high).

Adaptive Novelty+ provides one more tweak to the Walksat/Novelty+ approach: the noise parameter p is allowed to vary during search. It has been mentioned above that algorithm performance is sensitive to p : thus, the optimal value for p depends significantly on the particular class of input formulas. Adaptive Novelty+ [74] attempts to mitigate this problem. If p is increased, the probability of inner loop stagnation is reduced. If p is decreased, the ability of the algorithm to follow a gradient to a solution is improved. These two counteracting conditions are thought to explain the sensitivity of p to problem domain. Adaptive Novelty+ begins at $p = 0$ and witnesses a rapid improvement in the number of clauses satisfied. When stagnation is detected, p is increased. Such increases continue periodically until stagnation is overcome and then p is reduced. The cycle is continued until termination. Stagnation is detected when it is noticed that an objective function has not changed over a certain number of steps, called the Stagnation Detection Interval. The usual objective function is the number of satisfied clauses. One specific adaptation strategy is the following:

$$\begin{aligned} \text{Stagnation Detection Interval: } & m/6, m = \text{number of clauses} \\ \text{Incremental increase in } p: & p = p + (1 - p) * 0.2 \\ \text{Incremental decrease in } p: & p = p - 0.4 * p \end{aligned}$$

The asymmetry between increases and decreases in p is motivated by the fact that detecting search stagnation is computationally more expensive than detecting search progress and that it is advantageous to approximate optimal noise levels from above rather than from below [74]. After p has been reset, the current objective function value is stored and becomes the basis for detecting stagnation. Observe that the factors 1/6, 0.4, and 0.2 are parameters that could be adjusted, but according to [74], performance appears to be less sensitive to these parameters than it is to p .

5.8.3 Discrete Lagrangian Methods

Discrete Lagrangian methods are another class of SLS algorithms which control the ability of a search to escape a subspace that contains a local minimum [128]. Let $\psi = \{c_1, c_2, \dots, c_m\}$ be a CNF formula with clauses c_1, \dots, c_m ; let $V = \{v : \exists c \in \psi \text{ s.t. } v \in c \text{ or } \neg v \in c\}$; and attach labels to variables to write $V = \{v_1, v_2, \dots, v_n\}$. Define for all $c_i \in \psi$ and $v_j \in V$ as follows:

$$Q_{i,j}(v_j) = \begin{cases} 1 - v_j & \text{if } v_j \in c_i \\ v_j & \text{if } \neg v_j \in c_i \\ 1 & \text{otherwise.} \end{cases}$$

Let x be an n -dimensional 0-1 vector where x_j holds the value of variable v_j , and let $C_i(x) = \prod_{j=1}^n Q_{i,j}(v_j)$. Define

$$N(x) = \sum_{i=1}^m C_i(x).$$

Then $N(x)$ is the number of unsatisfied clauses in ψ under the assignment x . Consider the following optimization problem:

$$\begin{aligned} \text{minimize over } x \in \{0, 1\}^n & N(x) = \sum_{i=1}^m C_i(x) \\ \text{subject to} & C_i(x) = 0 \quad \forall i \in \{1, 2, \dots, m\}. \end{aligned}$$

The objective function (the first line of the above) is enough to specify the SAT problem. The extra constraints are added to guide the search. In particular, the extra constraints help bring the search out of a local minimum.

The above overconstrained optimization problem may be converted to an unconstrained optimization problem by applying a Lagrange multiplier λ_i to each constraint $C_i(x)$ and adding the result to the objective function. Writing λ to represent the vector $\langle \lambda_1, \dots, \lambda_m \rangle$ of Lagrange multipliers and $\mathbf{C}(x)$ to represent the vector $\langle C_1(x), \dots, C_m(x) \rangle$, define

$$L(x, \lambda) = N(x) + \lambda^T \mathbf{C}(x),$$

where $x \in \{0, 1\}^n$ and λ_i can be real valued. A saddle point (x^*, λ^*) of $L(x, \lambda)$ is defined to satisfy the following condition:

$$L(x^*, \lambda) \leq L(x^*, \lambda^*) \leq L(x, \lambda^*)$$

for all λ sufficiently close to λ^* and for all x whose Hamming distance between x^* and x is 1. The *discrete Lagrangian method* (DLM) for solving CNF SAT can be defined as a set of equations which update x and λ :

$$\begin{aligned} x^{k+1} &= x^k - \Delta_x L(x^k, \lambda^k) \\ \lambda^{k+1} &= \lambda^k + \mathbf{C}(x^k), \end{aligned}$$

where $\Delta_x L(x, \lambda)$ is the *discrete gradient operator* with respect to x such that $\Delta_x L(x, \lambda) = \langle \delta_1, \delta_2, \dots, \delta_n \rangle$, $\forall 1 \leq i \leq n \delta_i \in \{-1, 0, 1\}$, $\sum_{1 \leq i \leq n} |\delta_i| = 1$, and $(x - \Delta_x L(x, \lambda)) \in \{0, 1\}^n$ (i.e., $\Delta_x L(x, \lambda)$ identifies a variable to be flipped and $x - \Delta_x L(x, \lambda)$ is a neighbor of x – i.e., at Hamming distance 1 from x). There are two ways to calculate $\Delta_x L(x, \lambda)$. One way, termed *greedy*, replaces the current assignment with a neighboring assignment leading to the maximum decrease in the Lagrangian function value. Another way, termed *hill climbing*, replaces the current assignment with a neighboring assignment that leads to a decrease in the value of the Lagrangian function. Both involve some local search in the neighborhood of the current assignment, but for every greedy update, the complexity of this search is $O(n)$, whereas the hill-climbing update generally is less expensive.

Algorithm 6.

```

DLM ( $\psi$ )
/* Input:  $\psi$  is a set of sets of literals representing a CNF formula, */
/* Output is either a model for  $\psi$  or “give up” */
Set  $x \leftarrow$  a random  $n$ -dimensional 0-1 vector.
Set  $\lambda \leftarrow \langle 0, 0, \dots, 0 \rangle$ .
Construct  $\mathbf{C}(x)$  from  $\psi$ .
Repeat the following while  $N(x) > 0$ :
    Set  $x \leftarrow x - \Delta_x L(x, \lambda)$ .
    If condition to update  $\lambda$  is satisfied, do this:
         $\lambda \leftarrow \lambda + \gamma \cdot \mathbf{C}(x)$ .
Output  $x$ 
□

```

Fig. 23 Discrete Lagrangian method

An algorithmic sketch of DLM is shown in Fig. 23. The parameter γ controls the magnitude of the changes to λ_i . A value of $\gamma = 1$ is reported to be sufficient for many benchmarks, but a smaller γ has resulted in improved performance for some difficult ones. Experiments have shown that λ should not be updated every time the current assignment is replaced. This is because the changes in $L(x, \lambda)$ are usually very small and relatively larger changes in λ can overcompensate causing the search to become lost. Therefore, the DLM algorithm contains a line stating that a condition must be satisfied before λ can be updated. One possibility is that λ is not updated until $\Delta_x L(x, \lambda) = 0$. When that happens, the local minimum is reached and the change in λ is needed to jump to a different section of the search space. This strategy may cause a problem if a search-space plateau is entered. In that case, it will be prudent to change λ sooner. For improved variants of DLM, see [147, 148].

5.9 Binary Decision Diagrams

Binary decision diagrams (BDDs) as graphs were discussed in Sect. 3.2. In this section the associated BDD data structure and efficient operations on that data structure are discussed. Attention is restricted to reduced ordered binary decision diagrams (ROBDDs) due to its compact, efficient, canonical properties.

The following is a short review of Sect. 3.2. A ROBDD is a BDD such that (1) there is no vertex v such that $\text{then}(v) = \text{else}(v)$ and (2) the subgraphs of two distinct vertices v and w are not isomorphic. A ROBDD represents a Boolean function uniquely in the following way (symbol v will represent both a vertex of a ROBDD and a variable labeling a vertex). Define $f(v)$ recursively as follows:

1. If v is the terminal vertex labeled 0, then $f(v) = 0$.
2. If v is the terminal vertex labeled 1, then $f(v) = 1$.
3. Otherwise, $f(v) = (v \wedge f(\text{then}(v))) \vee (\neg v \wedge f(\text{else}(v)))$.

Algorithm 7.

```

findOrCreateNode ( $v, t, e$ )
/* Input: variable label  $v$ , Node object indices  $t$  and  $e$  */  

/* Output: an array index of a Node object  $\langle v, t, e \rangle$  */  

  If  $t == e$  then Return  $t$ .  

  Set  $node \leftarrow lookup(\langle v, t, e \rangle)$ .  

  If  $node \neq null$  then Return  $node$ .  

  Set  $node \leftarrow createNode(\langle v, t, e \rangle)$ .  

   $insert(\langle v, t, e \rangle, node)$ .  

  Return  $node$ .

```

□

Fig. 24 Procedure for finding a node or creating and inserting it

Then $f(root(v))$ is the function represented by the ROBDD. A Boolean function has different ROBDD representations, depending on the variable order imposed by $index$, but there is only one ROBDD for each ordering. Thus, ROBDDs are known as a canonical representation of Boolean functions. From now on BDD will be used to refer to a ROBDD.

A data structure representing a BDD consists of an array of Node objects (or nodes), each corresponding to a BDD vertex and each containing three elements: a variable label v , $then(v)$, and $else(v)$, where the latter two elements are BDD array indices. The first two nodes in the BDD array correspond to the 0 and 1 terminal vertices of a BDD. For both, $then(..)$ and $else(..)$ are empty. Denote by $terminal(1)$ and $terminal(0)$ the BDD array locations of these nodes. All other nodes fill up the remainder of the BDD array in the order they are created. A node that is not in the BDD array can be created and added to the BDD array, and its array index returned in constant time. A hashtable, commonly referred to as a *unique table*, is maintained for the purpose of finding a node's array location given v , $then(v)$, $else(v)$. If there is no corresponding entry in the hashtable, a new node is created and recorded in the hashtable with key v , $then(v)$, $else(v)$. A single procedure called **findOrCreateNode** takes v , $then(v)$, $else(v)$ as arguments and returns the BDD array index of a node, either a newly created one or an existing one. This procedure is shown in Fig. 24.

The main BDD construction operation is to find and attach two descendant nodes ($then(v)$ and $else(v)$) to a parent node (v). The procedure **findOrCreateNode** is used to ensure that no two nodes in the final BDD data structure represent the same function. The procedure for building a BDD data structure is **buildBDD**, shown in Fig. 25. It is assumed that variable indices match the value of $index$ applied to that variable (thus, $i = index(v_i)$). The complexity of **buildBDD** is proportional to the number of nodes that must be created. In all interesting applications, many BDDs are constructed. But they may all share the BDD data structure above. Thus, a node may belong to many BDDs.

Algorithm 8.

```

buildBDD ( $f, i$ )
/* Input: Boolean function  $f$ , index  $i$  */          */
/* Output: root Node of BDD representing  $f$  */      */
  If  $f \Leftrightarrow 1$  return terminal(1).           */
  If  $f \Leftrightarrow 0$  return terminal(0).           */
  Set  $t \leftarrow \text{buildBDD}(f|_{v_i=1}, i+1)$ .    */
  Set  $e \leftarrow \text{buildBDD}(f|_{v_i=0}, i+1)$ .    */
  Return findOrCreateNode( $v_i, t, e$ ).           */

```

□

Fig. 25 Algorithm for building a BDD: invoked using **buildBDD**($f, 1$)**Algorithm 9.**

reduce₁ (v, f) /* Input: variable v , BDD f */ */ /* Output: reduced BDD */ */ If $\text{root}(f) == v$ then Return <i>then</i> ($\text{root}(f)$). Return f .	reduce₀ (v, f) /* Input: variable v , BDD f */ */ /* Output: reduced BDD */ */ If $\text{root}(f) == v$ then Return <i>else</i> ($\text{root}(f)$). Return f .
--	--

□

Fig. 26 Operations **reduce₁** and **reduce₀**

The operations **reduce₁** and **reduce₀**, shown in Fig. 26, are used to describe several important BDD operations in subsequent sections. Assuming v is the root of the BDD representing f , the operation **reduce₁**(v, f) returns f constrained by the assignment of 1 to variable v and **reduce₀**(v, f) returns f constrained by the assignment of 0 to the variable v .

Details on performing the common binary operations of \wedge and \vee on BDDs will be ignored here. The reader may refer to [9] for detailed descriptions. Here, it is only mentioned that, using a dynamic programming algorithm, the complexity of these operations is proportional to the product of the sizes of the operands and the size of the result of the operation can be that great as well. Therefore, using \wedge alone, for example (as so many problems would require), could lead to intermediate structures that are too large to be of value. This problem is mitigated somewhat by operations of the kind discussed in the next four subsections, particularly existential quantification.

The operations considered next are included not only because they assist BDD-oriented solutions but mainly because they can assist search-oriented solutions when used properly. For example, if inputs are expressed as a collection of BDDs, then they may be preprocessed to reveal information that may be exploited later,

Algorithm 10.

```

exQuant ( $f, v$ )
/* Input: BDD  $f$ , variable  $v$  */  

/* Output: BDD  $f$  with  $v$  existentially quantified away */  

  If  $\text{root}(f) == v$  then Return  $\text{then}(\text{root}(f)) \vee \text{else}(\text{root}(f))$ .  

  If  $\text{index}(v) > \text{index}(\text{root}(f))$  then Return 0. // If  $v$  is not in  $f$  do nothing  

  Set  $h_{f_1} \leftarrow \text{exQuant}(\text{then}(\text{root}(f)), v)$ .  

  Let  $h_{f_0} \leftarrow \text{exQuant}(\text{else}(\text{root}(f)), v)$ .  

  If  $h_{f_0} == h_{f_1}$  then Return  $h_{f_1}$ .  

  Return FindOrCreateNode( $\text{root}(f), h_{f_1}, h_{f_0}$ ).  

□

```

Fig. 27 Algorithm for existentially quantifying variable v away from BDD f . The \vee denotes the *or* of BDDs

during search. In particular, inferences⁷ may be determined and used to reduce input complexity. The discussion of the next four sections emphasizes this role.

5.9.1 Existential Quantification

A Boolean function which can be written

$$f(v, \vec{x}) = (v \wedge h_1(\vec{x})) \vee (\neg v \wedge h_2(\vec{x}))$$

can be replaced by

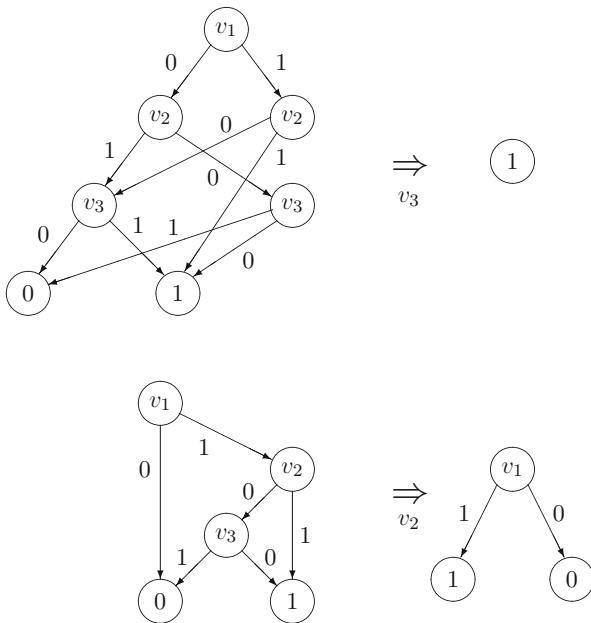

$$f(\vec{x}) = h_1(\vec{x}) \vee h_2(\vec{x}),$$

where \vec{x} is a list of one or more variables. There is a solution to $f(\vec{x})$ if and only if there is a solution to $f(v, \vec{x})$, so it is sufficient to solve $f(\vec{x})$ to get a solution to $f(v, \vec{x})$. Obtaining $f(\vec{x})$ from $f(v, \vec{x})$ is known as *existentially quantifying v away from $f(v, \vec{x})$* . This operation is efficiently handled if $f(v, \vec{x})$ is represented by a BDD. However, since most interesting BDD problems are formulated as a conjunction of functions and therefore as conjunctions of BDDs, existentially quantifying away a variable v succeeds easily only when just one of the input BDDs contains v . Thus, this operation is typically used together with other BDD operations for maximum effectiveness. The algorithm for existential quantification is shown in Fig. 27.

If inferences can be revealed in preprocessing, they can be applied immediately to reduce input size and therefore reduce search complexity. Although existential quantification can, by itself, uncover inferences (see, e.g., Fig. 28), those same inferences are revealed during BDD construction if inference lists for each node are built and maintained. Therefore, a more effective use of existential quantification is

⁷Finding inferences is referred to in the BDD literature as finding *essential* values to variables, and a set of inferences (a conjunction of literals) is referred to as a *cube*.

Fig. 28 Two examples of existentially quantifying a variable away from a function. Functions are represented as BDDs on the left. Variable v_3 is existentially quantified away from the top BDD leaving 1, meaning that regardless of assignments given to variables v_1 and v_2 , there is always an assignment to v_3 which satisfies the function. Variable v_2 is existentially quantified away from the bottom BDD leaving the inference $v_1 = 1$

in support of other operations, such as strengthening (see Sect. 5.9.5), to uncover those inferences that cannot be found during BDD construction or in tandem with \wedge to retard the growth of intermediate BDDs.

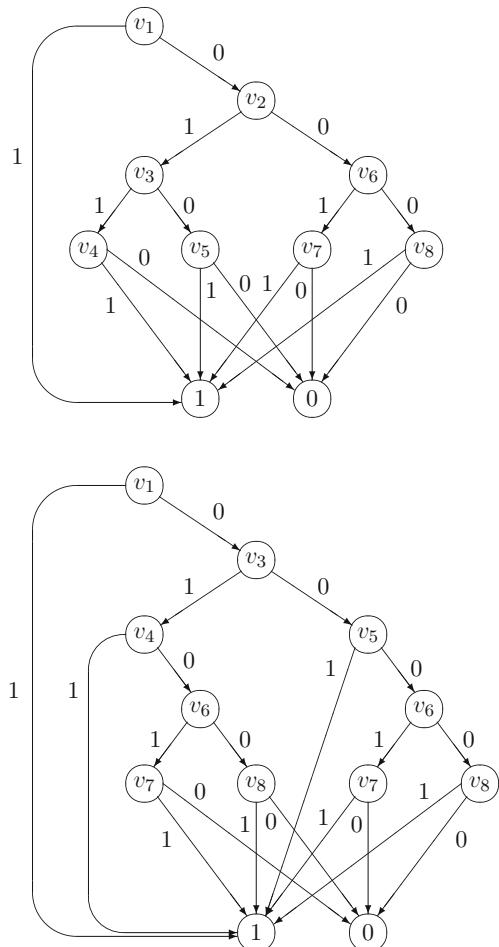

Existential quantification, if applied as a preprocessing step prior to search, can increase the number of choicepoints expanded per second but can increase the size of the search space. The increase in choicepoint speed is because existentially quantifying a variable away from the function has the same effect as branching from a choicepoint in both directions. Then overhead is reduced by avoiding heuristic computations. However, search-space size may increase since the elimination of a variable can cause subfunctions that had been linked only by that variable to become merged with the result that the distinction between the subfunctions becomes blurred. This is illustrated in Fig. 29. The speedup can overcome the lost intelligence but it is sometimes better to turn it off.

5.9.2 Reductions and Inferences

Consider the truth tables corresponding to two BDDs f and c over the union of variable sets of both f and c . Build a new BDD g with variable set no larger than the union of the variable sets of f and c and with a truth table such that on rows which c maps to 1, g maps to the same value that f maps to and on other rows g maps to any value, independent of f . It should be clear that $f \wedge c$ and $g \wedge c$ are identical so g can replace f in a collection of BDDs without changing its solution space.

There are at least three reasons why this might be done. The superficial reason is that g can be made smaller than f . A more important reason is that inferences can

Fig. 29 Existential quantification can cause blurring of functional relationships. The top function is seen to separate variables v_6 , v_7 , and v_8 from v_3 , v_4 , and v_5 if v_2 is chosen during search first. Existentially quantifying v_2 away from the top function before search results in the bottom function in which no such separation is immediately evident. Without existential quantification, the assignment $v_1 = 0$, $v_2 = 1$, $v_3 = 1$ reveals the inference $v_4 = 1$. With existential quantification the assignment must be augmented with $v_7 = 0$ and $v_8 = 0$ (but v_2 is no longer necessary) to get the same inference

be discovered. The third reason is that BDDs can be removed from the collection without loss. Consider, for example, BDDs representing functions

$$\begin{aligned} f &= (v_1 \vee \neg v_2 \vee v_3) \wedge (\neg v_1 \vee v_2) \text{ and} \\ c &= (v_1 \vee \neg v_2). \end{aligned}$$

Let a truth table row be represented by a 0-1 vector which reflects assignments of variables indexed in increasing order from left to right. Let g have the same truth table as f except for row $\langle 011 \rangle$ which c maps to 0 and g maps to 1. Then $g = (v_1 \leftrightarrow v_2)$ and $f \wedge c$ is the same as $g \wedge c$ but g is smaller than f . As an example of discovering inferences, consider

$$f = (v_1 \rightarrow v_2) \wedge (\neg v_1 \rightarrow (\neg v_3 \wedge v_4))$$

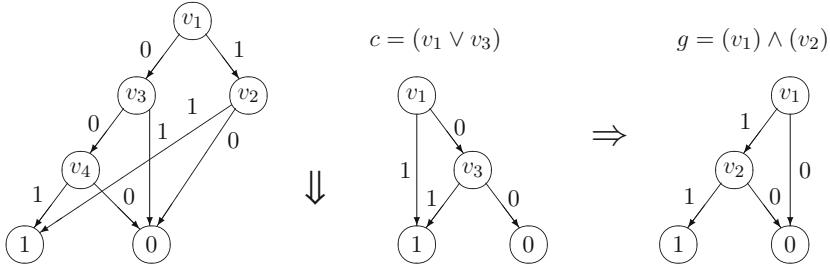

Fig. 30 A call to `restrict(f, c)` returns the BDD g shown on the *right*. In this case inferences $v_1 = 1$ and $v_2 = 1$ are revealed. The symbol \Downarrow denotes the operation

$$f = (v_1 \rightarrow v_2) \wedge (\neg v_1 \rightarrow (\neg v_3 \wedge v_4)) \text{ and}$$

$$c = (v_1 \vee v_3).$$

Let g have the same truth table as f except g maps rows $\langle 0001 \rangle$ and $\langle 0101 \rangle$ to 0, as does c . Then $g = (v_1) \wedge (v_2)$ which reveals two inferences. The BDDs for f , c , and g of this example are shown in Fig. 30. The example showing BDD elimination is deferred to Theorem 6, Sect. 5.9.4.

Clearly, there are numerous strategies for creating g from f and c and replacing f with g . An obvious one is to have g map to 0 all rows that c maps to 0. This strategy, which will be called zero-restrict in this chapter, turns out to have weaknesses. Its obvious dual, which has g map to 1 all rows that c maps to 0, is no better. For example, applying zero-restrict to f and c of Fig. 32 produces $g = \neg v_3 \wedge (v_1 \vee (\neg v_1 \wedge \neg v_2))$ instead of the inference $g = \neg v_3$ which is obtained from a more intelligent replacement strategy. An alternative approach, one of many possible ones, judiciously chooses some rows of g to map to 1 and others to map to 0 so that g 's truth table reflects a logic pattern that generates inferences. The truth table of c has many 0 rows and this is exploited. Specifically, c maps rows $\langle 010 \rangle$, $\langle 011 \rangle$, $\langle 101 \rangle$, and $\langle 111 \rangle$ to 0. The more intelligent strategy lets g map rows $\langle 011 \rangle$ and $\langle 111 \rangle$ to 0 and rows $\langle 010 \rangle$ and $\langle 101 \rangle$ to 1. Then $g = \neg v_3$.

Improved replacement strategies might target particular truth table patterns, for example, equivalences, or they might aim for inference discovery. Since there is more freedom to manipulate g if the truth table of c has many zeros, it is important to choose c as carefully as the replacement strategy. This is illustrated by the examples of Figs. 31 and 32 where, in the first case, no inference is generated but after f and c are swapped, an inference is generated. The next two subsections show two replacement strategies that are among the more commonly used.

5.9.3 Restrict

The original version of restrict is what is called zero-restrict above. That is, the original version of restrict is intended to remove paths to *terminal*(1) from f

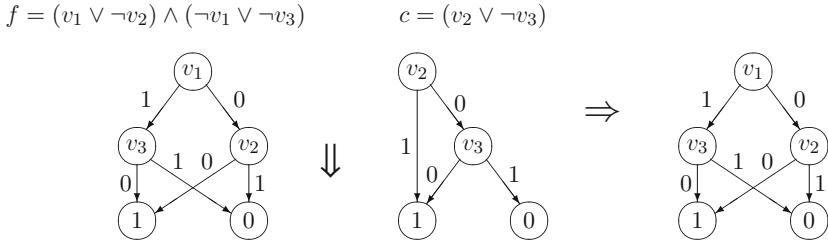

Fig. 31 A call to **restrict**(f, c) results in no change

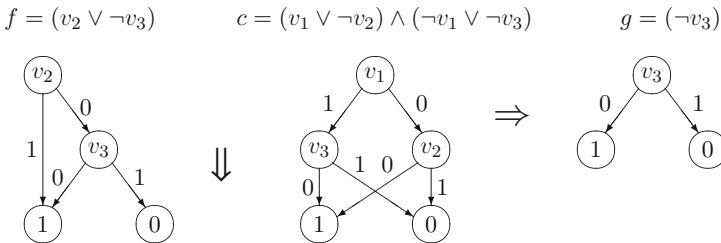

Fig. 32 Reversing the roles of f and c in Fig. 31, a call to **restrict**(f, c) results in the inference $g = \neg v_3$ as shown on the right. In this case, the large number of 0 truth table rows for c was exploited to advantage

that are made irrelevant by c . The idea was introduced in [43]. In this chapter an alternative version which is implemented as Algorithm 11 of Fig. 33 is considered. Use the symbol \Downarrow to denote the restrict operator. Then $g = f \Downarrow c$ is the result of zero-restrict after all variables in c that are not in f are existentially quantified away from c . Figures 30–32 show examples that were referenced in the previous subsection.

Procedure **restrict** is similar to a procedure called generalized cofactor (**gcf**) or constrain (see the next subsection for a description). Both **restrict**(f, c) and **gcf**(f, c) agree with f on interpretations where c is satisfied but are generally somehow simpler than f . Procedure **restrict** can be useful in preprocessing because the BDDs produced from it can never contain more variables than the BDDs they replace.

On the negative side, it can, in odd cases, cause a garbling of local information. Moreover, although **restrict** may reveal some of the inferences that strengthening would (see below), it can still cause the number of search choicepoints to increase. Both these issues are related: **restrict** can spread an inference that is evident in one BDD over multiple BDDs (see Fig. 34 for an example).

5.9.4 Generalized Cofactor

The *generalized cofactor* operation, also known as *constrain*, is denoted here by $|$ and implemented as **gcf** (Algorithm 12) in Fig. 35. It takes BDDs f and c as input

Algorithm 11.

```

restrict ( $f, c$ )
/* Input: BDD  $f$ , BDD  $c$  */  

/* Output: BDD  $f$  restricted by  $c$  */  

  If  $c$  or  $f$  is terminal(1) or if  $f$  is terminal(0) return  $f$ .
  If  $c == \neg f$  return terminal(0).
  If  $c == f$  return terminal(1).
  //  $f$  and  $c$  have a non-trivial relationship
  Set  $v_f \leftarrow \text{root}(f)$ . //  $v_f$  is a variable
  Set  $v_c \leftarrow \text{root}(c)$ . //  $v_c$  is a variable
  If  $\text{index}(v_f) > \text{index}(v_c)$  return restrict( $f$ , exQuant( $c, v_c$ )).
  If reduce0( $v_f, c$ ) is terminal(0) then
    Return restrict(reduce1( $v_f, f$ ), reduce1( $v_f, c$ )).  

  If reduce1( $v_f, c$ ) is terminal(0) then
    Return restrict(reduce0( $v_f, f$ ), reduce0( $v_f, c$ )).  

  Set  $h_{f_1} \leftarrow \text{restrict}(\text{reduce}_1(v_f, f), \text{reduce}_1(v_f, c))$ .
  Set  $h_{f_0} \leftarrow \text{restrict}(\text{reduce}_0(v_f, f), \text{reduce}_0(v_f, c))$ .
  If  $h_{f_1} == h_{f_0}$  then Return  $h_{f_1}$ .
  Return findOrCreateNode( $v_f, h_{f_1}, h_{f_0}$ ).  

□

```

Fig. 33 Algorithm for restricting a BDD f by a BDD c

$$f = (v_1 \vee \neg v_2) \wedge (\neg v_1 \vee v_3) \quad c = (\neg v_1 \vee v_3) \quad g = (v_1 \vee \neg v_2)$$

**Fig. 34** A call to **restrict**(f, c) spreads an inference that is evident in one BDD over multiple BDDs. If v_3 is assigned 0 in f , then $v_1 = 0$ and $v_2 = 0$ are inferred. After replacing f with $g = \text{restrict}(f, c)$, to get the inference $v_2 = 0$ from the choice $v_3 = 0$, visit c to get $v_1 = 0$ and then g to get $v_2 = 0$. Thus, restrict can increase work if not used properly. In this case, restricting in the reverse direction leads to a better result

and produces $g = f|c$ by *sibling substitution*. BDD g may be larger or smaller than f , but, more importantly, systematic use of this operation can result in the elimination of BDDs from a collection. Unfortunately, by definition, the result of this operation depends on the underlying BDD variable ordering, so it cannot be regarded as a logical operation. It was introduced in [42].

BDD g is a generalized cofactor of f and c if for any truth assignment t , $g(t)$ has the same value as $f(t')$ where t' is the *nearest* truth assignment to t that maps c to 1. The notion of *nearest* truth assignment depends on a permutation π of the numbers

Algorithm 12.

```

gcf ( $f, c$ )
/* Input: BDD  $f$ , BDD  $c$  */  

/* Output: greatest co-factor of  $f$  by  $c$  */  

If  $f == \text{terminal}(0)$  or  $c == \text{terminal}(0)$  return  $\text{terminal}(0)$ .
If  $c == \text{terminal}(1)$  or  $f == \text{terminal}(1)$  return  $f$ .
Set  $v_m \leftarrow \text{index}^{-1}(\min\{\text{index}(\text{root}(c)), \text{index}(\text{root}(f))\})$ .
//  $v_m$  is the top variable of  $f$  and  $c$ 
If  $\text{reduce}_0(v_m, c) == \text{terminal}(0)$  then
    Return gcf( $\text{reduce}_1(v_m, f)$ ,  $\text{reduce}_1(v_m, c)$ ).
If  $\text{reduce}_1(v_m, c) == \text{terminal}(0)$  then
    Return gcf( $\text{reduce}_0(v_c, f)$ ,  $\text{reduce}_0(v_c, c)$ ).
Set  $h_1 \leftarrow \text{gcf}(\text{reduce}_1(v_m, f), \text{reduce}_1(v_m, c))$ .
Set  $h_0 \leftarrow \text{gcf}(\text{reduce}_0(v_m, f), \text{reduce}_0(v_m, c))$ .
If  $h_1 == h_0$  then Return  $h_1$ .
Return FindOrCreateNode( $v_m, h_1, h_0$ ).
□

```

Fig. 35 Algorithm for finding a greatest common cofactor of a BDD

$1, 2, \dots, n$ which states the variable ordering of the input BDDs. Represent a truth assignment to n variables as a vector in $\{0, 1\}^n$ and, for truth assignment t , let t_i denote the i th bit of the vector representing t . Then the distance between two truth assignments t' and t'' is defined as $\sum_{i=1}^n 2^{n-i} (t'_{\pi_i} \oplus t''_{\pi_i})$. One pair of assignments is nearer to each other than another pair if the distance between that pair is less. It should be evident that distances between pairs are unique for each pair.

For example, Fig. 36 shows BDDs f and c under the variable ordering given by $\pi = \langle 1, 2, 3, 4 \rangle$. For assignment vectors $\langle * * 01 \rangle$, $\langle * * 10 \rangle$, and $\langle * * 11 \rangle$ (where $*$ is a wildcard meaning 0 or 1), $\text{gcf}(f, c)$, shown as the BDD at the bottom of Fig. 36, agrees with f since those assignments cause c to evaluate to 1. The closest assignment to $\langle 0000 \rangle$, $\langle 0100 \rangle$, $\langle 1000 \rangle$, and $\langle 1100 \rangle$ causing c to evaluate to 1 is $\langle 0001 \rangle$, $\langle 0101 \rangle$, $\langle 1001 \rangle$, and $\langle 1101 \rangle$, respectively. On all these inputs $\text{gcf}(f, c)$ has value 1, which the reader can check in Fig. 36.

The following expresses the main property of $|$ that makes it useful.

Theorem 6 Given BDDs f_1, \dots, f_k , for any $1 \leq i \leq k$, $f_1 \wedge f_2 \wedge \dots \wedge f_k$ is satisfiable if and only if $(f_1|f_i) \wedge \dots \wedge (f_{i-1}|f_i) \wedge (f_{i+1}|f_i) \wedge \dots \wedge (f_k|f_i)$ is satisfiable. Moreover, any assignment satisfying the latter can be mapped to an assignment that satisfies $f_1 \wedge \dots \wedge f_k$.

Proof If it can be shown that

$$(f_1|f_i) \wedge \dots \wedge (f_{i-1}|f_i) \wedge (f_{i+1}|f_i) \wedge \dots \wedge (f_k|f_i) \quad (4)$$

is satisfiable if and only if

$$(f_1|f_i) \wedge \dots \wedge (f_{i-1}|f_i) \wedge (f_{i+1}|f_i) \wedge \dots \wedge (f_k|f_i) \wedge f_i \quad (5)$$

is satisfiable, then, since (5) is equivalent to $f_1 \wedge \dots \wedge f_k$, the first part of the theorem will be proved. Suppose (5) is satisfied by truth assignment t . That t represents a truth table row that f_i maps to 1. Clearly that assignment also satisfies (4). Suppose no assignment satisfies (5). Then all assignments for which f_i maps to 1 do not satisfy (4) since otherwise (5) would be satisfied by any that do. Only truth assignments t which f_i maps to 0 need to be considered. Each $(f_j|f_i)$ in (4) and (5) maps to the same value that f_j maps the *nearest* truth assignment, say, r , to t that satisfies f_i . But r cannot satisfy (5) because it cannot satisfy (4) by the argument above. Hence, there is no truth assignment falsifying f_i but satisfying (4) so the first part is proved.

For the second part, observe that any truth assignment that satisfies (4) and (5) also satisfies $f_i \wedge \dots \wedge f_k$, so it is only necessary to consider assignments t that satisfy (4) but not (5). In that case, by construction of $(f_j|f_i)$, the assignment that is *nearest* to t and satisfies f_i also satisfies $(f_j|f_i)$. That assignment satisfies $f_1 \wedge \dots \wedge f_k$. \square

This means that, for the purposes of a solver, generalized cofactoring can be used to eliminate one of the BDDs among a given conjoined set of BDDs: the solver finds an assignment satisfying $\text{gcf}(f_1, f_i) \wedge \dots \wedge \text{gcf}(f_k, f_i)$ and then extends the assignment to satisfy f_i ; otherwise, the solver reports that the instance has no solution. However, unlike **restrict**, generalized co-factoring cannot by itself reduce the number of variables in a given collection of BDDs. Other properties of the **gcf** operation, all of which are easy to show, are:

1. $f = c \wedge \text{gcf}(f, c) \vee \neg c \wedge \text{gcf}(f, \neg c)$.
2. $\text{gcf}(\text{gcf}(f, g), c) = \text{gcf}(f, g \wedge c)$.
3. $\text{gcf}(f \wedge g, c) = \text{gcf}(f, c) \wedge \text{gcf}(g, c)$.
4. $\text{gcf}(f \wedge c, c) = \text{gcf}(f, c)$.
5. $\text{gcf}(f \wedge g, c) = \text{gcf}(f, c) \wedge \text{gcf}(g, c)$.
6. $\text{gcf}(f \vee g, c) = \text{gcf}(f, c) \vee \text{gcf}(g, c)$.
7. $\text{gcf}(f \vee \neg c, c) = \text{gcf}(f, c)$.
8. $\text{gcf}(\neg f, c) = \neg \text{gcf}(f, c)$.

9. If c and f have no variables in common and c is satisfiable, then $\text{gcf}(f, c) = f$.

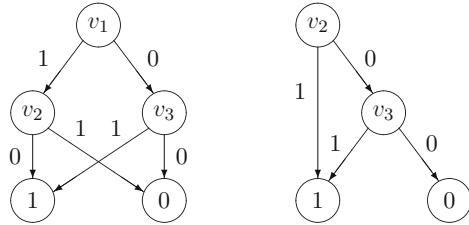

Care must be taken when cofactoring in *both* directions (exchanging f for c). For example, $f \wedge g \wedge h$ cannot be replaced by $(g|f) \wedge (f|g) \wedge h$ since the former may be unsatisfiable when the latter is satisfiable.

Examples of the application of **gcf** are shown in Figs. 36 and 37. Figure 36 illustrates the possibility of increasing BDD size. Figure 37 presents the same example after swapping v_1 and v_3 under the same variable ordering and shows that the result produced by **gcf** is sensitive to variable ordering. Observe that the functions produced by **gcf** in both figures have different values under the assignment $v_1 = 1$, $v_2 = 1$, and $v_3 = 0$. Thus, the function returned by **gcf** depends on the variable ordering as well.

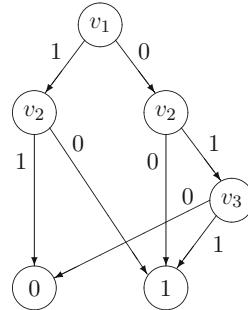

Fig. 36 Generalized cofactor operation on f and c as shown. In this case the result is more complicated than f . The variable ordering is $v_1 < v_2 < v_3$

$$f = (v_1 \rightarrow \neg v_2) \vee (\neg v_1 \rightarrow v_3)$$

$$c = (v_2 \vee v_3)$$

$$gcf(f, c) = (v_1 \rightarrow \neg v_2) \vee (\neg v_1 \rightarrow (v_2 \rightarrow v_3))$$

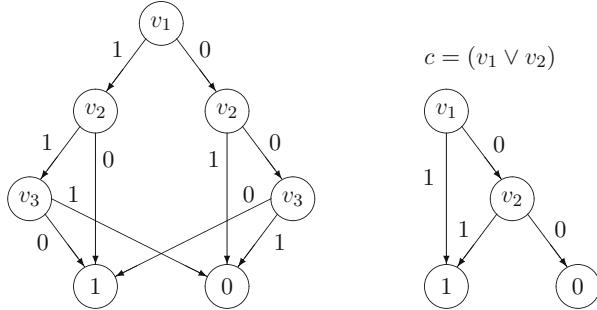

5.9.5 Strengthen

This binary operation on BDDs helps reveal inferences that are missed by **restrict** due to its sensitivity to variable ordering. Given two BDDs, b_1 and b_2 , strengthening conjoins b_1 with the *projection* of b_2 onto the variables of b_1 : that is, $b_1 \wedge \exists \vec{v} b_2$, where \vec{v} is the set of variables appearing in b_2 but not in b_1 . Strengthening each b_i against all other b_j 's sometimes reveals additional inferences or equivalences. Algorithm **strengthen** is shown in Fig. 38. Figure 39 shows an example.

Strengthening provides a way to pass important information from one BDD to another without causing a size explosion. No size explosion can occur because, before b_1 is conjoined with b_2 , all variables in b_2 that do not occur in b_1 are existentially quantified away. If an inference (of the form $v = 1$, $v = 0$, $v = w$, or $v = \neg w$) exists due to just two BDDs, then strengthening those BDDs against each other (pairwise) can *move* those inferences, even if originally spread across both BDDs, to one of the BDDs. Because **strengthen** shares information between BDDs, it can be thought of as sharing intelligence and *strengthening* the relationships between functions; the added intelligence in these strengthened functions can be exploited by a smart search heuristic. It has been found empirically that **strengthen** usually decreases the number of choicepoints when a particular search heuristic is employed, but sometimes it causes more choicepoints. It may be conjectured this is due to the delicate nature of some problems where duplicating information in the BDDs leads the heuristic astray.

$$f = (v_3 \rightarrow \neg v_2) \vee (\neg v_3 \rightarrow v_1)$$

$$gcf(f, c) = (v_1 \wedge (v_2 \rightarrow \neg v_3))$$

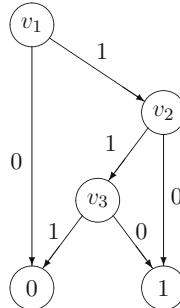

Fig. 37 Generalized cofactor operation on the same f and c of Fig. 36 and with the same variable ordering but with v_1 and v_3 swapped. In this case the result is less complicated than f and the assignment $\{v_1, v_2\}$ causes the output of gcf in this figure to have value 1, whereas the output of gcf in Fig. 36 has value 0 under the same assignment

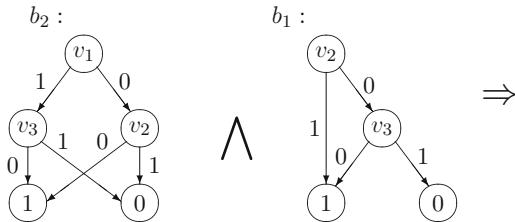

Algorithm 13.

```

Strengthen ( $b_1, b_2$ )
/* Input: BDD  $b_1$ , BDD  $b_2$                                 */
/* Output: BDD  $b_1$  strengthened by  $b_2$                   */
Set  $\vec{x} \leftarrow \{x : x \in b_2, x \notin b_1\}$ .
Repeat the following for all  $x \in \vec{x}$ :
    Set  $b_2 \leftarrow \text{exQuant}(b_2, x)$ .
Return  $b_1 \wedge b_2$ .
□

```

Fig. 38 Algorithm for strengthening a BDD by another

Strengthening example: Existentially quantify v_1 away from b_2 ...

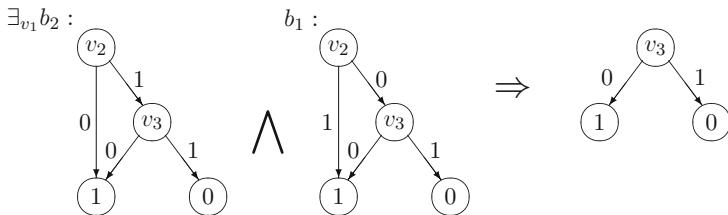

Fig. 39 ... then conjoin the two BDDs. Inference $v_3 = 0$ is revealed

Procedure **strengthen** may be applied to CNF formulas and in this case it is the same as applying Davis-Putnam resolution selectively on some of the clauses. When used on more complex functions, it is clearer how to use it effectively as the clauses being resolved are grouped with some meaning. Evidence for this comes from bounded model checking examples.

This section concludes by mentioning that for some classes of problems, resolution has polynomial complexity, while strictly BDD manipulations require exponential time, and for other classes of problems, resolution has exponential complexity, while BDD manipulations require polynomial time [67].

5.10 Decompositions

The variable elimination methods of Sects. 5.5 and 5.11 recursively *decompose* a given formula ψ into overlapping subformulas ψ_1 and ψ_2 such that the solution to ψ can be inferred from the solutions to ψ_1 and ψ_2 . The decompositions are based on occurrences of a selected variable v in clauses of ψ and each subformula has at least as many clauses as those of ψ which contain neither literal v nor literal $\neg v$. Intuitively, the speed of the methods usually depends on the magnitude of the size reduction from ψ to ψ_1 and ψ_2 . However, it is often the case that the number of occurrences of most variables in a formula or subformula is small which usually means small size reductions for most variables. For example, the average number of occurrences of a variable in a random k -SAT formula⁸ of m clauses developed

⁸Random k -SAT formulas are defined in Sect. 7, Page 440.

from n variables is km/n : so, if $k = 3$ and m/n is, say, 4, then the average number of occurrences of a randomly chosen variable is only 12. Hence, the methods often suffer computational inadequacies which can make them unusable in some cases. On the positive side, such methods can be applied to any CNF formula.

But there are other decomposition methods that sacrifice some generality for the sake of producing subformulas of relatively small size. Truemper's book [138] presents quite a few of these, all of which are capable of computationally efficient solutions to some problems that would be considered difficult for the more general variable elimination methods. This section presents one of these, called monotone decomposition, for illustration and because it is related to material that is elsewhere in this chapter.

5.10.1 Monotone Decomposition

Let CNF formula ψ of m clauses and n variables be represented as a $m \times n$ (0 ± 1)-matrix \mathcal{M}_ψ (defined in Sect. 3.1). A *monotone decomposition* of \mathcal{M}_ψ is a permutation of rows and columns of \mathcal{M}_ψ and the multiplication by -1 of some or all of its columns, referred to below as a column scaling, resulting in a partition into four submatrices as follows:

$$\left(\begin{array}{c|c} \mathcal{A}^1 & \mathcal{E} \\ \hline \mathcal{D} & \mathcal{A}^2 \end{array} \right), \quad (6)$$

where the submatrix \mathcal{A}^1 has at most one $+1$ entry per row; the submatrix \mathcal{D} contains only -1 or 0 entries; the submatrix \mathcal{A}^2 has no restrictions other than the three values of -1 , $+1$, and 0 for each entry; and the submatrix \mathcal{E} has only 0 entries.

The submatrix \mathcal{A}^1 represents a *Horn formula*. In Sect. 6.2 Horn formulas are shown to have the following two important properties: they are solved efficiently, for example, by Algorithm 20 of Fig. 46, and, by Theorem 15, there is always a unique minimum model for a satisfiable Horn formula. The second property means there is always a satisfying assignment M such that, for any other satisfying assignment M' , the variables that have value 1 according to M' are a superset of the variables set to 1 according to M (more succinctly, $M \subset M'$). This property, plus the nature of submatrices \mathcal{D} and \mathcal{E} , effectively allows a split of the problem of determining the satisfiability of ψ into two independent problems: namely, determine satisfiability for the Horn formula represented by \mathcal{A}^1 and determine satisfiability for the subformula represented by \mathcal{A}^2 . The algorithm of Fig. 40 shows this in more detail. The following theorem proves correctness of this algorithm:

Theorem 7 *Let CNF formula ψ be represented as a monotone decomposition (0 ± 1)-matrix. On input ψ , Algorithm 14 outputs “unsatisfiable” if and only if ψ is unsatisfiable, and if ψ is satisfiable, then the output set $M_1 \cup M_2$ is a model for ψ .*

Algorithm 14.

```

Monotone Decomposition Solver ( $\psi$ )
/* Input: CNF formula  $\psi$  as  $(0, \pm 1)$   $\mathcal{M}_\psi$  monotone decomposition */
/* Output: "unsatisfiable" or a model for  $\psi$  */
/* Locals: set of variables  $M_1, M_2$  */

    Let  $\mathcal{M}_\psi$  be partitioned according to (6).
    If Horn formula  $\mathcal{A}^1$  is unsatisfiable, Output "unsatisfiable."
    Let  $M_1$  be a unique minimum model for the Horn formula  $\mathcal{A}^1$ .
    Remove from  $\mathcal{A}^2$  all rows common to  $\mathcal{D}$ 's that are satisfied by  $M_1$ .
    If  $\mathcal{A}^2$  is unsatisfiable, Output "unsatisfiable."
    Let  $M_2$  be a model for  $\mathcal{A}^2$ .
    Output  $M_1 \cup M_2$ .

```

□

Fig. 40 Algorithm for determining satisfiability of a monotone decomposition

Proof Clearly, if Horn formula \mathcal{A}^1 is unsatisfiable, then so is ψ . So suppose there is a model M_1 for \mathcal{A}^1 and consider the rows of \mathcal{A}^2 remaining after rows common to those of \mathcal{D} which are satisfied by M_1 are removed. Since M_1 is a unique minimum model for \mathcal{A}^1 , no entries of \mathcal{D} are +1, and since variables of \mathcal{A}^1 are distinct from variables of \mathcal{A}^2 , no remaining row of \mathcal{A}^2 can be satisfied by any model for \mathcal{A}^1 . Therefore, if these rows of \mathcal{A}^2 are unsatisfiable, then so is ψ . On the other hand, if these rows are satisfied by model M_2 , then clearly, $M_1 \cup M_2$ is a model for ψ . □

A (0 ± 1) matrix \mathcal{M}_ψ representing CNF formula ψ may have more than one monotone decomposition. Of particular interest is the *maximum monotone decomposition* of \mathcal{M}_ψ , that is, the monotone decomposition of ψ such that \mathcal{A}^1 has the greatest number of rows and columns. A monotone decomposition is said to be maximal with respect to the dimensions of \mathcal{A}^1 . The following theorem says a unique maximal monotone decomposition is always possible.

Theorem 8 Any (0 ± 1) matrix \mathcal{M} has a unique maximal monotone decomposition.

Proof Suppose \mathcal{M} has two distinct maximal monotone decompositions, say, \mathcal{M}_1 and \mathcal{M}_2 . Let $\mathcal{A}_i^1, \mathcal{A}_i^2$, and \mathcal{D}_i , $i \in \{1, 2\}$, be the partition of \mathcal{M} , after column scaling, corresponding to \mathcal{M}_i (see the partition (6) on page 389). Construct a new partition \mathcal{M}' of \mathcal{M} into \mathcal{A}'^1 , \mathcal{A}'^2 , and \mathcal{D}' such that \mathcal{A}'^1 includes all rows and columns of \mathcal{A}_1^1 and \mathcal{A}_2^1 . For those columns of \mathcal{M}' that are also columns of \mathcal{A}_1^1 , use a column scaling that is exactly the same as the one used in \mathcal{M}_1 . For all other columns, use the same scaling as in \mathcal{M}_2 . The submatrix of \mathcal{A}'^1 that includes rows and columns of \mathcal{A}_1^1 is the same as \mathcal{A}_1^1 because the scaling of those columns is the same as for \mathcal{M}_1 . The submatrix of \mathcal{A}'^1 including rows of \mathcal{A}_1^1 and columns not in \mathcal{A}_1^1 must be a 0 submatrix by the monotone decomposition \mathcal{M}_1 . The submatrix of \mathcal{A}'^1 including columns of \mathcal{A}_1^1 and no rows of \mathcal{A}_1^1 must contain only 0 or -1 entries due to the \mathcal{M}_1 scaling and the submatrix including neither columns or rows of \mathcal{A}_1^1 must be Horn due to \mathcal{M}_2 column scaling. It follows that submatrix \mathcal{A}'^1 is Horn (at most one +1 in each row).

It is similarly easy to check that the submatrix of \mathcal{M}' consisting of rows of \mathcal{A}'^1 and columns other than those of \mathcal{A}'^1 is 0 and that the submatrix of \mathcal{M}' consisting of columns of \mathcal{A}'^1 and rows other than those of \mathcal{A}'^1 contains no +1 entries. It follows that \mathcal{M}' is a monotone decomposition. Since $\mathcal{A}_1^1 \supset \mathcal{A}'^1$ and $\mathcal{A}_2^1 \supset \mathcal{A}'^1$, neither \mathcal{M}_1 nor \mathcal{M}_2 is a maximal monotone decomposition in violation of the hypothesis. The theorem follows. \square

From [Theorem 8](#) there is always a maximum monotone decomposition for \mathcal{M}_ψ .

A maximum monotone decomposition is useful because (1) \mathcal{A}^1 , representing a Horn formula, is as large as possible so \mathcal{A}^2 is as small as possible; (2) Horn formulas may be efficiently solved by [Algorithm 20](#) and (3) a maximum monotone decomposition can be found efficiently, as will now be shown.

A maximum monotone decomposition can be found using [Algorithm 15](#) of [Fig. 41](#). The algorithm completes one or more stages where each stage produces a proper monotone decomposition of some matrix. All submatrices change dimensions during the algorithm, so primes are used as in \mathcal{E}' to refer to the current incarnation of corresponding submatrices. Initially, that matrix is \mathcal{M}_ψ . At the end of a stage, if the algorithm needs another stage to produce a bigger decomposition, \mathcal{A}^2 of the current stage becomes the entire input of the next stage and the next stage proceeds independently of previous stages. This can be done since the operation to be mentioned next does not multiply by -1 any of the rows and columns of the \mathcal{A}'^1 and \mathcal{D}' matrices of previous stages. The important operation is to move a nonpositive column that intersects \mathcal{A}'^2 to just right of the border of the current stage's \mathcal{A}'^1 matrix, move the border of \mathcal{A}'^1 and \mathcal{D}' to the right by one column, tag and move the rows containing 1 on the right boundary of the changed \mathcal{D}' up to just below the border of \mathcal{A}'^1 , and finally lower the border of \mathcal{A}'^1 and \mathcal{E}' down to include the tagged rows. Doing so keeps \mathcal{A}'^1 Horn and \mathcal{D}' nonpositive and enlarges \mathcal{A}'^1 . If no nonpositive column exists through \mathcal{A}'^2 , no column can be made nonpositive through \mathcal{A}'^2 by a -1 multiplication, and the initial moved column is not multiplied by -1 , then the initial moved column of the stage is multiplied by -1 and the stage is restarted.

Because of the following theorem, backtracking is limited to just one per stage and is used only to try to decompose with the initial moved column of the stage multiplied by -1 .

Theorem 9 Refer to [Algorithm 15](#) for specific variable names and terms:

1. If z is not a nonpositive column in \mathcal{E}' and z multiplied by -1 is not nonpositive in \mathcal{E}' , then there is no monotone decomposition at the current stage with the initial moved column v of the stage left as is.
2. If multiplying v by -1 also fails because a z cannot be made nonpositive in \mathcal{E}' , then not only does z block a monotone decomposition but multiplying any of the other columns in \mathcal{A}'^1 except v by -1 blocks a monotone decomposition as well.

Proof

1. There is no way to extend the right boundary of \mathcal{A}'^1 and stay Horn while making \mathcal{E}' 0 because column z prevents it.

Algorithm 15.

```

Find Maximum Monotone Decomposition ( $\psi$ )
/* Input: CNF formula  $\psi$  as  $(0, \pm 1)$  matrix  $\mathcal{M}_\psi$  */ 
/* Output: A maximum monotone decomposition of  $\mathcal{M}_\psi$  */ 
/* Locals: set of variables  $M_1, M_2$ , set of unusable literals  $N, L$  */ 

    Set  $N \leftarrow \emptyset$ .
    Set  $\mathcal{A}^2 \leftarrow \mathcal{M}_\psi$ .
    Repeat while there is a column  $v$  of  $\mathcal{A}^2$  such that  $v \notin N$  or  $\neg v \notin N$ :
        Remove 0 rows from  $\mathcal{A}^2$ .
        Choose any  $v$  such that either  $v \notin N$  or  $\neg v \notin N$ .
        Set  $L \leftarrow \emptyset$  and  $\alpha \leftarrow 1$ .
        If  $v \in N$ :
            Multiply all entries in column  $v$  of  $\mathcal{A}^2$  by  $-1$ .
            Set  $\alpha \leftarrow -1$ .
            Set  $N \leftarrow N \setminus \{v\} \cup \{\neg v\}$ .
        Set  $p \leftarrow v$ .
        Define  $\mathcal{A}'^1 = \mathcal{D}' = \mathcal{E}' = 0$ ,  $\mathcal{A}'^2 = \mathcal{A}^2$ , the initial partition of  $\mathcal{A}^2$ .
        Repeat the following:
            Move column  $p$  of  $\mathcal{A}'^2$  to the right border of  $\mathcal{A}'^1$ .
            Move the right border of  $\mathcal{A}'^1$  to the right by 1 column.
            Move and tag rows of  $\mathcal{D}'$  with 1 in its right column to the top.
            Move the bottom border of  $\mathcal{A}'^1$  down to include tagged rows.
            If  $\mathcal{E}' = 0$ , Set  $\mathcal{A}^2 \leftarrow \mathcal{A}'^2$  and Break.
            Choose column  $z$  through  $\mathcal{E}'$  with a non-zero entry in  $\mathcal{E}'$ .
            If  $(z \in N \text{ and } \neg z \in N) \text{ or}$ 
                 $(z \in N \text{ and column } z \text{ has } -1 \text{ entry}) \text{ or}$ 
                 $(\neg z \in N \text{ and column } z \text{ has } +1 \text{ entry}) \text{ or}$ 
                 $(\text{column } z \text{ has } +1 \text{ and } -1 \text{ entries}):$ 
                If  $\neg v \in N$  or  $\alpha = -1$ : Set  $N \leftarrow N \cup \{v, \neg v, z, \neg z\} \cup L$ .
                Break.
            Otherwise,
            If  $\neg z \notin N$  and column  $z$  has no  $-1$  entries:
                Multiply all entries in column  $z$  of  $\mathcal{A}^2$  by  $-1$ .
                If  $z \in N$ : Set  $N \leftarrow N \setminus \{z\} \cup \{\neg z\}$ .
                If  $\neg z \in L$ : Set  $L \leftarrow L \setminus \{\neg z\} \cup \{z\}$ .
                Set  $L \leftarrow L \cup \{\neg z\}$ .
                Set  $p \leftarrow z$ .
            Remove 0 rows from  $\mathcal{A}^2$ .
            Let  $\mathcal{M}$  be the permuted and scaled  $\mathcal{M}_\psi$  with lower right matrix  $\mathcal{A}^2$ .
            Output  $\mathcal{M}$ .

```

□

Fig. 41 Algorithm for finding the maximum monotone decomposition of a (0 ± 1) matrix

2. Consider columns in \mathcal{A}'^1 first. The proof is by induction on the number of columns processed in \mathcal{A}'^1 . The base case has no such column: that is, \mathcal{A}'^1 only contains the column v and is trivially satisfied. For the inductive step, change the column scaling to 1 for all columns and run the algorithm in the same column order it had been when it could not continue. Assume the hypothesis holds to k columns and consider processing at the $k + 1$ st column, call it column x . At this point \mathcal{A}'^1 has one 1 in each row, \mathcal{D}' is nonpositive, and since x is multiplied by 1, it is nonzero and nonpositive through \mathcal{E}' . If there is a monotone decomposition where x is multiplied by -1 , then x goes through \mathcal{A}^1 of that decomposition. The multiplication by -1 changes the nonzero nonpositive elements of x through \mathcal{E}' to nonzero nonnegative elements. Therefore, at least one of these elements, say, in row r , is $+1$. But \mathcal{A}^1 of the decomposition must have a $+1$ in each row, so it must be that row r has this $+1$ in, say, column c , a column of \mathcal{A}'^1 that is multiplied by -1 . But c cannot be the same as v since v multiplied by -1 blocks a monotone decomposition by hypothesis. On the other hand, if c is not v , then by the inductive hypothesis c cannot be multiplied by -1 in a monotone decomposition. Therefore, by contradiction, there is no monotone decomposition and the hypothesis holds to $k + 1$ columns.

Now consider column z . No scaling of column z can make z nonpositive in \mathcal{E}' . Then that part of z that goes through \mathcal{E}' has -1 and 1 entries. The hypothesis follows from the same induction argument as above. \square

Any column blocking a monotone decomposition need never be checked again.

The algorithm keeps track of blocking columns with set N , the long-term record of blocking columns, and set L , the temporary per stage record. If column indicator w is placed in N , it means the unmultiplied column w blocks, and if $-w$ is placed in N , it means column w multiplied by -1 blocks.

The algorithm has quadratic complexity. Complexity can be made linear by running the two possible starting points of each stage, namely, using column v as is and multiplying column v by -1 , concurrently, and breaking off computation when one of the two succeeds.

A formula ψ which has a maximum monotone decomposition where \mathcal{A}^2 is a member of an efficiently solved subclass of satisfiability obviously may be solved efficiently by [Algorithm 14](#) if \mathcal{A}^2 can efficiently be recognized as belonging to such a subclass. [Section 6](#) discusses several efficiently solved subclasses of satisfiability problems which may be suitable for testing. If \mathcal{A}^2 represents a 2-SAT formula (see [Sect. 6.1](#)), then ψ is said to be q-Horn. The class of q-Horn formulas was discovered and efficiently solved in [\[21, 22\]](#), and it was the results of that work that led to the development of maximum monotone decompositions [\[137\]](#).

5.10.2 Autarkies and Safe Assignments

Definition 1 An assignment to a set of variables is said to be *autark* or an *autarky* if all clauses that contain at least one of those variables are satisfied by the assignment. We will call a set of variables that is associated with an autarky an *autark set*.

If all clauses satisfied by an autarky are removed from a CNF formula ψ , then the resulting formula is equivalent in satisfiability to ψ . A simple example of an autarky set is a collection of one or more pure literals. A simple decomposition is to remove all clauses that contain pure literals. One can do the same for any autarky. However, discovering autarkies can be expensive. In some cases, though, an autarky can be found in polynomial time. This is treated in Sect. 6.9.

A similar decomposition exists for BDDs. Let f be a Boolean function and let $f|_v$ ($f|_{\neg v}$) denote the function obtained by setting variable v to 1 (respectively, 0).

Lemma 4 ([146]) *Given a conjunction of BDDs $f = f_1 \wedge \dots \wedge f_m$ and variable v occurring in one or more BDDs of f , let f' be the conjunction of all BDDs in f which contain v . Let $f'_v = \neg(f'|_v) \wedge (f'|_{\neg v})$. Let $f'_{\neg v} = (f'|_v) \wedge \neg(f'|_{\neg v})$.*

1. *If f'_v has value 0, then $f|_v$ is satisfiable if and only if f is satisfiable.*
2. *If $f'_{\neg v}$ has value 0, then $f|_{\neg v}$ is satisfiable if and only if f is satisfiable.*

Lemma 4 states that if any of the BDDs in f are falsified or if all of the BDDs in f are satisfied by setting v to 1 (respectively, 0), then it is safe to make that assignment because the satisfiability of f does not change by doing so. We emphasize that the safe value for v is *not necessarily inferred*. This lemma provides a way to test whether a safe value exists for a variable, that is, if $f'_v (f'_{\neg v})$ has value 0, then it is safe to set v to 1 (0) in f . However, to use this lemma directly requires conjoining all BDDs containing v , and from Sect. 5.9, this could be expensive. In pursuit of an efficient method for finding safe assignments, **Lemma 4** may be used to derive the following weaker result:

Theorem 10 ([146]) *Given a conjunction of BDDs $f = f_1 \wedge \dots \wedge f_m$ and variable v occurring in one or more BDDs of f , let f' be the conjunction of all BDDs in f which contain v . Without loss of generality, suppose $f' = f_1 \wedge \dots \wedge f_n$ where $n \leq m$. Let $f'_v = (\neg(f_1|_v) \wedge f_1|_{\neg v}) \vee \dots \vee (\neg(f_n|_v) \wedge f_n|_{\neg v})$. Let $f'_{\neg v} = (f_1|_v \wedge \neg(f_1|_{\neg v})) \vee \dots \vee (f_n|_v \wedge \neg(f_n|_{\neg v}))$.*

1. *If f'_v has value 0, then $f|_v$ is satisfiable if and only if f is satisfiable.*
2. *If $f'_{\neg v}$ has value 0, then $f|_{\neg v}$ is satisfiable if and only if f is satisfiable.*

According to **Theorem 10**, a safe assignment may be found without having to conjoin BDDs containing v . This is practical when BDDs are fairly small and is more practical than conjoining BDDs if v appears in many of them. However, it is possible that a safe assignment discovered using **Lemma 4** may be undiscoverable using **Theorem 10**.

The following is the corresponding theorem for safe assignments involving more than one variable:

Theorem 11 ([146]) *Given a conjunction of BDDs $f = f_1 \wedge \dots \wedge f_m$ and a set of variables $V = \{v_1, \dots, v_k\}$ each occurring in one or more BDDs of f , let f' be the conjunction of all BDDs in f which contain at least one of the variables in V . Let $\mathcal{M} = \{M_1, \dots, M_{2^k}\}$ be the set of all possible truth assignments to the variables*

in V . Without loss of generality, suppose $f' = f_1 \wedge \dots \wedge f_n$ where $n \leq m$. $\forall_{1 \leq i \leq 2^k}$ if $(\neg(f' |_{M_i}) \wedge (f' |_{M_1} \vee \dots \vee f' |_{M_{2^k}}))$ has value 0, then $f' |_{M_i}$ is satisfiable if and only if f' is satisfiable.

It is straightforward to turn [Theorems 10](#) and [11](#) into an algorithm, but this is not done here because numerous variants to speed up the search are possible and it is impractical to list all of them.

5.11 Branch and Bound

The DPLL algorithm of [Fig. 17](#) is sequential in nature. At any point in the search, only one node, representing a partial assignment $M_{1:}$, of the search tree is *active*: that is, open to exploration. This means exploration of a promising branch of the search space may be delayed for a potentially considerable period until search finally reaches that branch. Branch and bound aims to correct this to some extent. In branch and bound, quite a few nodes of the search space may be active at any point in the search. Each of the active nodes has a number $l(M_{1:})$ which is an aggregate estimate of how close the assignment represented at a node is to a solution or confirms that assignment cannot be extended to a *best* solution. Details concerning how $l(M_{1:})$ is computed will follow. A variable v is chosen for assignment from the subformula of the active node of lowest l value and that node is expanded. The expansion eliminates one active node and may create up to two others, one for each value to v . To help control the growth of active nodes, branch and bound maintains a monotonically decreasing number u for preventing nodes known to be unfruitful from becoming active. If the l value of any potential active node is greater than u , it is thrown out and not made active. Eventually, there are no active nodes left and the algorithm completes.

Branch and bound is intended to solve more problems than SAT, one of the most important being MAX-SAT ([Page 319](#)). It requires a function $g_\psi(M_{1:})$ which maps a given formula ψ and partial or total truth assignment $M_{1:}$ to a nonnegative number. The objective of branch and bound is to return an assignment M such that $g_\psi(M)$ is minimum over all truth assignments, partial or complete. That is,

$$M : \forall_x, g_\psi(X) \geq g_\psi(M).$$

For example, if $g_\psi(M_{1:})$ is just the number of clauses in $\psi_{M_{1:}}$, then branch and bound seeks to find M which satisfies the greatest number of clauses, maybe all.

Branch and bound discovers and discards search paths that are known to be fruitless, before they are explored, by means of a heuristic function $h(\psi_{M_{1:}})$ where $\psi_{M_{1:}}$ is obtained from ψ by removing clauses satisfied by and literals falsified by $M_{1:}$. The heuristic function returns a nonnegative number which, when added to $g_\psi(M_{1:})$, is a lower bound on $g(\psi_X)$ over all possible extensions X to $M_{1:}$. That sum is the $l(M_{1:})$ that was referred to above. That is,

Algorithm 16.

```

Branch-and-bound ( $\psi, h, g_\psi$ )
/* Input:  $n$  variable CNF formula  $\psi$ , heuristic function  $h$ ,          */
/*           objective function  $g_\psi$  mapping partial assignments to  $Z$       */
/* Output: Assignment  $M$  such that  $g_\psi(M)$  is minimized                 */
/* Locals: Integer  $u$ , priority queue  $P$                                 */

    Set  $M \leftarrow \emptyset$ ; Set  $M_{1:0} \leftarrow \emptyset$ ; Set  $u \leftarrow \infty$ .
    Insert  $P \leftarrow \langle\langle\psi, M_{1:0}\rangle, 0\rangle$ .
    Repeat the following while  $P \neq \emptyset$ :
        Pop  $\langle\psi', M_{1:i}\rangle \leftarrow P$ .
        If  $\psi' = \emptyset$  then Output  $M$ .
        Choose variable  $v$  from  $\psi'$ .
        Set  $\psi'_1 \leftarrow \{c \setminus \{v\} : c \in \psi'\text{ and } \neg v \notin c\}$ .
        Set  $\psi'_2 \leftarrow \{c \setminus \{\neg v\} : c \in \psi'\text{ and } v \notin c\}$ .
        Repeat the following for  $j = 1$  and  $j = 2$ :
            If  $j = 1$  then do the following:
                Set  $M_{1:i+1} \leftarrow M_{1:i}$ .
            Otherwise
                Set  $M_{1:i+1} \leftarrow M_{1:i} \cup \{v\}$ .
            If  $h(\psi'_j) + g_\psi(M_{1:i+1}) < u$  then do the following:
                Insert  $P \leftarrow \langle\langle\psi'_j, M_{1:i+1}\rangle, h(\psi'_j) + g_\psi(M_{1:i+1})\rangle$ .
                If  $g_\psi(M_{1:i+1}) < u$  then do the following:
                    Set  $u \leftarrow g_\psi(M_{1:i+1})$ .
                    Set  $M \leftarrow M_{1:i+1}$ .
        Output  $M$ .
    □

```

Fig. 42 Classic branch-and-bound procedure adapted to satisfiability

$$l(M_{1:}) = h(\psi_{M_{1:}}) + g_\psi(M_{1:}) \leq \min\{g_\psi(X) : X \text{ is an extension of } M_{1:}\}.$$

The algorithm maintains a number u that records the lowest g_ψ value that has been seen so far during search. If partial assignment $M_{1:i}$ is extended by one variable to $M_{1:i+1}$ and $g_\psi(M_{1:i+1}) < u$ then u , is updated to that value and $M_{1:i+1}$, the assignment that produced that value, is saved as M . In that case, $l(M_{1:i+1})$ must also be less than u because it is less than $g_\psi(M_{1:i+1})$. But if $l(M_{1:i+1}) > u$, then there is no chance, by definition of $l(M_{1:})$, that any extension to $M_{1:i+1}$ will yield the minimum g_ψ . Hence, if that test succeeds, the node that would correspond to $M_{1:i+1}$ is thrown out, eliminating exploration of that branch.

The algorithm in its general form for satisfiability is shown in Fig. 42 as **Algorithm 16**. A priority queue P is used to hold all active nodes as pairs where each pair contains a reduced formula and its corresponding partial assignment. Pairs are stored in P in increasing order of $l(M_{1:})$. It is easy to see, by definition of $l(M_{1:})$, that no optimal assignment gets thrown out. It is also not difficult to see that, given two heuristic functions h_1 and h_2 , if $h_1(\psi_{M_{1:}}) \leq h_2(\psi_{M_{1:}})$ for all M , then the search

explored using h_1 will be no larger than the search space explored using h_2 . Thus, to keep the size of the search space down, as tight a heuristic function as possible is desired. However, since overall performance is most important and since tighter heuristic functions typically mean more overhead, it is sometimes more desirable to use a weaker heuristic function which generates a larger search space in less time. [Section 5.12.2](#) shows how linear programming relaxations of integer programming representations of search nodes can be used as heuristic functions. This section concludes with an alternative to illustrate what else is possible.

Recall the problem of variable-weighted satisfiability which was defined in [Sect. 2](#): given CNF formula ψ and positive weights on variables, find a satisfying assignment for ψ , if one exists, such that the sum of weights of variables of value 1 is minimized. Let ψ_{M_1} be defined as above and let $Q_{\psi_{M_1}}$ be a subset of positive clauses of ψ_{M_1} such that no variable appears twice in $Q_{\psi_{M_1}}$. For example, $Q_{\psi_{M_1}}$ might look like this:

$$(v_1 \vee v_3 \vee v_7) \wedge (v_2 \vee v_6) \wedge (v_4 \vee v_5 \vee v_8).$$

A strictly lower bound on the minimum weight solution over all extensions to M_1 is $g_\psi(M_1) + h(\psi_{M_1})$, the sum of the weights of the minimum weight variable in each of the clauses of $Q_{\psi_{M_1}}$. Clearly, this is not a very tight bound. But it is computationally fast to acquire this bound, and the trade-off of accuracy for speed often favors this approach [61], particularly when weight calculations are made incrementally. Additionally, there are some tricks that help to find a *good* $Q_{\psi_{M_1}}$. For example, a greedy approach may be used as follows: choose a positive clause c with variables independent of clauses already in $Q_{\psi_{M_1}}$ and such that the ratio of the weight of the minimum weight variable in c to the number of variables in c is maximum [108]. The interested reader can consult [108] and [41] for additional ideas.

5.12 Algebraic Methods

A collection of Boolean constraints may be expressed as a system of algebraic equations or inequalities which has a solution if and only if the constraints are satisfiable. The attraction of these methods is that, in some cases, a single algebraic operation can simulate a large number of resolution operations. The problem is that it is not always obvious how to choose the optimal sequence of operations to take advantage of this, and often performance is disappointing due to nonoptimal choices.

5.12.1 Gröbner Bases Applied to SAT

It is interesting that at the same time resolution was being developed and understood as a search tool in the 1960s, an algebraic tool for computing a basis for highly *nonlinear* systems of equations was introduced: the basis it found was given the name Gröbner basis and the tool was called the Gröbner basis algorithm [29].

But it was not until the mid-1990s that Gröbner bases crossed paths with satisfiability when it was shown that Boolean expressions can be written as systems of multilinear equations which a simplified Gröbner basis algorithm can solve *using a number of derivations that is guaranteed to be within a polynomial of the minimum number possible* [37]. Also in that paper, it is shown that the minimum number of derivations cannot be much greater than, and may sometimes be far less than, the minimum number needed by resolution. Such powerful results led the authors to say “these results suggest the Gröbner basis algorithm might replace resolution as a basis for heuristics for NP-complete problems.”

This has not happened, perhaps partly because of the advances in the development of CNF SAT solvers in the 1990s and partly because, as is the case for resolution, it is generally difficult to find a minimum sequence of derivations leading to the desired conclusion. However, the complementary nature of algebraic and logic methods makes them an important alternative to resolution. Generally, in the algebraic world, problems that can be solved essentially using Gaussian elimination with a small or modest increase in the degree of polynomials are easy. A classic example where this is true is the systems of equations involving only the exclusive-or operator. By contrast, just expressing the exclusive-or of n variables in CNF requires 2^{n-1} clauses.

In the algebraic proof system outlined here, facts are represented as multilinear equations and new facts are derived a database of existing facts using rules described below. Let $\langle c_0, c_1, \dots, c_{2^n-1} \rangle$ be a 0-1 vector of 2^n coefficients. For $0 \leq j < n$, let $b_{i,j}$ be the j th bit in the binary representation of the number i . An input to the proof system is a set of equations of the following form:

$$\sum_{i=0}^{2^n-1} c_i v_1^{b_{i,0}} v_2^{b_{i,1}} \dots v_n^{b_{i,n-1}} = 0, \quad (7)$$

where all variables v_i can take value 0 or 1, and addition is taken modulo 2. An equation of the form (7) is said to be multilinear. A product $t_i = v_1^{b_{i,0}} v_2^{b_{i,1}} \dots v_n^{b_{i,n-1}}$, for any $0 \leq i \leq 2^n - 1$, will be referred to as a multilinear term or simply a term. The degree of t_i , denoted $\deg(t_i)$, is $\sum_{0 \leq j < n} b_{i,j}$. A term that has a coefficient of value 1 in an equation is said to be a nonzero term of that equation.

New facts may be derived from known facts using the following rules:

1. Any even sum of like nonzero terms in an equation may be replaced by 0. Thus, $v_1v_2 + v_1v_2$ reduces to 0 and $1 + 1$ reduces to 0. This reduction rule is needed to eliminate terms when adding two equations (see below).
2. A factor v^2 in a term may be replaced by v . This reduction rule is needed to ensure terms remain multilinear after multiplication (see below).
3. An equation of the form (7) may be multiplied by a term, and the resulting equation may be reduced to the form (7) by rule 2 above. Thus, $v_3v_4(v_1 + v_3 = 0)$ becomes $v_1v_3v_4 + v_3v_4 = 0$.
4. Two equations may be added to produce an equation that may be reduced by rule 1 above to the form (7). Examples will be given below.

An equation that is created by rule 3 or 4 is said to be derived. All derived equations are reduced by rules 1 and 2 before being added to the proof.

Observe that the solution spaces of two equations are complementary if they differ only in that $c_0 = 0$ for one and $c_0 = 1$ for the other. For example, the sets of solutions for the two equations

$$\begin{aligned} v_1v_2v_3 + v_1v_2 + v_2v_3 + v_1 + 1 &= 0 \text{ and} \\ v_1v_2v_3 + v_1v_2 + v_2v_3 + v_1 &= 0 \end{aligned}$$

are complementary.

It is left as evident that performing operations rules 3 and 4 with reductions rules 1 and 2 as needed results in a set of derived equations whose solution space is a superset of the original set. The set of all possible derived equations has a solution space which is identical to that of the original set of equations.

Theorem 12 *The equation $1 = 0$ is always derivable using rules 3 and 4 (and implicitly rules 1 and 2) from an inconsistent input set of multilinear equations and never derived from a consistent set.*

Proof Assume $1 = 0$ is not one of the input equations. Suppose $1 = 0$ is derived from a consistent input set. Then two equations were added to derive $1 = 0$. But the solution space of both must be complementary and therefore the solution space of the entire system must be empty. That is not possible since application of rules 3 and 4 does not reduce the solution space below that of the original set of equations, and there is at least one solution because the input set is consistent.

Suppose $1 = 0$ is not derivable from an inconsistent input set. Re-index terms, with the term of degree 0 taking the lowest index, and construct a sequence of derivations such that no two derived equations have the same nonzero term. If the derivation cannot continue to the lowest (0th) term, then the resulting system of equations is linearly independent and therefore must have a solution. But that is impossible by assumption.

Re-indexing is as follows: terms of degree i all have higher index than terms of degree j if $i > j$; among terms of the same degree, the order of index is decided lexicographically. Call the equations ψ and create set B , initially empty. Repeat the following until ψ is empty. Pick an equation e of ψ that has the highest index, nonzero term. As long as there is an equation g in B whose highest nonzero term has the same index as the highest index nonzero term of e , replace e with $e + g$. If $0 = 0$ is not produced, add e to B . This ensures B remains linearly independent. Create as many as n new equations by multiplying e by every variable and add those equations to ψ that have never been in ψ . This sets up the addition of e with all other equations in B . When ψ is empty, all original equations have been replaced by equations with the same solution space and are such that no two of them have the same highest index nonzero term. \square

Next some examples of inputs are shown and then two short derivations. The CNF clause

$$(v_1 \vee v_2 \vee v_3)$$

is represented by the equation

$$v_1(1 + v_2)(1 + v_3) + v_2(1 + v_3) + v_3 + 1 = 0,$$

which may be rewritten

$$v_1v_2v_3 + v_1v_2 + v_1v_3 + v_2v_3 + v_1 + v_2 + v_3 + 1 = 0.$$

The reader can verify this from the truth table for the clause. Negative literals in a clause are handled by replacing variable symbol v with $(1 + v)$. For example, the clause

$$(\neg v_1 \vee v_2 \vee v_3)$$

is represented by

$$(1 + v_1)(1 + v_2)(1 + v_3) + v_2(1 + v_3) + v_3 + 1 = 0,$$

which reduces to

$$v_1v_2v_3 + v_1v_2 + v_1v_3 + v_1 = 0. \quad (8)$$

As can be seen, just the expression of a clause introduces nonlinearities. However, this is not the case for some Boolean functions. For example, the exclusive-or formula

$$v_1 \oplus v_2 \oplus v_3 \oplus v_4$$

is represented by

$$v_1 + v_2 + v_3 + v_4 + 1 = 0.$$

An equation representing a BDD (Sect. 5.9) can be written directly from the BDD as a sum of algebraic expressions constructed from paths to 1 because each path represents one or more rows of a truth table and the intersection of rows represented by any two paths is empty. Each expression is constructed incrementally while tracing a path as follows: when a 1 branch is encountered for variable v , multiply by v , and when a 0 branch is encountered for variable v , multiply by $(1 + v)$. Observe that for any truth assignment, at most one of the expressions has value 1. The equation corresponding to the BDD at the upper left in Fig. 28 is

$$(1 + v_1)(1 + v_2)(1 + v_3) + (1 + v_1)v_2v_3 + v_1(1 + v_2)v_3 + v_1v_2 + 1 = 0,$$

which reduces to

$$v_1 + v_2 + v_3 + v_1 v_2 v_3 = 0.$$

Since there is a BDD for every Boolean function, this example illustrates the fact that a single equation can represent any complex function. It should be equally clear that a single equation addition may have the same effect as many resolution steps.

Addition of equations and the Gaussian-elimination nature of algebraic proofs is illustrated by showing steps that solve the following simple formula:

$$(v_1 \vee \neg v_2) \wedge (v_2 \vee \neg v_3) \wedge (v_3 \vee \neg v_1). \quad (9)$$

The equations corresponding to (9) are expressed below as (1), (2), and (3). All equations following those equations are derived as stated on the right.

$$\begin{array}{rcccl}
 v_1 v_2 & & +v_2 & = 0 & (1) \\
 & v_2 v_3 & & +v_3 & = 0 \quad (2) \\
 v_1 v_3 & & +v_1 & = 0 & (3) \\
 \hline
 v_1 v_2 v_3 & & +v_2 v_3 & = 0 & (4) \Leftarrow v_3 \cdot (1) \\
 v_1 v_2 v_3 & & & +v_3 & = 0 \quad (5) \Leftarrow (4) + (2) \\
 v_1 v_2 v_3 & & +v_1 v_3 & = 0 & (6) \Leftarrow v_1 \cdot (2) \\
 v_1 v_2 v_3 & & & +v_1 & = 0 \quad (7) \Leftarrow (6) + (3) \\
 v_1 v_2 v_3 + v_1 v_2 & & & = 0 & (8) \Leftarrow v_2 \cdot (3) \\
 v_1 v_2 v_3 & & +v_2 & = 0 & (9) \Leftarrow (8) + (1) \\
 & v_1 & +v_2 & = 0 & (10) \Leftarrow (9) + (7) \\
 v_1 & & +v_3 & = 0 & (11) \Leftarrow (5) + (7)
 \end{array}$$

The solution is given by the bottom two equations which state that $v_1 = v_2 = v_3$. If, say, the following two clauses are added to (9)

$$(\neg v_1 \vee \neg v_2) \wedge (v_3 \vee v_1),$$

the equation $v_1 + v_2 + 1 = 0$ could be derived. Adding this to (10) would give $1 = 0$ which proves that no solution exists.

Ensuring a derivation of reasonable length is difficult. One possibility is to limit derivations to equations of bounded degree where the degree of a term t , $\deg(t)$, is defined in the proof of [Theorem 12](#) and the degree of an equation is $\text{degree}(e) = \max\{\deg(t) : t \text{ is a nonzero term in } e\}$. An example is [Algorithm 17](#) of [Fig. 43](#) which is adapted from [37]. In the algorithm terms are re-indexed as in [Theorem 12](#). Then $\text{first_non-zero}(e_i)$ is used to determine the highest index of a nonzero term of e_i . The function $\text{reduce}(e)$ is an explicit statement that says reduction rules 1 and 2 are applied as needed to produce a multilinear equation.

Algorithm 17.

```

An Algebraic Solver ( $\psi, d$ )
/* Input: List of equations  $\psi = \langle e_1, \dots, e_m \rangle$ , integer  $d$  */  

/* Output: “satisfiable” or “unsatisfiable” */  

/* Locals: Set  $B$  of equations */  

Set  $B \leftarrow \emptyset$ .  

Repeat while  $\psi \neq \emptyset$ :  

    Pop  $e \leftarrow \psi$ .  

    Repeat while  $\exists e' \in B : \text{first\_non-zero}(e) = \text{first\_non-zero}(e')$ :  

        Set  $e \leftarrow \text{reduce}(e + e')$ . /* Rule 4. */  

    If  $e$  is 1 = 0: Output “unsatisfiable”  

    If  $e$  is not 0 = 0:  

        Set  $B \leftarrow B \cup \{e\}$ .  

        If  $\text{degree}(e) < d$ :  

            Repeat for all variables  $v$ :  

                If  $\text{reduce}(ve)$  has not been in  $\psi$ :  

                    Append  $\psi \leftarrow \text{reduce}(ve)$ . /* Rule 3. */  

    Output “satisfiable”.

```

Fig. 43 Simple algebraic algorithm for SAT

This section concludes by comparing equations and the algebraic method with BDDs and BDD operations. Consider an example taken from [Sect. 5.9](#). Equations corresponding to f and c in [Fig. 31](#) are

$$\begin{aligned} f : v_1v_3 + v_2 + v_1v_2 &= 0 \\ c : v_2v_3 + v_3 &= 0. \end{aligned}$$

Multiply f by v_2v_3 to get $v_2v_3 = 0$ which adds with c to get $v_3 = 0$, the inference that is missed by $\text{restrict}(f, c)$ in [Fig. 31](#). The inference can be derived from BDDs by reversing the role of f and c as shown in [Fig. 32](#). Consider what multiplying f by v_2v_3 and adding to c means in the BDD world. The BDD representing v_2v_3 , call it d , consists of two internal nodes v_2 and v_3 , a path to 0 following only 1 branches, and all other paths terminating at 1. Every path that terminates at 1 in f also terminates at 1 in d . Therefore, $d \wedge c$ can safely be added as a BDD as long as f remains. But it is easy to check that $d \wedge c$ is simply $v_3 = 0$.

The process used in the above example can be applied more generally. All that is needed is some way to create a *best* factor d from f and c . This is something a generalized cofactor, which is discussed in [Sect. 5.9.4](#), can sometimes do. However, the result of finding a generalized cofactor depends on BDD variable ordering. For the ordering $v_1 < v_2 < v_3$, the generalized cofactor $g = \text{gcf}(f, c)$ turns out to be $(v_1 \vee \neg v_2 \vee v_3) \wedge (\neg v_2 \vee \neg v_3)$ which is different from d in the leading clause but

is sufficient to derive the inference when conjoined with c . By the definition of **gcf**, since $f \wedge c = g \wedge c$, g may replace f – this is not the case for d above.

Existentially quantifying v away from a BDD has a simple counterpart in algebra: just multiply two polynomials, one with restriction $v = 1$ and the other with restriction $v = 0$. For example, the BDD of Fig. 28 may be expressed as

$$v_1 v_2 v_3 + v_1 v_3 + v_1 + 1 = 0.$$

The equations under restrictions $v_2 = 1$ and $v_2 = 0$, respectively, are

$$v_1 + 1 = 0 \quad \text{and} \quad v_1 v_3 + v_1 + 1 = 0.$$

The result of existential quantification is

$$(v_1 + 1)(v_1 v_3 + v_1 + 1) = v_1 + 1 = 0,$$

which reveals the same inference. As with BDDs, this can be done only if the quantified variable is in no other equation.

The counterpart to strengthening is just as straightforward. The BDDs of Fig. 39 have equation representations

$$b_2 : v_1 v_3 + v_2 + v_1 v_2 = 0$$

$$b_1 : v_3 + v_2 v_3 = 0.$$

Existentially quantify v_1 away from b_2 to get $v_2 v_3 = 0$ and add this to b_1 to get $v_3 = 0$.

5.12.2 Integer Programming

An integer program models the problem of maximizing or minimizing a linear function subject to a system of linear constraints, where all n variables are integral:

$$\begin{aligned} & \text{maximize or minimize } \mathbf{c} \alpha \\ & \text{subject to } \mathcal{M}\alpha \leq \mathbf{b} \\ & l \leq \alpha \leq u \\ & \alpha_i \text{ integral}, 1 \leq i \leq n, \end{aligned} \tag{10}$$

where \mathcal{M} is a constraint matrix, \mathbf{c} is a linear objection function, \mathbf{b} is a constant vector, and α is a variable vector.

The integer programming problem and its relaxation to linear programming are very well studied, and a large body of techniques have been developed to assist in establishing an efficient solution to (10). They are divided into the categories of preprocessing and solving. However, an important third aspect concerns the matrix \mathcal{M} that is used to model a given instance.

Modeling is important because the effective solution of integer programs often entails the use of linear programming relaxations. A solution to such a relaxation generally provides a bound on the actual solution, and the relaxation of one formulation of the input may provide a tighter bound than another. Generally, the tighter the bound, the better.

For example, consider two formulations of the pigeonhole problem. The pigeon-hole problem is as follows: can $n + 1$ pigeons be placed in n holes so that no two pigeons are in the same hole? Define Boolean variables $v_{i,j}$, $1 \leq i \leq n$, $1 \leq j \leq n + 1$ with the interpretation that $v_{i,j}$ will take the value 1 if and only if pigeon j is in hole i and otherwise will take value 0. The following equations, one per pigeon, express the requirement that every pigeon is to be assigned to a single hole:

$$\sum_{i=1}^n v_{i,j} = 1, \quad 1 \leq j \leq n + 1, \quad (11)$$

and the following inequalities express the requirement that two pigeons cannot occupy the same hole:

$$v_{i,j} + v_{i,k} \leq 1, \quad 1 \leq i \leq n, \quad 1 \leq j < k \leq n + 1. \quad (12)$$

There is no solution to this system of equations and inequalities. Relaxing integrality constraints, there is a solution at $v_{i,j} = 1/n$ for all i, j . If running the algorithm to be shown later, practically complete enumeration is necessary before finally it is determined that no solution exists [82]. However, the requirement that at most one pigeon is in a hole may alternatively be represented by

$$\sum_{j=1}^{n+1} v_{i,j} \leq 1, \quad 1 \leq i \leq n. \quad (13)$$

which may be used instead of (12). The new constraints are much tighter than (12) and the system (11) and (13) is easily solved [82].

The purpose of preprocessing is to reformulate a given integer program and tighten its linear programming relaxation. In the process it may eliminate redundant constraints and may even be able to discover unsatisfiability.

6 Algorithms for Easy Classes of CNF Formulas

For certain classes of CNF formulas, the satisfiability problem is known to be solved efficiently by specially designed algorithms. Some classes, such as the 2-SAT and Horn classes are quite important because they show up in real applications and others are quite interesting because results on these add to our understanding of

Algorithm 18.**Unit Resolution (ψ)**

```

/* Input: set of sets CNF formula  $\psi$  */  

/* Output: pair  $\langle$  CNF formula  $\phi$ , partial assignment  $P$   $\rangle$  */  

/*  $\psi$  is satisfiable if and only if  $\phi$  is satisfiable */  

/*  $\phi$  has no unit clauses */  

/* Locals: set of variables  $P$ , set of sets CNF formula  $\phi$  */  

Set  $\phi \leftarrow \psi$ ; Set  $P \leftarrow \emptyset$ .  

Repeat the following while  $\emptyset \notin \phi$  and there is a unit clause in  $\phi$ :  

    Let  $\{l\} \in \phi$  be a unit clause.  

    If  $l$  is a positive literal, Set  $P \leftarrow P \cup \{l\}$ .  

    Set  $\phi \leftarrow \{c - \{\neg l\} : c \in \phi, l \notin c\}$ .  

Output  $\langle \phi, P \rangle$ .

```

□

Fig. 44 Unit resolution for CNF formulas

the structural properties that make formulas hard or easy. Such an understanding can help develop a search heuristic that will obtain a solution more efficiently. In particular, knowledge that a large subset of clauses of a given formula belongs to some easy class of formulas can help reduce the size of the search space needed to determine whether some partial truth assignment can be extended to a solution. Because CNF formulas are so rich in structure, much space in this section is devoted to a few special cases. Hopefully this will help to fully appreciate the possibilities. In particular, results on minimally unsatisfiable and nested formulas are greatly detailed.

The reader may have the impression that the number of polynomial-time solvable classes is quite small due to the famous dichotomy theorem of Schaefer [121]. But this is not the case. Schaefer proposed a scheme for defining classes of propositional formulas with a generalized notion of *clause*. He proved that every class definable within his scheme was either \mathcal{NP} -complete or polynomial-time solvable, and he gave criteria to determine which. But not all classes can be defined within his scheme. The class of Horn formulas can be but several others, which will be described in this section, including q-Horn, extended Horn, CC-balanced, and SLUR cannot be so defined. The reason is that Schaefer's scheme is limited to classes that can be recognized in log space.

Below, some of the more notable easy classes and algorithms for solving them are presented. A crucial component of many of these algorithms is *unit resolution*. An implementation is given in Fig. 44.

6.1 2-SAT

Every clause of a 2-SAT formula contains at most two literals. A given 2-SAT formula ψ may be solved efficiently by constructing the implication graph \vec{G}_ψ

Algorithm 19.

```

2-SAT Solver ( $\psi$ )
/* Input: set of sets 2-CNF formula  $\psi$  */  

/* Output: “unsatisfiable” or a model for  $\psi$  */  

/* Locals: variable  $s$ , set of variables  $M, M'$ , set of sets formula  $\phi$  */  

Set  $\phi \leftarrow \psi$ ; Set  $s \leftarrow 1$ ; Set  $M \leftarrow \emptyset$ ; Set  $M' \leftarrow \emptyset$ ; Set  $\phi' \leftarrow \emptyset$ .  

Repeat the following until some statement outputs a value:  

    Set  $\langle \phi, M' \rangle \leftarrow \text{Unit Resolution } (\phi)$ .  

    If  $\emptyset \in \phi$  then do the following:  

        If  $s$  has value 1 or  $\phi' = \emptyset$  then Output “unsatisfiable”.  

        Set  $s \leftarrow 1$   

        Set  $M' \leftarrow \emptyset$ ;  $\phi \leftarrow \phi'$ ;  $l \leftarrow l'$ .  

        If  $l$  is a negative literal, Set  $M' \leftarrow \neg l$ .  

        Set  $\phi \leftarrow \{c - \{l\} : c \in \phi, \neg l \notin c\}$ .  

    Otherwise, if  $\phi \neq \emptyset$  then do the following:  

        Set  $s \leftarrow 0$ .  

        Choose a literal  $l$  arbitrarily from a clause of  $\phi$ .  

        Set  $M \leftarrow M \cup M'$ .  

        Set  $M' \leftarrow \emptyset$ .  

        Set  $\phi' \leftarrow \phi$ .  

        Set  $l' \leftarrow l$ .  

        If  $l$  is a positive literal, Set  $M' \leftarrow \{l\}$ .  

        Set  $\phi \leftarrow \{c - \{\neg l\} : c \in \phi, l \notin c\}$ .  

    Otherwise, Output  $M \cup M'$ .

```

□

Fig. 45 Algorithm for determining satisfiability of 2-CNF formulas

of ψ (see Sect. 3.3) and traversing its vertices, ending either at a cycle containing complementary literals or with no additional vertices to explore. The algorithm of Fig. 45 implicitly does this.

Unit resolution drives the exploration of strongly connected components of \vec{G}_ψ . The initial application of unit resolution, if necessary, is analogous to traversing all vertices reachable from the special vertex F . Choosing a literal l arbitrarily and temporarily assigning it the value 1 after unit resolution completes is analogous to starting a traversal of some strongly connected component with another round of unit resolution. If that round completes with an empty clause, a contradiction exists so l is set to 0, ϕ and M are reset to what they were just before l was set to 1, and exploration resumes. If an empty clause is encountered before the entire component is visited (i.e., while there still exist unit clauses), then the formula is unsatisfiable. Otherwise, the value of l is made permanent and so are values that were given to other variables during traversal of the component. This process repeats until the formula is found to be unsatisfiable or all components have been explored. The variable named s keeps track of whether variable l has been given one value or two,

the variable M' holds the temporary assignments to variables during traversal of a component, and the variables ϕ' and l' save the point to return to if a contradiction is found. This algorithm is adapted from [56].

The next two theorems are stated without proof.

Theorem 13 *On input CNF formula ψ , Algorithm **2-SAT Solver** outputs “unsatisfiable” if and only if ψ is unsatisfiable, and if it outputs a set M , then M is a model for ψ .* \square

Theorem 14 *On input CNF formula ψ containing m clauses and n variables, Algorithm **2-SAT Solver** has $O(m + n)$ worst-case complexity.* \square

6.2 Horn Formulas

A CNF formula is Horn if every clause in it has at most one positive literal. This class is widely studied, in part because of its close association with logic programming. To illustrate, a Horn clause $(\neg v_1 \vee \neg v_2 \vee \dots \vee \neg v_i \vee v)$ is equivalent to the rule $v_1 \wedge v_2 \wedge \dots \wedge v_i \rightarrow v$ or the implication $v_1 \rightarrow v_2 \rightarrow \dots \rightarrow v_i \rightarrow v$. However, the notion of causality is generally lost when translating from rules to Horn formulas.

The following states an important property of Horn formulas.

Theorem 15 *Every Horn formula has a unique minimum model.*

Proof Let ψ be a Horn formula. Let M be a minimal model for ψ , that is, a smallest subset of variables of value 1 that satisfies ψ . Choose any $v \in M$. Since $M \setminus \{v\}$ is not a model for ψ , there must be a clause $c \in \psi$ such that positive literal $v \in c$. Since all other literals of c are negative and M is minimal, all assignments not containing v cannot satisfy c and therefore ψ . It follows that all models other than M must have cardinality greater than $|M|$. Hence, M is a unique minimum model for ψ . \square

The satisfiability of Horn formulas can be determined in linear time using unit resolution [53, 78, 125]. One of several possible variants is shown in Fig. 46.

Theorem 16 *Given Horn formula ψ as input, Algorithm **Horn Solver** outputs “unsatisfiable” if and only if ψ is unsatisfiable, and if it outputs a set of variables M , then M is a unique minimum model for ψ .*

Proof When Algorithm **Horn Solver** completes with output set M , all remaining clauses have at least one negative literal. Since none of the remaining clauses are null and since v added to M serves to falsify negative literals, at least one of the remaining negative literals in a remaining clause has not been added to M and is therefore satisfied by M . Therefore, all remaining clauses are satisfied by M .

Algorithm 20.

```

Horn Solver ( $\psi$ )
/* Input: set of sets Horn formula  $\psi$  */  

/* Output: “unsatisfiable” or a model for  $\psi$  */  

/* Locals: set of variables  $M$  */  

Set  $M \leftarrow \emptyset$ .  

Repeat the following until no positive literal unit clauses are in  $\psi$ :  

    Choose  $v$  from a positive literal unit clause  $\{v\} \in \psi$ .  

    Set  $M \leftarrow M \cup \{v\}$ .  

    Set  $\psi \leftarrow \{c - \{\neg v\} : c \in \psi, v \notin c\}$ .  

    If  $\emptyset \in \psi$ , Output “unsatisfiable.”  

Output  $M$ .

```

□

Fig. 46 Algorithm for determining satisfiability of Horn formulas

A clause is removed when adding v to M only because it contains literal v . Therefore, all removed clauses are satisfied by M . Hence, M satisfies ψ .

Suppose M is not the unique minimum model for ψ . Then, for some variable v , the assignment $M \setminus \{v\}$ satisfies ψ . Variable v was added to M because some clause $c \in \psi$ containing positive literal v became a unit clause after all variables associated with the negative literals of c were placed in M . But then $M \setminus \{v\}$ cannot satisfy c . Therefore, M is the unique minimum model.

Now suppose the algorithm outputs *unsatisfiable* but there is a model for ψ . Let M' be the unique minimum model. Run the algorithm until reaching the point at which an empty clause is generated. Let this happen on the i th iteration of the Repeat block and let ψ' be the set of all clauses removed up to the test for an empty clause on the i -first iteration. Let v be the last variable added to M and c be the unit clause from which it was obtained. Clearly, ψ' is Horn and $M \setminus \{v\}$ is its unique minimum model. M' must contain all variables of $M \setminus \{v\}$ since it is the unique minimum model for ψ . Therefore, it cannot contain $\{v\}$. But then c is not satisfied by M' , a contradiction. □

Algorithm **Horn Solver** is only useful if the input formula is known to be Horn. It is easy to see that this can be checked in linear time.

6.3 Renamable Horn Formulas

Given CNF formula ψ and variable subset $V'_\psi \subset V_\psi$, define $switch(\psi, V'_\psi)$ to be the formula obtained from ψ by reversing the polarity of all occurrences of v and $\neg v$ in ψ for all $v \in V'_\psi$. If there exists a $V'_\psi \subset V_\psi$ such that $switch(\psi, V'_\psi)$ is Horn, then ψ is said to be *renamable Horn* or *hidden Horn*.

Renamable Horn formulas can be recognized and solved in $O(|\psi|)$ time [10, 104]. Algorithm **SLUR** on Page 410 solves renamable Horn formulas in linear time.

6.4 Linear Programming Relaxations

Let \mathcal{M}_ψ be a (0 ± 1) matrix representing a CNF formula ψ . If \mathcal{M}_ψ has a particular structure, it is possible to solve the inequalities (1) with non-integer constraints $0 \leq \alpha_i \leq 1$ to obtain a solution to ψ either directly or by rounding. Notable classes based on particular matrix structures are the extended Horn formulas and what in this chapter are called the CC-balanced formulas.

The class of *extended Horn formulas* was introduced by Chandru and Hooker [31] who were looking for conditions under which a linear programming relaxation could be used to find solutions to propositional formulas. It is based on a theorem of Chandrasekaran [30] which characterizes sets of linear inequalities for which 0-1 solutions can always be found (if one exists) by rounding a real solution obtained using an LP relaxation. Extended Horn formulas can be expressed as linear inequalities that belong to this family of 0-1 problems.

For the sake of clarity, an equivalent graph theoretic definition is presented here. A formula ψ is in the class of extended Horn formulas if one can construct a rooted directed tree T , called an extended Horn tree, indexed on the variables of ψ such that, for every clause $c \in \psi$:

1. All the positive literals of c are consecutive on a single path of T .
2. There is a partition of the negative literals of c into sets N_1, N_2, \dots, N_{n_c} , where n_c is at least 1, but no greater than the number of negative literals of c , such that for all $1 \leq i \leq n_c$, all the variables of N_i are consecutive on a single path of T .
3. For at most one i , the path in T associated with N_i begins at the vertex in T from which the path associated with positive literals begins.
4. For all remaining i , the path in T associated with N_i begins at the root of T .

Disallowing negative paths that do not originate at the root (point 3 above) gives a subclass of extended Horn called *simple extended Horn* [133]. Extended Horn formulas can be solved in polynomial time by Algorithm **SLUR** on Page 410 [122].

Chandru and Hooker showed that unit resolution alone can determine whether or not a given extended Horn formula is satisfiable. This is due to the following two properties of an extended Horn formula:

1. If ψ is extended Horn and has no unit clauses, then ψ is satisfiable.
2. If ψ is extended Horn and v is a variable in ψ , then

$$\psi_1 = \{c - \{v\} : c \in \psi, \neg v \notin c\} \text{ and } \psi_2 = \{c - \{\neg v\} : c \in \psi, v \notin c\}$$

are both extended Horn.

Chandru and Hooker proposed an algorithm that finds a model for a satisfiable extended Horn formula. First, apply unit resolution, setting values of unassigned variables to 1/2 when no unit clauses remain. Then round the result by a matrix multiplication. Their algorithm cannot, however, be reliably applied unless it is

Algorithm 21.

```

SLUR ( $\psi$ )
/* Input: a set of sets CNF formula  $\psi$  */  

/* Output: “unsatisfiable” or a model for  $\psi$  */  

/* Locals: set of variables  $M$ , flag  $d$ , formula  $\psi'$  */  

Set  $\langle \psi', M \rangle \leftarrow \text{Unit Resolution } (\psi)$ .  

If  $\emptyset \in \psi'$  then Output “unsatisfiable.”  

Set  $d \leftarrow 0$  /*  $d = 0$  iff execution is at the top level. */  

Repeat the following while  $\psi' \neq \emptyset$ :  

    Choose arbitrarily a variable  $v \in V_{\psi'}$ .  

    Set  $\langle \psi_1, M_1 \rangle \leftarrow \text{Unit Resolution } (\{c - \{v\} : c \in \psi', \neg v \notin c\})$ .  

    Set  $\langle \psi_2, M_2 \rangle \leftarrow \text{Unit Resolution } (\{c - \{\neg v\} : c \in \psi', v \notin c\})$ .  

    If  $\emptyset \in \psi_1$  and  $\emptyset \in \psi_2$  then do the following:  

        If  $d = 0$  then Output “unsatisfiable.”  

        Otherwise, Output “give up.”  

    Otherwise, do the following:  

        Arbitrarily choose  $i$  so that  $\emptyset \notin \psi_i$ .  

        Set  $\psi' \leftarrow \psi_i$ .  

        If  $i = 1$ ,  $M \leftarrow M \cup M_1$ .  

        Otherwise,  $M \leftarrow M \cup M_2 \cup \{v\}$ .  

    Set  $d \leftarrow 1$   

Output  $M$ 
□

```

Fig. 47 Algorithm for determining satisfiability of SLUR formulas

known that a given formula is extended Horn. Unfortunately, the problem of recognizing extended Horn formulas is not known to be solved in polynomial time. As will be shown later in this section, this problem has become moot since Algorithm **SLUR** solves extended Horn formulas in linear time without the need for recognition.

The class of CC-balanced formulas has been studied by several researchers (see [38] for a detailed account of balanced matrices and a description of CC-balanced formulas). The motivation for this class is the question, for SAT, when do linear programming relaxations have integer solutions? A formula ψ with (0 ± 1) matrix representation \mathcal{M}_ψ is *CC-balanced* if in every submatrix of \mathcal{M}_ψ with exactly two nonzero entries per row and per column, the sum of the entries is a multiple of 4 (this definition is taken from [138]). Recognizing that a formula is CC-balanced takes linear time. However, the recognition problem is moot because Algorithm **SLUR** solves CC-balanced formulas in linear time without the need for recognition.

As alluded to above, both extended Horn and CC-balanced formulas are subsets of a larger efficiently solved class of formulas solved by *single lookahead unit resolution* [122] (SLUR). The SLUR class is peculiar in that it is defined based on an algorithm rather than on properties of formulas. Algorithm **SLUR** of Fig. 47 selects variables sequentially and arbitrarily and considers a one-level lookahead,

under unit resolution, of both possible values that the selected variable can take. If unit resolution does not result in an empty clause in one direction, the assignment corresponding to that value choice is made permanent and variable selection continues. If all clauses are satisfied after a value is assigned to a variable (and unit resolution is applied), the algorithm returns a satisfying assignment. If unit resolution, applied to the given formula or to both subformulas created from assigning values to the selected variable on the first iteration, results in a clause that is falsified, the algorithm reports that the formula is unsatisfiable. If unit resolution results in falsified clauses as a consequence of both assignments of values to the selected variable on any iteration except the first, the algorithm reports that it has given up.

A formula is in the class SLUR if, for all possible sequences of selected variables, Algorithm **SLUR** does not give up on that formula. Observe that due to the definition of this class, the question of class recognition is avoided.

The worst-case complexity of Algorithm **SLUR**, as written, is quadratic in the length of the input formula. The complexity is dominated by the execution of $\{c - \{v\} : c \in \psi, \neg v \notin c\}$, $\{c - \{\neg v\} : c \in \psi, v \notin c\}$, and the number of unit clauses eliminated by unit resolution. The total number of times a clause is checked and a literal removed due to the first two expressions is at most the number of literals existing in the given formula if the clauses are maintained in a linked list indexed on the literals. However, the same unit clause may be removed by unit resolution on successive iterations of the Repeat block of Algorithm **SLUR** since once branch of execution is always cut. This causes quadratic worst-case complexity.

A simple modification to Algorithm **SLUR** brings the complexity down to linear time: run both calls of unit resolution simultaneously, alternating execution of their Repeat blocks. When one terminates without an empty clause in its output formula, abandon the other call.

Theorem 17 *Algorithm **SLUR** has $O(|\psi|)$ worst-case complexity if both calls to unit resolution are applied simultaneously and one call is immediately abandoned if the other finishes first without falsifying a clause.*

Proof For reasons mentioned above, only the number of steps used by unit resolution is considered. The number of times a literal from a unit clause is chosen and satisfied clauses and falsified literals removed in *non-abandoned* calls of unit resolution is $O(|\psi|)$ since no literal is chosen twice. Since the Repeat blocks of abandoned and non-abandoned calls alternate, the time used by abandoned calls is no greater than that used by non-abandoned ones. Thus, the worst-case complexity of Algorithm **SLUR**, with the interleave modification, is $O(|\psi|)$. \square

All Horn, renamable Horn, extended Horn, and CC-balanced formulas are in the class SLUR. Thus, an important outcome of the results on SLUR is the observation that no special preprocessing or testing is needed for some of the special polynomial-time solvable classes of SAT when using a reasonable variant of the DPLL algorithm.

A limitation of all the classes of this section is they do not represent many interesting unsatisfiable formulas. There are several possible extensions to the SLUR class which improve the situation. One is to add a 2-SAT solver to the unit resolution steps of Algorithm **SLUR**. This extension is at least able to handle all 2-SAT formulas which is something Algorithm **SLUR** cannot do. It can be elegantly incorporated due to the following observation: whenever Algorithm **SLUR** completes a sequence of unit resolutions and if at that time the remaining clauses are nothing but a subset of the original clauses (which they would have to be if all clauses have at most two literals), then effectively the algorithm can start all over. That is, if fixing of a variable to both values leads to an empty clause, then the formula has been proved to be unsatisfiable. Thus, one need not augment Algorithm **SLUR** by the 2-SAT algorithm, because the 2-SAT algorithm (at least one version of it) does exactly what the extended algorithm does. Another extension of Algorithm **SLUR** is to allow a polynomial number of backtracks, giving up if at least one branch of the search tree does not terminate at a leaf where a clause is falsified. This enables unsatisfiable formulas with short search trees to be solved efficiently by Algorithm **SLUR**.

6.5 q-Horn Formulas

This class of propositional formulas was developed in [22] and [23]. The class of q-Horn formulas may be characterized as a special case of maximum monotone decomposition of matrices [137, 138]. Express a CNF formula of m clauses and n variables as an $m \times n$ (0 ± 1)-matrix \mathcal{M} . In the monotone decomposition of \mathcal{M} , columns are scaled by -1 and the rows and columns are partitioned into submatrices as follows:

$$\left(\begin{array}{c|c} \mathcal{A}^1 & \mathcal{E} \\ \hline \mathcal{D} & \mathcal{A}^2 \end{array} \right),$$

where the submatrix \mathcal{A}^1 has at most one $+1$ entry per row; the submatrix \mathcal{D} contains only -1 or 0 entries; the submatrix \mathcal{A}^2 has no restrictions other than the three values of -1 , $+1$, and 0 for each entry; and the submatrix \mathcal{E} has only 0 entries. If \mathcal{A}^1 is the largest possible over columns, then the decomposition is a maximum monotone decomposition. If the maximum monotone decomposition of \mathcal{M} is such that \mathcal{A}^2 has no more than two nonzero entries per row, then the formula represented by \mathcal{M} is *q-Horn*.

Truemper [138] shows that a maximum monotone decomposition for a matrix associated with a q-Horn formula can be found in linear time (this is discussed in Sect. 5.10.1). Once a q-Horn formula is in its decomposed form, it can be solved in linear time by Algorithm **q-Horn Solver** of Fig. 48.

Theorem 18 *Given a q-Horn formula ψ , Algorithm **q-Horn Solver** outputs “unsatisfiable” if and only if ψ is unsatisfiable, and if ψ is satisfiable, then the output set $M_1 \cup M_2$ is a model for ψ .*

Algorithm 22.

```

q-Horn Solver ( $\mathcal{M}_\psi$ )
/* Input: a  $(0, \pm 1)$  matrix representation for q-Horn formula  $\psi$  */
/* Output: “unsatisfiable” or a model for  $\psi$  */
/* Locals: set of variables  $M_1, M_2$  */

    Find the maximum monotone decomposition of  $\mathcal{M}_\psi$  (Page 84).
    If Horn formula  $\mathcal{A}^1$  is unsatisfiable then Output “unsatisfiable”.
    Let  $M_1$  be a unique minimum model for the Horn formula  $\mathcal{A}^1$ .
    Remove from  $\mathcal{A}^2$  all rows whose columns in  $\mathcal{D}$  are satisfied by  $M_1$ .
    If  $\mathcal{A}^2$  is unsatisfiable then Output “unsatisfiable”.
    Let  $M_2$  be a model for the 2-SAT formula  $\mathcal{A}^2$ .
    Output  $M_1 \cup M_2$ .
```

□

Fig. 48 Algorithm for determining satisfiability of q-Horn formulas

Proof Clearly, if Horn formula \mathcal{A}^1 is unsatisfiable, then so is ψ . Suppose \mathcal{A}^2 is unsatisfiable after rows whose columns in \mathcal{D} are removed because they are satisfied by M_1 . Since M_1 is a unique minimum model for \mathcal{A}^1 and no entries of \mathcal{D} are $+1$, no remaining row of \mathcal{A}^2 can be satisfied by any model for \mathcal{A}^1 . Therefore, ψ is unsatisfiable in this case. The set $M_1 \cup M_2$ is a model for ψ if it is output since M_1 satisfies rows in \mathcal{A}^1 and M_2 satisfies rows in \mathcal{A}^2 . □

An equivalent definition of q-Horn formulas comes from the following.

Theorem 19 A CNF formula is q-Horn if and only if its satisfiability index is no greater than 1.

Proof Let ψ be a q-Horn formula with variable set V_ψ and suppose $|V_\psi| = n$. Let \mathcal{M}_ψ be a monotone decomposition for ψ . Let n_a be such that for $0 \leq i < n_a$, column i of \mathcal{M}_ψ coincides with submatrices \mathcal{A}^1 and \mathcal{D} and for $n_a \leq i < n$, column i coincides with submatrix \mathcal{A}^2 . Form the inequalities (2) from \mathcal{M}_ψ . Assign value 1 to all α_i , $0 \leq i < n_a$, and value $1/2$ to all α_i , $n_a \leq i < n$. This satisfies $0 \leq \alpha_i \leq 1$ of system (2). Since rows of \mathcal{A}^1 have nonzero entries in columns 0 to $n_a - 1$ only and at most one of those is $+1$, the maximum sum of the elements of the corresponding row of inequality (2) is 1. Since all rows of \mathcal{D} and \mathcal{A}^2 have at most two nonzero entries in columns n_a to $n - 1$ and no $+1$ entries in columns 0 to $n_a - 1$, the sum of elements of a corresponding row of inequality (2) has maximum value 1 too. Thus, inequality (2) is satisfied with $z = 1$.

Now, suppose ψ has satisfiability index I_ψ which is no greater than 1. Choose values for all α_i terms such that inequality (2) is satisfied for $z = I_\psi$. Let π be a permutation of the columns of \mathcal{M}_ψ so that $\alpha_{\pi_i} \leq \alpha_{\pi_j}$ if and only if $i < j$. Form \mathcal{M}'_ψ from \mathcal{M}_ψ by permuting columns according to π . Let n_b be such that $\alpha_{\pi_i} < 1/2$ for $0 \leq i < n_b$ and $1/2 \leq \alpha_{\pi_i}$ for $n_b \leq i < n$. Scale columns 0 through $n_b - 1$ of \mathcal{M}'_ψ by -1 . Then inequality (2), using \mathcal{M}'_ψ for \mathcal{M}_ψ , is satisfied with $z = I_\psi$ and

$1/2 \leq \alpha_i$ for all $0 \leq i < n$. It follows that each row of \mathcal{M}'_ψ can have at most two +1 entries or else the elements of the corresponding row of inequality (2) sums to greater than 1. Consider all rows of \mathcal{M}'_ψ with two +1 entries and mark all columns that contain at least one of those entries. Let ρ be a permutation of the columns of \mathcal{M}'_ψ so that all marked columns have higher index than all unmarked columns. Form \mathcal{M}''_ψ from \mathcal{M}'_ψ by permuting columns according to ρ and permuting rows so that all rows with only 0 entries in marked columns are indexed lower than rows with at least one nonzero entry in a marked column. Let n_c be such that columns n_c to $n-1$ in \mathcal{M}''_ψ are exactly the marked columns. The value of $\alpha_{\rho_{n_c}}, n_c \leq i < n$, must be exactly 1/2 or else the elements of some row of inequality (2) must sum to greater than 1. It follows that the number of nonzero entries in columns n_c to $n-1$ in any row of \mathcal{M}''_ψ must be at most two or else the elements of some row of the inequality sum to greater than 1. By construction of \mathcal{M}''_ψ , every row can have at most one +1 entry in columns 0 to $n_c - 1$. Hence, \mathcal{M}''_ψ is a monotone decomposition for ψ . \square

The following result from [23] is also interesting in light of [Theorem 19](#). It is stated without proof.

Theorem 20 *The class of all formulas with a satisfiability index greater than $1 + 1/n^\epsilon$, for any fixed $\epsilon < 1$, is NP-complete.* \square

There is an almost obvious polynomial-time solvable class larger than that of the q-Horn formulas: namely, the class of formulas which have a satisfiability index no greater than $1 + a \ln(n)/n$, where a is any positive constant. The \mathcal{M} matrix for any formula in this class can be scaled by -1 and partitioned as follows:

$$\left(\begin{array}{c|cc|c} \mathcal{A}^1 & \mathcal{E} & \mathcal{B}^1 \\ \hline \mathcal{D} & \mathcal{A}^2 & \mathcal{B}^2 \end{array} \right),$$

where submatrices \mathcal{A}^1 , \mathcal{A}^2 , \mathcal{E} , and \mathcal{D} have the properties required for q-Horn formulas and the number of columns in \mathcal{B}^1 and \mathcal{B}^2 is no greater than $O(\ln(n))$. Satisfiability for such formulas can be determined in polynomial time by solving the q-Horn system obtained after substitution of each of $2^{O(\ln(n))}$ partial truth assignments to the variables of \mathcal{B}^1 and \mathcal{B}^2 .

6.6 Matched Formulas

The matched formulas have been considered in the literature (see [136]) but not extensively studied, probably because this seems to be a rather useless and small class of formulas. Our interest in matched formulas is to provide a basis of comparison with other, well-known, well-studied classes. Let $G_\psi(V_1, V_2, E)$ be the variable-clause matching graph (see [Sect. 3.5](#)) for CNF formula ψ , where V_1 is the set of clause vertices and V_2 is the set of variable vertices. A total matching with respect

to V_1 is a subset of edges $E' \subset E$ such that no two edges in E' share an endpoint but every vertex $v \in V_1$ is an endpoint for some edge in E' . Formula ψ is a *matched formula* if its variable-clause matching graph has a total matching with respect to V_1 . A matched formula is trivially satisfied: for each edge $e \in E'$, assign the variable represented by the variable vertex in e a value that satisfies the clause represented by the clause vertex in e . The comparison with other classes is discussed in Sect. 6.12.

6.7 Generalized Matched Formulas

The class of matched formulas has been generalized by Szeider [135]. Let $G_\psi(V_1, V_2, E)$ be the variable-clause matching graph of ψ as above. Let $V'_1 \subset V_1$ and $V'_2 \subset V_2$ and suppose the subgraph $G'_\psi(V'_1, V'_2, E')$ induced by V'_1 and V'_2 is complete: that is, for every pair of vertices $v_1 \in V'_1$ and $v_2 \in V'_2$, there is an edge $e \in E'$. Call such a subgraph a *biclique*.

Theorem 21 *Let $G_\psi(V_1, V_2, E)$ be the variable-clause graph for ψ . Let $\{X_1, X_2, \dots, X_r\}$ be a collection of bicliques in $G_\psi(V_1, V_2, E)$ and suppose (1) the number of clause vertices in X_1 is less than 2 raised to the number of variable vertices in X_i , $1 \leq i \leq r$; (2) every $v_1 \in V_1$ (representing a clause) is in some X_i , $1 \leq i \leq r$; and (3) every $v_2 \in V_2$ (representing a variable) is in at most one X_i , $1 \leq i \leq r$. Then ψ is satisfiable.*

Proof Let V^{X_i} be the variables represented by vertices of X_i and let C^{X_i} be the clauses represented by the remaining vertices of X_i . Remove from all $c \in C^{X_i}$ all literals not associated with variables of V^{X_i} . Since X_i is complete, the number of literals in c is $|V^{X_i}|$ and the number of assignments to the variables of V^{X_i} which are falsified by c is 1. By condition (1), the total number of falsifying assignments for C^{X_i} is less than all possible assignments to V^{X_i} ; hence, some assignment satisfies C^{X_i} . By condition (3), $V^{X_i} \cap V^{X_j} = \emptyset$, $i \neq j$, so satisfying assignments for both C^{X_i} and C^{X_j} cannot conflict. By condition (2), every clause in ψ is in some biclique and is therefore satisfied by some assignment. \square

Clause width is typically fixed. In that case, a model for a formula satisfying the conditions of Theorem 21 can be found in time linear in the number of clauses of ψ . If the bicliques of G_ψ are all single edges, then ψ is a matched formula.

Unfortunately, the problem of recognizing a generalized matched formula is \mathcal{NP} -complete, even for 3-CNF formulas.

6.8 Nested and Extended Nested Satisfiability

The complexity of nested satisfiability, inspired by Lichtenstein's theorem of planar satisfiability [105], has been studied in [91]. Index all variables in a CNF formula consecutively from 1 to n and let positive and negative literals take the index of

their respective variables. A clause c_i is said to *straddle* another clause c_j if the index of a literal of c_j is strictly between two indices of literals of c_i . Two clauses are said to *overlap* if they straddle each other. A formula is said to be *nested* if no two clauses overlap. For example, the following formula is nested:

$$(v_6 \vee \neg v_7 \vee v_8) \wedge (v_2 \vee v_4) \wedge (\neg v_6 \vee \neg v_9) \wedge (v_1 \vee \neg v_5 \vee v_{10}).$$

The class of nested formulas is quite limited in size. A variable cannot show up in more than one clause of a nested formula where its index is strictly between the greatest and least of the clause: otherwise, two clauses overlap. Therefore, a nested formula of m clauses and n variables has at most $2m + n$ literals. Thus, no CNF formula consisting of k -literal clauses is a nested formula unless $m/n < 1/(k-2)$. This particular restriction will be understood better from the probabilistic perspective taken in [Sect. 6.13](#). Despite this, the class of nested formulas is not contained in either of the SLUR or q-Horn classes as shown in [Sect. 6.12](#). This adds credibility to the potential usefulness of the algorithm presented here. However, our main interest in nested formulas is due to an enlightening analysis and efficient dynamic programming solution which appears in [91] and is presented here.

Strong dependencies between variables of nested formulas may be exploited for fast solutions. In a nested formula, if clause c_i straddles clause c_j , then c_j does not straddle c_i , and if clause c_i straddles clause c_j and clause c_j straddles c_k , then c_i straddles c_k . Thus, the straddling relation induces a partial order on the clauses of a nested formula. It follows that the clauses can be placed in a total ordering using a standard linear time algorithm for topologically sorting a partial order: in the total ordering, a given clause does not straddle any clauses following it. In the example above, if clauses are numbered c_0 to c_3 from left to right, c_2 straddles c_0 , c_3 straddles c_1 and c_2 , and no other clause straddles any other, so these clauses are in the desired order already.

Once clauses are topologically sorted into a total order, the satisfiability question may be solved in linear time by a dynamic programming approach where clauses are processed one at a time, in order. The idea is to maintain a partition of variables as a list of intervals such that all variables in any clause seen so far are in one interval. Associated with each interval are four D values that express the satisfiability of corresponding processed clauses under all possible assignments of values to the endpoints of the interval. As more clauses are considered, intervals join and D values are assigned. By introducing two extra variables, v_0 and v_{n+1} and an extra clause $(v_0 \vee v_{n+1})$ which straddles all others and is the last one processed, there is one interval $[v_0, v_{n+1}]$ remaining at the end. A D value associated with that interval determines satisfiability for the given formula. What remains is to determine how to develop the interval list and associated D values incrementally. This task is made easy by the fact that a variable which appears in a clause c with index strictly between the highest and lowest indices of variables in c never appears in a following clause.

An efficient algorithm for determining the satisfiability of nested formulas is shown in [Fig. 49](#). The following lemma is needed to prove correctness. The actual dependence of h values on i is not shown to prevent the notation from going out of control. However, from the context, this dependence should be clear.

Algorithm 23.**Nested Solver (ψ)**

```
/* Input: set of sets CNF formula  $\psi$ , with variables indexed 1 to  $n$  */
/*           and  $m$  clauses indexed from 0 to  $m - 1$  */
/* Output: "unsatisfiable" or "satisfiable" */
/* Locals: Boolean variables  $D_{i,j}(s,t), E_{i,j}(s,t), G_{i,j}(s,t)$ ,
/*           set  $\mathcal{D}$  of Boolean variables. */
```

Apply unit resolution to eliminate all unit clauses in ψ .

Topologically sort the clauses of ψ as explained in the text.

Let c_0, \dots, c_{m-1} denote the clauses, in order.

Add the clause $c_m = \{v_0, v_{n+1}\}$.

Set $\mathcal{D} \leftarrow \{D_{j,j+1}(s,t) \leftarrow 1 : 0 \leq j \leq n, s, t \in \{0, 1\}\}$.

Repeat the following for $0 \leq i \leq m$:

Let $0 < h_1 < h_2 < \dots < h_k < n + 1$ be the intervals for $D \in \mathcal{D}$.

// That is, $\mathcal{D} = \{D_{0,h_1}(*,*), D_{h_1,h_2}(*,*), \dots, D_{h_k,n+1}(*,*)\}$.

Let $c_i = \{l_{h_p}, \dots, l_{h_q}\}$, where $l_{h_r} \in \{v_{h_r}, \neg v_{h_r}\}$, $p \leq r \leq q$.

Set $E_{h_p,h_p}(s,t) \leftarrow 0$ for all $s \in \{0, 1\}$, $t \in \{0, 1\}$.

Set $G_{h_p,h_p}(s,t) \leftarrow 0$ for all $s \in \{0, 1\}$, $t \in \{0, 1\}$.

If $l_{h_p} = v_{h_p}$ then do the following:

Set $E_{h_p,h_p}(1,1) \leftarrow G_{h_p,h_p}(0,0) \leftarrow 1$.

Set $E_{h_p,h_p}(0,0) \leftarrow G_{h_p,h_p}(1,1) \leftarrow 0$.

Otherwise, if $l_{h_p} = \neg v_{h_p}$ then do the following:

Set $E_{h_p,h_p}(1,1) \leftarrow G_{h_p,h_p}(0,0) \leftarrow 0$.

Set $E_{h_p,h_p}(0,0) \leftarrow G_{h_p,h_p}(1,1) \leftarrow 1$.

Repeat the following for $0 \leq j < q - p$, $s \in \{0, 1\}$, $t \in \{0, 1\}$:

If $t = 1$ then Set $l \leftarrow v_{h_{p+j+1}}$, Otherwise Set $l \leftarrow \neg v_{h_{p+j+1}}$.

Set $E_{h_p,h_{p+j+1}}(s,t) \leftarrow$

$(E_{h_p,h_{p+j}}(s,1) \wedge D_{h_{p+j},h_{p+j+1}}(1,t)) \vee$

$(E_{h_p,h_{p+j}}(s,0) \wedge D_{h_{p+j},h_{p+j+1}}(0,t)) \vee$

$(G_{h_p,h_{p+j}}(s,1) \wedge D_{h_{p+j},h_{p+j+1}}(1,t) \wedge l \in c_i) \vee$

$(G_{h_p,h_{p+j}}(s,0) \wedge D_{h_{p+j},h_{p+j+1}}(0,t) \wedge l \in c_i)$.

Set $G_{h_p,h_{p+j+1}}(s,t) \leftarrow$

$(G_{h_p,h_{p+j}}(s,1) \wedge D_{h_{p+j},h_{p+j+1}}(1,t) \wedge \neg(l \in c_i)) \vee$

$(G_{h_p,h_{p+j}}(s,0) \wedge D_{h_{p+j},h_{p+j+1}}(0,t) \wedge \neg(l \in c_i))$.

Repeat for $s \in \{0, 1\}$, $t \in \{0, 1\}$: Set $D_{h_p,h_q}(s,t) \leftarrow E_{h_p,h_q}(s,t)$.

Set $\mathcal{D} \leftarrow \mathcal{D} \setminus \{D_{h_p,h_{p+1}}(*,*), \dots, D_{h_{q-1},h_q}(*,*)\} \cup \{D_{h_p,h_q}(*,*)\}$.

If $D_{0,n+1}(1,1) = 1$, Output "satisfiable,"

Otherwise Output "unsatisfiable."

□

Fig. 49 Algorithm for determining satisfiability of nested formulas

Lemma 5 Assume, at the start of any iteration $0 \leq i \leq m$ of the outer Repeat loop of Algorithm **Nested Solver**, that

$$\mathcal{D} = \{D_{h_0, h_1}(*, *), D_{h_1, h_2}(*, *), \dots, D_{h_k, h_{k+1}}(*, *)\},$$

where $h_0 = 0$ and $h_{k+1} = n + 1$. Let

$$\psi_{p, p+j}^i = \{c : c \in \{c_0, \dots, c_{i-1}\}, h_p \leq \text{minIndex}(c) < \text{maxIndex}(c) \leq h_{p+j}\},$$

for any $0 \leq j \leq k - p + 1$. Then the following hold:

1. At the start of iteration i of the outer Repeat loop, each variable in c_i is the same as one of $\{v_{h_0}, v_{h_1}, \dots, v_{h_{k+1}}\}$, and for every clause $c \in \{c_0, \dots, c_{i-1}\}$, there exists an $0 \leq r \leq k$ such that all the variables of c have index between h_r and h_{r+1} . Moreover, for every h_r and h_{r+1} , there is at least one clause whose minimum indexed variable has index h_r and whose maximum indexed variable has index h_{r+1} .
2. At the start of iteration i of the outer Repeat loop, $D_{h_j, h_{j+1}}(s, t)$, $0 \leq j \leq k$, has value 1 if and only if $\psi_{j, j+1}^i$ is satisfiable with variable v_{h_j} set to value s and variable $v_{h_{j+1}}$ set to value t .
3. At the start of iteration $0 \leq j < q - p$ of the main inner Repeat loop, $E_{h_p, h_{p+j}}(s, t)$ has value 1 if and only if $\psi_{p, p+j}^i \cup \{\{l_x : l_x \in c_i, x \leq h_{p+j}\}\}$ is satisfiable with variable v_{h_p} set to value s and variable $v_{h_{p+j}}$ set to value t .
4. At the start of iteration $0 \leq j < q - p$ of the main inner Repeat loop, $G_{h_p, h_{p+j}}(s, t)$ has value 1 if and only if $\psi_{p, p+j}^i \cup \{\{l_x : l_x \in c_i, x \leq h_{p+j}\}\}$ is not satisfiable, but $\psi_{p, p+j}^i$ is satisfiable with variable h_p set to value s and variable $v_{h_{p+j}}$ set to value t .

Proof Consider point 1. At the start of iteration 0 of the outer Repeat loop, point 1 holds because all variables are in the set $\{h_0, \dots, h_{n+1}\}$. Suppose point 1 holds at the beginning of iteration i . As a result of the topological sort, c_i cannot be straddled by any clause in $\{c_0 \dots c_{i-1}\}$. If one variable of c_i is indexed strictly between h_r and h_{r+1} , by point 1, there is a clause in $\{c_0, \dots, c_{i-1}\}$ whose variable indices are as high as h_{r+1} and as low as h_r . But such a clause would straddle c_i . Hence, for every variable $v \in c_i$, $v \in \{v_{h_p}, v_{h_{p+1}}, \dots, v_{h_q}\}$. Since the last line of the outer Repeat loop replaces all $D_{h_p, h_{p+1}} \dots D_{h_{q-1}, q}$ with D_{h_p, h_q} , point 1 holds at the beginning of iteration $i + 1$ of the outer loop.

Consider point 2. At the start of iteration $i = 0$, all defined variables are $D_{j, j+1}(*, *)$, $0 \leq j \leq n$, and these have value 1. From the definition of $\psi_{p, j}^i$, $\psi_{j, j+1}^0 = \emptyset$. Thus, point 2 holds before iteration $i = 0$. Suppose point 2 holds at the start of iteration i . Since c_i contains no variables indexed less than h_p or greater than h_q and all $D_{h_r, h_{r+1}}(*, *)$ are unchanged by the algorithm for $r < p$ and $r \geq q$, then these D values are correct for iteration $i + 1$ (but the subscripts on h values change because there are fewer D variables on the next iteration). So, due to the short inner Repeat loop following the main inner Repeat loop, point 2 holds

at the start of iteration $i + 1$ if $E_{h_p, h_q}(s, t)$ has value 1 if and only if $\psi_{p,q}^i \cup \{c_i\}$ is satisfiable with variable v_{h_p} set to value s and variable v_{h_q} set to value t . This is shown below, thus taking care of point 2.

Assume, during iteration i of the outer loop and before the start of the main inner loop, that points 1 and 2 hold. Consider the iteration $j = 0$ of the main inner loop. As above, $\psi_{*,*}^0 = \emptyset$. Moreover, by point 1, $\{l_x : l_x \in c_0, x \leq h_p\} = \{l_{h_p}\}$ so $\psi_{p,p}^0 \cup \{\{l_{h_p}\}\} = \{\{l_{h_p}\}\}$. There is no satisfying assignment for this set if the value of the highest and lowest indexed variables of c_0 are opposite each other since the highest and lowest indexed variables are the same. Accordingly, $E_{p,p}(s, t)$ and $G_{p,p}(s, t)$ are set to 0 in the algorithm when s and t are of opposite value. However, if $s = t = 1$ and if $l_{h_p} = v_{h_p}$, then $\psi_{p,p}^0 \cup \{\{v_{h_p}\}\}$ is satisfiable. Accordingly, $E_{p,p}(1, 1)$ is set to 1 and $G_{p,p}(1, 1)$ is set to 0 in the algorithm. Otherwise, if $s = t = 1$ and $l_{h_p} = \neg v_{h_p}$, then $\psi_{p,p}^0 \cup \{\{\neg v_{h_p}\}\}$ is unsatisfiable. Accordingly, $E_{p,p}(1, 1)$ is set to 0 and $G_{p,p}(1, 1)$ is set to 1 in the algorithm. Similar reasoning applies to the case $s = t = 0$. Thus, points 3 and 4 hold for the case $j = 0$.

Now consider iteration i of the outer loop and iteration $j > 0$ of the main inner loop. Assume, at the start of iteration $j - 1$, that points 3 and 4 hold. Points 1 and 2 hold from before since no changes to these occur in the main inner loop. Let $c_i^{j-1} = \{l_x : l_x \in c_i, x \leq p + j - 1\}$ be the subset of literals of c_i that have index no greater than h_{p+j-1} . From Point 1, for every clause $c \in \{c_0, \dots, c_{i-1}\}$, there exists a positive integer $0 \leq r \leq k$ such that all variables of c have index between h_r and h_{r+1} . It follows that

$$\psi_{p,p+j}^i \cup \{c_i^{j-1}\} = (\psi_{p,p+j-1}^i \cup \{c_i^{j-1}\}) \cup \psi_{p+j-1,p+j}^i,$$

and $(\psi_{p,p+j-1}^i \cup \{c_i^{j-1}\}) \cap \psi_{p+j-1,p+j}^i = \emptyset$. For the sake of visualization, define $\psi_1 = \psi_{p,p+j-1}^i$ and $\psi_2 = \psi_{p+j-1,p+j}^i$. At most one variable, namely, $v_{h_{p+j-1}}$, is common to both ψ_1 and ψ_2 . Hence, when $v_{h_{p+j-1}}$ is set to some value, the following holds: both $\psi_1 \cup \{c_i^{j-1}\}$ and ψ_2 are satisfiable if and only if $\psi_{p,p+j}^i \cup \{c_i^{j-1}\}$ is satisfiable. Now consider $\psi_{p,p+j}^i \cup \{c_i^j\}$. Since every variable of c_i has an index matching one of $\{h_p, h_{p+1}, \dots, h_q\}$, $c_i^j \setminus c_i^{j-1}$, either is the empty set or $\{v_{h_{p+j}}\}$ or $\{\neg v_{h_{p+j}}\}$. Therefore, given $v_{h_{p+j-1}}$, $\psi_{p,p+j-1}^i \cup \{c_i^j\}$ is satisfiable if and only if either both $\psi_1 \cup \{c_i^{j-1}\}$ and ψ_2 are satisfiable or ψ_1 and ψ_2 are satisfiable, $\psi_1 \cup \{c_i^{j-1}\}$ is unsatisfiable, but $\psi_1 \cup \{c_i^{j-1} \cup \{l\}\}$ is satisfiable where $l \in \{v_{h_{p+j}}, \neg v_{h_{p+j}}\}$ or $\{l\} = \emptyset$. But since l does not occur in ψ_1 , $\psi_1 \cup \{c_i^{j-1}\}$ can be unsatisfiable with ψ_1 and $\psi_1 \cup \{c_i^{j-1} \cup \{l\}\}$ satisfiable only for assignments which satisfy l . Then, by hypothesis, the association of the E and G variables with $\psi_{p,p+j-1}^i$ and $\psi_{p+j-1,p+j}^i$, and the assignments to E and G in the main inner loop of Algorithm 23, the values of E and G match points 3 and 4 for the j th iteration of the main inner loop.

From point 3, upon completion of the main inner loop, $E_{h_p, h_q}(s, t)$ has value 1 if and only if $\psi_{h_p, h_q}^i \cup \{c_i\}$ is satisfiable. This matches the hypothesis of point 2, thereby completing the proof that point 2 holds. \square

Corollary 1 *Algorithm Nested Solver correctly determines satisfiability for a given nested formula.*

Proof Algorithm **Nested Solver** determines ψ is satisfiable if and only if $D_{0,n+1}(1, 1)$ has value 1. But, from Lemma 5, $D_{0,n+1}(1, 1)$ has value 1 if and only if $\psi \cup \{v_0, v_{n+1}\}$ is satisfiable and v_0 and v_{n+1} are set to value 1. The corollary follows. \square

The operation of **Nested Solver** is demonstrated by means of an example taken from [91]. Suppose the algorithm is applied to a nested formula containing the following clauses which are shown in proper order after the topological sort:

$$(v_1 \vee v_2) \wedge (v_2 \vee v_3) \wedge (\neg v_2 \vee \neg v_3) \wedge (v_3 \vee v_4) \wedge (v_3 \vee \neg v_4) \wedge (\neg v_3 \vee v_4) \wedge (\neg v_1 \vee v_2 \vee v_4).$$

The following table shows the D values that have been computed prior to the start of iteration 6 of the outer loop of the algorithm. The columns show s, t values and the rows show variable intervals.

$D_{*,*}(s, t)$	0, 0	0, 1	1, 0	1, 1
1, 2	0	1	1	1
2, 3	0	1	1	0
3, 4	0	0	0	1

Such a table could result from the following set of processed clauses at the head of the topological order (and before c): processing clause c , using the initial values and recurrence relations for E and G variables given above, produces values as shown in the following tables.

$E_{p,p+j}(s, t)$	0, 0	0, 1	1, 0	1, 1
1, 1	1	0	0	0
1, 2	0	1	0	1
1, 3	1	0	1	0
1, 4	0	0	0	1

$G_{p,p+j}(s, t)$	0, 0	0, 1	1, 0	1, 1
1, 1	0	0	0	1
1, 2	0	0	1	0
1, 3	0	0	0	1

The last line of the E table holds the new D values for the interval $[v_1, v_4]$ as shown by the following table.

$D_{*,*}(s, t)$	0, 0	0, 1	1, 0	1, 1
1, 4	0	0	0	1

Linear time is achieved by careful data structure design and from the fact that no more than $2m + n$ literals exist in a nested formula.

Theorem 22 *Algorithm Nested Solver has worst-case time complexity that is linear in the size of ψ .* \square

The question of whether the variable indices of a given formula can, in linear time, be permuted to make the formula nested appears to be open.

An extension to nested satisfiability has been proposed in [72]. The details are skipped. This extension can be recognized and solved in linear time. For details, the reader is referred to [72].

6.9 Linear Autark Formulas

This class is based on the notion of an autark assignment which was introduced in [111]. Repeating the definition from Page 393, an assignment to a set of variables is an autark assignment if all clauses that contain at least one of those variables are satisfied by the assignment. An autark assignment provides a means to partition the clauses into two groups: one that is satisfied by the autark assignment and one that is completely untouched by that assignment. Therefore, autark assignments provide a way to reduce a formula to one that is equivalent in satisfiability.

The following shows how to find an autark assignment in polynomial time. Let CNF formula ψ of m clauses and n variables be represented as a (0 ± 1) matrix \mathcal{M}_ψ . Let α be an n -dimensional real vector with components $\alpha_1, \alpha_2, \dots, \alpha_n$. Consider the following system of inequalities:

$$\begin{aligned} \mathcal{M}_\psi \alpha &\geq 0, \\ \alpha &\neq 0. \end{aligned} \tag{14}$$

Theorem 23 ([145]) *A solution to (14) implies an autark assignment for ψ .*

Proof Create the autark assignment as follows: if $\alpha_i < 0$ then assign $v_i = 0$, and if $\alpha_i > 0$ then assign $v_i = 1$, if $\alpha_i = 0$ then keep v_i unassigned. It is shown that either a clause is satisfied by this assignment or it contains only unassigned variables.

For every clause, by (1), it is necessary to satisfy the following:

$$a_1 v_1 + a_2 v_2 + \dots + a_n v_n \geq 1 - b, \tag{15}$$

where a_i factors are 0, -1 , or $+1$ and the number of negative a_i terms is b . Suppose α is a solution to (14). Write an inequality of (14) as follows:

$$a_1\alpha_1 + a_2\alpha_2 + \dots + a_n\alpha_n \geq 0. \quad (16)$$

Suppose at least one term, say, $a_i\alpha_i$, is positive. If α_i is positive, then $a_i = 1$ so, with $v_i = 1$ and since there are at most b terms of value -1 , the left side of (15) must be at least $1 - b$. On the other hand, if α_i is negative, then $a_i = -1$, $v_i = 0$, and the product $a_i v_i$ in (15) is 0. Since there are $b - 1$ negative factors left in (15), the left side must be at least $1 - b$. Therefore, in either case, inequalities of the form (16) with at least one positive term represent clauses that are satisfied by the assignment corresponding to α .

Now consider the case where no terms in (16) are positive. Since the left side of (16) is at least 0, there can be no negative terms either. Therefore, all the variables for the represented clause are unassigned. \square

A formula ψ for which the only solution to (14) is $\alpha = 0$ is said to be *linear autarky-free*.

System (14) is an instance of linear programming and can therefore be solved in polynomial time. Hence, an autark assignment, if one exists, can be found in polynomial time.

Algorithm **LinAut** of Fig. 50 is the central topic of study in this section and it will be used to define a polynomial-time solvable class of formulas called linear autarky formulas. The algorithm repeatedly applies an autark assignment as long as one can be found by solving (14). In a departure from [145], the algorithm begins with a call to **Unit Resolution** to eliminate all unit clauses. This is done to remove some awkwardness in the description of linear autarky formulas that will become clear shortly.

The following states an important property of Algorithm **LinAut**.

Lemma 6 *Let ψ be a CNF formula that is input to Algorithm **LinAut** and let ψ' be the formula that is output. If $\psi' = \emptyset$ then ψ is satisfiable and α^S transforms to a satisfying assignment for ψ .*

Proof An autark assignment t to ψ' induces a partition of clauses of ψ' into those that are satisfied by t and those that are untouched by t . Due to the independence of the latter group, a satisfying assignment for that group can be combined with the autark assignment for the former group to satisfy ψ' . If there is no satisfying assignment for either group, then ψ' cannot be satisfiable. Therefore, since each iteration finds and applies an autark assignment (via α), if $\psi' = \emptyset$ then the composition of the autark assignments of each iteration is a satisfying assignment for ψ . \square

The algorithm has polynomial-time complexity. In some cases it solves its input formula.

Algorithm 24.

```

LinAut ( $\psi$ )
/* Input: a set of sets CNF formula  $\psi$  */ 
/* Output: pair  $\langle$ real vector, subformula of  $\psi$   $\rangle$  or “unsatisfiable” */ 
Set  $\langle \psi', P \rangle \leftarrow \text{Unit Resolution}(\psi)$ .
If  $\emptyset \in \psi'$  then Output “unsatisfiable”.
Set  $\alpha^S \leftarrow 0$ .
For each  $v_i \in P$  Set  $\alpha_i^S \leftarrow 1$ .
For each  $v_i$  such that  $v_i \notin P$  and  $v_i \in V_P$  Set  $\alpha_i^S \leftarrow -1$ .
If  $\psi' = \emptyset$  then Output  $\langle \alpha^S, \emptyset \rangle$ .
Repeat the following until some statement generates output:
  Solve for  $\alpha : \mathcal{M}_{\psi'} \alpha \geq 0$  and  $\alpha_i^S = 0$  if column  $i$  in  $\mathcal{M}_{\psi'}$  is 0.
  If  $\alpha=0$  then Output  $\langle \alpha^S, \psi' \rangle$ .
  Otherwise, do the following:
    Set  $\alpha^S \leftarrow \alpha^S + \alpha$ .
    For every  $\alpha_i^S \neq 0$  do the following:
      Zero out rows of  $\mathcal{M}_{\psi'}$  with a non-zero entry in column  $i$ .
      Set  $\psi' \leftarrow \{c : c \in \psi', v_i \notin c, \neg v_i \notin c\}$ .

```

□

Fig. 50 Repeated decomposition of a formula using autark assignments. V_P is the set of variables whose values are set in partial assignment P . Output real vector α^S can be transformed to a truth assignment as described in the proof of [Theorem 23](#)

Theorem 24 Let ψ be Horn or renamable Horn. If ψ is satisfiable, then **LinAut** returns an α^S that transforms to a solution of ψ as described in the proof of [Theorem 23](#), and the formula returned by **LinAut** is \emptyset . If ψ is unsatisfiable, **LinAut** returns “unsatisfiable.”

Proof Horn or renamable Horn formula ψ is unsatisfiable only if there is at least one positive unit clause in ψ . In this case **Unit Resolution**(ψ) will output a formula containing \emptyset and **LinAut** will output *unsatisfiable*. Otherwise, **Unit Resolution**(ψ) outputs a Horn or renamable Horn formula ψ' with no unit clauses and a partial assignment P which is recorded in α^S . In the next paragraph, it will be shown that any such Horn or renamable Horn formula is not linear autarky-free, so there exists an autark assignment for it. By definition, the clauses that remain after the autark assignment is applied must be Horn or renamable Horn. Therefore, the Repeat loop of **LinAut** must continue until there are no clauses left. Then, by [Lemma 6](#), α^S transforms to a satisfying assignment for ψ .

Now it is shown that there is always an $\alpha \neq 0$ that solves (14). Observe that any Horn formula without unit clauses has at least one negative literal in every clause. Therefore, some all-negative vector α of equal components solves (14). In the case of renamable Horn, the polarity of α components in the switch set is reversed to get the same result. Therefore, there is always at least one autark assignment for a Horn or renamable Horn formula. Note that Algorithm **LinAut** may find an α that does not zero out all rows, so the Repeat loop may have more than 1 iteration, but since

the reduced formula ψ is Horn or renamable Horn, there is always an $\alpha \neq 0$ that solves (14) for the clauses that are left. \square

The following Horn formula would violate [Theorem 24](#) if the call to **Unit Resolution** had not been added to **LinAut**:

$$(v_1) \wedge (v_2) \wedge (v_3) \wedge (v_1 \vee \neg v_2 \vee \neg v_3) \wedge (\neg v_1 \vee v_2 \vee \neg v_3) \wedge (\neg v_1 \vee \neg v_2 \vee v_3).$$

This formula is satisfied with variables set to 1 but is linear autarky-free.

Theorem 25 *If ψ is a 2-SAT formula that is satisfiable, then **LinAut** outputs an α^S that represents a solution of ψ and the formula output by **LinAut** is \emptyset .*

Proof In this case **Unit Resolution**(ψ) outputs ψ and causes no change to α^S . The only nonzero autark solutions to $\mathcal{M}_\psi \alpha \geq 0$ have the following clausal interpretation: choose a literal in a clause and assign its variable a value that satisfies the clause; for all non-satisfied clauses that contain the negation of that literal, assign a value to the variable of the clause's other literal that satisfies that clause; continue the process until some clause is falsified or no variable is forced to be assigned a value to satisfy a clause. This is one iteration of Algorithm **2-SAT Solver**, so since ψ is satisfiable, the process never ends in a falsified clause. Since what is left is a satisfiable 2-SAT formula, this step is repeated until \emptyset is output. As in the proof of [Theorem 24](#), α^S transforms to a satisfying assignment for ψ . \square

If ψ is an unsatisfiable 2-SAT formula, then **LinAut**(ψ) will output an unsatisfiable 2-SAT formula.

The class of *linear autarky formulas* is the set of CNF formulas on which the application of **LinAut** either outputs *unsatisfiable* or a formula that is \emptyset or a linear autarky-free 2-SAT formula. In the middle case, the input formula is satisfiable; in the other two cases, it is unsatisfiable. Observe that in the last case, it is unnecessary to solve the remaining 2-SAT formula.

Theorem 26 *All q-Horn formulas are linear autark formulas.*

Proof Apply **LinAut** to q-Horn formula ψ . Then a linear autarky-free q-Horn formula is output. Assume that all clauses in the output formula have at least 2 literals – this can be done because all clauses of ψ' entering the Repeat loop for the first time have at least 2 literals and any subsequent autark assignment would not introduce a clause that is not already in ψ' . The rows and columns of $\mathcal{M}_{\psi'}$ representing the output q-Horn formula ψ' may be permuted, and columns may be scaled by -1 to get a form as shown on [Page 389](#) where \mathcal{A}^1 represents a Horn formula, \mathcal{D} is nonpositive, and \mathcal{A}^2 represents a 2-SAT formula. Construct vector α as follows. Assign equal negative values to all α_i where i is the index of a column through \mathcal{A}^1 (reverse the value if the column had been scaled by -1) and 0 to all other α_i . Then, since there are at least as many positive as negative entries in every

row through \mathcal{A}^1 , the product of any of those rows, unscaled, and α is greater than 0. Since there are only negative entries in rows through \mathcal{D} and all the entries through columns of \mathcal{A}^2 multiply by α_i values that are 0, the product of any of the rows through \mathcal{D} , unscaled, and α is also positive. Therefore, α shows that ψ' is not linear autarky-free, a contradiction. It follows that $\mathcal{A}^1 = \mathcal{D} = \emptyset$ and the output formula is either 2-SAT or \emptyset . If it is 2-SAT, it must be unsatisfiable as argued in [Theorem 25](#). \square

The relationship between linear autarky-free formulas and the satisfiability index provides a polynomial-time test for the satisfiability of a given CNF formula.

Theorem 27 *If the shortest clause of a CNF formula ψ has width k and if the satisfiability index of ψ is less than $k/2$, then ψ is satisfiable.*

Proof This is seen more clearly by transforming variables as follows. Define real n -dimensional vector β with components

$$\beta_i = 2\alpha_i - 1 \text{ for all } 0 \leq i < n.$$

The satisfiability index (2) for the transformed variables may be expressed, by simple substitution, as follows:

$$\mathcal{M}_\psi \beta \leq 2Z - I, \quad (17)$$

where I is an n -dimensional vector expressing the number of literals in all clauses and $Z = \langle z, z, \dots, z \rangle$. The minimum z that satisfies (17) is the satisfiability index of ψ . Apply Algorithm **LinAut** to ψ which, by hypothesis, has shortest clause of width k . The algorithm removes rows, so z can only decrease and k can only increase. Therefore, if $z < k/2$ for ψ , it also holds for the ψ' that is output by **LinAut**. Suppose $\psi' \neq \emptyset$. Formula ψ' is linear autarky-free so the only solution to $0 \leq \mathcal{M}_{\psi'} \beta$ is $\beta = 0$ which implies $0 \leq 2Z - I$. Since the shortest clause of ψ' is at least k , it follows that $k/2 \leq z$. This contradicts the hypothesis that $z < k/2$. Therefore, $\psi' = \emptyset$ and, by [Lemma 6](#), the input formula is satisfiable. \square

The effectiveness of this test on random k -CNF formulas⁹ will be discussed in [Sect. 6.13](#).

6.10 Minimally Unsatisfiable Formulas

An unsatisfiable CNF formula is *minimally unsatisfiable* if removing any clause results in a satisfiable formula. The class of minimally unsatisfiable formulas is

⁹Random k -SAT formulas are defined in [Sect. 7](#), Page 440

easily solved if the number of clauses exceeds the number of variables by a fixed positive constant k . This difference is called the formula's *deficiency*. This section begins with a discussion of the special case where deficiency is 1, then considers the case of any fixed deficiency greater than 1. The discussion includes some useful properties which lead to an efficient solver for this case and helps explain the difficulty of resolution methods for many CNF formulas.

The following result was proved in one form or another by several people (e.g., [5, 99]). A simple argument due to Truemper is presented.

Theorem 28 *If ψ is a minimally unsatisfiable CNF formula with $|V_\psi| = n$ variables, then the number of clauses in ψ must be at least $n + 1$.*

Proof Let ψ be a minimally unsatisfiable CNF formula with $n + 1$ clauses. Suppose $|V_\psi| \geq n + 1$. Let $G_\psi(V_1, V_2, E)$ be the variable-clause matching graph for ψ (see Sect. 3.5) where V_1 is the set of clause vertices and V_2 is the set of variable vertices. There is no total matching with respect to V_1 since this would imply ψ is satisfiable, a contradiction. Therefore, by Hall's Theorem [70] (stated as Theorem 36 in Sect. 6.13), there is a subset $V'_\psi \subset V_1$ with neighborhood smaller than $|V'_\psi|$. Let V'_ψ be such a subset of maximum cardinality. Define ψ_1 to be the CNF formula consisting of the clauses of ψ corresponding to the neighborhood of V'_ψ . By the minimality property of ψ , ψ_1 must be satisfiable. Delete from ψ the clauses of ψ_1 and from the remaining clauses all variables occurring in ψ_1 . Call the resulting CNF formula ψ_2 . There must be a matching of the clauses of ψ_2 into the variables of ψ_2 since otherwise V'_ψ and therefore ψ_1 were not maximal in size. Hence, ψ_2 is satisfiable. But if ψ_1 and ψ_2 are satisfiable, then so is ψ , a contraction. \square

Most of the remaining ideas of this section have been inspired by Oliver Kullmann [96].

A *saturated minimally unsatisfiable* formula ψ is a minimally unsatisfiable formula such that adding any literal l , existing in a clause of ψ , to any clause of ψ not already containing l or $\neg l$ results in a satisfiable formula. The importance of saturated minimally unsatisfiable formulas is grounded in the following lemma.

Lemma 7 *Let ψ be a saturated minimally unsatisfiable formula and let l be a literal from ψ . Then*

$$\psi' = \{c \setminus \{\neg l\} : c \in \psi, l \notin c\}$$

is minimally unsatisfiable. In other words, if satisfied clauses and falsified literals due to l taking value 1 are removed from ψ , what is left is minimally unsatisfiable.

Proof Formula ψ' is unsatisfiable if ψ is; otherwise, there is an assignment which sets l to 1 and satisfies ψ . Suppose there is a clause $c \in \psi'$ such that $\psi' \setminus \{c\}$ is unsatisfiable. Clause c must contain a literal l' that is neither l nor $\neg l$. Construct ψ'' by adding l' to all clauses of ψ containing $\neg l$. Since ψ is saturated, there is a truth assignment M satisfying ψ'' and therefore ψ' with literals l' added as

above. Assignment M must set l' to 1; otherwise, $\psi' \setminus \{c\}$ is satisfiable. Then, adjusting M so the value of l is 0 gives an assignment which also satisfies ψ' , a contradiction. \square

The following is a simple observation that is needed to prove [Theorem 29](#) below.

Lemma 8 *Every variable of a minimally unsatisfiable formula occurs positively and negatively in the formula.*

Proof Let ψ be any minimally unsatisfiable formula. Suppose there is a positive literal l such that $\exists c \in \psi : l \in c$ and $\forall c \in \psi, \neg l \notin c$. Let $\psi_1 = \{c : c \in \psi, l \notin c\}$. Let $\psi_2 = \psi \setminus \psi_1$ denote the clauses of ψ which contain literal l . Clearly, $|\psi_2| > 0$. Then, by definition of minimal unsatisfiability, ψ_1 is satisfiable by some truth assignment M . Hence, $M \cup \{l\}$ satisfies $\psi_1 \cup \psi_2 = \psi$. This contradicts the hypothesis that ψ is unsatisfiable. A similar argument applies if literal l is negative, proving the lemma. \square

Theorem 29 *Let ψ be a minimally unsatisfiable formula with $n > 0$ variables, and $n + 1$ clauses. Then there exists a variable $v \in V_\psi$ such that the literal v occurs exactly one time in ψ and the literal $\neg v$ occurs exactly one time in ψ .*

Proof If ψ is not saturated, there is some set of literals already in ψ that may be added to clauses in ψ to make it saturated. Doing so does not change the number of variables and clauses of ψ . So suppose from now on that ψ is a saturated minimally unsatisfiable formula with n variables and $n + 1$ clauses. Choose a variable v such that the sum of the number of occurrences of literal v and literal $\neg v$ in ψ is minimum. By [Lemma 8](#), the number of occurrences of literal v in ψ is at least one and the number of occurrences of literal $\neg v$ in ψ is at least one. By [Lemma 7](#),

$$\psi_1 = \{c \setminus \{\neg v\} : c \in \psi, v \notin c\} \text{ and } \psi_2 = \{c \setminus \{v\} : c \in \psi, \neg v \notin c\}$$

are minimally unsatisfiable. Clearly, $|V_{\psi_1}| = |V_{\psi_2}| = n - 1$ or else the minimality of variable v is violated. By [Theorem 28](#), the fact that ψ_1 and ψ_2 are minimally unsatisfiable and the fact that $|\psi_i| < |\psi|, i \in \{1, 2\}$, it follows that $|\psi_1| = |\psi_2| = n$. Therefore, the number of occurrences of literal v in ψ is one and the number of occurrences of literal $\neg v$ in ψ is one. \square

Lemma 9 *Let ψ be a minimally unsatisfiable CNF formula with $n > 0$ variables and $n + 1$ clauses. Let v be the variable of [Theorem 29](#) and define clauses c_v and $c_{\neg v}$ such that literal $v \in c_v$ and literal $\neg v \in c_{\neg v}$. Then there is no variable which appears as a positive literal in one of c_v or $c_{\neg v}$ and as a negative literal in the other.*

Proof Suppose there is a variable w such that literal $w \in c_v$ and literal $\neg w \in c_{\neg v}$. By the minimality of ψ and the fact that variable v appears only in c_v and $c_{\neg v}$, there exists an assignment M which excludes setting a value for variable v and

Algorithm 25.

```

Min Unsat Solver ( $\psi$ )
/* Input: a set of sets CNF formula  $\psi$  */          */
/* Output: either “unsat(1)” or “not unsat(1)” */      */
Repeat the following until all variables of  $\psi$  are eliminated:
  If the difference between clauses and variables is not 1,
    Output “not unsat(1).”
  If no variable of  $\psi$  occurs once positively and once negatively,
    Output “not unsat(1).”
  If, for some  $v$ ,  $\psi$  includes  $(v) \wedge (\neg v)$  and  $|\psi| > 2$ ,
    Output “not unsat(1).”
  Choose variable  $v$  such that  $v \in c_v$  and  $\neg v \in c_{\neg v}$ 
    and neither literals  $v$  nor  $\neg v$  are in  $\psi \setminus \{c_v, c_{\neg v}\}$ .
  Compute the resolvent  $\mathcal{R}_{c_{\neg v}}^{c_v}$  of clauses  $c_v$  and  $c_{\neg v}$ .
  Set  $\psi \leftarrow \psi \setminus \{c_v, c_{\neg v}\} \cup \{\mathcal{R}_{c_{\neg v}}^{c_v}\}$ .
Output “unsat(1).”
```

□

Fig. 51 Algorithm for determining whether a CNF formula with one more clause than variable is minimally unsatisfiable

satisfies $\psi \setminus \{c_v, c_{\neg v}\}$. But M must also satisfy either c_v , if w has value 1, or $c_{\neg v}$ if w has value 0. In the former case $M \cup \{\neg v\}$ satisfies ψ and in the latter case $M \cup \{v\}$ satisfies ψ , a contradiction. The argument can be generalized to prove the lemma. □

The next series of results shows the structure of minimally unsatisfiable formulas and how to exploit that structure for fast solutions.

Theorem 30 *Let ψ be a minimally unsatisfiable formula with $n > 1$ variables and $n + 1$ clauses. Let v be the variable of Theorem 29, let c_v be the clause of ψ containing the literal v , and let $c_{\neg v}$ be the clause of ψ containing the literal $\neg v$. Then $\psi' = \psi \setminus \{c_v, c_{\neg v}\} \cup \{\mathcal{R}_{c_{\neg v}}^{c_v}\}$ is a minimally unsatisfiable formula with $n - 1$ variables and n clauses.*

Proof By Lemma 9 the resolvent $\mathcal{R}_{c_{\neg v}}^{c_v}$ of c_v and $c_{\neg v}$ exists. Moreover, $\mathcal{R}_{c_{\neg v}}^{c_v} \neq \emptyset$ if $n > 1$ or else ψ is not minimally unsatisfiable. Therefore, ψ' is unsatisfiable, contains $n - 1$ variables, and has n nonempty clauses. Remove a clause c from $\psi \setminus \{c_v, c_{\neg v}\}$. By the minimality of ψ , there is an assignment M which satisfies $\psi \setminus \{c\}$. By Lemma 2, M also satisfies $\psi \setminus \{c, c_v, c_{\neg v}\} \cup \{\mathcal{R}_{c_{\neg v}}^{c_v}\}$. Hence, M satisfies $\psi' \setminus \{c\}$. Now remove c_v and $c_{\neg v}$ from ψ . Again, by the minimality of ψ , there is an assignment M which satisfies $\psi \setminus \{c_v, c_{\neg v}\}$ and hence $\psi' \setminus \{\mathcal{R}_{c_{\neg v}}^{c_v}\}$. Thus, removing any clause from ψ' results in a satisfiable formula and the theorem is proved. □

Theorem 30 implies the correctness of the polynomial-time algorithm of Fig. 51 for determining whether a CNF formula with one more clause than variable is

minimally unsatisfiable. If the output is “munsat(1)” the input formula is minimally unsatisfiable, with clause-variable difference of 1; otherwise, it is not.

The following results provide an interesting and useful characterization of minimally unsatisfiable formulas of the type discussed here.

Theorem 31 *Let ψ be a minimally unsatisfiable formula with $n > 1$ variables and $n + 1$ clauses. Then there exists a variable v , occurring once as a positive literal and once as a negative literal, and a partition of the clauses of ψ into two disjoint sets ψ_v and $\psi_{\neg v}$ such that literal v only occurs in clauses of ψ_v , literal $\neg v$ only occurs in clauses of $\psi_{\neg v}$, and no variable other than v that is in ψ_v is also in $\psi_{\neg v}$ and no variable other than v that is in $\psi_{\neg v}$ is also in ψ_v .*

Proof By induction on the number of variables. The hypothesis clearly holds for minimally unsatisfiable formulas of one variable, all of which have the form $(v) \wedge (\neg v)$. Suppose the hypothesis is true for all minimally unsatisfiable CNF formulas containing $k > 1$ or fewer variables and having deficiency 1. Let ψ be a minimally unsatisfiable CNF formula with $k + 1$ variables and $k + 2$ clauses. From Theorem 29 there is a variable v in ψ such that literal v occurs in exactly one clause, say, c_v , and literal $\neg v$ occurs in exactly one clause, say, $c_{\neg v}$. By Lemma 9 the resolvent $\mathcal{R}_{c_{\neg v}}^{c_v}$ of c_v and $c_{\neg v}$ exists and $\mathcal{R}_{c_{\neg v}}^{c_v} \neq \emptyset$ or else ψ is not minimally unsatisfiable. Let $\psi' = (\psi \setminus \{c_v, c_{\neg v}\}) \cup \{\mathcal{R}_{c_{\neg v}}^{c_v}\}$. That is, ψ' is obtained from ψ by resolving c_v and $c_{\neg v}$ on variable v . By Theorem 30 ψ' is minimally unsatisfiable with k variables and $k + 1$ clauses. Then, by the induction hypothesis, there is a partition $\psi'_{v'}$ and $\psi'_{\neg v'}$ of clauses of ψ' and a variable v' such that literal v' occurs only in one clause of $\psi'_{v'}$, literal $\neg v'$ occurs only in one clause of $\psi'_{\neg v'}$, and, excluding v' , there is no variable overlap between $\psi'_{v'}$ and $\psi'_{\neg v'}$. Suppose $\mathcal{R}_{c_{\neg v}}^{c_v} \in \psi'_{\neg v'}$. Then $\psi'_{v'}$ and $(\psi'_{\neg v'} \setminus \{\mathcal{R}_{c_{\neg v}}^{c_v}\}) \cup \{c_v, c_{\neg v}\}$ (denoted ψ_v and $\psi_{\neg v}$, respectively) form a nonvariable overlapping partition of clauses of ψ (excluding v' and $\neg v'$), literal v' occurs once in a clause of ψ_v , and literal $\neg v'$ occurs once in a clause of $\psi_{\neg v}$. A similar statement holds if $\mathcal{R}_{c_{\neg v}}^{c_v} \in \psi'_{v'}$. Therefore, the hypothesis holds for ψ or any other minimally unsatisfiable formula of $k + 1$ variables and $k + 2$ clauses. The theorem follows. \square

Theorem 32 *A CNF formula ψ with n variables and $n + 1$ clauses is minimally unsatisfiable if and only if there is a refutation tree for ψ in which every clause of ψ labels a leaf exactly one time, every variable of ψ labels exactly two edges (once as a positive literal and once as a negative literal), and every edge label of the tree appears in at least one clause of ψ .*

Proof (\leftarrow) By induction on the size of the refutation tree. Suppose there is such a refutation tree T_ψ for ψ . If T_ψ consists of two edges, they must be labeled v and $\neg v$ for some variable v . In addition, each clause labeling a leaf of T_ψ must consist of one literal that is opposite to that labeling the edge the leaf is the endpoint of. Hence, ψ must be $(v) \wedge (\neg v)$ which is minimally unsatisfiable.

Now suppose the theorem holds for refutation trees of $k > 2$ or fewer edges and suppose \mathcal{T}_ψ has $k + 1$ edges. Let v be the variable associated with the root of \mathcal{T}_ψ , and let ψ_v and $\psi_{\neg v}$ be the sets of clauses labeling leaves in the subtree joined to the root edges labeled v and $\neg v$, respectively. Define $\psi_1 = \{c \setminus \{\neg v\} : c \in \psi_v\}$ and $\psi_2 = \{c \setminus \{v\} : c \in \psi_{\neg v}\}$. It is straightforward to see that the relationships between each refutation subtree rooted at a child of the root of \mathcal{T}_ψ and ψ_1 and ψ_2 are as described in the statement of the theorem. Hence, by the induction hypothesis, ψ_1 and ψ_2 are minimally unsatisfiable. Let c be a clause in ψ_1 . Let M_1 be an assignment to variables of ψ_1 satisfying $\psi_1 \setminus \{c\}$. Let $M_2 = M_1 \cup \{v\}$. Clearly, M_2 satisfies ψ_v as well as all clauses of $\psi_{\neg v}$ which contain literal v . The remaining clauses of $\psi_{\neg v}$ are a proper subset of clauses of ψ_2 and are satisfied by some truth assignment M_3 to variables of ψ_2 since ψ_2 is minimally unsatisfiable. Since the variables of ψ_1 and ψ_2 do not overlap, $M_2 \cup M_3$ is an assignment satisfying $\psi_v \cup \psi_{\neg v} \setminus \{c\}$ and therefore $\psi \setminus \{c\}$. The same result is obtained if c is removed from ψ_2 . Thus, ψ is minimally unsatisfiable.

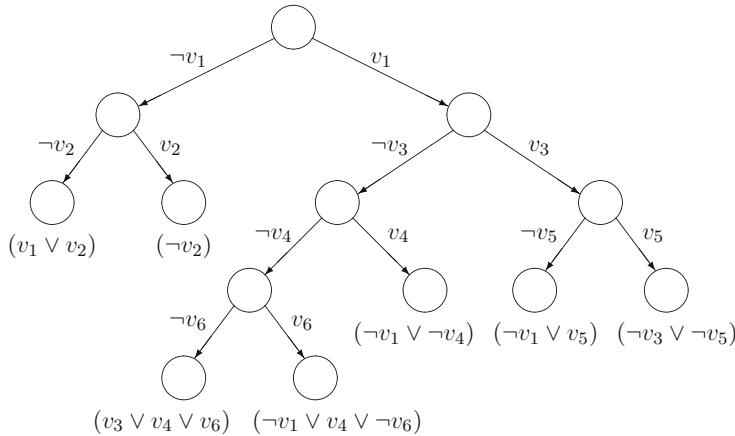

(\rightarrow) Build the refutation tree in conjunction with running Algorithm **Min Unsat Solver** as follows. Before running the algorithm, construct $n + 1$ (leaf) nodes and distinctly label each with a clause of ψ . While running the algorithm, add a new (non-leaf) node each time a resolvent is computed. Unlike the case for a normal refutation tree, label the new node with the resolvent. Construct two edges from the new node to the two nodes which are labeled by the two clauses being resolved (c_v and $c_{\neg v}$ in the algorithm). If the pivot variable is v , label the edge incident to the node labeled by the clause containing v (alternatively $\neg v$) $\neg v$ (v , respectively). Continue until a single tree containing all the original leaf nodes is formed.

The graph constructed has all the properties of the refutation tree as stated in the theorem. It must include one or more trees since each clause, original or resolvent, is used one time in computing a resolvent. Since two edges are added for each new non-leaf node and n new non-leaf nodes are added, there must be $2n + 1$ nodes and $2n$ edges in the structure. Hence, it must be a single tree. Any clause labeling a node contains all literals in clauses labeling leaves beneath that node minus all literals of pivot variables beneath and including that node. In addition, the label of the root is \emptyset . Therefore, all literals of a clause labeling a leaf are a subset of the complements of edge labels on a path from the root to that leaf. Obviously, the complement of each edge label appears at least once in leaf clauses. \square

An example of such a minimally unsatisfiable formula and corresponding refutation tree is shown in Fig. 52.

Now, attention is turned to the case of minimally unsatisfiable formulas with deficiency $\delta > 1$. Algorithms for recognizing and solving minimally unsatisfiable formulas in time $n^{O(k)}$ were first presented in [98] and [58]. The fixed-parameter tractable algorithm that is presented in [134] is discussed here.

Let ψ be a CNF formula with m clauses and n variables. The deficiency of ψ is the difference $m - n$. Each subformula of ψ has its own deficiency, namely, the difference between the number of clauses of the subformula and the number of variables it contains. The *maximum deficiency* of ψ is then the maximum of the deficiencies of all its subformulas. If, for every nonempty subset V' of variables

$$\psi = (v_1 \vee v_2) \wedge (\neg v_2) \wedge (v_3 \vee v_4 \vee v_6) \wedge (\neg v_1 \vee v_4 \vee \neg v_6) \wedge \\ (\neg v_1 \vee \neg v_4) \wedge (\neg v_1 \vee v_5) \wedge (\neg v_3 \vee \neg v_5)$$

Fig. 52 A minimally unsatisfiable CNF formula ψ of six variables and seven clauses and a corresponding refutation tree. Edge labels are variable assignments (e.g., $\neg v_1$ means v_1 has value 0). Each leaf is labeled with a clause that is falsified by the assignment indicated by the path from the root to the leaf

of ψ , there are at least $|V'| + q$ clauses $C \subset \psi$ such that some variable of V' is contained in C , then ψ is said to be q -expanding. The following four lemmas are stated without proof.

Lemma 10 *The maximum deficiency of a formula can be determined in polynomial time.* □

Lemma 11 *Let ψ be a minimally unsatisfiable CNF formula which has δ more clauses than variables. Then the maximum deficiency of ψ is δ .* □

Lemma 12 *Let ψ be a minimally unsatisfiable formula. Then for every nonempty set V' of variables of ψ , there is at least one clause $c \in \psi$ such that some variable of V' occurs in c .* □

Lemma 13 *Let ψ be a CNF formula with maximum deficiency Δ . A maximum matching of the bipartite variable-clause graph G_ψ of ψ does not cover Δ clause vertices.* □

Lemma 13 is important because it is used in the next lemma and because it shows that the maximum deficiency of a CNF formula can be computed with a $O(n^3)$ matching algorithm.

Lemma 14 Let ψ be a 1-expanding CNF formula with maximum deficiency δ . Let $\psi' \subset \psi$ be a subformula of ψ . Then the maximum deficiency of ψ' is less than δ .

Proof It is necessary to show that for any subset $\psi' \subset \psi$, if the number of variables contained in ψ' is n' , then $|\psi'| - n' < \delta$. Let G_ψ be the bipartite variable-clause graph of ψ . In what follows symbols will be used to represent clause vertices in G_ψ and clauses in ψ interchangeably. Choose a clause $c \in \psi \setminus \psi'$. Let M_{G_ψ} be a maximum matching on G_ψ that does not cover vertex c . There is always one such matching because, by hypothesis, every subset of variable vertices has a neighborhood which is larger than the subset, and this allows c 's cover to be moved to another clause vertex, if necessary. Let C be the set of all clause vertices of G_ψ that are not covered by M_{G_ψ} . By Lemma 13 $|C| = \delta$ so since $c \notin \psi'$, $|C \cap \psi'| < \delta$. Since M_{G_ψ} matches every clause vertex in $\psi' \setminus C$ to a variable that is in ψ' , the number of clauses in $\psi' \setminus C$ must be no bigger than n' . Therefore, $|\psi'| - n' \leq |\psi'| - |\psi' \setminus C|$. But $|\psi'| - |\psi' \setminus C|$ is the number of clauses in $C \cap \psi'$ which is less than δ . \square

Theorem 33 ([134]) Let ψ be a CNF formula with maximum deficiency δ . The satisfiability of ψ can be determined in time $O(2^\delta n^3)$ where n is the number of variables in ψ .

Proof Let m be the number of clauses in ψ . By hypothesis, $m \leq n + \delta$. Let $G = (V_1, V_2, E)$ be the variable-clause matching graph for ψ . Find a maximum matching M_G for G . Since $nm \leq n(n+\delta) = O(n^2)$, this can be done in $O(n^3)$ time by the well-known Hopcroft-Karp maximum cardinality matching algorithm for bipartite graphs [40]. The next step is to build a refutation tree for ψ of depth δ . \square

Theorem 34 ([134]) Let ψ be a minimally unsatisfiable CNF formula with δ more clauses than variables. Then ψ can be recognized as such in time $O(2^\delta n^4)$ where n is the number of variables in ψ .

Proof By Lemma 11 the maximum deficiency of ψ is δ which, by Lemma 13, can be checked in $O(n^3)$ time. Since, by Lemma 14, the removal of a clause from ψ reduces the maximum deficiency of ψ , the algorithm inferred by Theorem 33 may be used to check that, for each $c \in \psi$, $\psi \setminus \{c\}$ is satisfiable. The algorithm may also be used to check that ψ is unsatisfiable. Since the algorithm is applied $m + 1$ times and $m = n + \delta$, the complexity of this check is $O(2^\delta n^4)$. Therefore, the entire check takes $O(2^\delta n^4)$ time. \square

6.11 Bounded Resolvent Length Resolution

This class is considered here because it is a counterpoint to minimally unsatisfiable formulas. A CNF formula ψ is k-BRLR if Algorithm **BRLR** of Fig. 53 either generates all resolvents of ψ or returns *unsatisfiable*.

Algorithm 26.

```

BRLR( $\psi, k$ )
/* Input: a set of sets CNF formula  $\psi$  */ 
/* Output: “unsatisfiable,” “satisfiable,” or “give up” */
Repeat the following until some statement outputs a value:
  If there are clauses  $c_1, c_2 \in \psi$  that resolve to  $\mathcal{R}_{c_2}^{c_1} \notin \psi$ ,  $|\mathcal{R}_{c_2}^{c_1}| \leq k$ 
    Set  $\psi \leftarrow \psi \cup \mathcal{R}_{c_2}^{c_1}$ .
  Otherwise, if  $\emptyset \notin \psi$  do the following:
    If all resolvents have been generated then Output “satisfiable”.
    Otherwise, Output “give up”.
  If  $\emptyset \in \psi$ , Output “unsatisfiable.”
□

```

Fig. 53 Finding a k -bounded refutation

Algorithm **BRLR** implements a simplified form of *k -closure* [144]. It repeatedly applies the resolution rule to a CNF formula with the restriction that all resolvents are of size no greater than some fixed k . In other words, the algorithm finds what are sometimes called “ k -bounded” refutations.

For a given CNF formula with n variables and m clauses, the worst-case number of resolution steps required by the algorithm is

$$\sum_{i=1}^k 2^i \binom{n}{i} = 2^k \binom{n}{k} (1 + O(k/n)).$$

This essentially reflects the product of the cost of finding a resolvent and the maximum number of times a resolvent is generated. The latter is $2^k \binom{n}{k}$. The cost of finding a resolvent depends on the data structures used in implementing the algorithm.

For every clause, maintain a linked list of literals it contains, in order by index, and a linked list of possible clauses to resolve with such that the resolvent has no greater than k literals. Maintain a list \mathcal{T} of matrices of dimension $n \times 2, \binom{n}{2} \times 4, \dots, \binom{n}{k} \times 2^k$ such that each cell has value 1 if and only if a corresponding original clause of ψ or resolvent exists at any particular iteration of the algorithm. Also, maintain a list of clauses that may resolve with at least one other clause to generate a new resolvent: the list is threaded through the clauses. Assume a clause can be accessed in constant time and a clause can access its corresponding cell in \mathcal{T} in constant time by setting a link just one time as the clause is scanned the first time or created as a resolvent.

Initially, set to 1 all the cells of \mathcal{T} which correspond to a clause of ψ and set all other cells to 0. Over $\binom{m}{2}$ pairs of clauses, use $2L$ literal comparisons to determine whether the pair resolves. If so and their resolvent has k or fewer literals and the cell in \mathcal{T} corresponding to the resolvent has value 0, then set the cell to 1, add a link to the clause lists of the two clauses involved, and add to the potential resolvent

list any of the two clauses that is not already threaded through it. This accounts for complexity $O(Lm^2)$.

During an iteration, select a clause c_1 from the potential resolvent list. Scan through c_1 's resolvent list checking whether the cell of \mathcal{T} corresponding to the other clause, c_2 , has value 1. If so, delete c_2 from c_1 's list. If c_1 's list is scanned without finding a cell of value 0, delete c_1 from the potential resolvent list and try the next clause in the potential resolvent list. When some clause is paired with another having a cell of value 0 in \mathcal{T} , a new resolvent is generated. In this case, construct a new clause and create a resolvent list for the clause by checking for resolvents with all existing clauses.

6.12 Comparison of Classes

This section provides some intuition about the relative size and scope of the easy classes discussed above.

Observe that the SLUR, q-Horn, nested, and matched classes are incomparable; the class of q-Horn formulas without unit clauses is subsumed by the class of linear autark formulas and SLUR is incomparable with the linear autark formulas. All the other classes considered above are contained in one or more of the three. For example, Horn formulas are in the intersection of the q-Horn and SLUR classes and all 2-SAT formulas are q-Horn.

Any Horn formula with more clauses than distinct variables is not matched, but is both SLUR and q-Horn.

The following is a matched and q-Horn formula but is not a SLUR formula:

$$(v_1 \vee \neg v_2 \vee v_4) \wedge (v_1 \vee v_2 \vee v_5) \wedge (\neg v_1 \vee \neg v_3 \vee v_6) \wedge (\neg v_1 \vee v_3 \vee v_7).$$

In particular, in Algorithm **SLUR**, initially choosing 0 values for v_4 , v_5 , v_6 , and v_7 leaves an unsatisfiable formula with no unit clauses. To verify q-Horn membership, set $\alpha_1 = \alpha_2 = \alpha_3 = 1/2$ and the remaining α 's to 0 in (2).

The following formula is matched and SLUR but is not q-Horn:

$$(\neg v_2 \vee v_3 \vee \neg v_5) \wedge (\neg v_1 \vee \neg v_3 \vee v_4) \wedge (v_1 \vee v_2 \vee \neg v_4).$$

In particular, the satisfiability index of this formula is 4/3. To verify SLUR membership, observe that in Algorithm **SLUR** no choice sequence leads to an unsatisfiable formula without unit clauses.

The following formula is nested but not q-Horn (minimum Z is 5/4):

$$(\neg v_3 \vee \neg v_4) \wedge (v_3 \vee v_4 \vee \neg v_5) \wedge (\neg v_1 \vee v_2 \vee \neg v_3) \wedge (v_1 \vee v_3 \vee v_5).$$

The following formula is nested but not SLUR (choose v_3 first, use the branch where v_3 is 0 to enter a situation where satisfaction is impossible):

$$(v_1 \vee v_2) \wedge (v_1 \vee \neg v_2 \vee v_3) \wedge (\neg v_1 \vee v_4) \wedge (\neg v_1 \vee \neg v_4).$$

The following is a linear autark formula that is not q-Horn ($\alpha = \langle 0.5, -0.5, 0 \rangle$ and the minimum Z is 3/2):

$$(v_1 \vee v_2 \vee v_3) \wedge (\neg v_1 \vee \neg v_2 \vee \neg v_3).$$

The following is SLUR but is not a linear autark formula (by symmetry, any variable choice sequence in **SLUR** leads to the same result which is a satisfying assignment and only $\alpha = \langle 0, 0, 0 \rangle$ satisfies the inequality of (14)):

$$(\neg v_1 \vee v_2 \vee v_3) \wedge (v_1 \vee \neg v_2 \vee v_3) \wedge (v_1 \vee v_2 \vee \neg v_3) \wedge (\neg v_1 \vee \neg v_2 \vee \neg v_3).$$

The following formula is minimally unsatisfiable with one more clause than variable but is not 3-BRLR:

$$\begin{aligned} & (v_0 \vee v_1 \vee v_{48}) \wedge (v_0 \vee \neg v_1 \vee v_{56}) \wedge (\neg v_0 \vee v_2 \vee v_{60}) \wedge (\neg v_0 \vee \neg v_2 \vee v_{62}) \wedge \\ & (v_3 \vee v_4 \vee \neg v_{48}) \wedge (v_3 \vee \neg v_5 \vee v_{56}) \wedge (\neg v_3 \vee v_5 \vee v_{60}) \wedge (\neg v_3 \vee \neg v_5 \vee v_{62}) \wedge \\ & (v_6 \vee v_7 \vee v_{49}) \wedge (v_6 \vee \neg v_7 \vee \neg v_{56}) \wedge (\neg v_6 \vee v_8 \vee v_{60}) \wedge (\neg v_6 \vee \neg v_8 \vee v_{62}) \wedge \\ & (v_9 \vee v_{10} \vee \neg v_{49}) \wedge (v_9 \vee \neg v_{10} \vee \neg v_{56}) \wedge (\neg v_9 \vee v_{11} \vee v_{60}) \wedge (\neg v_9 \vee \neg v_{11} \vee v_{62}) \wedge \\ & (v_{12} \vee v_{13} \vee v_{50}) \wedge (v_{12} \vee \neg v_{13} \vee v_{57}) \wedge (\neg v_{12} \vee v_{14} \vee \neg v_{60}) \wedge (\neg v_{12} \vee \neg v_{14} \vee v_{62}) \wedge \\ & (v_{15} \vee v_{16} \vee \neg v_{50}) \wedge (v_{15} \vee \neg v_{16} \vee v_{57}) \wedge (\neg v_{15} \vee v_{17} \vee \neg v_{60}) \wedge (\neg v_{15} \vee \neg v_{17} \vee v_{62}) \wedge \\ & (v_{18} \vee v_{19} \vee v_{51}) \wedge (v_{18} \vee \neg v_{19} \vee \neg v_{57}) \wedge (\neg v_{18} \vee v_{20} \vee \neg v_{60}) \wedge (\neg v_{18} \vee \neg v_{20} \vee v_{62}) \wedge \\ & (v_{21} \vee v_{22} \vee \neg v_{51}) \wedge (v_{21} \vee \neg v_{22} \vee \neg v_{57}) \wedge (\neg v_{21} \vee v_{23} \vee \neg v_{60}) \wedge (\neg v_{21} \vee \neg v_{23} \vee v_{62}) \wedge \\ & (v_{24} \vee v_{25} \vee v_{52}) \wedge (v_{24} \vee \neg v_{25} \vee v_{58}) \wedge (\neg v_{24} \vee v_{26} \vee v_{61}) \wedge (\neg v_{24} \vee \neg v_{26} \vee \neg v_{62}) \wedge \\ & (v_{27} \vee v_{28} \vee \neg v_{52}) \wedge (v_{27} \vee \neg v_{28} \vee v_{58}) \wedge (\neg v_{27} \vee v_{29} \vee v_{61}) \wedge (\neg v_{27} \vee \neg v_{29} \vee \neg v_{62}) \wedge \\ & (v_{30} \vee v_{31} \vee v_{53}) \wedge (v_{30} \vee \neg v_{31} \vee \neg v_{58}) \wedge (\neg v_{30} \vee v_{32} \vee v_{61}) \wedge (\neg v_{30} \vee \neg v_{32} \vee \neg v_{62}) \wedge \\ & (v_{33} \vee v_{34} \vee \neg v_{53}) \wedge (v_{33} \vee \neg v_{34} \vee \neg v_{58}) \wedge (\neg v_{33} \vee v_{35} \vee v_{61}) \wedge (\neg v_{33} \vee \neg v_{35} \vee \neg v_{62}) \wedge \\ & (v_{36} \vee v_{37} \vee v_{54}) \wedge (v_{36} \vee \neg v_{37} \vee v_{59}) \wedge (\neg v_{36} \vee v_{38} \vee \neg v_{61}) \wedge (\neg v_{36} \vee \neg v_{38} \vee v_{62}) \wedge \\ & (v_{39} \vee v_{40} \vee \neg v_{54}) \wedge (v_{39} \vee \neg v_{40} \vee v_{59}) \wedge (\neg v_{39} \vee v_{41} \vee \neg v_{61}) \wedge (\neg v_{39} \vee \neg v_{41} \vee \neg v_{62}) \wedge \\ & (v_{42} \vee v_{43} \vee v_{55}) \wedge (v_{42} \vee \neg v_{43} \vee \neg v_{59}) \wedge (\neg v_{42} \vee v_{44} \vee \neg v_{61}) \wedge (\neg v_{42} \vee \neg v_{44} \vee \neg v_{62}) \wedge \\ & (v_{45} \vee v_{46} \vee \neg v_{55}) \wedge (v_{45} \vee \neg v_{46} \vee \neg v_{59}) \wedge (\neg v_{45} \vee v_{47} \vee \neg v_{61}) \wedge (\neg v_{45} \vee \neg v_{47} \vee \neg v_{62}). \end{aligned}$$

This formula was obtained from a complete binary refutation tree, variables v_0 to v_{47} labeling edges of the bottom two levels and v_{48} to v_{62} labeling edges of the top four levels. Along the path from the root to a leaf, the clause labeling that leaf contains all variables of the bottom two levels and one variable of the top four levels. Thus, resolving all clauses in a subtree rooted at variable v_{3i} , $0 \leq i \leq 15$, leaves a resolvent of four literals, all taking labels from edges in the top four levels.

To any k -BRLR formula ψ that is unsatisfiable, add another clause arbitrarily using the variables of ψ . The result is a formula that is not minimally satisfiable.

The above ideas can be extended to show that each of the classes contains a formula that is not a member of any of the others. These examples may be extended to infinite families with the same properties.

The subject of comparison of classes will be revisited in Sect. 6.13 using probabilistic measures to determine relative sizes of the classes.

6.13 Probabilistic Comparison of Incomparable Classes

Formulas that are members of certain polynomial-time solvable classes that have been considered in this section appear to be much less frequent than formulas that can usually be solved efficiently by some variant of DPLL. This statement is supported by a probabilistic analysis of these classes where a random formula is an instance of k -SAT with m clauses chosen uniformly and without replacement from all possible width k clauses taken from n variables. A few examples may help to illuminate. In what follows ψ is used to denote a random k -SAT formula.

Consider the class of Horn formulas (Sect. 6.2) first. The probability that a randomly generated clause is Horn is $(k+1)/2^k$, so the probability that ψ is Horn is $((k+1)/2^k)^m$. This tends to 0 as m tends to ∞ for any fixed k . For a hidden Horn formula (Sect. 6.3), regardless of switch set, there are only $k+1$ out of 2^k ways (k ways to place a positive literal and 1 way to place only negative literals) that a random clause can become Horn. Therefore, the expected number of successful switch sets is $2^n((k+1)/2^k)^m$. This tends to 0 for increasing m and n if $m/n > 1/(k - \log_2(k+1))$. Therefore, by Markov's inequality, ψ is not hidden Horn, with probability tending to 1, if $m/n > 1/(k - \log_2(k+1))$. Even when $k = 3$, this is $m/n > 1$. This bound can be improved considerably by finding complex structures that imply a formula cannot be hidden Horn. Such a structure is presented next.

The following result for q-Horn formulas (Sect. 6.5) is taken from [59]. For $p = \lfloor \ln(n) \rfloor \geq 4$, call a set of p clauses a *c-cycle* if all but two literals can be removed from each of $p-2$ clauses, all but three literals can be removed from two clauses, the variables can be renamed, and the clauses can be reordered in the following sequence:

$$(v_1 \vee \neg v_2) \wedge (v_2 \vee \neg v_3) \wedge \dots \wedge (v_i \vee \neg v_{i+1} \vee v_{p+1}) \wedge \dots \wedge (v_j \vee \neg v_{j+1} \vee \neg v_{p+1}) \wedge \dots \wedge (v_p \vee \neg v_1), \quad (18)$$

where $v_i \neq v_j$ if $i \neq j$. Use the term *cycle* to signify the existence of cyclic paths through clauses which share a variable: that is, by jumping from one clause to another clause only if the two clauses share a variable, one may eventually return to the starting clause. Given a c-cycle $\mathcal{C} \subset \psi$, if no two literals removed from \mathcal{C} are the same or complementary, then \mathcal{C} is called a *q-blocked c-cycle*.

If ψ has a q-blocked c-cycle, then it is not q-Horn. Let a q-blocked c-cycle in ψ be represented as above. Develop satisfiability index inequalities (2) for ψ . After rearranging terms in each, a subset of these inequalities is as follows

$$\alpha_1 \leq Z - 1 + \alpha_2 - \dots \quad (19)$$

...

$$\alpha_i \leq Z - 1 + \alpha_{i+1} - \alpha_{p+1} - \dots$$

...

$$\begin{aligned} \alpha_j &\leq Z - 1 + \alpha_{j+1} - (1 - \alpha_{p+1}) - \dots \\ &\dots \\ \alpha_p &\leq Z - 1 + \alpha_1 - \dots \end{aligned} \tag{20}$$

From inequalities (19) to (20), it can be deduced that

$$\alpha_1 \leq pZ - p + \alpha_1 - (1 - \alpha_{p+1} + \alpha_{p+1}) - \dots$$

or

$$0 \leq pZ - p - 1 + \dots$$

where all the terms in \dots are nonpositive. Thus, all solutions to (19) through (20) require $Z > (p+1)/p = 1 + 1/p = 1 + 1/\lfloor \ln^2 n \rfloor > 1 + 1/n^\beta$ for any fixed $\beta < 1$. This violates the requirement (Theorem 19) that $Z \leq 1$ in order for ψ to be q-Horn.

The expected number of q-blocked c-cycles can be found and the second moment method applied to give the following result.

Theorem 35 *A random k -SAT formula is not q-Horn, with probability tending to 1, if $m/n > 4/(k^2 - k)$.* \square

For $k = 3$ this is $m/n > 2/3$.

A similar analysis yields the same results for hidden Horn, SLUR, CC-balanced, or extended Horn classes. The critical substructure which causes ψ not to be SLUR is called a crisscross loop. An example is shown in Fig. 54 as a propositional connection graph. Just one crisscross loop in ψ prevents it from being SLUR. Comparing Fig. 54 and expression (18), it is evident that both the SLUR and q-Horn classes are *vulnerable* to certain types of *cyclic* structures. Most other polynomial-time solvable classes are similarly vulnerable to cyclic structures of various kinds. But random k -SAT formulas are constructed without consideration of such cyclic structures: at some point as m/n is increased, cycles begin to appear in ψ in abundance, and when this happens, cycles that prevent membership in one of the above named polynomial-time solvable classes also show up. Cycles appear in abundance when $m/n > 1/O(k^2)$. It follows that a random k -SAT formula is *not* a member of one of the above named polynomial-time solvable classes, with probability tending to 1, when $m/n > 1/O(k^2)$. By contrast, simple polynomial-time procedures will solve a random k -SAT formula with high probability when $m/n < 2^k/O(k)$. The disappointing conclusion that many polynomial-time solvable classes are relatively rare among random k -SAT formulas because they are vulnerable to cyclic structures is given added perspective by considering the class of matched formulas.

A k -CNF formula is a matched formula (see Page 415) if there is a total matching in its variable-clause matching bipartite graph: a property that is *not* affected by cyclic structures as above. A probabilistic analysis tells us that a random k -SAT

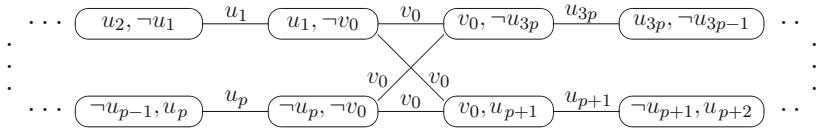

Fig. 54 A criss-cross loop of $t = 3p + 2$ clauses represented as a propositional connection graph. Only cycle literals are shown in the nodes; padding literals, required for $k \geq 3$ and different from cycle literals, are present but are not shown

generator produces *many more* matched formulas than SLUR or q-Horn formulas. Let $Q \subset \psi$ be any subset of clauses of ψ . Denote by $\mathbf{V}(Q)$ the neighborhood of Q : that is, the set of variables that occur in Q . Then $\mathbf{V}(Q)$ is the set variables corresponding to a subset of vertices in V_2 of G_ψ that are adjacent to the vertices in V_2 that correspond to clauses in Q . Denote the deficiency of Q by $\Delta(Q)$. From the definition of deficiency (Page 430), $\Delta(Q) = |Q| - |\mathbf{V}(Q)|$. A subset $Q \subset \psi$ is said to be *deficient* if $\Delta(Q) > 0$. The following theorem is well known.

Theorem 36 (Hall's Theorem [70]) *Given a bipartite graph with vertex sets V_1 and V_2 , a matching that includes every vertex of V_1 exists if and only if no subset of V_1 is deficient.* \square

Theorem 37 *Random k -SAT formulas are matched formulas with probability tending to 1 if $m/n < r(k)$ where $r(k)$ is given by the following table [59].*

k	$r(k)$
3	0.64
4	0.84
5	0.92
6	0.96
7	0.98
8	0.990
9	0.995
10	0.997

\square

Theorem 37 may be proved by finding a lower bound on the probability that a corresponding random variable-clause matching graph has a total matching. By [Theorem 36](#) it is sufficient to prove an upper bound on the probability that there exists a deficient subset of clause vertices, and then show that the bound tends to 0 for $m/n < r(k)$ as given in the theorem. This bound is obtained by the first moment method, that is, by finding the expected number of deficient subsets.

The results in this subsection up to this point are interesting for at least two reasons. First, [Theorem 37](#) says that random k -SAT formulas are matched formulas with high probability if $m/n < r(k)$ which is approximately 1. But, by [Theorem 35](#) and similar results, a random k -SAT formula is almost never a member of one of the well-studied classes mentioned earlier unless $m/n < 1/O(k^2)$. As already pointed out, this is somewhat disappointing and surprising because all the other classes were proposed for rather profound reasons, usually reflecting cases when corresponding instances of integer programming present polytopes with some special properties. Despite all the theory that helped establish these classes, the matched class, mostly ignored in the literature because it is so trivial in nature, turns out to be, in some probabilistic sense, much bigger than all the others.

Second, the results provide insight into the nature of larger polynomial-time solvable classes of formulas. Classes vulnerable to cyclic structures appear to be handicapped relative to classes that are not. In fact, the matched class has been generalized considerably to larger polynomial-time solvable classes such as linear autarkies [97, 145] which are described in [Sect. 6.9](#) and biclique satisfiable formulas of [Sect. 6.7](#).

But there is disappointing news concerning linear autarkies. Consider the test for satisfiability that is implied by [Theorem 27](#): find the satisfiability index z of the given formula and compare against the width, say, k , of the formula's shortest clause; if $z < k/2$, then the formula is satisfiable. This test is based on the fact that Algorithm **LinAut**, [Page 422](#), will output $\psi' = \emptyset$ on any formula for which $z < k/2$.

Theorem 38 *The above test for satisfiability does not succeed on a random k -SAT formula ψ with probability tending to 1 as $m, n \rightarrow \infty$ and $m/n > 1$.* □

7 The k -SAT Problem

The previous sections present SAT algorithm designs and applications. Those sections are intended for people who use SAT technology, want to find out more about what is going on under the hood, and may want to experiment with new algorithm designs to suit particular problems. Those sections may also be useful to people who find SAT interesting and want to see what others have accomplished before trying out their new ideas. This section complements those sections. The success of SAT algorithms is somewhat mysterious owing to the very simple and cumbersome representation of constraints in conjunctive normal form. Is there any particular reason that SAT solvers can often perform so well, defying normal, reasonable intuition? Why can a few tweaks to SAT algorithms result in orders of magnitude performance improvements? Theoretical results have contributed partial answers to such questions and have even influenced the design of SAT solvers. [Section 6](#) presents some of these results. This section highlights some others. In particular, the results of this section apply to the k -SAT problem. In this section a k -SAT formula is a Boolean formula expressed in conjunctive normal form where each clause has exactly k distinct literals, no two of which

are complementary. A *random k -SAT formula* (restated from Sect. 6.13) is a Boolean formula in conjunctive normal form with m clauses, each of which is chosen uniformly and without replacement from all possible width k clauses taken from n variables. The *clause density* of a random k -SAT formula is the ratio m/n .

The theoretical results on k -SAT are best understood in terms of the so-called satisfiability threshold r_k which is the limiting clause density below which random k -SAT formulas are nearly always satisfiable and above which random k -SAT formulas are nearly always unsatisfiable. In [1, 2] the second moment method was applied to a variant of k -SAT to show that $r_k = 2^k \log 2 - O(k)$. In Sect. 6.13 several algorithms that are designed to solve subclasses of CNF formulas were analyzed with respect to random k -SAT formulas. It was shown that none of these algorithms could solve a significant proportion of random k -SAT formula if density is greater than 1.

Non- or limited backtracking variants of DPLL have been analyzed with respect to random k -SAT formulas with results that are significantly better than and equally insightful to those of Sect. 6.13. In [32–34] it was shown that DPLL will nearly always solve a random k -SAT formula if $m/n < O(2^k/k)$. The analysis can be visualized as a system of clause flows between nodes that represent a collection of clauses of widths from 1 to k . Each node holds a number of clauses of a particular width and on every iteration there is some average flow out of a node as clauses are satisfied and literals are falsified. The outward flow due to falsified literals becomes an inward flow to a node holding clauses of one fewer literal. The reason for the k in the denominator of the right side becomes apparent from this analysis: the average flow of clauses into the node representing unit clauses rises above 1 if $m/n = \omega(2^k/k)$, and since only 1 clause is removed from that node in one iteration, on average, the number of unit clauses rises and eventually it becomes likely that a complementary pair of unit clauses exists in the partially assigned formula. These results may be made to apply to any *myopic algorithm* (i.e., a straight line algorithm whose distribution of expressions corresponding to a particular coalesced state under the spectral coalescence of states) can be expressed by its spectral components alone: that is, by the *number* of clauses of width i , for all $1 \leq i \leq k$, and the *number* of assigned variables. But in [3] it is shown that no myopic algorithm can succeed in solving random 3-SAT formulas with high probability if $m/n > 3.26$. However, using a non-myopic greedy algorithm, m/n may be as high as 3.52 before finding solutions becomes unlikely [69, 83, 84]. Note this is well below the presumed threshold $r_3 = 4.26$ and is also well inside the range of densities for which Walksat and Survey Propagation do a good job of solving random 3-SAT formulas.

Analyses have been performed on the unsatisfiable side of the threshold as well. In particular, the probability that the length of a shortest resolution proof (this includes DPLL algorithms) is bounded by a polynomial in n when $m/n > c'_k 2^k$, c'_k some constant, and $\lim_{m,n \rightarrow \infty} m/n = O(1)$ tends to 0 [17, 35]. But, if m is great enough, a random k -SAT formula can, with high probability, be efficiently

proven to have no solution. For example, if $m/n = \Theta(n^{k-1})$, the probability that there exist 2^k clauses containing the same variables spanning all different literal complementation patterns tends to 1, and since such a pattern can be identified in polynomial time and certifies there is no solution, random expressions can be proven not to have a solution with probability tending to 1 in this case. The best resolution can do is not much different from $m/n = \Theta(n^{k-1})$ [14]. This lack of success has led to investigation of alternatives to resolution. A notable example is to cast SAT as a HITTING SET problem and sum the number of variables that are *forced* to be set to 1 and the number that are forced to be set to 0. If this sum can be shown to be greater than n in polynomial time, a *short* proof of unsatisfiability follows. This idea has been applied to random k -SAT and yields a polynomial-time algorithm that nearly always proves unsatisfiability when $m/n = n^{k/2+o(1)-1}$ or greater, a considerable improvement over resolution results [64]. This may be regarded as an example of how probabilistic analysis has driven the search for improved, alternative algorithms.

Theoretical results on random k -SAT have provided a visual record of the nature of problems that are hard for some algorithms and not for others. If one were to produce a figure in which formulas appear as points at some distance above the figure *floor*, where distance is measured in the number of clauses that must be falsified for any assignments and where points are connected to other points which are *close* in terms of Hamming distance, one would see one or more inverted *hills*, some of which may actually touch the floor. Each hill reaches a local minimum called a *local energy minimum* (a contribution from physicists who have studied this). When clause density is low, there exists a single local energy minimum. Then as density is increased, there is a sudden change to several local minima. Finally, there is another jump where exponentially many local minima materialize. The first jump occurs at $m/n = O(2^k)$, and the second jump occurs at $m/n = O(2^k)$. Thus, it is not surprising that so many algorithms perform miserably on unsatisfiable formulas with density just above the transition point. Presumably, as density is increased further, these local minima coalesce (since the minima cannot go below 0), and verifying unsatisfiability becomes easy again. Theoretical results corroborate this [14, 64].

Theoretical results have revealed performance upper bounds on solving k -SAT. The algorithms that are inferred by these results are not considered practical, at least not on their own, and are surprisingly simple. For example, consider the probabilistic algorithm of Fig. 55. The analysis of [123] shows that this algorithm almost always terminates in time that is within a polynomial factor of 1.334^n for any 3-SAT input, of 1.5^n for any 4-SAT input, of 1.6^n for any 5-SAT input, and so on. These complexities, although not considered to represent efficient algorithms, are far below the 2^n complexity of a brute force search. Other results followed. Notably, the bound for 3-SAT was lowered to 1.324^n by combining Schöning's algorithm with the probabilistic algorithm of [115] in a nontrivial way [79], and the

best probabilistic bound is currently $O\left(2^{n\left(1-\frac{m}{\ln(n)}+\frac{1}{\ln(\ln(m))}\right)}\right)$ [48].

```

ProbSat ( $\psi$ )
/* Input:  $\psi$  is a set of sets of literals representing a CNF formula, */
/*           $\psi$  contains  $m$  clauses taken from variable set  $V$ ,  $|V| = n$  */
Randomly choose  $M \subseteq V$ . /*  $M$  is a truth assignment */
 $\psi = \{c \in \psi : \text{for all } l \in c, \text{ if } l \text{ is positive } l \notin M, \text{ otherwise } l \in M\}$ .
Repeat the following  $3n$  times:
  If  $\psi = \emptyset$ , stop and return "satisfiable"
  Randomly choose  $c \in \psi$ .
  Randomly choose  $l \in c$ .
  If  $l$  is positive,  $M = M \cup \{l\}$  else  $M = M \setminus \{\neg l\}$ .
   $\psi = \{c \in \psi : \text{for all } l \in c, \text{ if } l \text{ is positive } l \notin M, \text{ otherwise } l \in M\}$ .
  return "unknown."

```

Fig. 55 Probabilistic algorithm of Schöning

Upper bounds have also been obtained for deterministic algorithms. An early upper bound of $O(\alpha_k^n \cdot |\psi|)$ was obtained in (B. Monien and E. Speckenmeyer, 1979, 3-Satisfiability is testable in $O(1.62^r)$ steps, Unpublished manuscript) [111] for a simple algorithm that seeks and eliminates autarkies (Page 393) when possible. The factor α_k^n bounds the Fibonacci-like recursion

$$\begin{aligned} T_k(1) &= T_k(2) = \dots = T_k(k-1) = 1 \quad \text{and} \\ T_k(n) &= T_k(n-1) + T_k(n-2) + \dots + T_k(n-k+1), \quad \text{for } n \geq k, \end{aligned}$$

where $T_k(n)$ expresses the worst-case complexity for solving k -SAT in this manner. For example, $\alpha_3 \geq 1.681$, $\alpha_4 \geq 1.8393$, and $\alpha_5 \geq 1.9276$. Specifically, the algorithm looks for a shortest clause $c = \{l_1 \vee \dots \vee l_{|c|}\}$ in the current formula ψ . If c has $k-1$ or fewer literals, then ψ is split into at most $k-1$ subformulas according to the following subassignments:

$$\begin{aligned} (1) \quad l_1 &= 1 \\ (2) \quad l_1 &= 0, l_2 = 1 \\ &\dots \\ |c|) \quad l_1 &= l_2 = \dots = l_{|c|-1} = 0, l_{|c|} = 1. \end{aligned}$$

If all clauses c of ϕ have length k , then ϕ is split into k subformulas as described, and each subformula either contains a clause of length at most $k-1$ or one of the resulting subformulas only contains clauses of length k . In the latter case, the corresponding subassignment is autark (Page 393), that is, all clauses containing these variables are satisfied by this subassignment, thereby pruning a branch of the search space. Numerous results reducing the deterministic upper bounds followed. The best deterministic bound for solving k -SAT is $O((2 - \frac{2}{k+1})^n)$ [49]. For CNF formulas of unrestricted clause length, the best worst-case time bound for

a deterministic algorithm is $O(2^{n(1-\frac{1}{\log(2m)})})$ [47]. The algorithm was obtained by derandomizing a probabilistic algorithm of [124].

8 Other Topics

Several significant topics are not treated in this chapter. There are experimental algorithms that control the space of solutions with linear or quadratic cuts. The Handbook on Satisfiability [19] is a good source of information about these. Several probabilistic algorithms other than those presented here have been proposed, for example, simulated annealing and genetic algorithm variants. These were omitted in favor of more influential varieties. Message passing algorithms such as Survey Propagation have been omitted as they seem to have a special niche. More general constraint programming algorithms have been omitted as the focus here is strictly on SAT. The use of SAT in non-monotonic settings was mentioned in the applications section, but the topic is too broad to cover adequately in this chapter so stable models, well-founded semantics, and answer set programming algorithms, among others, have been omitted.

9 Conclusion

Resolution continues to be the foundation for modern SAT solvers. Resolution alone is inadequate for most inputs. However, advances known collectively as conflict-driven clause learning, plus advanced search and cache heuristics, have resulted in CNF solvers that are quite useful in a variety of roles related to problems in combinatorial optimization. One of the most useful roles of SAT to date is to support solvers of mixed logic systems, known as Satisfiability Modulo Theory solvers.

Resolution-based solvers are gaining in performance and are replacing reduced ordered binary decision diagrams in some roles. Gröbner bases applied to SAT promise to replace resolution-based algorithms in significantly many roles, but this has not happened yet because producing an optimal order of operations has remained illusive. The same can be said for other algebraic systems such as cutting planes. For awhile it seemed stochastic local search algorithms would replace resolution-based algorithms in many roles, but this has not happened due to the advances in conflict-driven clause learning noted above and because local search techniques, as developed, are not able to prove unsatisfiability.

Some classes of SAT are solvable in polynomial time. There are many such classes and many of those have been analyzed over the years. Using a probabilistic measure, the scope of such classes seems limited.

Theoretical analyses illustrate the reasons why some algorithms work under certain circumstances. Theoretical results have been used to design new algorithms such as the probabilistic algorithm presented in this chapter. Theoretical results also reveal upper bounds on algorithm performance.

Glossary

Algorithm: (328, 336, 340)

A specific set of instructions for carrying out a procedure or solving a problem, usually with the requirement that the algorithm terminate at some point.

Boolean Function: (316)

A mapping $\{0, 1\} \times \{0, 1\} \times \dots \times \{0, 1\} \mapsto \{0, 1\}$. If the dimension of the domain is n , the number of possible functions is 2^{2^n} .

Clause: (314, also see **Formula, CNF**)

In CNF formulas a clause is a disjunction of literals such as the following: $(\bar{a} \vee b \vee c \vee d)$. A clause containing only negative (positive) literals is called a *negative clause* (alternatively, a *positive clause*). In this chapter a disjunction of literals is also written as a set such as this: $\{\bar{a}, b, c, d\}$. Either way, the *width* of a clause is the number of literals it contains. In logic programming a clause is an implication such as the following: $(a \wedge b \wedge c \rightarrow g)$. In this chapter, if a formula is a conjunction or disjunction of expressions, each expression is said to be a *clause*.

Clause Width: (see **Clause**)

Edge: (see **Graph**)

Endpoint: (338, 338, 345, 415, 416, 429)

One of two vertices spanned by an edge. See **Graph**.

Formula, DNF: (344)

DNF stands for disjunctive normal form. Let a literal be a variable or a negated variable. Let a *conjunctive clause* be a single literal or a conjunction of two or more literals (see **Clause**). A DNF formula is an expression of the form $C_1 \vee C_2 \vee \dots \vee C_m$ where each C_i , $1 \leq i \leq m$, is a conjunctive clause: that is, a DNF formula is a disjunction of some number m of conjunctive clauses. A conjunctive clause evaluates to *true* under an assignment of values to variables if all its literals has value *true* under the assignment.

Formula, CNF: (327, 329, 340, 313)

CNF stands for conjunctive normal form. Let a literal be a variable or a negated variable. Let a *disjunctive clause* be a single literal or a disjunction of two or more literals (see **Clause**). A CNF formula is an expression of the form $C_1 \wedge C_2 \wedge \dots \wedge C_m$ where each C_i , $1 \leq i \leq m$, is a disjunctive clause: that is, a CNF formula is a conjunction of some number m of disjunctive clauses. In this chapter a disjunctive clause, sometimes called a clause when the context is clear, is regarded to be a set of literals and a CNF formula to be a set of clauses. Thus, the following is an example of how a CNF formula is expressed in this chapter.

$$\{\{\bar{a}, b\}, \{a, c, d\}, \{c, \bar{d}, \bar{e}\}\}.$$

A CNF formula is said to be *satisfied* by an assignment of values to its variables if the assignment causes all its clauses to evaluate to *true*. A clause evaluates to *true* under an assignment of values to variables if at least one of its literals has value *true* under the assignment.

Formula, Horn: (315, 328)

A CNF formula in which every clause has at most one positive literal. Satisfiability of Horn formulas can be determined in linear time [53, 78]. Horn formulas have the remarkable property that, if satisfiable, there exists a unique minimum satisfying assignment with respect to the value *true*. In other words, the set of all variables assigned value *true* in any satisfying assignment other than the unique minimum one includes the set of variables assigned value *true* in the minimum one.

Formula, Minimally Unsatisfiable: (317)

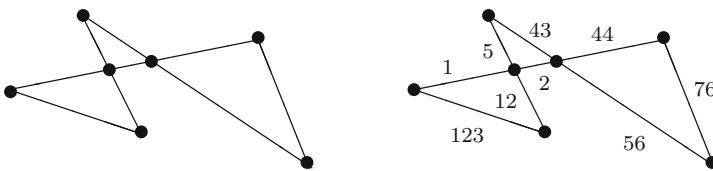

An unsatisfiable CNF formula such that removal of any clause makes it satisfiable.

Formula, Propositional or Boolean: (327, 336, 340, 342, 315)

A Boolean variable is a formula. If ψ is a formula, then (ψ) is a formula. If ψ is a formula, then $\neg\psi$ is a formula. If ψ_1 and ψ_2 are formulas and \mathcal{O}_b is a binary Boolean operator, then $\psi_1 \mathcal{O}_b \psi_2$ is a formula. In some contexts other than logic programming, \bar{a} or $\overline{\psi}$ is used instead of $\neg a$ or $\neg\psi$ to denote negation of a variable or formula. Formulas evaluate to *true* or *false* depending on the operators involved. Precedence from highest to lowest is typically from parentheses, to \neg , to binary operators. Association, when it matters as in the case of \rightarrow (implies), is typically from right to left.

Graph: (340)

A mathematical object composed of points known as vertices or nodes and lines connecting some (possibly empty) subset of them, known as edges. Each edge is said to span the vertices it connects. If weights are assigned to the edges, then the graph is a *weighted graph*. Below is an example of a graph and a weighted graph.

**Graph, Directed:** (321)

A graph in which some orientation is given to each edge.

Graph, Directed Acyclic: (324, 321, 320)

A directed graph such that, for every pair of vertices v_a and v_b , there is not both a path from v_a to v_b and a path from v_b to v_a .

Graph, Rooted Directed Acyclic: (324, 321, 320)

A connected, directed graph with no cycles such that there is exactly one vertex, known as the *root*, whose incident edges are all oriented away from it.

Literal: (313) see also **Formula, CNF**

A Boolean variable or the negation of a Boolean variable. In the context of a formula, a negated variable is called a *negative* literal and an unnegated variable is called a *positive* literal.

Logic Program, Normal: (315)

A formula consisting of implicational clauses. That is, clauses have the form $(a \wedge b \wedge c \rightarrow g)$ where atoms to the left of \rightarrow could be positive or negative literals.

Maximum Satisfiability (MAX-SAT): ()

The problem of determining the maximum number of clauses of a given CNF formula that can be satisfied by some truth assignment.

Model, Minimal Model: (316)

For the purposes of this chapter, a model is a truth assignment satisfying a given formula. A minimal model is such that a change in value of any *true* variable causes the assignment not to satisfy the formula. See also **Formula, Horn**.

\mathcal{NP} -hard: (327)

A very large class of difficult combinatorial problems. There is no known polynomial-time algorithm for solving any \mathcal{NP} -hard problem, and it is considered unlikely that any will be found. For a more formal treatment of this topic, see M.R. Garey and D.S. Johnson. *Computers and Intractability: A Guide to the Theory of \mathcal{NP} -completeness*, W.H. Freeman, San Francisco, 1979.

Operator, Boolean: (334, 313, 345)

A mapping from binary Boolean vectors to $\{0, 1\}$. Most frequently used binary operators are

Or	\vee :	$\{00 \mapsto 0; 10, 01, 11 \mapsto 1\}$
And	\wedge :	$\{00, 01, 10 \mapsto 0; 11 \mapsto 1\}$
Implies	\rightarrow :	$\{10 \mapsto 0; 00, 01, 11 \mapsto 1\}$
Equivalent	\leftrightarrow :	$\{01, 10 \mapsto 0; 00, 11 \mapsto 1\}$
XOR	\oplus :	$\{00, 11 \mapsto 0; 01, 10 \mapsto 1\}$

out of the 16 possible mappings. A Boolean operator \mathcal{O} shows up in a formula like this: $(v_l \mathcal{O} v_r)$ where v_l is called the left operand of \mathcal{O} and v_r is called the right operand of \mathcal{O} . Thus, the domain of \mathcal{O} is a binary vector whose first component is the value of v_l and whose second component is the value of v_r . In the text patterns of 4 bits are sometimes used to represent an operator: the first bit is the mapping from 00, the second from 01, the third from 10, and the fourth from 11. Thus, the operator 0001 applied to v_l and v_r has the same functionality as $(v_l \wedge v_r)$, the operator 0111 has the same functionality as $(v_l \vee v_r)$, and the operator 1101 has the same functionality as $(v_l \rightarrow v_r)$. The only meaningful unary operator is $\neg:\{1 \mapsto 0; 0 \mapsto 1\}$. Sometimes \bar{a} or ψ is written for $\neg a$ or $\neg \psi$ where a is a variable and ψ is a formula.

Operator, Temporal: (334, 334)

An operator used in temporal logics. Basic operators include *henceforth* ($\square \psi_1$), *eventually* ($\diamond \psi_1$), *next* ($\circ \psi_1$), and *until* ($\psi_1 \mathcal{U} \psi_2$).

Satisfied Clause: see **Formula, CNF**

Satisfiability (SAT): (327, 330, 340)

The problem of deciding whether there is an assignment of values to the variables of a given Boolean formula that makes the formula *true*. In 1971, Cook showed that the general problem is NP-complete even if restricted to CNF formulas containing clauses of width 3 or greater or if the Boolean operators are restricted

to any truth-functionally complete subset. However, many efficiently solved subclasses are known.

State: (334, 334, 336)

A particular assignment of values to the parameters of a system.

Subgraph: (340, 340, 342)

A graph whose vertices and edges form subsets of the vertices and edges of a given graph where an edge is contained in the subset only if both its endpoints are.

Unit Clause: (342)

A clause consisting of one literal. See also **Clause** in the glossary.

Variable, Propositional or Boolean: (330, 340, 342))

An object taking one of two values {0, 1}.

Vertex: see **Graph****Vertex Weighted Satisfiability:** (328)

The problem of determining an assignment of values to the variables of a given CNF formula, with weights on the variables, that satisfies the formula and maximizes the sum of the weights of *true* variables. The problem of finding a minimal model for a given satisfiable formula is a special case.)

Weighted Maximum Satisfiability: (340, 342)

The problem of determining an assignment of values to the variables of a given CNF formula, with weights on the clauses, which maximizes the sum of the weights of satisfied clauses.

Acknowledgements We thank John S. Schlipf for his help in writing some of the text, particularly the sections on the diagnosis of circuit faults and Binary Decision Diagrams. We especially appreciate John's attention to detail which was quite valuable to us.

Abstract

The survey presents an overview of approximation algorithms for the classical bin packing problem and reviews the more important results on performance guarantees. Both on-line and off-line algorithms are analyzed. The investigation is extended to variants of the problem through an extensive review of dual versions, variations on bin sizes and item packing, as well as those produced by additional constraints. The bin packing papers are classified according to a novel scheme that allows one to create a compact synthesis of the topic, the main results, and the corresponding algorithms.

1 Introduction

In the classical version of the bin packing problem, one is given an infinite supply of bins with capacity C and a list L of n items with sizes no larger than C : the problem is to pack the items into a minimum number of bins so that the sum of the sizes in each bin is no greater than C . In simpler terms, a set of numbers is to be partitioned into a minimum number of blocks subject to a sum constraint common to each block. Bin packing rather than partitioning terminology will be used, as it eases considerably the problem of describing and analyzing algorithms.

The mathematical foundations of bin packing were first studied at Bell Laboratories by M.R. Garey and R.L. Graham in the early 1970s. They were soon joined by J.D. Ullman; then at Princeton, these three published the first [103] of many papers to appear in the conferences of the computer science theory community over the next 40 years. The second such paper appeared within months; in that paper, D.S. Johnson [125] extended the results in [103] and studied general classes of approximation algorithms. In collaboration with A. Demers at Princeton, researchers Johnson, Garey, Graham, and Ullman published the first definitive analysis of bin packing approximation algorithms [129]. In parallel with the research producing this landmark paper, Johnson completed his 1973 Ph.D. thesis at MIT which gave a more comprehensive treatment and more detailed versions of the abbreviated proofs in [129].

The pioneering work in [129] opened an extremely rich research area; it soon turned out that this simple model could be used for a wide variety of different practical problems, ranging from a large number of cutting stock applications to packing trucks with a given weight limit, assigning commercials to station breaks in television programming, or allocating memory in computers. The problem is well-known to be \mathcal{NP} -hard (see, e.g., Garey and Johnson [100]); hence, it is unlikely that efficient (i.e., polynomial-time) optimization algorithms can be found for its solution. Researchers have thus turned to the study of approximation algorithms, which do not guarantee an optimal solution for every instance, but attempt to find a near-optimal solution within polynomial time. Together with closely related partitioning problems, bin packing has played an important role in applications of complexity theory and in both the combinatorial and average-case analysis of approximation algorithms (see, e.g., the volume edited by Hochbaum [115]).

Starting with the seminal papers mentioned above, most of the early research focused on combinatorial analysis of algorithms leading to bounds on worst-case behavior, also known as performance guarantees. In particular, letting $A(L)$ be the number of bins used by an algorithm A and letting $OPT(L)$ be the minimum number of bins needed to pack the items of L , one tries to find a least upper bound on $A(L)/OPT(L)$ over all lists L (for a more formal definition, see Sect. 2). Much of the research can be divided along the boundary between *on-line* and *off-line* algorithms. In the case of on-line algorithms, items are packed in the order they are encountered in a scan of L ; the bin in which an item is packed is chosen without knowledge of items not yet encountered in L . These algorithms are the only ones that can be used in certain situations. For example, the items to be packed may arrive in a sequence according to some physical process and have to be assigned to a bin as soon as they arrive. Off-line algorithms have complete information about the entire list throughout the packing process.

Since the early 1980s, progressively more attention has been devoted to the probabilistic analysis of packing algorithms. A book by Coffman and Lueker [46] covers the methodology in some detail (see also the book by Hofri [119, Chap. 10]). Nevertheless, combinatorial analysis remains a central research area, and from time to time, numerous new results need to be collected into survey papers. The first comprehensive surveys of bin packing algorithms were by Garey and Johnson [101]

in 1981 and by Coffman et al. [50] in 1984. The next such survey was written some 10 years later by Galambos and Woeginger [96] who gave an overview restricted to on-line algorithms. New surveys appeared at the end of the 1990s. Csirik and Woeginger [62] concentrated on on-line algorithms, while Coffman et al. [52] extended the coverage to include off-line algorithms, and Coffman et al. [53] considered both classes of algorithms in an earlier version of the present survey. Worst-case and average-case analysis are surveyed in [62] and [52]. More recently, classical bin packing and its variants were covered in Coffman and Csirik [43] and in Coffman et al. [54, 55].

This survey gives a broad summary of results in the one-dimensional bin packing arena, concentrating on combinatorial analysis, but in contrast to other surveys, greater space is devoted to variants of the classical problem. Important new variants continue to arise in many different settings and help account for the thriving interest in bin packing research. The survey does not attempt to give a self-contained work, for example, it does not present all algorithms in detail nor does it give formal proofs, but it refers to certain proof techniques which have been used frequently to establish the most important results. Also, in the coverage of variants, the restriction to partitioning problems in one dimension is maintained. Packing in higher dimensions, for example, strip packing and two-dimensional bin packing, is itself a big subject, one deserving its own survey. The interested reader is referred to the recent survey by Epstein and van Stee [79].

Another important feature of this survey is that it adopts the novel classification scheme for bin packing papers recently introduced by Coffman and Csirik [44]. This scheme allows one to create a compact synthesis of the topic, the main results, and the corresponding algorithms.

Section 2 covers the main definitions and as well as a full description of the classification scheme. For the classical bin packing problem, on-line (and semi-on-line) algorithms are discussed in Sect. 3 and off-line algorithms in Sect. 4. (Section 4.4 is a slight departure from this organization: it deals with anomalous behavior both for on-line and off-line algorithms.)

The second part of this survey concentrates on special cases and variants of the classical problem. Variations on bin size are considered in Sect. 5, dual versions in Sect. 6, variations on item packing in Sect. 7, and additional conditions in Sect. 8. Finally, Sect. 9 gives a series of examples to familiarize the reader with the classification scheme. The classification of the papers considered in the survey is also given, when appropriate, in the Bibliography.

2 Definitions and Classification

This section introduces more formally all of the relevant notation required to define, analyze, and classify bin packing problems. Starting with the classical problem, the notation is then extended to more general versions, and finally, the new classification scheme is described. Additional definitions needed by specific variants are introduced in the appropriate sections.

2.1 Basic Definitions for Classical Bin Packing

The classical bin packing problem is defined by an infinite supply of bins with capacity C and a list $L = (a_1, \dots, a_n)$ of items (or elements). A value $s_i \equiv s(a_i)$ gives the size of item a_i and satisfies $0 < s_i \leq C$, $1 \leq i \leq n$. The problem is to pack the items into a minimum number of bins under the constraint that the sum of the sizes of the items in each bin is no greater than C .

In the classical problem, the bin capacity C is just a scale factor, so without loss of generality, one can adopt the normalization $C = 1$. Unless stated otherwise, this convention is in force throughout. One of the exceptions will be in the sections treating variants of the classical problem in which bins B_j have varying sizes. In those sections, bin sizes will be denoted by $s(B_j)$.

In the algorithmic context, nonempty bins will be classified as either *open* or *closed*. Open bins are available for packing additional items. Closed bins are unavailable and can never be reopened. It is convenient to regard a completely full bin as open under any given algorithm until it is specifically closed, even though such bins can receive no further items. Denote the bins by B_1, B_2, \dots . When no confusion arises, B_j will also denote the set of items packed in the j -th bin, and $|B_j|$ will denote the number of such items.

The items are always organized into a list L (or a list L_j in some indexed set of lists). The notation for list *concatenation* is as usual; $L = L_1 L_2 \dots L_k$ means that the items of list L_i are followed by the items of list L_{i+1} for each $i = 1, 2, \dots, k - 1$. When the number of items in a list is needed as part of the notation, an index in parentheses is used: $L_{(n)}$ denotes a list of n items.

If B_j is nonempty, its current *content* or *level* is defined as

$$c(B_j) = \sum_{a_i \in B_j} s_i.$$

A bin (necessarily empty) is *opened* when it receives its first item. Of course, it may be closed immediately thereafter, depending on the algorithm and the item size. It is assumed, without loss of generality, that all algorithms open bins in order of increasing index. Within any collection of nonempty bins, the *earliest opened*, the *leftmost*, and the *lowest indexed* all refer to the same bin.

In general, in the considered lists, the item sizes are taken from the interval $(0, \alpha]$, with $\alpha \in (0, 1]$. It is usually assumed that $\alpha = \frac{1}{r}$, for some integer $r \geq 1$, and many results apply only to $r = \alpha = 1$.

There are two principal measures of the worst-case behavior of an algorithm. Recall that $A(L)$ denotes the number of bins used by algorithm A to pack the elements of L ; OPT denotes an optimal algorithm, one that uses a minimum number of bins. Define the set V_α of all lists L for which the maximum size of the items is bounded from above by α . For every $k \geq 1$, let

$$R_A(k, \alpha) = \sup_{L \in V_\alpha} \left\{ \frac{A(L)}{k} : OPT(L) = k \right\}.$$

Then the *asymptotic worst-case ratio* (or *asymptotic performance ratio*, APR) as a function of α is given by

$$R_A^\infty(\alpha) = \overline{\lim}_{k \rightarrow \infty} R_A(k, \alpha).$$

Clearly, $R_A^\infty(\alpha) \geq 1$, and this number measures the quality of the packings produced by algorithm A compared to optimal packings in the worst case. In an equivalent definition, $R_A^\infty(\alpha)$ is a smallest number such that there exists a constant $K \geq 0$ for which

$$A(L) \leq R_A^\infty(\alpha) OPT(L) + K.$$

for every list $L \in V_\alpha$. Hereafter, if α is left unspecified, the APR of algorithm A refers to $R_A^\infty \equiv R_A^\infty(1)$.

The second way to measure the worst-case behavior of an algorithm A is the *absolute worst-case ratio* (AR)

$$R_A(\alpha) = \sup_{L \in V_\alpha} \left\{ \frac{A(L)}{OPT(L)} \right\}.$$

The comparison of algorithms by asymptotic bounds can be strikingly different from that by absolute bounds. Generally speaking, the number of items n must be sufficiently large (how large will depend on the algorithm) for the asymptotic bounds to be the better measure for purposes of comparison. Note that the ratios are bounded below by 1; the better algorithms have the smaller ratios. When algorithm A is an on-line algorithm, the asymptotic ratio is also called the *competitive ratio*.

There are some further proposals to measure the quality of a packing, like *differential approximation measure* (see Demange et al. [66], [67]), *random-order ratio* (see Kenyon [136]), *relative worst-order ratio* (see Boyar and Favrholdt [27]), and *accommodation function* (see Boyar et al. [28]).

It is finally worth mentioning a special sequence t_i of integers which was investigated by Sylvester [170] in connection with a number theoretic problem and later generalized by Golomb [107]. (In describing the performance of various algorithms in later sections, such sequence will occasionally be considered.) For an integer $r \geq 1$, define

$$t_1(r) = r + 1$$

$$t_2(r) = r + 2$$

$$t_{i+1}(r) = t_i(r)(t_i(r) - 1) + 1, \quad \text{for } i \geq 2.$$

(The Sylvester sequence was defined for $r = 1$). It was conjectured by Golomb that for $r = 1$, this sequence gives the closest approximation to 1 from below among

the approximations by sums of reciprocals of k integers, the basis of the conjecture being

$$\sum_{i=1}^k \frac{1}{t_i(1)} + \frac{1}{t_{k+1}(1) - 1} = 1.$$

Furthermore, it is also easily proved that the following expression is valid for the Golomb sequences:

$$\frac{(r-1)}{t_1(r)} + \sum_{i=2}^k \frac{1}{t_i(r)} + \frac{1}{t_{k+1}(r) - 1} = 1 \quad \text{for any } r \geq 1.$$

On the other hand, the following value appears in several results:

$$h_\infty(r) = 1 + \sum_{i=2}^{\infty} \frac{1}{t_i(r) - 1}.$$

The first few values of $h_\infty(r)$ are the following: $h_\infty(1) \approx 1.69103$, $h_\infty(2) \approx 1.42312$, $h_\infty(3) \approx 1.30238$.

2.2 General Definitions

This survey covers results on several variants of the one-dimensional bin packing problem. In such variants, the meaning of a number of notations can be different, so more general definitions are necessary. These will be introduced in the present section, together with the basic ideas behind the adopted classification scheme.

The notion of packing items into a sequence of initially empty bins helps visualize algorithms for constructing partitions. It is also helpful in classifying algorithms according to the various constraints under which they must operate in practice. The items are normally given in the form of a sequence or *list* $L = (a_1, \dots, a_n)$, although the ordering in many cases will not have any significance. To economize on notation, a harmless abuse is adopted whereby s_i denotes the name as well as the size of the i -th item. The generic symbol for packing is \mathbf{P} , the number of items in \mathbf{P} is denoted by $|\mathbf{P}|$, the sum of the sizes of the items in \mathbf{P} is denoted by $c(\mathbf{P})$, and the number of bins in \mathbf{P} is denoted by $\#\mathbf{P}$. In the classical bin packing optimization problem, the objective is to find a packing \mathbf{P} of all the items in L such that $\#\mathbf{P}$ is minimized over all partitions of L satisfying the sum constraints. Recall that C is only a scale factor in this problem; it is usually convenient to replace the s_i by s_i/C and take $C = 1$.

Let $\mathbf{P}_A(L)$ denote the packing of L produced by algorithm A . In the literature, one finds the notation $A(L)$ representing metrics such as $\#\mathbf{P}$, but since $A(L)$ may denote different metrics for different problems (the same algorithm A may apply to problems with different objective functions), the alternative notation will be

necessary on occasion. The minimum of $\#\mathbf{P}$ over all partitions \mathbf{P} of L satisfying the sum constraints will have the notation $OPT(L) := \min_{\pi(L)} \#\mathbf{P}(L)$, where $\pi(L)$ denotes the set of all such partitions. The notation $OPT(L)$ suffers from the same ambiguity as before, that is, the objective function to which it applies is determined by context. Moreover, in contrast to other algorithm notation, OPT does not denote a unique algorithm.

There are two variants of classical bin packing that arise immediately from the definition. In one, a general bin capacity C and a number m of bins are part of the problem instance, and the problem is to find a maximum cardinality subset of $\{s_i\}$ that can be packed into m bins of capacity C . In the other, all n items must be packed into m bins, and the problem is to find a smallest bin capacity C such that there exists a packing of all the items in m bins of capacity C . The first problem suggests yet another in which the total size of the items in a subset S is the quantity of interest rather than the number $|S|$ of items. Problems fixing the number of bins fall within scheduling theory whose origins in fact predate those of bin packing theory. In scheduling theory, which is very large in its own right, makespan scheduling is more likely to be described as scheduling a list of tasks or jobs (items) on m identical processors (bins) so as to minimize the schedule length or makespan (bin capacity). This incursion into scheduling problems will be limited to the most elementary variants and applications of bin packing problems, such as those above.

Bin covering problems are also included in bin packing theory for classification purposes, and these change the sum constraints to $c(B_j) \geq 1$, where again, bin capacity is normalized to 1. The classical covering problem asks for a partition, \mathbf{C} , called a *cover*, which *maximizes* the number $\#\mathbf{C}$ of bins satisfying the new constraint. Both the packing and covering combinatorial optimization problems are \mathcal{NP} -hard. With problems defined on restricted item sizes or number of items per bin being the major exceptions, this will be the case for nearly all problem variants in the classification scheme. Note that there are immediate variants to bin covering, just as there were for bin packing. For example, one can take the number m of bins to be fixed and ask for a *minimum* cardinality subset of $\{a_i\}$ from which a cover of m bins can be obtained. Or one can consider the problem of finding a *largest* capacity C such that L can be made to cover m bins of capacity C .

Order-of-magnitude estimates of time complexities of fundamental algorithms and their extensions are usually easy to derive. The analysis of parallel algorithms for computing packings is an example where deriving time complexities is not always so easy. However, the research in this area, in which results take the form of complexity measures, has been very limited.

Several results quantify the trade-off between the running time of algorithms and the quality of the packings. They produce polynomial-time (or fully polynomial-time) approximation schemes [100], denoted by PTAS (or FPTAS). In simplified terms, a typical form of such results is illustrated by “Algorithm A produces packings with $O(\varepsilon)$ wasted space and has a running time that is polynomial in $1/\varepsilon$.”

The most common approach to the analysis of approximation algorithms has been *worst-case* analysis by which the worst possible performance of an algorithm is compared with the performance of an optimization algorithm. (Detailed definitions will be provided shortly.) The term *performance guarantee* puts a more positive slant on results of this type. So also does the term *competitive analysis*, which usually refers to a worst-case analysis comparing an on-line approximation algorithm with an optimal off-line algorithm. Probability models also enjoy wide use and have grown in popularity, as they bring out typical, *average-case* behavior rather than the normally rare worst-case behavior. In probabilistic analysis, algorithms have random inputs; the items are usually assumed to be independent, identically distributed random variables. For a given algorithm A , $A(L_n)$ is a random variable whose distribution becomes the goal of the analysis. Because of the major differences in probabilistic results and in the analysis that produces them, they are not covered in this survey, which focuses exclusively on combinatorial analysis. For a general treatment of average-case analysis of packing and related partitioning problems, see the text by Coffman and Lueker [46].

2.3 Classification Scheme

The scheme for classifying problems and solutions is aimed at giving the reader a good idea of the results in bin packing theory to be found in any given paper on the subject. Although in many, if not most cases, it is impractical to describe every result contained in a paper, an indication of the main results should be useful to the reader.

The classification uses four fields, presented in the form

problem | algorithm class | results | parameters

For a brief preview, observe that, normally, the *problem* is to minimize or maximize a metric under sum constraints and refers, for example, to the number of bins of fixed capacity and the capacity of a fixed number of bins. The *algorithm class* refers to paradigms such as on-line, off-line, or bounded space. The *results* field specifies performance in terms of absolute or asymptotic worst-case ratios, problem complexity, etc. Lastly, the *parameters* field describes restrictions on problem parameters, such as a limit on item sizes or on the number of items per bin, and a restriction of all data to finite or countable sets. In many cases, there are no additional parameters to specify, in which case the *parameters* field will be omitted. The three remaining fields will normally be nonempty.

In the following, a detailed description of the classification scheme is introduced. Section 9 gives a number of annotated examples to familiarize the reader with the proposed classification. The special terms or abbreviations adopted for entries will be given in bold face. In the large majority of cases, the entry will have a mnemonic quality that makes the precise meaning of an entry clear in spite of its compact form.

2.3.1 Problem

The combinatorial optimization problems of interest can easily be expressed in the notation given so far, but for readability, abbreviations of the names by which the problems are commonly known will be used. Most, but not all, of the problems below were discussed earlier. Moreover, some of them are not treated in this survey and are listed for the sake of completeness.

1. **pack** refers to the problem of minimizing $\#\mathbf{P}(L)$. The default sum constraints are $c(B_j) \leq 1$. But they are $c(B_j) \leq s(B_j)$, if variable bin capacities $s(B_j)$ are considered, and more simply $c(B_j) \leq C$ if there is only a common bin capacity C .
2. **maxpack** problems invert the problem above, that is, $\#\mathbf{P}$ is to be maximized. Clearly, such problems trivialize unless there is some constraint placed on opening new bins. The tacit assumption will be that packings under approximation algorithms must obey a conservative, any-fit constraint: a new bin cannot be opened for an item s_i unless s_i cannot fit into any currently open bin. Optimal packings by definition must be such that, for some permutation of the bins, no item in B_i fits into B_j for any $j < i$.
3. **mincap** refers to the problem of minimizing the common bin capacity needed to pack L into a given number m of bins. *Bin-stretching* analysis applies if the problem instances are restricted to those for which an optimization rule can pack L into m unit-capacity bins. Under this assumption, in the analysis of algorithm A , one asks how large must the bin capacity be (how much must it be stretched) for algorithm A to pack L into the same number of bins.
4. **maxcard(subset)** has the number m of bins and their common capacity C as part of the problem instance. The problem is to find a largest cardinality subset of L that can be packed into m bins of capacity C .
5. **maxsize(subset)** has the number m of bins and their common capacity C as part of the problem instance. The problem is to find a subset of L with maximum total item size that can be packed into m bins of capacity C .
6. **cover** refers to the problem of finding a partition of L into bins that maximizes $\#\mathbf{P}(L)$ subject to the constraints $c(B_j) \geq 1$. The partition is called a *cover*.
7. **capcover** refers to the problem of finding, for a given number m of bins, the *maximum* capacity C such that a covering of m bins of capacity C can be obtained from L .
8. **cardcover(subset)** is the related problem of minimizing the cardinality of the subset of L needed to cover a given number m of bins with a given capacity C .

2.3.2 Algorithm Class

1. **on-line** algorithms sequentially assign items to bins, in the order encountered in L , without knowledge of items not yet packed. Thus, the bin to which a_i is assigned is a function only of the sizes s_1, \dots, s_i .
2. **off-line** algorithms have no constraints beyond the intrinsic sum constraints; an off-line algorithm simply maps the entire list L into a packing $\mathbf{P}(L)$. All items are known in advance, so the ordering of L plays no role.

3. **bounded-space** algorithms decide where an item is to be packed based only on the current contents of at most a finite number k of bins, where k is a parameter of the algorithm. A more precise definition and further discussion of these algorithms appear later.
4. **linear-time** algorithms have $O(n)$ running time. More precisely, all such algorithms take constant time to pack each item.

The three characterizations above are orthogonal. But the literature suggests that the following convention allows to use one term in classifying algorithms most of the time: *bounded space implies linear time and linear time implies online*. Exceptions will be noted explicitly: it will be seen below (under **repack**) how off-line algorithms can be linear time.

5. **open-end** refers to certain cover approximation algorithms. An open bin B_j , that is, one for which $c(B_j) < s(B_j)$ and further packing is allowed, must be closed just as soon as $c(B_j) \geq s(B_j)$. (The item causing the “overflow” is left in the bin.)
6. **conservative** algorithms are those required to pack the current item into an open bin with sufficient space, whenever such a bin exists; in particular, it cannot choose to open a new bin. Scheduling algorithms satisfying a similar constraint are sometimes called *work conserving*.
7. **repack** refers to packing problems which allow the repacking (possibly limited in some way) of items, that is, moving an item, say s_i , from one bin to another.
8. **dynamic** packing introduces the time dimension; an instance L of this problem consists of a sequence of triples (s_i, b_i, d_i) with b_i and d_i denoting arrival and departure times, respectively. Under a packing algorithm A , $A(L, t)$ denotes the number of bins occupied at time t , that is, the number of bins occupied by those items a_i for which $b_i \leq t < d_i$.

2.3.3 Results

Almost all results fall into the broad classes mentioned in Sect. 2.1.

1. R_A^∞ is the asymptotic worst-case ratio, with algorithm A specified when appropriate. When only a bound is proved, the word **bound** is appended.
2. R_A is the absolute worst-case ratio. When only a bound is proved, the word **bound** is appended.
3. Where possible, complexity of the problem will be given in the standard notation of problem complexity. Approximation schemes are classified as complexity results and have entries like **PTAS** and **FPTAS** as noted earlier.
4. Complexity of the algorithm may also be a result; it refers to running-time complexity and will be signaled by the entry **running time**.

A paper classified as a worst-case analysis may also have complexity results (but not conversely, unless both types of results figure prominently in the paper, in which case both classifications will be given).

2.3.4 Parameters

These typically correspond to generalizations whereby limitations can be placed on the problem instance, or further properties of the algorithm classification. In some

cases, problems may be simplified by certain limitations, such as a specific upper limit of two to the number of items per bin.

1. **{B_i}** means that there can be more than one bin size and an unlimited supply of each size.
2. **stretch** refers to certain asymptotic bounds which compare the number of bins of capacity C needed to pack L by algorithm A to the number of unit-capacity bins needed by an optimal packing.
3. **mutex** stands for mutual exclusion and introduces constraints, where needed, in the form of a sequence of pairs (s_i, s_j) , $i \neq j$, meaning that s_i and s_j cannot be put in the same bin.
4. **card(B) ≤ k** gives a bound on the number of items that can be packed in a bin.
5. $s_i \leq \alpha$ or $s_i \geq \alpha$ denotes bounds on item sizes, the former being far more common in the literature. In some cases, α is specialized to a discrete parameter $1/k$, k an integer. The problems with item-size restrictions are called *parametric* cases in the literature.
6. **restricted s_i** refers to simplified problems where the number of different item sizes is finite.
7. **discrete** calls for discrete sets of item sizes, in particular, item sizes that, for a given integer r , are all multiples of $1/r$ with $C = 1$. Equivalently, the bin size could be taken as r and item sizes restricted to the set $\{1, \dots, j\}$ for some $j \in \{1, \dots, r\}$. While this may not be a significant practical constraint, it will affect the difficulty of the analysis and may create significant changes in the results.
8. **controllable** means that one has the possibility not to pack an item as is, but to first take some decision about it, such as rejecting it or splitting it into parts.

3 On-Line Algorithms

Recall that a bin packing algorithm is called *on-line* if it packs each element as soon as it is inspected, without any knowledge of the elements not yet encountered (either the number of them or their sizes). This review starts with results for some classical algorithms and then generalizes to the *Any-Fit* and the *Almost Any-Fit* classes of on-line algorithms. The subclass of *bounded-space* on-line algorithms will also be considered: an algorithm is bounded space if the number of open bins at any time in the packing process is bounded by a constant. (The practical significance of this condition is clear; e.g., one may have to load trucks at a depot where only a limited number of trucks can be at the loading dock). This section will be concluded by a detailed discussion of lower bounds on the APRs of certain classes of on-line algorithms, but before doing so, relevant variations of old algorithms and the current best-in-class algorithms will be presented. Anomalous behavior occurring in on-line algorithms is discussed in Sect. 4.4.

3.1 Classical Algorithms

In describing an on-line algorithm, it will occasionally be convenient, just before a decision point, to refer to the next item to be packed as the *current* item; right after A packs a_i , $i < n$, a_{i+1} becomes the current item. A simple approach is to pack the bins one at a time according to

Next-Fit (NF): After packing the first item, NF packs each successive item in the bin containing the last item to be packed, if it fits in that bin; if it does not fit, NF closes that bin and packs the current item in an empty bin.

The time complexity of NF is clearly $O(n)$. Note that only one bin is ever open under NF, so it is bounded space. This advantage is compensated by a relatively poor APR, however.

Theorem 1 (Johnson et al. [129]) *One has*

$$R_{\text{NF}}^{\infty}(\alpha) = \begin{cases} 2 & \text{if } \frac{1}{2} \leq \alpha \leq 1 \\ (1 - \alpha)^{-1} & \text{if } 0 < \alpha < \frac{1}{2} \end{cases}.$$

Fisher [86] discovered an interesting property that NF does not share with other classical approximation algorithms. He proved that NF packs any list and its reverse into the same number of bins. The conspicuous disadvantage of NF is that it closes bins that could be used for packing later items. An immediate improvement would seem to be never to close bins. But then the next question is: if an item can be put into more than one open bin, which bin should be selected? One possible rule drawn from scheduling theory (where it is known as the *greedy* or *largest processing time* rule) is the following

Worst-Fit (WF): If there is no open bin in which the current item fits, then WF packs the item in an empty bin. Otherwise, WF packs the current item into an open bin of smallest content in which it fits; if there is more than one such bin, WF chooses the lowest indexed one.

Although one might expect WF to behave better than NF, it does not.

Theorem 2 (Johnson [127]) *For all $\alpha \in (0, 1]$*

$$R_{\text{WF}}^{\infty}(\alpha) = R_{\text{NF}}^{\infty}(\alpha).$$

To achieve smaller APRs, there are many better rules for choosing from among the open bins. One that quickly comes to mind is

First-Fit (FF): FF packs the current item in the lowest indexed nonempty bin in which it fits, assuming there is such a bin. If no such bin exists, FF packs the current item in an empty bin. FF is neither linear time nor bounded space.

A natural complement to WF packs each item into a bin that *minimizes* the space leftover.

Best-Fit (BF): If there is no open bin in which the current item fits, then BF packs the item in an empty bin. Otherwise, BF packs the current item into an open bin of largest content in which it fits; if there is more than one, such bin BF chooses the lowest indexed one.

By adopting appropriate data structures for representing packings, it is easy to verify that the time complexity of these algorithms is $O(n \log n)$. The analysis of the worst-case behavior of the packings they produce is far more complicated. The basic idea of the upper bound proofs is the *weighting function* technique, which has played a fundamental role in bin packing theory. So, before proceeding with other algorithms, it is convenient to describe this technique, which was introduced in [103, 129] and subsequently applied in many other papers (see, e.g., [13, 92, 127, 143]).

3.2 Weighting Functions

To bound the asymptotic worst-case behavior of an algorithm A , one can try to find a function $W_A : (0, 1] \rightarrow \mathbb{R}$ with the properties: (i) There exists a constant $K \geq 0$ such that for any list L

$$\sum_{a \in L} W_A(a) \geq A(L) - K \quad (1)$$

and (ii) there exists a constant K^* such that for any set B of items summing to no more than 1

$$\sum_{a \in B} W_A(a) \leq K^*. \quad (2)$$

The value $W_A(a)$ is the *weight* of item a under A 's *weighting function* W_A . Note that (1) requires that, for large packings (large $A(L)$), the average total weight of the items in a bin must satisfy a lower bound close to 1 for all lists L . On the other hand, (2) says that the total weight in any bin of any packing is at most K^* , so for an optimal packing

$$\sum_{a \in L} W_A(a) = \sum_{j=1}^{OPT(L)} \sum_{a \in B_j} W_A(a) \leq K^* OPT(L). \quad (3)$$

Together, (1) and (3) obviously imply the bound $A(L) \leq K^* OPT(L) + K$, and hence $R_A^\infty \leq K^*$. Note that the technique above is only representative; it is easy to find weaker conditions on the weighting function which will produce the same upper bound for the APR.

The proof of the NF upper bound is not appreciably simplified by a weighting function argument, but it does offer a simple example of such arguments. Consider the case $\alpha = 1$ and define $W_{\text{NF}}(a) = 2s(a)$ for all a , where $s(a)$ denotes the size of item a . An observation is needed about NF when $\text{NF}(L) > 1$: Since the first item of B_{j+1} did not fit in B_j , $1 \leq j < \text{NF}(L)$, the sum of the item sizes in $B_j \cup B_{j+1}$

exceeds 1, and hence the sum of the weights of the items in $B_j \cup B_{j+1}$ exceeds 2. Then

$$\begin{aligned} \sum_{j=1}^{\text{NF}(L)} \sum_{a \in B_j} W_{\text{NF}}(a) &\geq \sum_{j=1}^{\lfloor \text{NF}(L)/2 \rfloor} \sum_{a \in B_{2j-1} \cup B_{2j}} W_{\text{NF}}(a) \\ &\geq 2 \lfloor \text{NF}(L)/2 \rfloor \geq \text{NF}(L) - 1, \end{aligned}$$

so (1) holds with $K = 1$. The inequality (2) with $K^* = 2$ is immediate from the definition of W_{NF} , so $R_{\text{NF}}^\infty \leq 2$, as desired.

There is no systematic way to find appropriate weighting functions, and the approach can be difficult to work out. For example, consider the proof of the following result.

Theorem 3 (Johnson et al. [129])

$$R_{\text{FF}}^\infty = R_{\text{BF}}^\infty = \begin{cases} \frac{17}{10} & \text{if } \frac{1}{2} < \alpha \leq 1 \\ 1 + \lfloor \frac{1}{\alpha} \rfloor^{-1} & \text{if } 0 < \alpha \leq \frac{1}{2} \end{cases}.$$

The proof of the $\frac{17}{10}$ upper bound consists of verifying that the following weighting function suffices

$$W(x) = \begin{cases} \frac{6}{5}x & \text{if } 0 \leq x \leq \frac{1}{6} \\ \frac{9}{5}x - \frac{1}{10} & \text{if } \frac{1}{6} < x \leq \frac{1}{3} \\ \frac{6}{5}x + \frac{1}{10} & \text{if } \frac{1}{3} < x \leq \frac{1}{2} \\ \frac{6}{5}x + \frac{2}{5} & \text{if } \frac{1}{2} < x \leq 1 \end{cases}$$

and it requires a substantial effort. (The argument encompasses several pages of case analysis.) Yet, despite a few hints that emerge in this effort, a clear understanding of how this function was obtained in the first place requires still more effort.

Theorem 3 for $\alpha \leq \frac{1}{2}$ can be proved without weighting functions (see [129]), but the reader may find it instructive to prove the $1 + \lfloor \frac{1}{\alpha} \rfloor^{-1}$ upper bound with the weighting function

$$W_{\text{FF}}(a) = \frac{r+1}{r} s(a), \quad \alpha = \frac{1}{r}, \quad r \geq 2.$$

Sequences of specific examples establish lower bounds for R_A^∞ . In particular, one seeks a sequence of lists $L_{(n_1)}, L_{(n_2)}, \dots$ satisfying $L_{(n_k)} \in V_\alpha$ ($k = 1, 2, \dots$), $\lim_{k \rightarrow \infty} OPT(L_{(n_k)}) = \infty$, and for some constant K_* ,

$$\lim_{k \rightarrow \infty} \frac{A(L_{(n_k)})}{OPT(L_{(n_k)})} = K_*.$$

Then $R_A^\infty \geq K_*$, and if K_* is equal to K^* of the upper bound analysis, one has the APR for the algorithm considered. Finding worst-case examples can be anywhere from quite easy to quite hard. For example, the reader would have little trouble with NF but would probably find FF to be quite challenging.

3.3 Any-Fit and Almost Any-Fit Algorithms

The algorithms described so far belong to a much larger class of on-line heuristics satisfying similar worst-case properties. It is clear that FF, WF, and BF satisfy the following condition:

Any-Fit constraint: *If B_1, \dots, B_j are the current nonempty bins, then the current item will not be packed into B_{j+1} unless it does not fit in any of the bins B_1, \dots, B_j .*

The class of on-line heuristics satisfying the Any-Fit constraint will be denoted by \mathcal{AF} . The following result shows that FF and WF are best and worst algorithms in \mathcal{AF} , in the APR sense.

Theorem 4 (Johnson [127]) *For every algorithm $A \in \mathcal{AF}$ and for every $\alpha \in (0, 1]$*

$$R_{\text{FF}}^\infty(\alpha) \leq R_A^\infty(\alpha) \leq R_{\text{WF}}^\infty(\alpha).$$

By a slight tightening of the Any-Fit constraint, one can eliminate the high-APR algorithms like WF and define a class of heuristics all having the same APR.

Almost Any-Fit constraint: *If B_1, \dots, B_j are the current nonempty bins, and B_k ($k \leq j$) is the unique bin with the smallest content, then the current item will not be packed into B_k unless it does not fit in any of the bins to the left of B_k .*

Clearly, WF does not satisfy this condition, but it is easy to verify that both FF and BF do. The class of on-line algorithms satisfying both constraints above will be denoted by \mathcal{AAF} .

Theorem 5 (Johnson [127]) *$R_A^\infty(\alpha) = R_{\text{FF}}^\infty(\alpha)$ for every A in \mathcal{AAF} .*

Almost Worst-Fit (AWF) is a modification of WF whereby the current item is always placed in a bin having the second lowest content, if such a bin exists and the current item fits in it; the current item is packed in a bin with smallest content only if it fits nowhere else. Interestingly, though it seems to differ little from WF, AWF has a substantially better APR, since it is in \mathcal{AAF} and hence $R_{\text{AWF}}^\infty(\alpha) = R_{\text{FF}}^\infty(\alpha) = \frac{17}{10}$.

3.4 Bounded-Space Algorithms

An on-line bin packing algorithm uses *k-bounded space* if, for each item, the choice of where to pack it is restricted to a set of at most k open bins. One obtains bounded-space counterparts of the algorithms of the previous section by specifying a suitable policy for closing bins.

As previously observed, NF uses only 1-bounded space; the only algorithm to use less is the trivial algorithm that puts each item in a separate bin. To improve on the APR of NF, yet stay with bounded-space algorithms, Johnson [126] proposed an algorithm that packs items according to the First-Fit rule, but considers as candidates only the k most recently opened bins; when a new bin has to be opened and there are already k open bins, then the lowest indexed open bin is closed. It can be expected that the APR of the resulting algorithm, which is known as *Next- k -Fit* (NF_k), tends to $\frac{17}{10}$ as k increases. Finding the exact bound was not an easy task, although Johnson did give a narrow range for the APR. Later, Csirik and Imreh [58] constructed the worst-case sequences, and then Mao was able to prove the exact bound:

Theorem 6 (Mao [153]) *For any $k \geq 2$,* $R_{\text{NF}_k}^{\infty} = \frac{17}{10} + \frac{3}{10(k-1)}$.

In general, a bounded-space algorithm is defined by specifying the packing and closing rules. An interesting class of such rules is based on FF and BF as follows:

- **Packing rules:** The elements are packed following either the First-Fit rule or the Best-Fit rule.
- **Closing rules:** The next bin to close is either the lowest indexed one or one of largest content.

The algorithm that uses packing rule X, closing rule Y, and k -bounded space is denoted by AXY_k , where $X = F$ or B for FF or BF and $Y = F$ or B for the lowest indexed (First) open bin or the largest-content (Best) open bin. With this terminology, NF_k can also be classified as AFF_k . Note that, independently of the chosen rules, if $k = 1$, then one always gets NF.

Algorithm ABF_k was first analyzed by Mao, who called it *Best- k -Fit*. He proved that for any fixed k , this algorithm is slightly better than NF_k .

Theorem 7 (Mao [152]) *For any $k \geq 2$,* $R_{\text{ABF}_k}^{\infty} = \frac{17}{10} + \frac{3}{10k}$.

The tight asymptotic bound for AFB_k was found by Zhang [184] (see also the paper version [187]).

Theorem 8 (Zhang [187]) *For any $k \geq 2$,* $R_{\text{AFB}_k}^{\infty} = R_{\text{NF}_k}^{\infty}$.

Finally, consider the algorithm ABB_k whose asymptotic behavior is, rather surprisingly, independent of $k \geq 2$ and equal to that of FF and BF.

Theorem 9 (Csirik and Johnson [60]) *If $k \geq 2$ then $R_{\text{ABB}_k}^{\infty} = \frac{17}{10}$.*

Since all of the above algorithms fulfill the Any-Fit constraint with respect to the open bins, the overall bound $R_A^{\infty} \geq \frac{17}{10}$ is to be expected from [Theorem 4](#). A better on-line algorithm can only be obtained without the Any-Fit constraint. In the remaining part of this section, it is shown how the fruitful idea of *reservation techniques* (introduced by Yao [180] for unbounded-space algorithms and discussed

in the next section) led to on-line algorithms which are neither in class \mathcal{AF} nor in \mathcal{AAF} .

Yao's idea appeared in the work of Lee and Lee [143] who developed the *Harmonic-Fit* algorithm, which will be denoted by HF_k since, for the case $\alpha = 1$, it uses at most k open bins. The algorithm divides the interval $(0, 1]$ into subintervals $I_j = (\frac{1}{j+1}, \frac{1}{j}]$ ($1 \leq j \leq k-1$) and $I_k = (0, \frac{1}{k}]$. An element is called an I_j -element if its size belongs to interval I_j . Similarly, there are k different bin types: an I_j -bin is reserved for I_j -elements only. An I_j -element is always packed into an I_j -bin following the Next-Fit rule, and so at most, k bins are open at the same time. Galambos [92] extended the idea to general α . Observe that, by selecting $\alpha \in (\frac{1}{r+1}, \frac{1}{r}]$, the number, say M , of bin types exceeds the space bound k by $r-1$; this is because I_j -bins for $j < r$ are never opened. Instead of notation HF_k with k the space bound, the literature often uses HF_M with $M = k + r - 1$ being the number of bin types.

The general APR can be formulated as follows. (See the end of Sect. 2 for the definitions of the quantities $t_s(r)$ and $h_\infty(r)$.)

Theorem 10 (Lee and Lee [143], Galambos [92]) *Suppose that $L \in V_\alpha$ with $\alpha \in (\frac{1}{r+1}, \frac{1}{r}]$ for some positive integer r and choose any sequence k_s , $s \geq 1$, such that $t_s(r) < k_s + 1 \leq t_{s+1}(r)$. Then*

$$\lim_{s \rightarrow \infty} R_{\text{HF}_{k_s}}^\infty(\alpha) = \lim_{s \rightarrow \infty} \left(1 + \sum_{j=2}^s \frac{1}{t_j(r)-1} + \frac{k_s + r - 1}{(t_{s+1}(r)-1)(M-1)} \right) = h_\infty(r).$$

The results in [92, 143] gave tight bounds only for the cases $k = t_j(r) - r + 1$ and $k = t_{j+1}(r) - r$ for integers $j \geq 1$. Also, considering only the $\alpha = 1$ case, one can see that, to obtain an APR better than $\frac{17}{10}$, at least seven open bins are needed. These observations raised two further questions:

- For the case $\alpha = 1$, is there an on-line, bounded-space algorithm that uses fewer than 7 bins and has an APR better than $\frac{17}{10}$?
- What are tight bounds on HF_k for specific k ?

An affirmative answer to the first question was given by Woeginger [175]. Using a more sophisticated interval structure, one based on the Golomb sequences, the performance of his *Simplified Harmonic* (SH_k) algorithm improved on the $\frac{17}{10}$ bound with six open bins; precisely, $R_{\text{SH}_6}^\infty \approx 1.69444$. Moreover, Woeginger proved the following deeper, more general result.

Theorem 11 (Woeginger [175]) *To achieve the worst-case performance ratio of heuristic HF_k with k open bins and $\alpha = 1$, heuristic SH_k only needs $O(\log \log k)$ open bins.*

The second question was investigated by Csirik and Johnson [60] (see also [59]) and van Vliet [172, 173]. They gave tight bounds for the case $\alpha = 1$ with $k = 4$ and 5. Tight bounds for further k remain open problems.

Table 1 APR values for bounded-space algorithms, rounded to five decimals. The values in column $\text{HF}_k \leq$ are upper bounds and are tight if starred. Note that $42 = t_4(1) - 1$

k	NF_k	ABF_k	ABB_k	$\text{HF}_k \leq$	SH_k	best
2	2.00000	1.85000	1.70000	2.00000*	2.00000	1.70000
3	1.85000	1.80000	1.70000	1.75000*	1.75000	1.70000
4	1.80000	1.77500	1.70000	1.71429*	1.72222	1.70000
5	1.77500	1.76000	1.70000	1.70000*	1.70000	1.70000
6	1.76000	1.75000	1.70000	1.70000*	1.69444	1.69444
7	1.75000	1.74286	1.70000	1.69444*	1.69388	1.69388
8	1.74286	1.73750	1.70000	1.69388	1.69106	1.69106
9	1.73750	1.73333	1.70000	1.69345	1.69104	1.69104
10	1.73333	1.73000	1.70000	1.69312	1.69104	1.69104
42	1.70732	1.70714	1.70000	1.69106*	1.69103	1.69103
$+\infty$	1.70000	1.70000	1.70000	1.69103	1.69103	1.69103

Similarly, the general case has not been discussed exhaustively, and some questions raised by Woeginger [175] are still open:

- What is the smallest k such that there exists an on-line heuristic using k -bounded space and having an APR strictly less than $\frac{17}{10}$?
- What is the best possible APR for any on-line heuristic using 2-bounded space? (ABB_2 achieves a worst-case ratio of $\frac{17}{10}$.)
- By considering only algorithms that pack the items by the Next-Fit rule according to some fixed partition of $(0, 1]$ into k subintervals, which partition gives the best APR ? (It is known that for $k \leq 2$, the best possible APR is 2 (see Csirik and Imreh [58]), but for $k \geq 3$, no tight bound is known.)

Tables 1 and 2 show the best results known for bounded-space algorithms. Note that the worst-case ratios of all algorithms in Table 1 are never smaller than $h_\infty(1) \approx 1.69103$. As pointed out by Lee and Lee [143] for the $\alpha = 1$ case, bounded-space algorithms cannot do better. The result holds for general α too, as shown by Galambos, that is,

Theorem 12 (Lee and Lee [143], Galambos [92]) *Every bounded-space on-line bin packing algorithm A satisfies $R_A^\infty(\alpha) \geq h_\infty(r)$ for all α , $\frac{1}{r+1} < \alpha \leq \frac{1}{r}$.*

None of the known bounded-space algorithms achieves the lower bound using a finite number of open bins. It will be later shown (see Sect. 3.7) that the bound can be achieved with three open bins if repacking among the open bins is allowed, but without such a relaxation, the question remains open.

3.5 Variations and the Best-in-Class

Chronologically, Yao [180] was the first to break through the $h_\infty(1)$ barrier with his *Refined First-Fit* (RFF) algorithm. RFF classifies items into types 1, 2, 3, or 4

Table 2 APR values for $\text{HF}_k(\frac{1}{r})$. Starred values are tight

k	$r = 1$	$r = 2$	$r = 3$	$r = 4$	$r = 5$	$r = 6$
2	2.00000*	1.50000*	1.33333*	1.25000*	1.20000*	1.18888*
3	1.75000*	1.44444*	1.31250*	1.24000*	1.19444*	1.16326*
4	1.71429*	1.43750	1.31000	1.23888	1.19387	1.16294
5	1.70000*	1.43333	1.30833	1.23809	1.19345	1.16269
6	1.70000*	1.43055	1.30714	1.23750	1.19312	1.16250
7	1.69444*	1.42857	1.30625	1.23703	1.19285	1.16233
8	1.69388	1.42708	1.30555	1.23666	1.19264	1.16220
9	1.69345	1.42592	1.30500	1.23636	1.19246	1.16208
10	1.69312	1.42499	1.30454	1.23611	1.19230	1.16198
$+\infty$	1.69103	1.42307	1.30238	1.23441	1.19102	1.16102

accordingly as their sizes are in the respective intervals $(0, \frac{1}{3}]$, $(\frac{1}{3}, \frac{2}{5}]$, $(\frac{2}{5}, \frac{1}{2}]$, and $(\frac{1}{2}, 1]$. RFF packs four sequences of bins, one for each type. With one exception, RFF packs type- i items into the sequence of type- i bins using First-Fit. The exception is that every sixth type-2 item (with a size in $(\frac{1}{3}, \frac{2}{5}]$) is thrown in with the type-4 items, that is, packed by First-Fit into the sequence of type-4 bins. It is easily verified that RFF uses unbounded space and has a time complexity $O(n \log n)$. Yao proved that $R_{\text{RFF}}^{\infty} = \frac{5}{3} = 1.666\dots$. Yao did not use the usual weighting function technique but based his proof on enumeration of the elements in each class. Also, the APR remains unchanged if the special treatment given every sixth type-2 item is instead given every m -th type-2 item, where m is taken to be one of 7, 8, or 9.

It was immediately clear that this reservation technique was a promising approach, a fact supported by the Harmonic-Fit algorithm discussed in the previous section. The main disadvantage of the latter algorithm is that each I_1 -element, even with a size slightly over $\frac{1}{2}$, is packed alone into a bin. An immediate improvement is to try to add other items to these bins. In their algorithm *Refined Harmonic-Fit* (RHF), Lee and Lee [142, 143] modified HF_{20} by subdividing intervals I_1 and I_2 into two subintervals:

$$\begin{aligned} I_1 &= I_{1,s} \cup I_{1,b}, \\ I_2 &= I_{2,s} \cup I_{2,b} \end{aligned}$$

with $I_{2,s} = (\frac{1}{3}, \frac{37}{96}]$, $I_{2,b} = (\frac{37}{96}, \frac{1}{2}]$, $I_{1,s} = (\frac{1}{2}, \frac{59}{96}]$, and $I_{1,b} = (\frac{59}{96}, 1]$. This brought the number of bin types to $M = 22$. The packing strategy for I_j -elements ($3 \leq j \leq M - 2 = 20$), $I_{1,b}$ -elements, and $I_{2,b}$ -elements is the same as in Harmonic-Fit, but the $I_{1,s}$ -elements and the $I_{2,s}$ -elements are allowed to share the same bins in certain situations. The details are omitted. Note however that the time complexity of RHF is $O(n)$, but the algorithm is no longer bounded space. Its APR is given by

Theorem 13 (Lee and Lee [143]) $R_{\text{RHF}}^{\infty} \leq \frac{373}{228} \approx 1.63596$.

It is not known whether this bound is tight.

In 1989, several improved algorithms were presented by Ramanan et al. [159]. The first one, called *Modified Harmonic-Fit* (MHF), applies Yao's idea in a more sophisticated way. Instead of choosing $\frac{59}{96}$ as the point dividing $(\frac{1}{2}, 1]$, the problem is handled in a more general fashion. Let the number of bin types satisfy $M \geq 5$, and consider the subdivision of $(0, 1]$:

$$(0, 1] = \bigcup_{j=1}^{M-2} I_j$$

with $I_1 = I_{1,s} \cup I_{1,b}$ and $I_2 = I_{2,s} \cup I_{2,b}$ as earlier, but now

$$\begin{aligned} I_{1,s} &= (\frac{1}{2}, 1 - y] & I_{2,s} &= (\frac{1}{3}, y] \\ I_{1,b} &= (1 - y, 1] & I_{2,b} &= (y, \frac{1}{2}] \end{aligned}$$

for some y satisfying $\frac{1}{3} < y < \frac{1}{2}$. Initially, the set of empty bins is divided into M infinite classes, each associated with a subinterval. All $I_{1,b}$ -bins, $I_{2,s}$ -bins, $I_{2,b}$ -bins, and I_j -bins ($3 \leq j \leq M - 2$) are only used to pack elements from the associated interval (as in Harmonic-Fit). $I_{1,s}$ -bins on the other hand can contain $I_{1,s}$ -elements and some of the $I_{2,s}$ -elements and I_j -elements ($j \in \{3, 6, 7, \dots, M - 2\}$). The algorithm also includes more complicated rules for packing and for deciding when items with sizes in different intervals can share the same bin. For this algorithm with $M = 40$, the following bounds hold.

Theorem 14 (Ramanan et al. [159])

$$1.6156146 < \frac{3}{2} + \frac{1}{9} + \frac{1}{222} - \frac{1}{987012} \leq R_{\text{MHF}}^{\infty} < \frac{3}{2} + \frac{1}{9} + \frac{1}{222} = 1.615615\dots$$

The above algorithm was further generalized by Ramanan et al. [159] who introduced a sequence of classes of on-line linear-time algorithms, called $C^{(h)}$; an algorithm A belongs to $C^{(h)}$, for a given $h \geq 1$, if it divides $(0, 1]$ into disjoint subintervals including

$$\begin{aligned} I_{1,b} &= (1 - y_1, 1], & I_{2,b} &= (y_h, \frac{1}{2}], \\ I_{1,j} &= (1 - y_{j+1}, 1 - y_j], & I_{2,j} &= (y_{h-j}, y_{h-j+1}], \quad 1 \leq j \leq h, \end{aligned}$$

and

$$I_{\lambda,1} = (0, \lambda], \quad I_{\lambda,2} = (\lambda, \frac{1}{3}], \quad 0 < \lambda \leq \frac{1}{3}$$

where $\frac{1}{3} = y_0 < y_1 < \dots < y_h < y_{h+1} = \frac{1}{2}$, and $I_{\lambda,2} = \emptyset$ if $\lambda = \frac{1}{3}$. Elements are classified, as usual, according to the intervals in which their sizes fall.

Note that algorithm MHF belongs to $C^{(1)}$. Ramanan et al. [159] developed an algorithm (*Modified Harmonic-2*, MH2), which is in $C^{(2)}$ and proved that $R_{\text{MH2}}^{\infty} \leq 1.612\dots$. The algorithm is quite elaborate and beyond the scope of this survey.

The authors discussed further improvements aimed at reducing the APR to 1.59. They also proved the lower bound result.

Theorem 15 (Ramanan et al. [159]) *There is no on-line algorithm A in $C^{(h)}$ such that $R_A^\infty < \frac{3}{2} + \frac{1}{12} = 1.58333\dots$*

The HARMONIC+1 algorithm of Richey [160] subdivides intervals $(\frac{1}{2}, 1]$ and $(\frac{1}{3}, \frac{1}{2}]$ very finely (using 76 classes of subintervals!) in order to allow a precise item pairing in these two intervals. It also allows items of size $(\frac{1}{4}, \frac{1}{3}]$ to be mixed with larger items of various sizes and not just with those of size at least $\frac{1}{2}$. Seiden [163] showed that such result was flawed and gave a new algorithm, HARMONIC++, whose asymptotic performance ratio is at most 1.58889, which is the current best APR for on-line bin packing.

3.6 APR Lower Bounds

In previous sections, some results concerning lower bounds on the APR were mentioned, but the fundamental problem was not considered yet: what is the best an on-line algorithm can do in the asymptotic worst case? In this section, lower bound results are discussed in chronological order.

Most of the existing lower bounds come from the same idea. To obtain a good packing, it seems advisable to first pack the large elements so that either a bin is “full enough” or its empty space can be reduced by subsequent small elements. Therefore, in order to force bad behavior on a heuristic algorithm A , one should challenge it with a list in which small items come first. If A adopts a policy that packs these small items tightly, then it will not be able to find a good packing for the large items which may come later. If, instead, A leaves space for large items while packing the small ones, then the expected large items might not appear in the list. In both cases, the resulting packing will be poor.

To give a more precise description, consider a simple example involving two lists L_1 and L_2 , each containing n identical items. The size of each element in L_1 is $\frac{1}{2} - \varepsilon$, and the size of each element in L_2 is $\frac{1}{2} + \varepsilon$. The asymptotic behavior of an arbitrary approximation algorithm A will be investigated on two lists: L_1 alone and the concatenated list $L_1 L_2$. It is easy to see that $OPT(L_1) = \frac{n}{2}$ and $OPT(L_1 L_2) = n$. Consider the behavior of this algorithm on L_1 : it will pack some elements alone into bins (say x of them), and it will match up the remaining $n - x$. Hence $A(L_1) = \frac{n+x}{2}$. For the concatenated list $L_1 L_2$, when processing the elements of L_2 , the best that A can do is to add one element of L_2 to each of x bins containing a single element of L_1 and to pack alone the remaining $n - x$ elements. Therefore, $A(L_1 L_2) = \frac{3n-x}{2}$. Since n may be arbitrarily large,

$$R_A^\infty \geq \max \left\{ \frac{A(L_1)}{OPT(L_1)}, \frac{A(L_1 L_2)}{OPT(L_1 L_2)} \right\} = \max \left\{ \frac{n+x}{n}, \frac{3n-x}{2n} \right\}$$

Table 3 Lower bounds and R_A^∞ for various algorithms

r	Lower bound	R_{HF}^∞	R_{FF}^∞	R_{NF}^∞	Best known
1	1.54037	1.69103	1.70000	2.00000	1.58889
2	1.38966	1.42307	1.50000	2.00000	1.42307
3	1.29144	1.30238	1.33333	1.50000	1.30238
4	1.22986	1.23441	1.25000	1.33333	1.23441
5	1.18881	1.19102	1.20000	1.25000	1.19102
6	1.15982	1.16102	1.16667	1.20000	1.16102

for which the minimum is attained when $x = \frac{n}{3}$, implying a lower bound of $\frac{4}{3}$ for the APR of *any* on-line algorithm A .

The above idea can be easily generalized by taking a carefully chosen series of lists L_1, \dots, L_k and evaluating the performance of a heuristic on the concatenated lists $L_1 \dots L_j$, ($1 \leq j \leq k$). The first step along these lines was made by Yao [180]. He proved a lower bound of $\frac{3}{2}$ based on three lists of equal-size elements, the sizes being $\frac{1}{2} + \varepsilon$, $\frac{1}{3} + \varepsilon$, and $\frac{1}{6} - 2\varepsilon$. Using Sylvester's sequences, Brown [32] and Liang [147] independently gave a further improvement to 1.53634577 (The largest sizes in their sequences were as follows: $\frac{1}{2} + \varepsilon$, $\frac{1}{3} + \varepsilon$, $\frac{1}{7} + \varepsilon$, $\frac{1}{43} + \varepsilon$, and $\frac{1}{1807} + \varepsilon$.) Galambos [92] used the Golomb sequences to extend the idea to general α . The proof in [92] was considerably simplified by Galambos and Frenk [93]. van Vliet gave an exhaustive analysis of the lower bound constructions with a linear programming technique applied to all α and gave the following lower bound:

Theorem 16 (van Vliet [171]) *For any on-line algorithm A , $R_A^\infty \geq 1.54015 \dots$*

The current best-in-class, $R_A^\infty \geq 1.54037$, was given by Balogh et al. [15]. Table 3 gives a comparison for several values of $\alpha = \frac{1}{r}$ between the best lower bounds and the corresponding upper bounds for various algorithms. It is interesting to note that the gap between the lower and upper bounds becomes rather small for $r \geq 2$.

Faigle, Kern, and Turán [83] proved that if there are only two item sizes, then no on-line algorithm can be better than 4/3.

Chandra [38] has examined the effect on lower bounds when randomization is allowed in the construction of on-line algorithms, that is, when coin flips are allowed in determining where to pack items. The performance ratio for randomized algorithm A is now $E[A(L)]/OPT(L)$, where $E[A(L)]$ is the expected number of bins needed by A to pack the items in L . Chandra has shown that there are lists such that this ratio exceeds 1.536 for all randomized on-line algorithms, and so from this limited standpoint, results suggest that randomization is not a valuable tool in the design of on-line algorithms.

3.7 Semi-on-line Algorithms

The APR of on-line algorithms cannot break through the $1.540\dots$ barrier (see Sect. 3.6). For almost 20 years, only the pure on-line and off-line algorithms were analyzed, and no attention was paid to algorithms lying between these two classes. In a more general setting, one can consider giving the algorithm more information about the list and/or more freedom with respect to the pure on-line case. This section deals with *semi-on-line* (SOL) algorithms that can

- Repack elements
- Look ahead to later elements before assigning the current one
- Assume some preordering of the elements

First consider the case where repacking is allowed. SOL algorithms allowing only a restricted number of elements to be repacked at each step are called *c-repacking SOL* algorithms. It was seen in Sect. 3.4 that no known on-line bounded-space algorithm reaches the bound $h_\infty(1)$ using finitely many open bins. It will be shown that this is possible with SOL algorithms.

In 1985, Galambos [91] made a first step in this direction. His *Buffered Next-Fit* (BNF) algorithm uses two open bins, say B_1 and B_2 . The arriving elements are initially packed into B_1 , until the first element arrives for which B_1 does not have enough space. This element and those currently packed in B_1 are then reordered by decreasing size and repacked in B_1 and B_2 following the Next-Fit rule. B_1 is now closed, B_2 is renamed B_1 , and a new bin B_2 is opened. Using a weighting function approach, it was proved that $h_\infty(1) \leq R_{\text{BNF}}^\infty \leq \frac{18}{10}$.

Galambos and Woeginger [95] generalized the above idea, adopting a better weighting function. Let $w(B)$ be the sum of the weights associated with the items currently packed in bin B . Their *Repacking* algorithm (REP_3) uses three open bins. When a new item a_i arrives, the following steps are performed: (i) a_i is packed into an empty bin; (ii) all the elements in the three open bins, sorted by nonincreasing size, are repacked by the FF strategy, with the result that either one bin becomes empty or at least one bin B has $w(B) \geq 1$; and (iii) all bins B with $w(B) \geq 1$ are closed and replaced by new empty bins. In [95], it was proved that this repacking in fact helps, since $R_{\text{REP}_3}^\infty = h_\infty(1)$. It is not known whether the same result can be obtained with two bins.

Gambosi et al. [99] (see also [97] and [98]) were the first to beat the 1.540 on-line bound via repacking. They gave two algorithms. Both of them use an unusual step to repack the elements: the small elements are grouped into a “bundle” of $O(n)$ elements, which can be repacked in a single step.

In the first algorithm, A_1 , the interval $(0, 1]$ is divided into four subintervals, and the elements are packed into bins in a Harmonic-like way. As each new item is packed, groups of small elements can be repacked – in a bundle – so as to fill up gaps in bins that are not full enough. By using appropriate data structures, this repacking is performed in constant time. The algorithm has linear time and space complexity, and it has an APR, $R_{A_1}^\infty \leq \frac{3}{2}$. In the second algorithm, A_2 , the unit interval is divided into six subintervals, and, as

each new item is encountered, the elements are repacked more carefully, in $O(\log n)$ time, by means of a pairing technique analogous to that introduced by Martel (see Sect. 4.2). The time complexity of A_2 is $O(n \log n)$, and its APR is $R_{A_2}^\infty \leq \frac{4}{3}$.

Ivkovic and Lloyd [122] gave a further improvement on SOL algorithms achieving a $\frac{5}{4}$ worst-case ratio. Their algorithm is much more complicated than the previous ones, as it was designed for handling the dynamic packing case. The dynamic bin packing problem will be considered in Sect. 7.1 in detail, but here it is enough to know that in case of dynamic packing, deletions of some elements are allowed in each step and $A(L)$ is considered as the maximum number of occupied bins during the packing. Ivkovic and Lloyd proved a $\frac{4}{3}$ lower bound for the c-repacking SOL algorithms. This result was improved by Balogh et al. [14].

Theorem 17 (Balogh et al. [14]) *For any c-repacking SOL algorithm A, the APR satisfies $R_A^\infty \geq 1.3871 \dots$*

Ivkovic and Lloyd [121] also presented approximation schemes for their dynamic, SOL model, applying the techniques of Fernandez de la Vega and Lueker and those of Karmarkar and Karp cited in Sect. 4.3.

Consider now the case in which the algorithm is allowed to look ahead, in the sense that, when an element arrives, it is not necessary to pack it immediately; one is allowed to collect further elements whose sizes can effect the packing decision. In order to avoid relaxation to off-line algorithms, consider the case of *bounded* lookahead. Grove [111] proposed a k -bounded algorithm which had, in addition, a capacity (or *warehouse*) constraint W . The algorithm can delay the packing of item a_i until it has collected all subsequent elements a_{i+1}, \dots, a_j such that $\sum_{r=i}^j a_r \leq W$. For any fixed k and W , the $h_\infty(1)$ lower bound (see Theorem 12) remains valid, but Grove's *Revised Warehouse* (RW) algorithm reaches the bound if W is sufficiently large. In his proof, Grove uses a weighting function argument.

Another subclass of the lookahead SOL problems arises if the input list is divided into a number of batches. If an algorithm works on a batched list, then it has to pack each batch as an off-line list (i.e., lookahead is only possible within the current batch). However, while packing elements of the current batch, the items of earlier batches cannot be moved. If the number of batches is bounded by m , the problem is called *m-batched bin packing* (BBP) problem. Gutin et al. [112] were the first to study the BBP problem: they investigated in depth the 2-BBP problem and proved a lower bound of $1.3871 \dots$ for this case.

The rarely considered class of algorithms in which it is assumed that the input list is *presorted* is finally considered. Because of the lower bound constructions, it is easy to see that, if the list is presorted by increasing item size, the on-line lower bounds remain valid. Moreover, the Johnson result holds: if the list is presorted by decreasing item size, then $\frac{11}{9} \leq R_A^\infty \leq \frac{5}{4}$ for any algorithm $A \in \mathcal{AF}$ (see Theorem 21). This begged the broader question of lower bounds: how good can an arbitrary algorithm be? Based on two different lists, a partial answer was given in

the early 1980s by Csirik et al. [64]. They proved that if the list is presorted by decreasing item size, then $R_A^\infty \geq \frac{8}{7}$ for all algorithms A. Although this approach seemed to be very simple (the authors used only two different list types), no progress was made until very recently Balogh et al. [15] gave an improved lower bound:

Theorem 18 (Balogh et al. [15]) *If the list is presorted by decreasing item size, then $R_A^\infty \geq \frac{54}{47}$ for all algorithms A.*

4 Off-line Algorithms

An *off-line* algorithm has all items available for preprocessing, reordering, grouping, etc. before packing. It has been seen that most of the classical on-line algorithms achieve their worst-case ratio when the items are packed in increasing order of size (see, e.g., FF and BF), or if small and large items are merged (see, e.g., NF). Thus, one is led to expect improved behavior by a sorting of the items in decreasing order of size. Note that the $O(n \log n)$ sorting step makes the algorithm no longer linear time.

The review starts with results for approaches that sort the items before executing one of the on-line algorithms. Linear-time heuristics are then considered. The section is concluded by approximation schemes and by a discussion of the anomalous behavior that is exhibited by many bin packing algorithms, including both on-line and off-line algorithms.

4.1 Algorithms with Presorting

When the sorted list is packed according to the Next-Fit rule, one obtains the *Next-Fit Decreasing* (NFD) algorithm. This heuristic was investigated by Baker and Coffman, who proved by a weighting function argument that its APR is slightly better than that of FF and BF:

Theorem 19 (Baker and Coffman [13]) *If $\alpha \in (\frac{1}{r+1}, \frac{1}{r}]$ ($r \geq 1$), then $R_{\text{NFD}}^\infty(\alpha) = h_\infty(r)$.*

Packing the sorted list according to First-Fit or Best-Fit gives the algorithms *First-Fit Decreasing* (FFD) and *Best-Fit Decreasing* (BFD), with much better asymptotic worst-case performance.

Theorem 20 (Johnson et al. [129]) $R_{\text{FFD}}^\infty = R_{\text{BFD}}^\infty = \frac{11}{9}$.

The original proof was based on the weighting function technique, but subsequent proofs introduced dramatic changes; the giant case analysis made in 1973 by Johnson [126] was considerably shortened by Baker [12] in 1985, and in 1991, Yue

[183] presented the shortest proof known so far. In parallel, the additive constant was also improved; Johnson had proved that $\text{FFD}(L) \leq \frac{11}{9} \text{OPT}(L) + 4$, but Baker reduced the constant to 3, and Yue reduced it to 1. Then, in 1997, Li and Yue [146] further reduced the constant to $\frac{7}{9}$ and conjectured the tight value to be $\frac{5}{9}$. However, in 2007, Dósa [68] closed the issue by proving that the tight value is $\frac{6}{9}$.

The behavior of BFD for general α is not known, but that of FFD has been intensively investigated. Johnson et al. [129] analyzed several cases, showing that

$$R_{\text{FFD}}^{\infty}(\alpha) = \begin{cases} \frac{11}{9} & \text{if } \frac{1}{2} < \alpha \leq 1 \\ \frac{71}{60} & \text{if } \frac{8}{29} < \alpha \leq \frac{1}{2} \\ \frac{7}{6} & \text{if } \frac{1}{4} < \alpha \leq \frac{8}{29} \\ \frac{23}{20} & \text{if } \frac{1}{5} < \alpha \leq \frac{1}{4} \end{cases}$$

and conjecturing that, for any integer $m \geq 4$,

$$R_{\text{FFD}}^{\infty}\left(\frac{1}{m}\right) = F_m := 1 + \frac{1}{m+2} - \frac{2}{m(m+1)(m+2)}.$$

Twenty years later, Csirik [57] proved that the above conjecture is valid only for m even, and that, for m odd,

$$R_{\text{FFD}}^{\infty}\left(\frac{1}{m}\right) = G_m := 1 + \frac{1}{m+2} - \frac{1}{m(m+1)(m+2)}.$$

In the same year, the complete analysis of FFD for arbitrary values of $\alpha \leq \frac{1}{4}$ was published by Xu [178] (see also [179]), who showed that if m is even, then F_m is the correct APR for any α in $(\frac{1}{m+1}, \frac{1}{m}]$, while for m odd, the interval has to be divided into two parts, with

$$R_{\text{FFD}}^{\infty}(\alpha) = \begin{cases} F_m, & \text{if } \frac{1}{m+1} < \alpha \leq d_m \\ G_m, & \text{if } d_m < \alpha \leq \frac{1}{m} \end{cases}$$

where $d_m := (m+1)^2/(m^3 + 3m^2 + m + 1)$.

Recall that, after a presorting stage, all of the above algorithms belong to the Any-Fit class (see Sect. 3.3). Johnson showed that, after a presort in increasing order, Any-Fit algorithms do not perform well in the worst case; for example, their APRs must be at least $h_{\infty}(1)$ when $\alpha = 1$. But presorting in decreasing order is much more useful.

Theorem 21 (Johnson [126, 127]) *Any algorithm $A \in \mathcal{AF}$ operating on a list presorted in decreasing-size order must have*

$$\frac{11}{9} \leq R_A^{\infty}(1) \leq \frac{5}{4}$$

$$\frac{1}{m+2} - \frac{2}{m(m+1)(m+2)} \leq R_A^{\infty}(\alpha) \leq \frac{1}{m+2}, \text{ where } m = \lfloor \frac{1}{\alpha} \rfloor \text{ and } \alpha < 1.$$

For a long time, the FFD bound was the smallest proved APR. Johnson [126] made an interesting attempt to obtain a better APR. His *Most-k-Fit* (MF_k) algorithm takes elements from both ends of the sorted list, packing bins one at a time. At any step, after trying to place the largest unpacked element into the current bin, the algorithm attempts to fill up the remaining space in the bin using the smallest k (or fewer) as yet unpacked items. As soon as the available space becomes smaller than the smallest unpacked element, the algorithm starts packing a new bin. The algorithm has time complexity $O(n^k \log n)$, so it is practical only for small k . Johnson conjectured that $\lim_{k \rightarrow \infty} R_{\text{MF}_k}^\infty = \frac{10}{9}$, but almost 20 years later, the conjecture was contradicted by Friesen and Langston [90], who gave examples for which $R_{\text{MF}_k}^\infty \geq \frac{5}{4}$, $k \geq 2$.

Yao [180] devised the first improvement to FFD. He presented a complicated $O(n^{10} \log n)$ algorithm, called *Refined First-Fit Decreasing* (RFFD), with worst-case ratio $R_{\text{RFFD}}^\infty \leq \frac{11}{9} - 10^{-7}$. Following this result, further efforts were made to develop better off-line algorithms. Garey and Johnson [102] proposed the *Modified First-Fit Decreasing* (MFFD) algorithm. The main idea is to supplement FFD with an attempt to improve that part of the packing containing bins with items of sizes larger than $\frac{1}{2}$ by trying to pack in these bins pairs of items (to be called S items) with sizes in $(\frac{1}{6}, \frac{1}{3}]$. The non-FFD decisions of MFFD occur only during the packing of S items. At the time these items come up for packing, the bins currently containing a single item larger than $\frac{1}{2}$ are packed first, where possible, in decreasing-gap order as follows. In packing the next such bin, MFFD first checks whether there are two still unpacked S items that can fit into the bin; if not, MFFD finishes out the remaining packing just like FFD. Otherwise, the smallest available S item is packed first in the bin; the largest remaining available S item that fits with it is packed second. The running time of MFFD is not appreciably larger than that for FFD, but Garey and Johnson proved that

Theorem 22 (Garey and Johnson [102]) $R_{\text{MFFD}}^\infty = \frac{71}{60} = 1.18333 \dots$

Another modification of FFD was presented by Friesen and Langston [90]. Their *Best Two-Fit* (B2F) algorithm starts by filling one bin at a time, greedily; when no further element fits into the current bin, and the bin contains more than one element, an attempt is made to replace the smallest one by two unpacked elements with sizes at least $\frac{1}{6}$. When all the unpacked elements have sizes smaller than $\frac{1}{6}$, the standard FFD algorithm is applied. Friesen and Langston proved that $R_{\text{B2F}}^\infty = \frac{5}{4}$, which is worse than $\frac{11}{9}$. However, they further showed that a combined algorithm (CFB), which runs both B2F and FFD and takes the better packing, has an improved APR.

Theorem 23 (Friesen and Langston [90]) $1.16410 \dots = \frac{227}{195} \leq R_{\text{CFB}}^\infty \leq \frac{6}{5} = 1.2$.

Concerning the absolute worst-case ratio, Johnson et al. [129] had already conjectured that, if the number of bins in the optimal solution is more than 20, then the absolute worst-case ratio of FF is no more than 1.7. The first results were given by

Johnson et al. [129] and Simchi-Levi [169]. They showed that FF and BF have an absolute performance bound not greater than 1.75 and that FFD and BFD have an absolute performance ratio of 1.5. The latter is the best possible for the classical bin packing problem, unless $\mathcal{P} = \mathcal{NP}$. Xie and Liu [177] improved the bound for FF to 1.737. Zhang et al. [188] provided a linear-time bounded-space off-line approximation algorithm with an absolute worst-case ratio of 1.5 and a linear-time bounded-space on-line algorithm with an absolute worst-case ratio of 1.75. Berghammer and Reuter [24] gave a different linear-time algorithm with an absolute worst-case ratio of 1.5.

4.2 Linear Time, Randomization, and Other Approaches

The off-line algorithms analyzed so far have time complexity at least $O(n \log n)$. It is also interesting to see what can be accomplished in linear time – in particular, without sorting. The first such heuristic was constructed by Johnson [127]. His *Group-X-Fit Grouped* (GXFG) algorithm depends on the choice of a set of breakpoints X , defined by a sequence of real numbers $0 = x_0 < x_1 < \dots < x_p = 1$. For a given X , the algorithm partitions the items, according to their size, into at most p classes, and renames them in such a way that items of the same class are consecutive and classes are ordered by decreasing maximum size. The bins are also collected into p groups according to their *actual gap*, defined as the maximum x_j such that the current empty space in the bin is at least x_j . The items are packed using the Best-Fit rule with respect to the actual gaps. The algorithm can be implemented so as to require linear time and has the following APR.

Theorem 24 (Johnson [127]) *For all $m \geq 1$, if X contains $\frac{1}{m+2}, \frac{1}{m+1}$, and $\frac{1}{m}$, then $R_{\text{GXFG}}^{\infty}(\alpha) = \frac{m+2}{m+1}$ for all $\alpha \leq 1$ such that $m = \lfloor \frac{1}{\alpha} \rfloor$.*

For $\alpha = 1$, the above theorem gives $R_{\text{GXFG}}^{\infty} = \frac{3}{2}$, a bound subsequently improved by Martel. His algorithm, H_4 , uses a set $X = \{\frac{1}{4}, \frac{1}{3}, \frac{1}{2}, \frac{2}{3}\}$, but it does not reorder the items. It instead inserts them into heaps and uses a linear search for the median-size item. The packing strategy makes use of an elaborate pairing technique.

Theorem 25 (Martel [154]) $R_{H_4}^{\infty} = \frac{4}{3}$.

Later, Békési et al. [23] applied the Martel idea to a set $X = \{\frac{1}{5}, \frac{1}{4}, \frac{1}{3}, \frac{3}{8}, \frac{1}{2}, \frac{2}{3}, \frac{4}{5}\}$ and improved the bound to $\frac{5}{4}$. Making experimental comparisons, they further showed that this linear-time algorithm is faster than the less complicated FFD rule even for small problem instances. They also mentioned that, by using more breakpoints, one can further improve the above result, but the resulting algorithms would be linear time with a constant term so large that they would not be useful in practice.

Table 4 Worst-case ratios of off-line algorithms. NA means “not analyzed”

Algorithm	Time	$R_A^\infty(1)$	$R_A^\infty(2)$	$R_A^\infty(3)$	$R_A^\infty(4)$
NFD	$O(n)$	1.691...	1.424...	1.302...	1.234
FFD	$O(n \log n)$	1.222...	1.183...	1.183...	1.15
BFD	$O(n \log n)$	1.222...	1.183...	1.183...	1.15
GXFD	$O(n)$	1.5	1.333...	1.25	1.2
MFFD	$O(n \log n)$	1.183...	1.183...	1.183...	1.15
H ₄	$O(n)$	1.333...	NA	NA	NA
H ₇	$O(n)$	1.25	NA	NA	NA
B2F	$O(n \log n)$	1.25	NA	NA	NA
CFB	$O(n \log n)$	1.2	$\leq 1.183\dots$	$\leq 1.183\dots$	≤ 1.15

Table 4 summarizes the tightest worst-case ratios of off-line algorithms (H_7 denotes the algorithm of Békési and Galambos [22]).

As a final note on fast off-line algorithms, the reader is referred to the work of Anderson et al. [4] for the implementation of approximation algorithms on parallel architectures. They show that, with $n / \log n$ processors in the EREW PRAM model, a packing can be obtained in parallel in $O(\log n)$ time which has the same asymptotic $\frac{11}{9}$ bound as FFD.

Caprara and Pferschy [34] proposed a simple (although non-polynomial) algorithm, discussed in Sect. 7.2, for which they proved an upper bound on the worst-case ratio of $4/3 + \ln 4/3 = 1.62102\dots$.

4.3 Asymptotic Approximation Schemes

In 1980, Yao [180] raised an interesting question: does there exist an $\varepsilon > 0$ such that every $O(n)$ -time algorithm A must satisfy the lower bound $R_A^\infty \geq 1 + \varepsilon$? Fernandez de la Vega and Lueker [84] answered the question in the negative by constructing an asymptotic linear approximation scheme for bin packing. In their important paper, LP (linear programming) relaxations were first introduced as a technique for devising bin packing approximation algorithms. (See Sect. 8.1 for an integer programming formulation of the bin packing problem.) In this section, their result is first discussed, and then some improvements proposed by Johnson and by Karmarkar and Karp are introduced. Further discussion can be found in [52, 116].

The main idea in [84] is the following. Given an ε , $0 < \varepsilon < 1$, define ε_1 so that $\frac{\varepsilon}{2} < \varepsilon_1 \leq \frac{\varepsilon}{\varepsilon+1}$. Instead of packing the given list L , the algorithm packs a concatenation of three lists $L_1 L_2 L_3$ determined as follows:

- L_1 contains all the elements of L with sizes smaller than ε_1 .
- L_2 is a list of $(m - 1)h$ dummy elements with “rounded” sizes, corresponding to the $(m - 1)h$ smallest elements of $L \setminus L_1$, where $m = \lceil \frac{4}{\varepsilon^2} \rceil$ and $h = \left\lfloor \frac{|L \setminus L_1|}{m} \right\rfloor$.

The elements of L_2 have only $m - 1$ different sizes, and, for each size s , the list has h elements; the sizes of the corresponding h elements in $L \setminus L_1$ are no greater than s .

- L_3 contains the remaining elements of $L \setminus L_1$, that is, those not having a corresponding rounded element in L_2 , hence $|L_3| \leq 2h - 1$.

By construction, for each group of h elements of L_2 having the same size s , there exists a distinct group of h elements of $L \setminus L_1$ having sizes at least s . It follows that $OPT(L_2) \leq OPT(L \setminus L_1)$.

It is first proved that for a given ε , one can construct, in linear time via an LP relaxation, a packing for the elements of L_2 that requires no more than $OPT(L \setminus L_1) + \frac{4}{\varepsilon}$ bins. The next step is to pack each element of L_3 into a separate bin, so the number of open bins at this point is bounded by

$$OPT(L \setminus L_1) + \frac{4}{\varepsilon} + 2h - 1 < OPT(L \setminus L_1) + \frac{4}{\varepsilon} + |L \setminus L_1| \frac{\varepsilon^2}{2} \leq OPT(L \setminus L_1)(1 + \varepsilon) + \frac{4}{\varepsilon}$$

(using the fact that $OPT(L \setminus L_1) \geq \frac{\varepsilon}{2}|L \setminus L_1|$).

Finally, the items of L_1 are added to the current packing, one bin at a time, using the Next-Fit rule. If no new bin is opened in this phase, the resulting packing has the desired performance. If at least one new bin is opened, this implies that all the bins, except possibly the last one, are filled to at least $(1 - \varepsilon_1)$, and hence the total number of bins is bounded by

$$\frac{OPT(L)}{1 - \varepsilon_1} + 1 \leq OPT(L)(1 + \varepsilon) + 1 \leq OPT(L)(1 + \varepsilon) + \frac{4}{\varepsilon}.$$

Combining this with an analysis of the time to pack L_2 , Fernandez de la Vega and Lueker proved the following result.

Theorem 26 (Fernandez de la Vega and Lueker [84]) *For any $\varepsilon > 0$, there exists a bin packing algorithm A with asymptotic worst-case ratio $R_A^\infty \leq 1 + \varepsilon$, requiring time $C_\varepsilon + Cn \log \frac{1}{\varepsilon}$, where C_ε depends only on ε and C is an absolute constant.*

Although the time complexity of the above approximation scheme is polynomial in the number of elements, it is exponential in $\frac{1}{\varepsilon}$.

The first improvement was given by Johnson [128], who observed that, if ε is allowed to grow suitably slowly with $OPT(L)$, one can use the above approach to construct a polynomial-time algorithm A such that $A(L) \leq OPT(L) + o(OPT(L))$; incorporating a scheme suggested by Karmarkar and Karp, he achieved $A(L) \leq OPT(L) + O(OPT(L)^{1-\delta})$, where δ is a positive constant. Thus, as a corollary to [Theorem 26](#), there exists a polynomial-time approximation algorithm for bin packing with an APR equal to 1.

Karmarkar and Karp [132] made further improvements and produced an asymptotic fully polynomial-time approximation scheme. They brought several new

techniques into play. The ellipsoid method applied to an LP relaxation drove the approach; a feasible packing was determined by an extension of the approach of Fernandez de la Vega and Lueker. A function T , estimated below, describes the time complexity of the LP problem in terms of properties of the problem instance. Let $c(L)$ denote the total size of the items in L and recall that k denotes the number, perhaps infinite, of possible item sizes. The main results are several different forms of asymptotic optimality and their associated running-time bounds. Recalling that the absolute error for an algorithm A is simply $A(L) - OPT(L)$, one has the following.

Theorem 27 (Karmarkar and Karp [132]) *For each row in the table below, there is an approximation algorithm with the given running-time and absolute-error bounds; the approximation parameters in the last two rows satisfy $\alpha \in [0, 1]$ and $\varepsilon > 0$:*

Running-time bound	Absolute-error bound
$O(T_n(c(L)))$	$O(\log^2 OPT(L))$
$O(T_n(k))$	$O(\log^2 k)$
$O(T_n(c(L)^{1-\alpha}))$	$O(OPT(L)^\alpha)$
$O(T_n(\varepsilon^{-2}))$	$\varepsilon OPT(L) + O(\varepsilon^{-2})$

where

$$T_n(v) = O(v^8 \log v \log^2 n + v^4 n \log v \log n).$$

The bound on $T_n(v)$ is not especially attractive, so this approach as it stands is not likely to be very practical, although the authors mention that a mixture of their technique with a column generation method [105, 106] may be very efficient in practice.

Taking a complementary approach, Hochbaum and Shmoys [118] (see also [117]) define an ε -dual approximation algorithm for bin packing, denoted in the following by M_ε . For a given $\varepsilon > 0$, M_ε finds in polynomial time a packing of L in $OPT(L)$ bins, each of capacity $C = 1 + \varepsilon$. A primary objective of M_ε is the approximation scheme for the capacity minimization problem discussed in Sect. 6.1, but such algorithms also find use in bin packing settings where precise bin capacities vary or are unknown.

The above dual approach can be likened to a search for near-feasible, optimal solutions rather than feasible, near-optimal solutions. The construction of M_ε exploits a reduction of the problem to bin packing with a finite number of item sizes and hence the integer program formulation in Sect. 5.2. A general discussion of the details has been given by Hochbaum [116], who describes a version of M_ε that requires only linear running time (with constants depending on ε).

4.4 Anomalies

For a given algorithm A , one usually expects that if a list is made shorter, or its items made smaller, then the number of bins needed by A to pack the list could not increase, and if the reductions were large enough, then the number of bins required would actually decrease. This is certainly true for optimal algorithms, but as this section shows, it is not the case for many of the better on-line and off-line approximation algorithms. This anomalous behavior can explain the difficulty in analyzing algorithms; with such behavior, inductive arguments cannot normally be expected to work. The following instances illustrate bin packing anomalies. Define

$$\begin{aligned} L &= (0.7, 0.68, 0.5399, 0.3201, 0.15, 0.14, 0.08, 0.08, 0.08, 0.08, 0.08, 0.07) \\ L' &= (0.7, 0.68, 0.5399, 0.32, 0.15, 0.14, 0.08, 0.08, 0.08, 0.08, 0.08, 0.07) \end{aligned}$$

and note that the two instances differ only in the fourth element, which is slightly smaller in L' . BF and BFD produce the same packing of L :

$$\begin{aligned} c(B_1) &= 0.7 + 0.15 + 0.08 + 0.07 \\ c(B_2) &= 0.68 + 0.08 + 0.08 + 0.08 \\ c(B_3) &= 0.5399 + 0.3201 + 0.14 \end{aligned}$$

BF and BFD also produce the same packing of L' , which is larger by one bin:

$$\begin{aligned} c(B_1) &= 0.7 + 0.15 + 0.14 \\ c(B_2) &= 0.68 + 0.32 \\ c(B_3) &= 0.5399 + 0.08 + 0.08 + 0.08 + 0.08 + 0.08 \\ c(B_4) &= 0.07 \end{aligned}$$

A list $L_{(n)} = (a_1, a_2, \dots, a_n)$ *dominates* a list $L'_{(m)} = (a'_1, a'_2, \dots, a'_m)$ if $n \geq m$ and the size of each element a_i is no less than the size of the corresponding element a'_i . An algorithm A is *monotonic* if $A(L) \geq A(L')$ whenever L dominates L' . An *anomalous* algorithm is one that is not monotonic.

Graham [110] and Johnson [126] observed that algorithms FF and FFD are anomalous. However, the current insights into the anomalous behavior of bin packing algorithms are due mainly to Murgolo. In the notation of Sect. 3.4 (with W meaning Worst-Fit), he proved

Theorem 28 (Murgolo [156]) *Algorithms NF and NF₂ are monotonic, but each of BF, BFD, WF, WFD, ABF₂, AWF₂, and AFF_k with k ≥ 3 is anomalous.*

Murgolo also obtained upper and lower bounds on the behavior of anomalous algorithms. An algorithm is called *conservative* if it never opens a new bin unless

the current element cannot fit into an open bin. For conservative algorithms, the following bound applies.

Theorem 29 (Murgolo [156]) *If L' dominates L and A is conservative, then $A(L') \leq 2A(L)$. In addition, if $A \in \{FFD, BFD\}$, then $A(L') \leq \frac{11}{9}A(L) + 4$.*

He also proved the following complementary results:

Theorem 30 (Murgolo [156]) *There exist arbitrarily long lists L_i and L'_i , with L'_i dominating L_i , ($i = 1, 2, 3$), such that*

$$\begin{aligned} \text{if } A \in \{\text{BF}, \text{BFD}\} & \text{ then } A(L_1) \geq \frac{43}{42}A(L'_1), \\ \text{if } A \in \{\text{FF}\} & \text{ then } A(L_2) \geq \frac{76}{75}A(L'_2), \\ \text{if } A \in \{\text{WF}, \text{WFD}\} & \text{ then } A(L_3) \geq \frac{16}{15}A(L'_3). \end{aligned}$$

The following sections discuss problems in which special types of lists, alternative objective functions, or any of various constraints on items or packings are considered. It will be seen that in some cases the problem becomes easier, in the sense of approximability, while in others it becomes harder. Similarly, adaptations of classical heuristics give more or less attractive results depending on the new problem.

5 Variations on Bin Sizes

5.1 Variable-Sized Bins

Consider the case where one is given different bin types, B_1, B_2, \dots, B_k with sizes $1 = s(B_1) > s(B_2) > \dots > s(B_k)$. For each type, an unlimited number of bins are available, and the aim is to pack a list L of elements a_i , with $s_i \in (0, 1]$, into a subset of bins having the smallest total size. Let $s(A, L)$ denote the total size of the bins used by algorithm A to pack the items of L . Then

$$R_A^\infty = \lim_{k \rightarrow +\infty} \sup \left\{ \frac{s(A, L)}{s(OPT, L)} : s(OPT, L) \geq k \right\}.$$

The problem has practical importance in many of the classical bin packing applications, for example, cutting stock problems, the assignment of commercials to variable size breaks in television or radio broadcasting, and memory allocation for computer operating systems.

At first glance, one might expect variable-sized bin packing to be harder than the classical problem. However, this need not be true in general. For example, if there are bin types for all sizes between $\frac{1}{2}$ and 1, then packing large elements with sizes at

least $\frac{1}{2}$ can be done without wasted space. Similarly, smaller elements can be packed together without any waste, so long as their sum is at least $\frac{1}{2}$.

For general sets of bin sizes, an on-line algorithm must select the bin size for packing the current element whenever a new bin is opened. Friesen and Langston [89] proposed an on-line algorithm based on the Next-Fit rule, which always selects the largest bin size (*Next-Fit, using Largest possible bins*, NFL), and proved that its APR is 2. Kinnersley and Langston [138] showed that the same APR is obtained by adopting the First-Fit rule, both for an algorithm that uses the largest possible bins and for an algorithm that uses the smallest bins. Burkard and Zhang [33] pointed out that this APR characterizes a large class of algorithms that use one of the above bin-opening rules.

Kinnersley and Langston [138] analyzed other fast on-line algorithms. They proposed a scheme based on a user-specified *fill factor*, $f \geq \frac{1}{2}$, and proved that this strategy guarantees an APR smaller than $\frac{3}{2} + \frac{f}{2} \leq 1.75$. Zhang [185] proved that with $f = \frac{1}{2}$, the APR is $\frac{17}{10}$.

Csirik [56] investigated an algorithm based on the Harmonic-Fit strategy (*Variable Harmonic-Fit*, VH) and showed that its APR is at most $h_\infty(1) \approx 1.69103$. For special collections of bin types, the algorithm may perform better; for example, Csirik proved that if there are only two types of bins, with $s(B_1) = 1$ and $s(B_2) = \frac{7}{10}$, then $R_{\text{VH}}^\infty = \frac{7}{5}$.

This result is very interesting since the bound is smaller than the 1.54 on-line lower bound of Balogh et al. [15] for the classical problem (see Sect. 3.6), and implies that, for certain sets of two or more bin sizes, on-line algorithms can behave better than those restricted to a single bin size.

Csirik's VH algorithm suffers from the same “illness” as the classical HF_k algorithm (see Sect. 3.4); it reaches the $h_\infty(1)$ bound only for a very large number of open bins. More precisely, let $M > 1$ be a positive integer, and suppose that the algorithm can use l different bin types. Let $M_j = \lceil M s(B_j) \rceil$ ($j = 1, \dots, l$), and denote by VH_M the resulting VH algorithm, which is a k -bounded-space algorithm with $k = \sum_{j=1}^l M_j - l + 1$. If $M_l \leq 5$ then $R_{\text{VH}_M}^\infty \geq \frac{17}{10}$.

This raised further questions. If there are only two different bin types, which combination of sizes produces the smallest APR? What lower bounds depending on bin sizes can be proved? What can be said about the problem with at least three (or an arbitrary number of) bin sizes?

Some of the above questions were answered by Seiden [162], who revisited the VH algorithm. For the case where there are two bin sizes, he developed an algorithm that provides a lower bound for any fixed α . Specifically, he proved the following result:

$$1.37530 < \frac{78,392,621}{57,000,000} \leq \inf_{\alpha \in (0,1]} R_{OPT}^\infty(\alpha) \leq \frac{395,101,163}{287,280,000} < 1.37532.$$

He additionally proved that the upper bound $h_\infty(1) \approx 1.69103$, given in [56], is tight and that algorithm VH is optimal among bounded-space algorithms.

To obtain this result, Seiden used the weighting function technique and developed “twin” mathematical programs, which have the same sets of conditions but different objective functions. He used the mathematical programs to get lower and upper bounds for the asymptotic performance ratio of VH. He proved the asymptotic optimality of VH, although the precise value could not be computed.

The third question remained open even in the case of three different sizes.

Burkard and Zhang [33] investigated other bounded-space algorithms for variable-sized bin packing. They distinguished three different components: the opening rule, packing rule, and closing rule. The opening rule was fixed as follows. If the current item has size $s_i > \frac{1}{2}$ and there exist bin sizes smaller than 1 that can accommodate a_i , then the rule opens the smallest such bin; otherwise, it opens a bin of size 1. The packing rules analyzed were First-Fit (the F rule) and Best-Fit (the B rule). The closing rule closes a bin of size less than 1, if one exists; otherwise, it closes either the lowest indexed bin (the first-bin or F rule) or the most nearly full bin (the best-bin or B rule). With this terminology, VXY_k denotes the k -bounded algorithm that incorporates packing rule X and closing rule Y . Burkard and Zhang showed that, among the four resulting algorithms (VFF_k , VFB_k , VBF_k , and VBB_k), VBB_k is the best and that the following holds.

Theorem 31 (Burkard and Zhang [33]) $R_{VBB_k}^\infty = \frac{17}{10}$. Moreover, $R_{VH_M}^\infty \geq R_{VBB_k}^\infty$ if and only if $M_l < 7$, with $k \geq 6l + 1$.

The authors proved the theorem by a weighting function technique. They also mentioned that, with a small modification in the weighting function, they could prove that $R_{VFB_k}^\infty = \frac{17}{10} + \frac{3}{10(k-1)}$ for any $k \geq 2$. So, one of the more interesting questions remains open: does there exist an on-line algorithm with an APR strictly less than $h_\infty(1)$ for all collections of bin sizes?

For the off-line case, few results have been proved. Friesen and Langston [89] presented two algorithms based on the First-Fit Decreasing strategy. The first one, *FFD using Largest bins and Repack* (FFDLR), begins by packing the presorted elements into the largest bins, then repacks the contents of each open bin into the smallest possible empty bin. The second algorithm, *FFD using Largest bins and Shift* (FFDLS), improves on the first phase of FFDLR: whenever the bin (say of type B_j) where the current item has been packed contains an item of size at least $\frac{1}{3}$, the contents of the bin are shifted, if possible, to the smallest empty bin (say of type B_h) such that $s(B_h) \geq \tilde{c} \geq \frac{3}{4}s(B_h)$, where \tilde{c} denotes the total item size packed into the current bin. Friesen and Langston proved that $R_{FFDLR}^\infty = \frac{3}{2}$ and $R_{FFDLS}^\infty = \frac{4}{3}$.

Seiden et al. [164] made great strides by improving the upper bound and giving the first – and to this very day the only – general lower bound for the case with two bin sizes. First, they introduced a parameter $\mu \in (\frac{1}{3}, \frac{1}{2})$. They gave an algorithm $VH1(\mu)$ for all $\alpha \in (0, 1)$, and an algorithm $VH2(\mu)$, only defined for $\alpha > \max\{\frac{1}{2(1-\mu)}, \frac{1}{3\mu}\}$. Both algorithms are combinations of the Harmonic and Refined Harmonic algorithms. The upper bound was achieved by optimizing μ over each choice of α , and the authors chose the best value among $VH1(\mu)$, $VH2(\mu)$, and

VH. The resulting upper bound is at most $\frac{373}{228} < 1.63597$ for all α . Note that this is the asymptotic performance ratio of the RHF algorithm in the classic bin packing context. The lower bound result is summarized by the following theorem.

Theorem 32 (Seiden et al. [164]) *Any on-line algorithm for the variable-sized bin packing problem with two bin sizes has asymptotic performance ratio at least $\frac{495,176,908,800}{370,749,511,199} > 1.33561$.*

The result is quite good since the largest gap between the two bounds is 0.18193 for $\alpha = 0.9071$, and the smallest gap is 0.003371 for $\alpha = 0.6667$.

Murgolo [157] proposed an efficient approximation scheme. He first gave an algorithm with a running time linear in the number of items but exponential in $\frac{1}{\varepsilon}$ and the number of bin sizes. Then, following the ideas in Karmarkar and Karp [132], he solved a linear programming formulation of the problem by the ellipsoid method, thus obtaining a fully polynomial-time approximation scheme.

Zhang [186] considered a variant of the on-line version of the problem, in which item-size information is known in advance, but no information on bin sizes is available, except that each bin size is known to be no less than the size of the largest item. Bins arrive one at a time, and one has to decide which items to pack into the current bin. Zhang proved that the analogues of the classical NF, FF, NFD, and FFD algorithms all have an APR equal to 2 and left as an open question whether one can devise an algorithm with an APR better than 2.

Kang and Park [130] investigated a problem where there are m different bin sizes, and the total cost of a unit of each bin size does not increase with the bin size, that is,

$$\frac{c_{i_1}}{s(B_{i_1})} \leq \frac{c_{i_2}}{s(B_{i_2})}, \quad \text{if } 1 \leq i_1 < i_2 \leq m.$$

They analyzed two algorithms, *Iterative First-Fit Decreasing* (IFFD) and *Iterative Best-Fit Decreasing* (IBFD), for three cases. If both the bin and item sizes are divisible, then both algorithms are optimal. If only the bin sizes are divisible, then $R_{\text{IFFD}} = R_{\text{IBFD}} = \frac{11}{9}$, whereas for the general (non-divisible) case, $R_{\text{IFFD}} = R_{\text{IBFD}} = \frac{3}{2}$. In addition, they proved that an algorithm by Coffman et al. [51] for the variable-sized bin case does not provide the optimal solution.

The case of weak divisibility has not been treated.

5.2 Resource Augmentation

The idea of *resource augmentation* was introduced by Csirik and Woeginger [63]. The motivation is that the worst-case examples are “pathological,” that is, if for a unit-capacity bin one considers items with size $\frac{1}{2} + \varepsilon$ with a sufficiently small ε , then only one item per bin can be packed. If the size of the bins is slightly increased, then two items can be packed in a bin, thus sparing a lot of capacity. (This is also called *bin stretching*.)

In this problem, an algorithm A has to pack a list L of elements in $(0, 1]$ into a minimal number of bins of capacity $C \geq 1$. Denote by $A_C(L)$ the number of bins used by A for packing L into bins of capacity C . Then the APR is defined as follows:

$$R_C^\infty = \lim_{OPT_1(L) \rightarrow \infty} \sup_L A_C(L),$$

where $OPT_1(L)$ is the optimal (off-line) packing of L into unit-capacity bins. Csirik and Woeginger considered on-line bounded-space algorithms and gave a complete analysis. For each C , a sequence $T(C) = \langle t_1, t_2, \dots, \rangle$ of positive integers is defined:

$$t_1 = \lfloor 1 + C \rfloor \quad \text{and} \quad r_1 = \frac{1}{C} - \frac{1}{t_1}$$

and, for $i = 2, 3, \dots$,

$$t_i = \left\lfloor 1 + \frac{1}{r_{i-1}} \right\rfloor \quad \text{and} \quad r_i = r_{i-1} - \frac{1}{t_i}.$$

It is clear that this is a simple transformation of the Sylvester sequence, so

$$\frac{1}{C} = \sum_{i=1}^{\infty} \frac{1}{t_i}.$$

They defined a new function

$$\rho(C) = \sum_{i=1}^{\infty} \frac{1}{t_i - 1}$$

for which it is easy to prove that $\rho(C)$ is strictly decreasing on $[1, \infty)$, and $\rho(1) = h_\infty(1) \approx 1.69103$, $\rho(2) \approx 0.69103$. Furthermore, the following inequalities hold:

$$\frac{1}{m} \leq \rho(m) \leq \frac{1}{m-1} \text{ for integer } m \geq 2.$$

For a given $l \geq 3$, they defined t_l intervals: $\mathcal{I}_j = (\frac{C}{j+1}, \frac{C}{j}]$ for $j = 1, \dots, t_l - 1$, and $\mathcal{I}_{t_l} = (0, \frac{C}{t_l}]$. For these intervals, they constructed a Harmonic-Fit type algorithm. There is one active bin for every interval \mathcal{I}_j , and all items from the interval $\mathcal{I}_j \cap (0, 1]$ are packed into it using a Next-Fit rule. Using a weighting function (which is an adaptation of the one defined for the classical Harmonic-Fit algorithm), they proved the following theorem.

Theorem 33 (Csirik and Woeginger [63]) *For every bin size $C \geq 1$, there exist on-line, bounded-space bin packing algorithms with APRs arbitrarily close to $\rho(C)$.*

For every bin size $C \geq 1$, the bound $\rho(C)$ cannot be beaten by an on-line bounded-space bin packing algorithm.

Azar and Regev [7] presented two on-line algorithms, each guaranteeing a worst-case performance of $5/3$ for any number of bins. They also combined the algorithms to obtain an algorithm with a tight worst-case performance of $13/8 = 1.625$. This turns out to be an interesting result, as the best lower bound for any algorithm is equal to $4/3$ for $m \geq 2$.

On-line bounded-space bin packing with limited repacking was considered by Epstein and Kleiman [75], who extended to this case the ideas of Galambos and Woeginger [95]. They defined a semi-on-line algorithm, *Resource Augmented REP₃(C)* (*RAR₃(C)*), which is allowed to repack the elements within three active bins, and proved the following theorem.

Theorem 34 (Epstein and Kleiman [75]) *For every bin size $C \geq 1$, and for any on-line bounded-space bin packing algorithm A that allows repacking within k active bins, $R_A^\infty(C) \geq \rho(C)$. Algorithm RAR₃(C) has the best possible APR.*

Epstein and van Stee [80] extended the study to on-line algorithms, investigating both lower and upper bounds. For the upper bound, they started with an analysis of the harmonic type algorithms. Recall that by introducing two new interval endpoints, $\Delta > 1/2$ and $1 - \Delta$, one can combine one small element with an item in the interval $(1/2, \Delta]$. Also recall that in this case, only a fraction of the bins belonging to interval i can be used to reserve space for a (possibly later arriving) element from the interval $(1/2, \Delta]$. This fraction is denoted as α^i . (The values of α^i 's obviously depend on the number of intervals, and they are the crucial point of any such algorithm.) On this basis, they developed four algorithms, which are applied to the intervals $[1, 6/5]$, $[6/5, 4/3]$, $[4/3, 12/7]$, and $[12/7, 2]$, respectively.

An analytical solution was given only for the *Tiny Modified-Fit* algorithm, which was applied to interval $[12/7, 2]$. To examine the worst-case behavior of the other algorithms, they defined two weighting functions and constructed a linear program $P(f)$. By applying it to the cost function, they could use the method introduced by Seiden [163], thus obtaining upper bounds for the asymptotic behavior of the algorithms. The cost functions were not given explicitly, but program P was solved for many C values, and a diagram was given to show the upper bounds.

Concerning lower bounds, Epstein and van Stee [80] followed the argument laid down by van Vliet [171]. In this case too, an LP was generated for many values of C , and appropriate sublists were obtained through specialized greedy algorithms.

Chan et al. [37] further extended the study to dynamic bin packing. They considered the case where the items may depart at any time and where moving items among the open bins is disallowed. They first investigated Any-Fit algorithms, proving the following theorem.

Theorem 35 (Chan et al. [37]) Consider the resource augmentation problem with bin capacity C , and let A be an Any-Fit algorithm. Then A can achieve 1-competitiveness if and only if $C = 2$.

They also gave a new lower bound, as a function of C , for on-line algorithms. Let m be the largest integer such that $C - \frac{1}{m} < 1$, and define, for any positive integer $1 \leq i \leq m$,

$$\alpha(1) = m!(m-1)! \quad \beta(i) = \sum_{j=1}^i \alpha(j) \quad \alpha(i) = \frac{\beta(i-1)}{(m-i+2)(m-i+1)}.$$

Theorem 36 (Chan et al. [37]) Let A be an on-line algorithm. Then

$$R_A^\infty(C) \geq \max \left\{ \frac{\beta(m)}{m!(m-1)!}, \frac{2}{C} \right\}.$$

They also analyzed certain classical algorithms:

Theorem 37 (Chan et al. [37])

$$R_{\text{FF}}^\infty(C) \leq \min \left\{ \frac{2C+1}{2C-1}, \frac{5-C}{2C-1}, \frac{C^2+3}{C(2C-1)} \right\},$$

$$R_{\text{BF}}^\infty(C) = \frac{1}{C-1}$$

and

$$\min \left\{ \frac{2C+2}{2C}, \frac{C^2-8C+20}{C(4C)} \right\} \leq R_{\text{WF}}^\infty(C) \leq \frac{4}{C^2}. \quad (4)$$

Very recently, Boyar et al. [31] gave a complete APR analysis of algorithms WF and NF for the resource augmentation case. They showed that WF is strictly better than NF in the interval $1 < C < 2$ but has the same APR for all $C \geq 2$:

Theorem 38 (Boyar et al. [31]) Let $t_C = \lfloor \frac{1}{C-1} \rfloor$. Then

$$R_{\text{WF}}^\infty(C) = \begin{cases} \frac{2C}{3C-2}, & \text{if } C \in [1, 2] \\ \frac{1}{C-1}, & \text{if } C \in [2, \infty) \end{cases}$$

and

$$R_{\text{NF}}^\infty(C) = \frac{2t_C^2 C - 2t_C^2 - 4t_C + 2 + 2Ct_C}{t_C^2 C + 2Ct_C - t_C^2 - 3t_C - 2 + 2C}.$$

6 Dual Versions

6.1 Minimizing the Bin Capacity

Suppose that the number of bins is fixed, and let the objective be a smallest C such that a given list L of items can be packed in m bins of capacity C . This dual of bin packing actually predates bin packing and is known as multiprocessor or parallel-machine scheduling. It is a central problem of scheduling theory and is surveyed in depth elsewhere (see, e.g., Lawler et al. [141] and Hall [114]), so only relevant results and research directions will be highlighted. The problem is referred to as $P||C_{\max}$ in scheduling notation.

Optimal and heuristic capacities normally differ by at most a maximum item size, so absolute worst-case ratios rather than asymptotic ones are considered. The first analysis of approximation algorithms was presented by Graham [108, 109], who studied the worst-case performance of various algorithms. For the on-line case, he investigated the Worst-Fit algorithm (better known as the *List Scheduling*, LS algorithm), which initially opens m empty bins and then iteratively packs the current item into the bin having the minimum current content (breaking ties in favor of the lowest bin index). Graham proved that $R_{\text{LS}} = 2 - \frac{1}{m}$, a bound that for many years was thought to be best among on-line algorithms. Galambos and Woeginger were first to prove that the bound could be improved. Let $A(L, m)$ denote the bin capacity needed under A for m bins, and define

$$R_A(m) = \sup_L \left\{ \frac{A(L, m)}{\text{OPT}(L, m)} \right\} \quad \text{and} \quad R(m) = \inf_A R_A(m).$$

Theorem 39 (Galambos and Woeginger [94]) *There exists a sequence of nonnegative numbers $\varepsilon_1, \varepsilon_2, \dots$, with $\varepsilon_m > 0$, $m \geq 4$ and $\varepsilon_m \rightarrow 0$ as $m \rightarrow \infty$, such that $R(m) \leq 2 - \frac{1}{m} - \varepsilon_m$.*

This result encouraged further research; important milestones on the way to the current position on the problem are as follows. Bartal et al. [19] presented an algorithm with a worst-case ratio $2 - \frac{1}{70} = 1.98571\dots$ for all $m \geq 70$. Earlier, Faigle et al. [83] proved lower bounds for different values of m . They pointed out that for $m \leq 3$, the LS algorithm is optimal among on-line algorithms, and they proved a $1 + \frac{1}{\sqrt{2}} = 1.70710\dots$ lower bound for $m \geq 4$. Then these bounds were improved, as shown below.

Theorem 40 (Chen et al. [41]) *For all $m = 80 + 8k$ with k a nonnegative integer, $R(m) \geq 1.83193$.*

Theorem 41 (Bartal et al. [20]) *For all $m \geq 3,454$, $R(m) \geq 1.8370$.*

For some time, the following result gave the best upper bound for $R(m)$ and was a generalization of the methods in [20].

Theorem 42 (Karger et al. [131]) $R(m) \leq 1.945$ for all m .

A tighter result was found by Albers [2], who proved the next two bounds.

Theorem 43 (Albers [2]) $R(m) \leq 1.923$ for all m .

Just as previous authors, Albers recognized that, during the packing process, a good algorithm must try to avoid packings in which the content of each of the bins is about the same, for in such cases many small items followed by a large item can create a poor worst-case ratio. Albers' new algorithm attempts to maintain throughout the packing process $\lfloor \frac{m}{2} \rfloor$ bins with small total content and $\lceil \frac{m}{2} \rceil$ bins with large total content. The precise aim is always to have a total content in the small-content bins that is at most γ times the total content in the large-content bins. With an optimal choice of γ , one obtains a worst-case ratio of at most 1.923.

For her new lower bound, Albers proved

Theorem 44 (Albers [2]) $R(m) \geq 1.852$ for all $m \geq 80$.

Attempts to further reduce the general gap of about .07 continue. For the special case $m = 4$, it is proved in Chen et al. [41] that $1.73101 \leq R(4) \leq \frac{52}{30} = 1.7333\dots$, but the exact value of $R(4)$ remains an open problem. Another enticing open problem is: does $R(m) < R(m + 1)$ hold for any m ?

The off-line case is now considered. By preordering the elements according to nonincreasing size and applying the LS algorithm, one obtains the so-called *Largest Processing Time* (LPT) algorithm for $P \parallel C_{\max}$. Graham [109] proved that $R_{\text{LPT}} = \frac{4}{3} - \frac{1}{3m}$. The *Multifit* algorithm by Coffman et al. [47] adopts a different strategy, leading to better worst-case behavior. The algorithm determines, by binary search over an interval with crude but easily established lower and upper bounds, the smallest capacity C such that the FFD algorithm can pack all the elements into m bins. Coffman, Garey, and Johnson proved that if k binary search iterations are performed, then the algorithm, denoted by MF_k , requires $O(n \log n + kn \log m)$ time and has an absolute worst-case ratio satisfying

$$R_{\text{MF}_k} \leq 1.22 + 2^{-k}.$$

Friesen [87] improved the bound uniform in k to 1.2, but Yue [182] later settled the question by proving that this bound is $\frac{13}{11}$. Friesen and Langston [89] developed a different version of the Multifit algorithm, proving that its worst-case ratio is bounded by $\frac{72}{61} + 2^{-k}$.

A different off-line approach was proposed by Graham [109]. His algorithm Z_k optimally packs the $\min\{k, n\}$ largest elements and completes the solution by packing the remaining elements, if any, according to the LS algorithm. Graham

proved that

$$R_{Z_k} \leq 1 + \frac{1 - \frac{1}{m}}{1 + \left\lfloor \frac{k}{m} \right\rfloor}$$

and that the bound is tight when m divides k . Algorithm Z_k implicitly defines an approximation scheme. By selecting $k = k_\varepsilon = \lceil \frac{m(1-\varepsilon)-1}{\varepsilon} \rceil$, one obtains $R_{Z_{k_\varepsilon}} \leq 1 + \varepsilon$. The running time is $O(n \log n + m^{m(1-\varepsilon)/\varepsilon})$, and so the method is unlikely to be practical. The result was improved by Sahni [161], in the sense that the functional dependence on m and ε was reduced substantially. His algorithm A_ε has running time $O(n(\frac{n^2}{\varepsilon})^{m-1})$ and satisfies $R_{A_\varepsilon} \leq 1 + \varepsilon$; hence it is a fully polynomial-time approximation scheme for any fixed m .

For m even moderately large, the approach of Hochbaum and Shmoys [118] offers major improvements. They developed an ε -approximate algorithm that removed the running-time dependence on m and reduced the dependence on n . The dependence on $\frac{1}{\varepsilon}$ is exponential, which is to be expected, since a polynomial dependence would imply $\mathcal{P} = \mathcal{NP}$. Their algorithm is based on the binary search of an interval (like MF_k), but it uses the ε -dual approximation algorithm of Sect. 4.3 at each iteration. Hochbaum and Shmoys show that, after k steps of the binary search, the bin capacity is at most $(1 + \varepsilon)(1 + 2^{-k})$ times optimal. From this fact and the properties of M_ε given in Sect. 4.3, one obtains a linear-time approximation scheme for the capacity minimization problem. (See also Hochbaum's [116] for a more extensive discussion of this interesting technique.) The Hochbaum and Shmoys result was generalized by Alon et al. [3], who gave conditions under which a number of scheduling problems on parallel machines admit a polynomial-time approximation scheme.

6.2 Maximizing the Number of Items Packed

This section considers another variant in which the number of bins is fixed; the objective is now to pack a maximum cardinality subset of a given list $L_{(n)}$. The problem arises in computing applications, when one wants to maximize the number of records stored in one or more levels of a memory hierarchy or to maximize the number of tasks performed on multiple processors within a given time interval.

The classical bin packing notation is extended in an obvious way by defining

$$\hat{R}_A(m, n) = \min \left\{ \frac{A(L_{(n)}, m)}{OPT(L_{(n)}, m)} \right\}$$

so that the APR is defined by

$$\hat{R}_A^\infty(m) = \liminf_{n \rightarrow \infty} \hat{R}_A(m, n)$$

and has values less than or equal to 1.

First consider off-line algorithms. The problem was first studied by Coffman et al. [48], who adapted the *First-Fit Increasing* (FFI) heuristic. The items are preordered according to nondecreasing size, the m bins are opened, and the current item is packed into the lowest indexed bin into which it fits, stopping the process as soon as an item is encountered that does not fit into any bin. It is proved in [48] that $\hat{R}_{\text{FFI}}^\infty(m) = \frac{3}{4}$ for all m .

The *Iterated First-Fit Decreasing* (IFFD) algorithm was investigated by Coffman and Leung [45]. The algorithm sorts the items by nonincreasing size and iteratively tries to pack all the items into the m bins following the First-Fit rule. Whenever the current item cannot be packed, the process is stopped, the largest item is removed from the list, and a new FFD iteration is performed on the shortened list. The search terminates as soon as FFD is able to pack all the items of the current list. Coffman and Leung showed that IFFD performs at least as well as FFI on every list and that $\frac{6}{7} \leq \hat{R}_{\text{IFFD}}^\infty(m) \leq \frac{7}{8}$. The time complexity of IFFD is $O(n \log n + mn \log m)$, but a tight APR is not known.

Lower bounds on the APR are now considered. If an algorithm A packs items a_1, \dots, a_t from a list $L = (a_1, \dots, a_n)$ so that $s_i > 1 - s(B_j)$ for any j and for any $i > t$ (i.e., no unpacked item fits into any bin), then it is said to be a *prefix algorithm*. Note that both FFI and IFFD are prefix algorithms.

Theorem 45 (Coffman et al. [48]) *Let A be a prefix algorithm and let $k = \min_{1 \leq j \leq m} \{|B_j|\}$ be the least number of items packed into any bin. Then*

$$\hat{R}_A^\infty(m) \geq \frac{mk}{mk + m - 1}.$$

Moreover, the bound is achievable for all $m \geq 1$ and $k \geq 1$.

The case of divisible item sizes was investigated by Coffman et al. [51]. They proved that both FFI and IFFD produce optimal packings if (L, C) is strongly divisible. IFFD remains optimal even if (L, C) is weakly divisible, but FFI does not.

The case of variable-sized bins was first analyzed by Langston [140], who proved that if the bins are rearranged by nonincreasing size, then $\hat{R}_{\text{FFI}}^\infty(m) = \frac{1}{2}$ and $\frac{2}{3} \leq \hat{R}_{\text{IFFD}}^\infty(m) \leq \frac{8}{11}$ for all m . Friesen and Kuhl [88] gave a new efficient algorithm, which is a hybrid of two algorithms defined earlier: *First-Fit Decreasing* (FFD) and *Best-Two-Fit* (B2F). The hybrid is iterative: it attempts to pack smaller and smaller suffixes of its list of items until it succeeds in packing the entire suffix. During each attempt, the hybrid partitions the current list of items and packs one part by B2F and then the other part by FFD. They proved an APR of $\frac{3}{4}$ for this hybrid.

Coming to the on-line case, Azar et al. [9] (see also [8]) studied the behavior of so-called fair and unfair algorithms. When there is a fixed number of bins, an on-line algorithm is *fair* if it rejects an item only if it does not fit in any bin, while an *unfair* algorithm is allowed to discard an item even if it fits. They show that an unfair algorithm may get better performance compared with the performance achieved by the fair version. In particular, they show that an unfair variant of

First-Fit can pack approximately $2/3$ of the items for sequences for which an optimal off-line algorithm can pack all the items, while the standard (fair) First-Fit algorithm has an asymptotically tight performance arbitrarily close to $5/8$. Later, Epstein and Favrholdt [74] proved that the APR of any fair, deterministic algorithm is $\frac{1}{2} \leq R_A \leq \frac{2}{3}$ and that a class of algorithms including BF has an APR of $\frac{n}{2n-1}$.

6.3 Maximizing the Number of Full Bins

In this variant of the problem, the objective is to pack a list of items into a maximum number of bins subject to the constraint that the content of each bin be no less than a given threshold T . Each such bin is said to be full. Potential practical applications are (i) the packing of canned goods so that each can contains at least its advertised net weight and (ii) the stimulation of economic activity during a recession by allocating tasks to a maximum number of factories, all working at or beyond the minimal feasible level.

This problem is yet another dual of bin packing. A comprehensive treatment can be found in Assmann's Ph.D. thesis [5]; Assmann's collaboration with Johnson, Kleitman and Leung (see [6]) established the main results. They first analyzed an on-line algorithm, a dual version of NF (*Dual Next-Fit*, DNF): pack the elements into the current bin B_j until $s(B_j) \geq T$, then open a new empty bin B_{j+1} as the current bin. If the current bin is not full when all items have been packed, then merge its contents with those of other full bins. All on-line algorithms are allowed this last repacking step to ensure that all bins are full. It is proved in [6] that $\tilde{R}_{\text{DNF}}^\infty = \frac{1}{2}$, where

$$\tilde{R}_A^\infty = \liminf_{m \rightarrow \infty} \left(\min \left\{ \frac{A(L)}{\text{OPT}(L)} : \text{OPT}(L) = m \right\} \right).$$

Assmann et al. [6] also studied a parametrized dual of FF, called *Dual First-Fit* (DFF[r]). Given a parameter r ($1 < r < 2$), the current item a_i is packed into the first bin B_j for which $c(B_j) + s_i \leq rT$. If there are at least two nonempty and unfilled bins (i.e., bins B_j with $0 < c(B_j) < T$) when all items have been packed, an item is removed from the rightmost such bin and added to the leftmost, thus filling it. Finally, if a single nonempty and unfilled bin remains, then its contents are merged with those of previously packed bins. It was shown that $\tilde{R}_{\text{DFF}[r]}^\infty = \frac{1}{2}$, although a better bound might have been expected. But some years later, Csirik and Totik proved that DNF is optimal among the on-line algorithms.

Theorem 46 (Assmann et al. [6] and Csirik and Totik [61]) $\tilde{R}_{\text{DFF}[r]}^\infty = \frac{1}{2}$ and there is no on-line dual bin packing algorithm A for which $\tilde{R}_A^\infty > \frac{1}{2}$.

Turning now to off-line algorithms, first consider the observation of Assmann et al. [6] that presorting does not help the adaptations of algorithms Next-Fit Decreasing and Next-Fit Increasing, for which $\tilde{R}_{\text{NFD}}^\infty = \tilde{R}_{\text{NFI}}^\infty = \frac{1}{2}$. On the other hand, the

off-line version DFFD[r] of DFF[r], obtained by presorting the items according to nonincreasing size, has better performance.

Theorem 47 (Assmann et al. [6]) $\tilde{R}_{\text{DFFD}[r]}^{\infty} = \frac{2}{3}$ if $\frac{4}{3} < r < \frac{3}{2}$ and $\lim_{r \rightarrow 1} \tilde{R}_{\text{DFFD}[r]}^{\infty} = \lim_{r \rightarrow 2} \tilde{R}_{\text{DFFD}[r]}^{\infty} = \frac{1}{2}$.

The *Iterated Lowest-Fit Decreasing* (ILFD) algorithm was also investigated in [6]. It is analogous to algorithm IFFD described in Sect. 6.2. The items are preordered by nonincreasing size. At each iteration, a prefixed number m of bins is considered, and a Lowest-Fit packing is obtained by iteratively assigning the current item to the bin with minimum contents. Binary search on m determines the maximum value for which all m bins are filled. Since n is an obvious upper bound on the optimal solution value, it is easily seen that the algorithm has $O(n \log^2 n)$ time complexity. Moreover,

Theorem 48 (Assmann et al. [6]) $\tilde{R}_{\text{ILFD}}^{\infty} = \frac{3}{4}$.

It is not difficult to see that DNF does not produce optimal packings even when (L, C) is strongly divisible. However, the following optimality results hold.

Theorem 49 (Coffman et al. [51]) *If (L, C) is strongly divisible, then the dual version of NFD (DNFD) produces an optimal packing. For weakly divisible lists, DNFD is no longer optimal, but ILFD is.*

Concerning approximation schemes for the dual bin packing problem, first observe that the approach used by Fernandez de la Vega and Lueker [84] and Karmarkar and Karp [132] (see Sect. 4.3), which eliminates the effect of small items on worst-case behavior, does not appear applicable, as in the dual problem, small items can play an important role in filling small gaps. Csirik et al. [65] have given a PTAS for this problem. Later, an FPTAS was presented by Jansen and Solis-Oba [124].

7 Variations on Item Packing

7.1 Dynamic Bin Packing

The idea of *Dynamic Bin Packing* (DBP) was introduced by Coffman et al. [49]. In the case of dynamic packing, deletion of some elements is allowed at each step, and $A(L)$ is defined as the maximum number of bins used during the packing.

Consider the generalization in which each item a_i is characterized by a triple (s_i, b_i, d_i) , where b_i is the start (arrival) time, d_i (with $d_i > b_i$) is the departure time, and, as usual, s_i is the size. Item a_i remains in the packing during the time interval $[b_i, d_i]$. Assume that $b_i \leq b_j$ if $i < j$. The problem calls for the minimization

of the maximum number, $OPT_D(L)$, of bins ever required in dynamically packing list L when repacking of the current set of items is allowed each time a new item arrives. More formally, if $A(L, t)$ denotes the number of bins used by algorithm A to pack the current set of items at time t , the objective is to minimize

$$A(L) = \max_{0 \leq t \leq b_n} A(L, t).$$

Note that, in this case, an open bin can later become empty, so the classical open/close terminology is no longer valid. The definition of the APR is straightforward:

$$R_A^\infty = \lim_{n \rightarrow \infty} \sup \left\{ \frac{A(L)}{OPT_D(L)} : |L| = n \right\}.$$

The problem models an important aspect of multiprogramming operating systems: the dynamic memory allocation for paged or other virtual memory systems (see, e.g., Coffman [42]), or data storage problems where the bins correspond to storage units (e.g., disk cylinders or tracks), and the items correspond to records which must be stored for certain specified periods of time (see Coffman et al. [49]).

Research on dynamic packing is at the boundary between bin packing and dynamic storage allocation. The most significant difference between the two areas lies in the repacking assumption of dynamic bin packing; repacking is disallowed in dynamic storage allocation, so fragmentation of the occupied space can occur. Coffman et al. [49] studied two versions of the classical FF algorithm. The first is a direct generalization of the classical algorithm. The second is a variant (*Modified First-Fit*, MFF) in which the elements with $s_i \geq \frac{1}{2}$ are handled separately, in an attempt to pair each of them with smaller elements.

Theorem 50 (Coffman et al. [49]) *If $\frac{1}{k+1} < \max\{s_i\} \leq \frac{1}{k}$, then*

$$\frac{11}{4} \leq R_{\text{FF}}^\infty(k) \leq \frac{5}{2} + \frac{3}{2} \ln \frac{\sqrt{13}-1}{2} = 2.89674 \dots \text{ if } k = 1;$$

$$\frac{k+1}{k} + \frac{1}{k^2} \leq R_{\text{FF}}^\infty(k) \leq \frac{k+1}{k} + \frac{1}{k-1} \ln \frac{k^2}{k^2-k+1} \text{ if } k \geq 2;$$

$$2.77 \leq R_{\text{MFF}}^\infty(1) \leq \frac{5}{2} + \ln \frac{4}{3} = 2.78768 \dots$$

For $k = 2$, one gets $\frac{7}{4} \leq R_{\text{FF}}^\infty(2) \leq 1.78768 \dots$. Although these results are worse than their classical counterparts, relative performance is much better than one might think. This can be seen in the following lower bounds.

Theorem 51 (Coffman et al. [49]) *For any on-line dynamic bin packing algorithm A , $R_A^\infty \geq \frac{5}{2}$ and $R_A(k) \geq 1 + \frac{k+2}{k(k+1)}$ if $k \geq 2$, which gives $R_A(2) \geq 1.666 \dots$*

By restricting attention to strongly divisible instances (see Sect. 8.1), then matters improve, as expected. The gap between the general lower bound and that for FF disappears. Indeed,

Theorem 52 (Coffman et al. [51]) *If (L, C) is strongly divisible and L is such that $s_1 > s_2 > \dots > s_k$ ($k \geq 2$), then the APR of the dynamic version of FF is*

$$R_{\text{FF}}^{\infty} = \prod_{i=1}^{k-1} \left(1 + \frac{s_i}{C} - \frac{s_{i+1}}{C} \right).$$

Moreover, for any on-line algorithm A that operates only on strongly divisible instances, $R_A^{\infty} \geq R_{\text{FF}}^{\infty}$.

By a straightforward inductive argument, it can be shown that the continued product has the upper bound

$$\lim_{k \rightarrow +\infty} \left(1 + \frac{1}{2^{k-2}} \right) \prod_{i=1}^{k-2} \left(1 + \frac{1}{2^i} \right) = 2.384 \dots$$

Other algorithms were developed, which, in addition to deletion, allow at least one of the following capabilities: repacking, look ahead, and preordering. For those algorithms which may use all of the above operations, Ivkovic and Lloyd [122] (see also [120]) introduced the *fully dynamic bin packing* (FDBP) term and presented an algorithm, MMP, which is $\frac{5}{4}$ -competitive.

7.2 Selfish Bin Packing

Consider the case in which the items are controlled by selfish agents, and the cost of a bin is split among the agents in proportion to the fraction of the occupied bin space their items require. Namely, if an agent packs its item a of size $s(a)$ into bin B , then its cost is $\frac{s(a)}{c(B)}$, where $c(B)$ is the content of the bin. In other words, the selfish agents would like their items to be packed in a bin that is as full as possible. Hence, given a feasible solution, the agents are interested in bins B' such that $s(a) + c(B') \leq 1$ and $\frac{s(a)}{s(a)+c(B')} < \frac{s(a)}{c(B)}$. If such a bin exists, then a unilaterally migrates from B to B' , as in this new feasible packing its cost decreases. When no such bin exists for any agent, a stable state has been reached. The *social optimum* is to minimize the number of bins used, which is the aim of the standard BP problem.

This problem corresponds to a noncooperative game, and the stable state is a pure *Nash Equilibrium* (NE). There is a *Strong Nash Equilibrium* (SNE) if there is no subset of agents, which can profit by jointly moving their items to different bins so that all agents in the subset obtain a strictly smaller cost.

More precisely, a noncooperative strategic game is a tuple $G = \langle N, (S_i)_{i \in N}, (c_i)_{i \in N} \rangle$ where N is a finite set of players. Each player has a finite set S_i of strategies and a cost function c_i , and each player has complete information about the strategy of all players. Players choose their strategies independently

of each other. A combination of strategies chosen by the players is denoted by $s = (x_j)_{j \in N} \in \times_{j \in N} S_j$ and is called a *strategy profile*. The *social cost* of a game is an objective function $SC(s) : X \rightarrow \mathbb{R}$, that gives the cost of an outcome of the game for a strategy profile $s \in X$, where X denotes the set of all strategy profiles. The *social optimum* of the game is then $OPT(G) = \min_{s \in X} SC(s)$.

The quality of an NE is measured by the *Price of Anarchy* (PoA) and the *Price of Stability* (PoS), which are defined as follows:

$$PoA = \sup_{s \in NE(G)} \frac{SC(s)}{OPT(G)} \quad PoS = \inf_{s \in NE(G)} \frac{SC(s)}{OPT(G)}.$$

By using the SNE, one gets the *Strong Price of Anarchy* (SPoA) and the *Strong Price of Stability* (SPoS):

$$SPoA = \sup_{s \in SNE(G)} \frac{SC(s)}{OPT(G)} \quad SPoS = \inf_{s \in SNE(G)} \frac{SC(s)}{OPT(G)}.$$

For the bin packing problem asymptotic measures are used:

$$PoA(BP) = \limsup_{OPT(G) \rightarrow \infty} \sup_{G \in BP} PoA(G) \quad PoS(BP) = \limsup_{OPT(G) \rightarrow \infty} \inf_{G \in BP} PoS(G)$$

and

$$SPoA(BP) = \limsup_{OPT(G) \rightarrow \infty} \sup_{G \in BP} SPoA(G) \quad SPoS(BP) = \limsup_{OPT(G) \rightarrow \infty} \inf_{G \in BP} SPoS(G).$$

To stress the connection with game theory the problem is called the *bin packing game*. The first publication which discussed this problem from a game theoretical perspective was presented by Biló (see [25]). He showed that starting from an arbitrary feasible packing, one can always reach an NE using an exponential number of migration steps. This result implies that, for every instance of the bin packing game, there exists an optimal packing which provides a NE, that is, $PoS(BP) = 1$. He also proved that computing the best NE is $\mathcal{NP-hard}$. Yu and Zhang [181] constructed an $O(n^4)$ -time Recursive First-Fit Decreasing (RFFD) algorithm for finding an NE. They also investigated the $PoA(BP)$ and proved the following theorem:

Theorem 53 (Yu and Zhang [181]) *For the bin packing game,*

$$1.6416 \approx \sum_{l=1}^{\infty} \frac{1}{2^{\frac{l(l-1)}{2}}} \leq PoA(BP) \leq \frac{41 + \sqrt{145}}{32} \approx 1.6575.$$

Epstein and Kleiman [76] improved the upper bound to 1.64286 and conjectured that the best bound is equal to the lower bound.

Bin packing algorithms look for a good global solution; hence, in general, they do not produce a Nash equilibrium. An exception is the *Subset Sum* (SS) algorithm by Caprara and Pferschy [34], which produces an NE by repeatedly solving a knapsack problem to pack a bin as full as possible. Unfortunately, the knapsack problem is not polynomial unless $\mathcal{P} = \mathcal{NP}$. Indeed, Epstein and Kleiman [76] on the one hand proved equality among the $SPoS(BP)$ and the $SPoA(BP)$ and the asymptotic behavior of the Subset Sum algorithm and on the other hand showed that finding an SNE is \mathcal{NP} -hard.

Caprara and Pferschy proved that $1.6062 \leq R_{SS}^{\infty} \leq 1.6210$. So, by comparing $PoA(BP)$ and $SPoA(BP)$, it appears that they have similar values. Therefore, the efficiency in the bin packing game is only due to selfishness, and coalitions do not help. In addition, $PoS(BP)$ is significantly better than $SPoS(BP)$, which in turn equals $SPoA(BP)$, implying that in the bin packing game the best equilibrium is less efficient if coalition among agents is allowed.

7.3 Bin Packing with Rejection

This variation is motivated by the following problem, arising in file management. Suppose that files are used by a local system. Either a file is downloaded in advance or the system downloads it only when it is actually requested. The first option needs space on a local server, and it has a local transmission cost, while a program uses the file. The second option has a communication cost that one incurs, while the system downloads the file from an external server. An algorithm which manages the local file system has the choice of either packing a file (item) on the local storage device or (according to the costs) downloading it when needed. The problem can be modeled as the following bin packing problem. A pair (s_i, r_i) is associated with each item i ($i = 1, \dots, n$), where s_i is the size and r_i is the *rejection cost* of the item. An algorithm has the choice of either packing an element into the bins or rejecting it. The objective is to minimize the number of bins used, plus the sum of all rejection costs. (If all rejection costs are larger than 1 then every item will be packed, and a standard problem arises.) This model was introduced by Dósa and He [69], who considered both off-line and on-line algorithms, and investigated their absolute and asymptotic behavior.

For off-line algorithms, Dósa and He gave an algorithm with absolute worst-case ratio 2. They also observed that the lower bound for the standard problem remains valid, that is, there is no algorithm with absolute worst-case ratio better than $\frac{3}{2}$, unless $\mathcal{P} = \mathcal{NP}$. The lower bound was reached by Epstein [73] (see also [70]). Based on the ratio r_i/s_i , Dósa and He classified the elements into subclasses and used a sophisticated greedy-type algorithm, RFF4, for which they proved that $R_{RFF4}^{\infty} \leq \frac{3}{2}$.

For the on-line case, they investigated an algorithm, called RFF1, and proved that the absolute worst-case ratio of the best on-line algorithm lies in the interval (2.343, 2.618). For the asymptotic competitive ratio, they introduced another algorithm, RFF2, and proved the following:

Theorem 54 (Dósa and He [69]) *For any positive integer $m \geq 2$, $R_{RFF_2}^\infty(m) \leq \frac{7m-3}{4m-2}$. Hence there exists an on-line algorithm with an APR arbitrarily close to $7/4 = 1.75$.*

Not surprisingly, this result was beaten by a variant of the HF algorithm proposed by Epstein [73]. Her RejH_k algorithm classifies the items as HF. Then thresholds are defined for the rejection choice as follows. Suppose that the next item is $a_i \in I_j$, where $I_j = (\frac{1}{j+1}, \frac{1}{j}]$ for some $1 \leq j \leq k$. Item a_i will be rejected if either $j = k$ and $r_i \leq \frac{k}{k-1}s_i$ or $j < k$ and $r_i \leq \frac{1}{j}$. Using the weighting function technique, Epstein proved the following theorem.

Theorem 55 (Epstein [73]) *The APR of RejH_k tends to $h_\infty(1) = 1.6901$ if $k \rightarrow \infty$. No algorithm with a constant number of open bins can have a smaller APR.*

For the unbounded-space case, the latter result was improved by a *Rejective Modified Harmonic* (MHR) algorithm, which is an adaptation of the Modified Harmonic analyzed by Ramanan et al. [159]:

Theorem 56 (Epstein [73]) *The APR of MHR is at most $\frac{538}{333}$.*

Starting from the classical results of Fernandez de la Vega and Lueker [84] and Hochbaum and Shmoys [118], Epstein [73] also proposed an APTAS for bin packing with rejection, having time complexity $O(n^{O((\varepsilon^{-4})^{\varepsilon}-1)})$. Using some results on the multiple knapsack problem (see Chekuri and Khanna [40] and Kellerer [134]) a faster, $O(n^{O(\varepsilon^{-2})})$ time, approximation scheme was constructed by Bein et al. [21].

7.4 Item Fragmentation

Menakerman and Rom [155] investigated a variant of the bin packing problem in which items may be subdivided into pieces of smaller size, called *fragments*. Fragmenting an item is associated with a cost, which makes the problem \mathcal{NP} -hard. They studied two possible cost functions. In the first variant, called *Bin Packing with Size-Increasing Fragmentation* (BP-SIF), whenever an item is fragmented, overhead units are added to the size of every fragment. In the second variant, called *Bin Packing with Size-Preserving Fragmentation* (BP-SPF), each item has a size and a cost, and, whenever it is fragmented, one overhead unit is added to its cost without changing its total size. (Actually, problem BP-SIF was first introduced by Mandal et al. [150] who showed that it is \mathcal{NP} -hard.)

It is supposed that the item sizes are positive integers and the bins are all of size C . It is obvious that a good algorithm should try to perform the minimum number of fragmentations. Menakerman and Rom developed algorithms that do not fragment items unnecessarily. More precisely, an algorithm is said to prevent unnecessarily fragmentation if it follows the next two rules:

1. No unnecessary fragmentation: An item (or a fragment of an item) is fragmented only if it must be packed into a bin that cannot contain it. In case of fragmentation, the item (or fragment) is divided into two fragments. The first fragment must fill one of the bins, while the second is packed according to the rules of the algorithm.
2. No unnecessary bins: An item is packed into a new bin only if it cannot fit in any of the open bins.

For the BP-SIF problem, it is proved that for any algorithm A that prevents unnecessary fragmentation, $R_A^\infty \leq \frac{C}{C-2}$ for every $C > 2$. For the obvious generalization of the Next-Fit algorithm, called *Next-Fit with item fragmentation* (NF_f), a $\frac{C}{C-2}$ bound for all $C \geq 6$ was proved. For a more sophisticated algorithm, which is actually an iterated version of First-Fit Decreasing, they proved that the APR is not greater than $\frac{C}{C-1}$ when $C \leq 15$, while it is between $\frac{C}{C-1}$ and $\frac{C}{C-2}$ when $C \geq 16$.

As to the BP-SPF problem, the performance of an algorithm for a given list L , $OH_A(L)$ is measured by its overhead, that is, by the difference between the cost of the solution produced by the algorithm and the cost of an optimal solution. The worst-case performance of an algorithm is

$$OH_A^m = \inf\{h : OH_A(L) \leq h \text{ for all } L \text{ with } OPT(L) = m\}.$$

Menakerman and Rom [155] proved that for any algorithm A that prevents unnecessary fragmentation, $OH_A^m \leq m - 1$ and that an appropriate modification of Next-Fit reaches this bound. First-Fit Decreasing performs better when the bin size is small.

Naaman and Rom [158] considered two generalizations of the BP-SPF. The first one is quite simple: r overhead units are added to the size of every fragment. This changes the performance of Next-Fit to $\frac{C}{C-2r}$. The other generalization is more challenging: a set B of m bins is given, whose (integer) bin sizes may be different. Denote by $\bar{C} = \frac{1}{m} \sum_{j=1}^m s(B_j)$ the average bin size. In this case, the asymptotic worst-case bound for Next-Fit is $\frac{\bar{C}}{\bar{C}-2r}$ for every $\bar{C} > 4r$.

Shachnai et al. [168] studied slightly modified versions of BP-SIF and BP-SPF. For the BP-SIF, a header of fixed size Δ is attached to each (whole or fragmented) item, that is, the size required for packing a_i is $s_i + \Delta$. When an item is fragmented, each fragment gets the header. For the BP-SPF, the number of possible splits is bounded by a given value. They presented a dual PTAS and an APTAS for each of the problems. The dual PTASs pack all the items in $OPT(L)$ bins of size $(1 + \varepsilon)$, while the APTASs use at most $(1 + \varepsilon)OPT(L) + 1$ bins. All of these schemes have running times that are polynomial in n and exponential in $1/\varepsilon$. They also showed that both problems admit a dual AFPTAS, which packs the items in $OPT(L) + O(1/\varepsilon^2)$ bins of size $1 + \varepsilon$. Shachnai and Yehezkely [167] developed fast AFPTASs for both problems. Their schemes pack the items in $(1 + \varepsilon)OPT(L) + O(\varepsilon^{-1} \log \varepsilon^{-1})$ bins in a time that is linear in n and polynomial in $1/\varepsilon$.

Epstein and van Stee [81] investigated a version where the items may be split without extra cost, but each bin may contain at most k (parts of) items, for a given constant k . They provided a polynomial-time approximation scheme and a dual approximation scheme for this problem.

7.5 Fragile Objects

Bansal et al. [17] (see also [16]) investigated two interrelated optimization problems: bin packing with fragile objects and frequency allocation in cellular networks (which is a special case of the former problem). In this problem, each item has two attributes: size and fragility. The goal is to pack the items so that the sum of the item sizes in each bin is not greater than the fragility of any item in the bin. They provided a 2-approximation algorithm for the problem of minimizing the number of bins and proved a lower bound of $\frac{3}{2}$ on the asymptotical approximation ratio. They also considered the approximation with respect to fragility and gave a 2-approximation algorithm.

Chan et al. [35] considered the on-line version of the problem and proved that the asymptotic competitive ratio of any on-line algorithm is at least 2. They also considered the case where the ratio between maximum and minimum fragility is bounded by a value k , showing that the APR of an Any-Fit algorithm (including First-Fit and Best-Fit) is at least k . For the case where k is bounded by a constant, they developed a class of on-line algorithms which achieves an APR of $\frac{1}{4} + 3\frac{r}{2}$ for any $r > 1$.

7.6 Packing Sets and Graphs

Let the bin capacity C be a positive integer and suppose that the items are sets of elements drawn from some universal set. A collection of items can fit into a bin if and only if their union has at most C elements. As usual, the object is to pack the items in the smallest number of bins. Good approximation algorithms have yet to be analyzed for this problem; adaptations of the classical bin packing approximation algorithms do not have finite APRs. One observes immediately that while classical algorithms prioritize items based on cardinality and position in sequence, a good algorithm for set packing will have to consider the intersections among a given set of items, an orthogonal basis for prioritizing the items. It is thought that approximation algorithms with a finite APR for this problem are unlikely to exist, but a rigorous treatment of this question has yet to appear.

Dror (Dror, Private communication) points out that scheduling setups in a manufacturing process is an application of set packing. As an example, he describes a machine that produces many types of circuit boards, each requiring a given set of components. The machine has a magazine (bin) that holds at most C components. At any time, only the circuit boards with their component sets (items) in the magazine

can be in production. The problem is to plan the overall production process so as to minimize the number of setups.

Khanna (Khanna, Private communication) mentions that, in connection with studies of multimedia communications, graph packing is an interesting special case. Items are edges (pairs of vertices) in a given graph G . An edge is packed in a bin if both of the vertices to which it is incident are in the bin, and so the problem is to pack the edges of G into as few bins as possible subject to the constraint that there can be at most C vertices in any bin. The approximability of this problem has yet to be studied.

Katona [133] investigated a special case of graph packing. A graph is called *p-polyp* if it consists of p simple paths of the same length and sharing a common end vertex. *Polyp Packing* is the following generalization of bin packing: pack a set of paths of different lengths into a minimum number of edge disjoint polyps. He proved that the problem is \mathcal{NP} -hard and gave bounds on the performance of a modification of First-Fit.

8 Additional Conditions

8.1 Item-Size Restrictions

Perhaps the simplest (and most practical) restriction is simply to have a finite number k of item sizes, say s_1, \dots, s_k , and thus a finite number N of feasible item configurations in a bin. This class of problems arose in studies on approximation schemes (see [84, 132]) and was considered in its own right by Blazewicz and Ecker [26]. Let the i -th configuration be denoted by $p_i = (p_{i1}, \dots, p_{ik})$ where p_{ij} is the number of items of size s_j in p_i . By the definition of feasibility, $\sum_{j=1}^k p_{ij} s_j \leq 1$ for all i . Let y_i be the number of bins in a packing of a given list L that contain configuration p_i , and let n_j be the number of items of size s_j in L . Then a solution to the bin packing problem for L is a solution to the integer programming formulation:

$$\begin{aligned} \min & \sum_{i=1}^N y_i \\ \text{subject to } & \sum_{i=1}^N p_{ij} y_i \geq n_j \quad (j = 1, \dots, k) \\ & y_i \geq 0 \text{ and integer } (i = 1, \dots, N). \end{aligned}$$

Note that, if $\frac{1}{r}$ lower bounds the item sizes, then $N = O(k^{r-1})$, so the constraint matrix above has k rows and $O(k^{r-1})$ columns. This problem can be solved in time polynomial in the number of constraints (see Lenstra [144]), which is a constant independent of the number of items. The optimal overall packing can then be constructed in linear time.

If the exact solution is not needed, then one can use the classical approach of Gilmore and Gomory [105, 106]) and compute LP relaxations (see Sect. 4.3); this method gives solutions that are at most k off the optimal in significantly less time.

Gutin et al. [113] investigated an on-line problem in which one only has two different element sizes. They gave a $\frac{4}{3}$ lower bound for this problem and provided an asymptotically optimal algorithm for it. Epstein and Levin [77] focused on the parametric case, where both item sizes are bounded from above by $\frac{1}{k}$ for some natural number $k \geq 1$.

Next consider the classical problem restricted to lists L of items whose sizes form a *divisible sequence*, that is, the distinct sizes $s_1 > s_2 > \dots$ taken on by the items are such that s_{i+1} divides s_i for all $i \geq 1$. The number of items of each size is arbitrary. Given the bin capacity C , the pair (L, C) is *weakly divisible* if L has divisible item sizes and *strongly divisible* if in addition the largest item size s_1 in L divides C .

This variant has practical applications in computer memory allocation, where device capacities and memory block sizes are commonly restricted to powers of 2. It is important to recognize such applications when they are encountered, because approximation algorithms for many types of \mathcal{NP} -hard bin packing problems generate significantly better packings when items satisfy divisibility constraints. In some cases, the restriction leads to algorithms that are asymptotically optimal. The problem was studied by Coffman, Garey, and Johnson, who proved the following result for classical off-line algorithms.

Theorem 57 (Coffman et al. [51]) *If (L, C) is strongly divisible, then NFD and FFD packings are optimal.*

Indeed, the residual capacity in a bin is always either zero or at least as large as the last (smallest) item packed in the bin. The last packed item is at least as large as any remaining (unpacked) item, so either the bin is totally full or it has room for the next item. Therefore, the FFD and NFD algorithms have the same behavior: they initialize a new bin only when the previous one is totally full, so the packings they produce are identical and perfect.

The optimality of FFD holds in the less restrictive case of the following theorem as well.

Theorem 58 (Coffman et al. [51]) *If (L, C) is weakly divisible, then an FFD packing is always optimal.*

For strongly divisible instances, optimal performance can also be obtained without sorting the items.

Theorem 59 (Coffman et al. [51]) *If (L, C) is strongly divisible, then an FF packing is always optimal.*

In the *Unit-Fractions Bin Packing Problem*, n items are given, and the size of each item i is $\frac{1}{w_i}$, with w_i a positive integer ($1 \leq i \leq n$). This problem was initially studied by Bar-Noy et al. [18]. Let $H = \lceil \sum_{i=1}^n \frac{1}{w_i} \rceil$ be a lower bound on the required number of bins. They presented an off-line algorithm which uses at most $H + 1$ bins. For the on-line version, they analyzed an algorithm which uses $H + O(\sqrt{H})$ bins. It is also proved that any on-line algorithm for the unit-fractions bin packing problem uses at least $H + \Omega(\ln H)$ bins.

Dynamic bin packing problems with unit-fractions items were considered by Chan et al. [36]. They investigated the family of Any-Fit algorithms and proved the following results:

$$R_{\text{BF}}^\infty = R_{\text{WF}}^\infty = 3$$

$$2.45 \leq R_{\text{FF}}^\infty \leq 2.4985.$$

In addition they proved the following lower bound result:

Theorem 60 (Chan et al. [36]) *For a dynamic bin packing problem with unit-fractions items, there is no on-line algorithm A with $R_A^\infty < 2.428$.*

It would be interesting to examine how approximation algorithms behave with other special size sequences (e.g., Fibonacci numbers), as mentioned by Chandra et al. [39] in the context of memory allocation.

8.2 Cardinality Constrained Problems

The present section deals with the generalization in which the maximum number of items packed into a bin is bounded by a positive integer p . The problem has practical applications in multiprocessor scheduling with a single resource constraint, when the number p of processors is fixed, or in multitasking operating systems where the number of tasks is bounded. If the maximum number of items in a bin is bounded by p , then the problem is called the *p-Cardinality Constrained Bin Packing Problem*. Observe which is the difficulty when one tries to construct a good algorithm for this problem. Without the cardinality constraint, a huge number of small elements slightly affect the number of occupied bins: either they can be packed together into few bins, or they can be packed into bins which are “almost full.” In the considered case, having packed many small elements results in almost empty bins, because of the cardinality constraint. Therefore, when a large item arrives, it has to be packed into a new bin even if it would fit into an already open bin.

In the context of the above applications, Krause et al. [139] modified classical algorithms so as to deal with the restricted number of items per bin. Their on-line algorithm, pFF, is FF with an additional check on the number of items in open bins. They proved that if $p \geq 3$, then

$$\frac{27}{10} - \frac{37}{10p} \leq R_{\text{pFF}}^{\infty} \leq \frac{27}{10} - \frac{24}{10p}.$$

As p tends to ∞ , the bound is much worse than the corresponding APR of the unrestricted problem (2.7 versus 1.7). Whether this upper bound can be improved remains an open question.

On-line algorithms were also studied by Babel et al. [11] (see also [10]), who investigated four algorithms, denoted as A_1, \dots, A_4 .

- Algorithm A_1 operates with the BF strategy while packing the subsequent element. Different classes of blocked bins are defined according to the number of items in a bin. The algorithm tries to pack the element first into all blocked bins that satisfy a threshold condition, then into all formerly blocked and currently unblocked bins, and finally into the remaining bins. It is proved that for every $p \geq 3$,

$$R(p) = 2 + \frac{p + k_p(k_p - 3)}{(p - k_p + 1)k_p}, \quad \text{where} \quad k_p = \left[\frac{-p + \sqrt{p^3 - 2p}}{p - 2} \right],$$

so $\lim_{p \rightarrow \infty} A_1 = 2$.

- In algorithm A_2 , a bin is closed if $c(B) \geq \frac{1}{2}$ and it contains at least $\frac{p}{2}$ items. Furthermore, a pair of bins, B_1 and B_2 , is also closed if $c(B_1) + c(B_2) \geq 1$ and $|B_1| + |B_2| \geq k$. The open bins are subdivided into three classes, and the algorithm tries to pack the current item, in turn, into bins of such classes. If the item does not fit in any of these bins, a new bin is open. It is proved that for every $p \geq 3$, algorithm A_2 has an APR of 2.
- Algorithm A_3 deals with the case $p = 2$. The basic idea of the algorithm is that, when a small item is packed, a balance should be kept between the number of bins with only one small item and the number of bins which have two such items. It is proved that $R_{A_3} = 1 + \frac{1}{\sqrt{5}}$.
- For the 3-cardinality problem, a Harmonic-type algorithm is defined, with four bin classes. The score intervals are as follows: $I_1 = (0; \frac{1}{3}]$, $I_2 = (\frac{1}{3}, \frac{1}{2}]$, $I_3 = (\frac{1}{2}, \frac{2}{3}]$, and $I_4 = (\frac{2}{3}, 1]$. The resulting Algorithm A_4 is a much more complicated version of the classical HF algorithm and has an asymptotic competitive ratio of 1.8.

Two lower bounds are also given:

Theorem 61 (Babel et al. [11]) *There is no 2-cardinality on-line bin packing algorithm A with APR $R_A < \sqrt{2}$.*

Theorem 62 (Babel et al. [11]) *There is no 3-cardinality on-line bin packing algorithm A with APR $R_A < \frac{3}{2}$.*

For unbounded-space algorithms, some further cases were investigated by Epstein [71]. She considered a Harmonic-type algorithm that defines five

subintervals and packs the items into bins with a more sophisticated procedure. Her algorithm for the case $p = 3$ improves the APR of [11] to $\frac{7}{4} = 1.75$. For the cases $p = 4$, $p = 5$ and $p = 6$, she refined the basic algorithm, designing three algorithms with APRs $\frac{71}{38} = 1.86842$, $\frac{771}{398} = 1.93719$, and $\frac{284}{144} = 1.99306$. She proved that an algorithm with an APR strictly better than 2 cannot be bounded space (unless $p \leq 3$).

For the bounded-space case, Epstein defined the *Cardinality Constrained Harmonic- p* (CCHp) algorithm. She considered the Sylvester sequence, defined the sum

$$S_p = \sum_{i=1}^p \left\{ \frac{1}{t_i - 1}, \frac{1}{p} \right\},$$

and proved the following theorems:

Theorem 63 (Epstein [71]) *The value of S_p is a strictly increasing function of $p \geq 2$ such that $\frac{3}{2} \leq S_p < h_\infty(1) + 1$ and $\lim_{p \rightarrow \infty} S_p = h_\infty(1) + 1 \approx 2.69103$.*

Theorem 64 (Epstein [71]) *For every $p \geq 2$, the APR of CCHp is S_p , and no on-line algorithm which uses bounded space can have a better competitive ratio.*

In addition, Epstein extended her results to the variable-sized and the resource-augmentation cases (see Sects. 5.1 and 5.2).

An off-line algorithm (*Largest Memory First*, LMF), based on an adaptation of FFD, was studied by Krause et al. [139]. They proved that $R_{\text{LMF}}^\infty = 2 - \frac{2}{p}$ if $p \geq 2$. Here the gap between the unrestricted and the restricted case is large (2 versus $\frac{11}{9}$). The authors' search for an algorithm with better worst-case behavior resulted in the *Iterated Worst-Fit Decreasing* (IWFD) algorithm. IWFD starts by sorting the items according to nonincreasing size, and by opening q empty bins, where $q := \lceil \max(\frac{n}{p}, \sum_{i=1}^n s_i) \rceil$ is an obvious lower bound on $OPT(L)$. Then (i) IWFD tries to place the items into these q bins using the Worst-Fit rule (an item is placed into the open bin whose current number of items is less than p and whose current content is minimum, breaking ties by highest bin index); (ii) whenever the current item a_i does not fit in any of the q bins, q is increased by 1, all items are removed from the bins and the processing is restarted from (i). If one implements this approach using a binary search on q , the time complexity of IWFD is $O(n \log^2 n)$. Krause, Shen, and Schwetman proved that the algorithm behaves very well in certain special cases:

- If $p = 2$, then $IWFD(L) = OPT(L)$ for any list L .
- If in the final schedule no capacity constraint is operative, that is, no open bin has residual capacity smaller than the size of the smallest item, then $IWFD(L) = OPT(L)$.
- If in the final schedule no cardinality constraint is operative, that is, no open bin containing p items has residual capacity at least equal to the size of the smallest item, then $R_{\text{IWFD}}^\infty < \frac{4}{3}$.

For the general case, where the final packing contains both bins for which the capacity constraint is operative and bins for which it is not, the constants are

significantly worse but still small: $\frac{4}{3} \leq R_{\text{IWFD}}^{\infty} \leq 2$. The authors conjecture that $R_{\text{IWFD}}^{\infty} = \frac{4}{3}$.

For a long time, it was an open question whether there exists a heuristic algorithm with an APR better than 2. Kellerer and Pferschy [135] proposed a new algorithm based on a method that proved to be fruitful in scheduling theory, namely, one that performs a binary search on the possible $OPT(L)$ values. At each search step, they run a procedure that tries to pack all items into a number of bins equal to $\frac{3}{2}$ times the current search value. The procedure basically tries to solve a multiprocessor scheduling problem using the classical LPT rule with a cardinality constraint. The time complexity of this *Binary Search* (BS) algorithm is $O(n \log^2 n)$, and the improved bound is $\frac{4}{3} \leq R_{\text{BS}}^{\infty} \leq \frac{3}{2}$. Although the gap has been reduced, the exact bound is still not known.

8.3 Class Constrained Bin Packing

In the *Class Constrained Bin Packing Problem* (CLCP), each item a_i has two parameters: the size s_i and the color c_i , where $s_i \in (0, 1]$ and a color is represented by a positive integer, that is, $c_i \in [1, q]$. A further parameter $Q \in \mathbb{N}$ is associated with the problem as a bound for the number of the different colors within a bin. Different items may have the same color, and the items with the same color are classified into *color classes*. The objective is to pack the items into the minimum number of bins $\{B_1, B_2, \dots, B_m\}$, such that $\sum_{a_j \in B_i} s_j \leq 1$ for $i = 1, \dots, m$ and each such bin has items from at most Q color classes. Clearly, if $q = n$, then one gets the p -cardinality constrained problem (see Sect. 8.2), and if $q \leq Q$, then a classical bin packing problem arises. Shachnai and Tamir [165] proved that the problem is \mathcal{NP} -hard even in the case of identical item sizes.

For the case of on-line bounded-space algorithms, Xavier and Miyazawa [176] presented inapproximability results. More precisely, they proved that if $s_i \in [K_1, K_2]$, with $0 < K_1 < K_2 \leq 1$, for all $i = 1, \dots, n$, then any bounded-space on-line algorithm has an APR of $\Omega(\frac{1}{QK_1})$.

Shachnai and Tamir [166] studied unbounded-space algorithms for the case of identically sized items. Suppose that $s_i \in (\frac{1}{r+1}, \frac{1}{r}]$ for each a_i : they denoted by $S_{Q,r}(k, h)$ the set of those lists which have $kQ < q \leq (k+1)Q$ and $hr < n \leq (h+1)n$, where n is the number of elements in the list. They proved that for any deterministic algorithm A ,

$$R_A \geq 1 + \frac{k+1 - \lceil \frac{kQ+1}{r} \rceil}{h+1},$$

and that the lower bound can be reached by the FF algorithm.

Sachnai and Tamir also introduced the notion of *Color-Set algorithm* (CS). This algorithm partitions the colors into $\lceil q/Q \rceil$ color sets and packs the items of each color set in a greedy way. Note that only one bin is open for each color-set at a time.

They proved that $R_{CS} < 2$. The set of Any-Fit algorithms was also investigated, and it was shown that $R_A \leq \min(r/Q, Q+1)$ for any such algorithm. They further proved that the absolute worst-case ratio of the Next-Fit algorithm is $R_{NF} = r/Q$.

The idea of CS was used to develop new algorithms. Color classes are divided *on-line* into sets of Q colors each, in order of appearance. Each open bin is assigned one color set. As a new item arrives, the algorithm tries to pack it into a bin having the color of the item. If the FF rule is used, then one gets the *Color-Set First-Fit* (CSFF) algorithm, while the NF rule gives the *Color-Set Next-Fit* (CSNF) algorithm. For the case of identical item sizes considered in [165], the authors proved that the competitive ratio of both CSFF and CSNF is at most 2.

The case $Q = 2$ was exhaustively studied by Epstein et al. [82], who proved that the upper bound for identical items is tight for algorithms FF and CSFF. Furthermore, they showed that, for arbitrary item sizes, the competitive ratio is at least $9/4$. A 1.5652 lower bound was also given for any on-line algorithm with arbitrary item sizes, thus showing that, even if $Q = 2$, the on-line algorithms for CLCP behave worse than those for the classical bin packing. For what concerns upper bounds, they proved that for arbitrary values of Q , $R_{CSFF} \infty \leq 3 - \frac{1}{Q}$.

Xavier and Miyazawa [176] investigated the FF algorithm and proved that $R_{FF} \in [2.7, 3]$. They defined algorithm \mathcal{A}_Q , which subdivides the items, in a harmonic way, into three classes, and packs the next item, according to its size, into the class it belongs to. The algorithm also considers the color constraint Q . It was proved that $R_{\mathcal{A}_Q} \in (2.666, 2.75]$. Epstein et al. [82] developed an algorithm which has a competitive ratio of 2.65492, valid for every Q .

For fixed values of q , there are approximability results for CLCP. Note that, if q is fixed, then Q is also constant since $Q \leq q$. For equal item sizes, Shachnai and Tamir [165] constructed a dual PTAS whose time complexity is polynomial in n . The scheme uses the optimal number of bins, but the bin capacity is $1 + \varepsilon$. Xavier and Miyazawa [176] developed an APTAS. They also gave an AFPTAS with time complexity $O(\frac{n}{\varepsilon^2})$. Epstein et al. [82] proved that if q is considered as a parameter, then there is no APTAS for CLCP for any value of Q . They also gave an AFPTAS for the case of constant q , with time complexity $O(\frac{n}{\varepsilon^2})$.

8.4 LIB Constraints

In certain applications, the positions of the items within a bin are restricted: a larger item cannot be put on top of a smaller one. This leads to the variant with the LIB (Larger Item on the Bottom) constraint. The problem was first discussed by Finlay and Manyem [85] and Manyem et al. [151]. They studied the Next-Fit algorithm and proved that it cannot achieve a finite APR. For the First-Fit algorithm, they showed that $2 \leq R_{FF} \leq 3$. They also analyzed a variant of Harmonic-Fit (HARM) which partitions the items into classes following the classical rule and packs them by applying to each class of bins the FF rule (instead of NF, which performs

very badly). They showed that $2 \leq R_{\text{HARM}}^\infty$. The parametric case of HARM was considered in Epstein [72], who proved the following result:

Theorem 65 (Epstein [72]) *Let $r > 0$ be a positive integer, and suppose that $\frac{1}{r+1} < \max\{s_i\} \leq \frac{1}{r}$. Let k denote the number of bin classes. Then $R_{\text{HARM}}(r) = \Theta(k - r + 1)$ for any fixed value of $k < \infty$.*

This result has an interesting consequence: contrary to the standard problem, for which the performance of the Harmonic-Fit algorithm improves when the number of bin classes is increased, in this case, the competitive ratio worsens, and algorithm HARM has an unbounded ratio as $k \rightarrow \infty$. Unfortunately, neither BF nor WF nor AWF behave better than HARM, that is, their APRs are also unbounded. In the same paper, Epstein analyzed the FF algorithm, proving that $R_{\text{FF}}(1) = 2.5$ and $R_{\text{FF}}(r) = 2 + \frac{1}{r}$ if $r \geq 2$. Very recently, her result was improved by Dósa, Tuza, and Ye (Dósa et al., 2010, Private communication), who proved that $R_{\text{FF}}(1) = 2 + \frac{1}{6}$ and $R_{\text{FF}}(r) = 2 + \frac{1}{r(r+2)}$ if $r \geq 2$.

As to lower bounds, very little is known. Clearly, the FFD algorithm automatically fulfills the LIB constraint, so $\frac{11}{9}$ is a lower bound for any semi-on-line algorithm which packs preordered elements. The only nontrivial lower bound was obtained by Epstein [72]:

Theorem 66 (Epstein [72]) *The competitive ratio of any on-line algorithm for bin packing with LIB constraints is at least 2. The result is valid for the parametric case as well, for any value of $r \geq 1$.*

8.5 Bin Packing with Conflicts

In this problem, a set of items $L = a_1, a_2, \dots, a_n$ with sizes s_1, s_2, \dots, s_n and a conflict graph $G(L, E)$ are given. The objective is to find the minimum number of independent sets such that the sum of the sizes within each set is at most one. The problem is a generalization of both the classical bin packing problem (when $E = \emptyset$) and the graph coloring problem (when $s_i = 0$ for all i). In the on-line version of the problem, when a new item arrives, one gets its size and the edges of the conflict graph which connect it to previous items. Instead of examining the APR, most investigations focused on the absolute worst-case ratio AR, since the conflict graph that proves the worst case is valid both for small and large instances. Therefore, the APR may not be better than the AR.

It is known that graph coloring is hard to approximate for general graphs (see, e.g., Lovász et al. [149]); the problem at hand has been studied for specific graphs. The early studies on the *bin packing with conflicts* (BPC) dealt with *perfect graphs*, since the coloring problem is polynomially solvable for them. Jansen and Öhring [123] gave an algorithm with an APR of 2.7. Epstein and Levin [78] improved this result with an algorithm having the performance guarantee $h_\infty(1) + 1 = 2.690103$.

Jansen and Öhring also proposed an algorithm that uses the so-called *Precoloring Extension Problem* (PEP) as a preprocessing stage to get a partition of the conflict graph. In the PEP, one is given an undirected graph $G = (V, E)$ and k distinct vertices v_1, v_2, \dots, v_k . The aim is to find a minimum coloring f of G such that $f(v_i) = i$ for $i = 1, 2, \dots, k$. The minimum number of colors is denoted by $\chi_I(G)$. The PEP is polynomially solvable for a number of graph classes (interval graphs, forests, K-trees, etc.), whereas it is \mathcal{NP} -hard for bipartite graphs. Let \mathcal{C} be the class of those graphs for which the PEP is polynomially solvable for any induced subgraph of G .

Let $G \in \mathcal{C}$ be a conflict graph and let $BIG = \{a_j \in L : s_j > \frac{1}{2}\}$. The algorithm by Jansen and Öhring uses BIG as the set of pre-colored vertices and then determines a feasible coloring of G using $\chi_I(G)$ colors: in this coloring, each pair of items in BIG has different colors. Finally, it uses a bin packing heuristic for each color class. Denote this algorithm by $\mathcal{A}(H)$, where H is the bin packing heuristic. They proved the following theorem:

Theorem 67 (Jansen and Öhring [123]) *For the BPC problem, the $\mathcal{A}(FFD)$ has a performance ratio $2.4231 = h_\infty(2) + 1 \leq R_{\mathcal{A}(FFD)} \leq 2.5$.*

Later, Epstein and Levin [78] revisited the algorithm, proving that the lower bound of $R_{\mathcal{A}(FFD)}$ is tight. Instead of using the PEP for preprocessing, they used a matching-based preprocessing (MP) algorithm, for which they proved that $R_{MP} = 2.5$, and that the result remains valid for all classes of graphs for which there exists a polynomial-time algorithm to find a coloring with a minimum number of colors. They also suggested a greedy algorithm which tries to pack two or three independent items into a single bin and then applies FFD to each color class. They proved that the approximation ratio of this algorithm is $\frac{7}{3}$.

As already mentioned, the PEP is \mathcal{NP} -hard for bipartite graphs. However, Jansen and Öhring [123] proved that by defining a simple algorithm which finds a coloring of the conflict graph with two colors, and packs each color class with NF, one gets an AR of 2. They also pointed out that the AR does not change if NF is replaced by FFD. Using a more complicated pairing technique, Epstein and Levin [78] presented an algorithm with approximation ratio exactly equal to $\frac{7}{4}$.

For the on-line version, the BPC is hard to approximate for many classes of graphs. Success depends on the on-line coloring phase. For *interval graphs*, Kierstead and Trotter [137] presented an on-line coloring algorithm, which uses $3\omega - 2$ colors in the worst case, where ω is the maximum clique size of the graph. Epstein and Levin [78] pointed out that, using NF for each color class, one obtains a 5-competitive algorithm. They also proved a combination of FFD with the algorithm in [137] produces an algorithm with competitive ratio 4.7. For interval graphs, there exists a lower bound for any on-line algorithm:

Theorem 68 (Epstein and Levin [78]) *The competitive ratio of any on-line algorithm for BPC on interval graphs is at least $\frac{155}{36} \approx 4.30556$.*

The theorem is a direct consequence of two interesting lemmas:

Lemma 1 (Epstein and Levin [78]) *Let c be a lower bound on the APR of any on-line algorithm for classical bin packing, which knows the value OPT in advance. Then the AR of any on-line algorithm for BPC on interval graphs is at least $3 + c$.*

Lemma 2 (Epstein and Levin [78]) *Any on-line algorithm for classical bin packing, which knows the value OPT in advance, has an AR of at least $\frac{47}{36} \approx 1.30556$.*

The on-line problem for other graph classes is still open.

8.6 Partial Orders

In this generalization, precedence constraints among the elements are given, where precedence refers to the relative ordering of bins. Let \prec denote the partial order giving the precedence constraints. Then $a_i \prec a_j$ means that, if a_i and a_j are packed in B_r and B_s , respectively, then $r \leq s$. Call the model *strict* if $r < s$ replaces $r \leq s$ in this definition.

Two practical applications have been considered in the literature. The first one is the assembly line balancing problem, in which the assembly line consists of identical workstations (the bins) where the products stop for a period of time equal to the bin capacity. The item sizes are the durations of tasks to be performed, and a partial order is imposed: $a_i \prec a_j$ means that the workstation to which a_i is assigned cannot be downstream of the one to which a_j is assigned. The second application arises in multiprocessing scheduling; here each item corresponds to a unit-duration process having a memory (or other resource) requirement equal to the item size. The bin capacity measures the total memory availability. In the given partial order, $a_i \prec a_j$ imposes the requirement that a_i must be executed before a_j finishes. The objective is then to find a feasible schedule that finishes the set of processes in minimum time (number of bins).

The first problem was studied by Wee and Magazine [174] and the second one by Garey et al. [104]. In both cases, the *Ordered First-Fit Decreasing* (OFFD) algorithm was applied. An item is called *available* if all its immediate predecessors have already been packed. At each stage, the set of currently available items is sorted according to nonincreasing size, and each item is packed into the lowest indexed bin where it fits and no precedence constraint is violated. Note that, if no partial order is given, this algorithm produces the same packing as FFD. In general, however, its worst-case behavior is considerably worse. The APR is $R_{\text{OFFD}}^\infty = 2$, except in the strict model, where $R_{\text{OFFD}}^\infty = \frac{27}{10}$.

Liu and Sidney [148] considered the case in which there is an *ordinal assumption*: initially, the actual sizes of the items are unknown, but their ordering is known, that is, $s_1 \geq s_2 \geq \dots \geq s_n \geq 0$. Now assume that perfect knowledge of some of the sizes can be “purchased” by specifying the ordinal position of the desired sizes. It is shown that a worst-case performance ratio of ρ (where $\rho \geq 2$ is an

integer) can be achieved if knowledge of $\lfloor \ln(n(\rho - 1) + 1)/\ln \rho \rfloor$ weights can be purchased.

8.7 Clustered Items

In this generalization, a function $f(a_i, a_j)$ is given, measuring the “distance” between items a_i and a_j . A distance constraint D is also given; two items a_i and a_j may be packed into the same bin only if $f(a_i, a_j) \leq D$. The problem has several obvious practical applications in contexts where geographical location constraints are present. Chandra et al. [39] studied different cases, their main result being for the case where the items in a bin must all reside within the same unit square. They proposed a geometric algorithm A and proved that $3.75 \leq R_A^\infty \leq 3.8$.

8.8 Item Types

In studying the packing of advertisements on Web pages, Adler et al. [1] encountered a variant of bin packing in which items are classified into *types*; the set of types is given, and there are no constraints on the number of items of any type. The problem is to pack the items into as few bins as possible subject to the constraint that no bin can have two items of the same type. They design optimal algorithms for restricted cases and then bound the performance of these algorithms viewed as approximations to the general problem.

9 Examples of Classification

In this section, the classification scheme proposed in Sect. 2.3 is resumed. The following examples should help familiarize the reader with it:

1. The classification of [157] shows a bin-size extension of **pack**.

pack|off-line|FPTAS|{B_i}

Results: An approximation algorithm for variable-sized bin packing is presented which for any given positive ε produces a scheme with approximation ratio $1 + \varepsilon$. This algorithm has time complexity polynomial in the number of items, the number of bins, and $1/\varepsilon$.

2. The classification of [145] gives another such example:

pack|on-line, off-line, open-end|R_A[∞]bound; FPTAS

Results: For this hybrid of *pack* and *cover*, it is shown that any open-end version of on-line algorithms must have an asymptotic worst-case ratio

of at least 2. Next-Fit achieves this ratio. There is a fully polynomial-time approximation scheme for this problem.

3. The classification of [7] illustrates a capacity minimization problem with bin-stretching analysis:

$$\min_{\text{cap}} \text{on-line} |R_A| \text{bound} | \text{stretching}$$

Results: A combined algorithm achieves a worst-case bound of 1.625. The best lower bound for any on-line algorithm is 4/3.

4. Reference [48] studies a subset-cardinality objective function:

$$\max_{\text{card}} (\text{subset}) | \text{off-line} |R_A|$$

Results: $R_{\text{WFI}} = \frac{1}{2}$, $R_{\text{FFI}} = \frac{3}{4}$.

5. Reference [61] is classified as a covering problem.

$$\text{cover} | \text{on-line} |R_A^\infty| \text{bound}$$

Results: Asymptotic bound: $R_A^\infty \leq 1/2$ for any on-line algorithm A . There exists an asymptotically optimal on-line algorithm.

6. The classification of [90] is

$$\text{pack} | \text{off-line} |R_A^\infty| \text{bound}$$

Algorithm: Combined Best-Fit (CBF) which takes the better of the First-Fit Decreasing solution and Best Two-Fit (B2F) solution, where the latter algorithm is a grouping version of Best-Fit limiting the number of items per bin.

Results: $R_{\text{B2F}}^\infty = 5/4$, $\frac{227}{195} \leq R_{\text{CBF}}^\infty \leq \frac{6}{5}$

Note that the word “variant” may be simplistic in that it occasionally hides details of relatively complicated algorithms.

7. Reference [95] shows an example for the combination of two algorithm classes:

$$\text{pack} | \text{bounded-space, repack} |R_A^\infty| \text{bound}$$

Algorithm: REP₃, an adaptation of FFD using at most three open bins.

Result: $R_{\text{REP}_3}^\infty \approx 1.69 \dots$

8. The classification of [139] illustrates a case where one is allowed to constrain the number of items per bin.

$$\text{pack} | \text{on-line, off-line} |R_A^\infty| \text{bound} | \text{card}(B) \leq k$$

Result:

$$\left(\frac{27}{10} - \left\lceil \frac{37}{10k} \right\rceil \right) \leq R_{\text{FF}_k}^\infty \leq \left(\frac{27}{10} - \frac{24}{10k} \right),$$

where FF_k is the obvious adaptation of FF.

9. For [175], the classification mentions yet another constraint:

$$\text{pack}|\text{bounded-space, on-line}|R_A^\infty$$

Result: $R_{SH_k}^\infty(k) = R_{H_k}^\infty$, where SH_k is a simplified version of H_k that uses only $O(\log k)$ open bins at any time.

10. Classification of [6] aggregates several results:

$$\text{cover}|\text{on-line, off-line, open-end}|R_A^\infty$$

Algorithms: Open-end variant of Next-Fit called DNF, of First-Fit Decreasing with a parameter r (FFD_r), and of an iterated version of Worst-Fit (IWFD).

Results:

$$R_{\text{DNF}}^\infty = \frac{1}{2}, \text{FFD}_r^\infty = \frac{2}{3} \text{ for all } r, \frac{4}{3} \leq r \leq \frac{3}{2}, \text{ and } R_{\text{IWFD}}^\infty = \frac{3}{4}.$$

11. A more recent such publication is [29, 30]:

$$\text{maxpack}|\text{on-line, off-line}|R_A^\infty|s_i \leq 1/k$$

Results:

- a. No off-line approximation algorithm can have an asymptotic bound larger than $17/10$, a bound achieved by FFD.
 - b. For the off-line case, $R_{\text{FFI}}^\infty = 6/5$, $R_{\text{FFI}}^\infty(1/k) = 1 + 1/k$, $k \geq 2$
 - c. For the on-line case, $R_{\text{FF}}^\infty(1/k) = R_{\text{BF}}^\infty(1/k) = 1 + 1/(k-1)$, $k \geq 3$.
 - d. No deterministic algorithm A has a finite asymptotic bound R_A^∞ for either the `card(subset)_min` or `orc(subset)_min` problems, except for the latter problem in the parametric case with $k > 1$, in which case the bound is again $1 + 1/(k-1)$.
12. An analysis with similarities to bin stretching is used in [31] to compare WF and NF.

$$\text{pack}|\text{on-line}|R_A^\infty|\text{stretching}$$

Results: A derivation of the asymptotic ratios for WF and NF under the assumption that they use bins of capacity C while OPT uses unit-capacity bins shows that WF and NF have the same asymptotic bound for all $C \geq 1$, except when $1 < C < 2$, in which case WF has the smaller bound.

Abstract

In recent years the unconstrained quadratic binary program (UQP) has emerged as a unified framework for modeling and solving a wide variety of combinatorial optimization problems. The unexpected versatility of the UQP model is opening doors to the solution of a diverse array of important and challenging applications. Developments in this evolving area are illustrated by describing its methodology with examples and by reporting substantial computational experience demonstrating the viability and robustness of latest methods for solving the UQP model, showing that they obtain solutions to wide-ranging instances of the model that rival or surpass the best solutions obtained by today's best special-purpose algorithms.

1 Introduction

The unconstrained quadratic binary program (UQP) has a lengthy history as an interesting and challenging combinatorial problem. Simple in its appearance, the model is given by

$$\text{UQP : } \text{Opt } x'Qx$$

where x is an n -vector of binary variables and Q is an n -by- n symmetric matrix of constants. Published accounts of this model go back at least as far as the 1960s in the work of Hammer and Rudeanu [31] and have applications in such diverse areas as spin glasses [18, 30], machine scheduling [1], the prediction of epileptic seizures [35], solving satisfiability problems [12, 13, 31, 33], and determining maximum cliques [13, 55, 56]. The application potential of UQP is much greater than might be imagined, due to the reformulation possibilities afforded by the use of quadratic infeasibility penalties as an alternative to imposing constraints in an explicit manner. In fact, any linear or quadratic discrete (deterministic) problem with linear constraints in bounded integer variables can *in principle* be recast in the form of UQP via the use of such penalties.

As will be shown, this outcome has more than theoretical significance. A broad range of challenging problems in combinatorial optimization can not only be reexpressed as UQP problems but can be solved in a highly effective manner when expressed this way. The process of reformulating a given combinatorial problem into an instance of UQP is easy to carry out. The common modeling framework that results, coupled with recently reported advances in solution methods for UQP, serve to make the model a viable alternative to more traditional combinatorial optimization models as illustrated in the sections that follow.

1.1 Recasting into the Unified Framework

For certain types of constraints, equivalent quadratic penalty representations are known in advance making it easy to embody the constraints within the UQP

objective function. For instance, let x_i and x_j be binary variables and consider the constraint

$$x_i + x_j \leq 1 \quad (1)$$

which precludes setting both variables to one simultaneously. A quadratic infeasibility penalty that imposes the same condition on x_i and x_j is

$$Px_i x_j \quad (2)$$

where P is a large positive scalar. This penalty function is positive when both variables are set to one (i.e., when (1) is violated), and otherwise the function is equal to zero. For a minimization problem then, adding the penalty function to the objective function is an alternative equivalent to imposing the constraint of (1) in the traditional manner.

In the context of transformations involving UQP, a penalty function is said to be a *valid infeasible penalty (VIP)* if it is zero for feasible solutions and otherwise positive. Including quadratic VIPs in the objective function for each constraint in the original model yields a transformed model in the form of UQP. VIPs for several commonly encountered constraints are given below (where x and y are binary variables and P is a large positive scalar):

Note that the penalty term in each case is zero if the associated constraint is satisfied, and otherwise the penalty is positive. These penalties, then, can be directly employed as an alternative to explicitly introducing the original constraints. For other more general constraints, however, VIPs are not known in advance and need to be “discovered.” A simple procedure for finding an appropriate VIP for any linear constraint is given in the next section.

1.2 Accommodating General Linear Constraints

To recast a constrained problem in the form of UQP when the VIPs are not known in advance, consider as a starting point the general constrained problem

$$\begin{aligned} & \min x_0 = xQx \\ & \text{subject to} \\ & \quad Ax = b, \quad x \text{ binary} \end{aligned} \quad (3)$$

This model accommodates both quadratic and linear objective functions since the linear case results when Q is a diagonal matrix (observing that $x_j^2 = x_j$ when x_j is a 0-1 variable). Under the assumption that A and b have integer components, problems with inequality constraints can also be put in this form by representing their bounded slack variables by a binary expansion. These constrained quadratic optimization models are converted into equivalent UQP models by adding a quadratic infeasibility penalty function to the objective function in place of explicitly imposing the constraints $Ax = b$.

Specifically, for a positive scalar P ,

$$\begin{aligned} x_0 &= xQx + P(Ax - b)^t(Ax - b) \\ &= xQx + xDx + c \\ &= x\hat{Q}x + c \end{aligned} \tag{4}$$

where the matrix D and the additive constant c result directly from the matrix multiplication indicated. Dropping the additive constant, the equivalent unconstrained version of the constrained problem becomes

$$UQP : \min x\hat{Q}x, \quad x \text{ binary} \tag{5}$$

From a theoretical standpoint, a suitable choice of the penalty scalar P can always be chosen so that the optimal solution to UQP is the optimal solution to the original constrained problem. Remarkably, as demonstrated later, it is often easy to find such a suitable value in practice as well.

The preceding general transformation that transforms (3) and (4) into (5) will be called *Transformation 1*. A fuller discussion of this transformation along with related material can be found in [13, 32, 34]. Transformation 1 provides the general procedure alluded to earlier that can in principle be employed to transform any problem in the form of (3) into an equivalent instance of UQP .

For problems where VIPs are known in advance, as by the penalty transformations given in Table 1, it is usually preferable to use the known VIP directly rather than applying Transformation 1. One special constraint in particular

$$x_j + x_k \leq 1$$

where the VIP takes the simple form Px_jx_k appears in many important applications. Due to the broad applicability of this constraint, it is convenient to refer to this special case as *Transformation 2*.

This process of transforming a given problem into the unified framework of xQx is illustrated by the following three examples.

Example 1 Set Packing

Set packing problems have the form $\text{Max } cx : Ax \leq e$ and x binary where A is a matrix of 0s and 1s and c and e are both vectors of 1s. These problems are important in the field of combinatorial optimization due to their application potential and their computational challenge. Consider the following example:

$$\begin{aligned} \max x_0 &= x_1 + x_2 + x_3 + x_4 \\ \text{st} \\ x_1 + x_3 + x_4 &\leq 1 \\ x_1 + x_2 &\leq 1 \end{aligned}$$

Table 1 Known penalties

Classical constraint	Equivalent penalty (VIP)
$x + y \leq 1$	$P(xy)$
$x + y \geq 1$	$P(1 - x - y + xy)$
$x + y = 1$	$P(1 - x - y + 2xy)$
$x \leq y$	$P(x - xy)$
$x_1 + x_2 + x_3 \leq 1$	$P(x_1x_2 + x_1x_3 + x_2x_3)$

The VIPs in [Table 1](#) make it possible to immediately recast this classical model into the UQP unified framework. Representing the positive scalar penalty P by $2M$, the equivalent unconstrained problem is

$$\max x_0 = x_1 + x_2 + x_3 + x_4 - 2Mx_1x_3 - 2Mx_1x_4 - 2Mx_3x_4 - 2Mx_1x_2$$

which can be rewritten as

$$\max (x_1 \ x_2 \ x_3 \ x_4) \begin{bmatrix} 1 & -M & -M & -M \\ -M & 1 & 0 & 0 \\ -M & 0 & 1 & -M \\ -M & 0 & -M & 1 \end{bmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{pmatrix}$$

This model has the form $\max x'Qx$ where Q , as shown above, is a square, symmetric matrix. The procedure illustrated here can be used with any set packing problem and has proven to be an effective approach for solving problems with thousands of variables and constraints (see [\[4\]](#)).

Example 2 Set Partitioning

The classical set partitioning problem has the form $\text{Min } dx: Ax = e$, x binary where again A is a matrix of 0s and 1s, e is a vector of 1s, and (in contrast to the vector c of set packing problems) d is a vector of integers, typically nonnegative. The set partitioning problem is found in applications that range from vehicle routing to crew scheduling [\[36, 51\]](#). As an illustration, consider the following small example:

$$\min x_0 = 3x_1 + 2x_2 + x_3 + x_4 + 3x_5 + 2x_6$$

subject to

$$\begin{aligned} x_1 + x_3 + x_6 &= 1 \\ x_2 + x_3 + x_5 + x_6 &= 1 \\ x_3 + x_4 + x_5 &= 1 \\ x_1 + x_2 + x_4 + x_6 &= 1 \end{aligned}$$

and x binary. Applying Transformation 1 with $P = 10$ gives the equivalent UQP model:

$$\min x \hat{Q}x, \quad x \text{ binary}$$

where the additive constant, c , is 40 and the symmetric \hat{Q} matrix is

$$\hat{Q} = \begin{bmatrix} -17 & 10 & 10 & 10 & 0 & 20 \\ 10 & -18 & 10 & 10 & 10 & 20 \\ 10 & 10 & -29 & 10 & 20 & 20 \\ 10 & 10 & 10 & -19 & 10 & 10 \\ 0 & 10 & 20 & 10 & -17 & 10 \\ 20 & 20 & 20 & 10 & 10 & -28 \end{bmatrix}$$

Solving this UQP formulation provides an optimal solution $x_1 = x_5 = 1$ (with all other variables equal to 0) to yield $x_0 = 6$. In the straightforward application of Transformation 1 to this example, the replacement of the original problem formulation by the UQP model does not require any new variables to be introduced. Set partitioning problems with thousands of variables have been successfully solved by reformulating them in this manner, as reported in [47].

In many applications, Transformations 1 and 2 can be used in concert to produce an equivalent UQP model, as demonstrated next.

Example 3 The K-Coloring Problem

Vertex coloring problems seek to assign colors to nodes of a graph in such a way that adjacent nodes receive different colors. The K-coloring problem attempts to find such a coloring using exactly K colors. A wide range of applications, ranging from frequency assignment problems to printed circuit board design problems, can be represented by the K-coloring model.

These problems can be modeled as satisfiability problems using the assignment variables as follows:

Let x_{ij} be 1 if node i is assigned color j , and 0 otherwise.

Since each node must be colored,

$$\sum_{j=1}^K x_{ij} = 1 \quad i = 1, \dots, n \quad (6)$$

where n is the number of nodes in the graph. A feasible coloring, in which adjacent nodes are assigned different colors, is assured by imposing the constraints

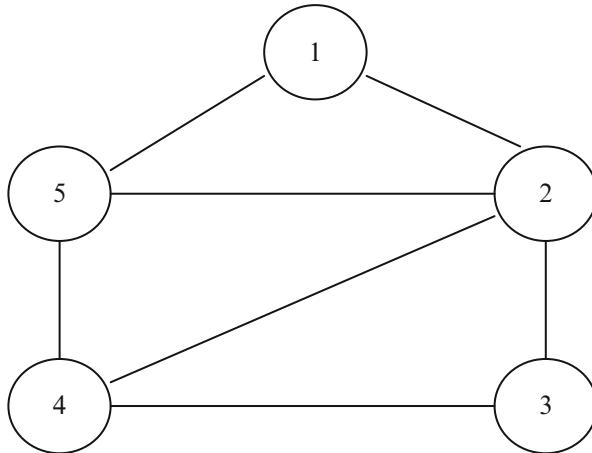

$$x_{ip} + x_{jp} \leq 1 \quad p = 1, \dots, K \quad (7)$$

for all adjacent nodes (i, j) in the graph.

This problem can be recast in the form of UQP by using Transformation 1 on the assignment constraints of (6) and Transformation 2 on the adjacency constraints of (7). No new variables are required. Since the resulting model has no explicit objective function, any positive value for the penalty P will do. The following example gives a concrete illustration of the reformulation process.

Find a feasible coloring of the following graph using three colors.

Thus, the goal is to find a solution to the system:

$$x_{i1} + x_{i2} + x_{i3} = 1 \quad i = 1, 5 \quad (8)$$

$$x_{ip} + x_{jp} \leq 1 \quad p = 1, 3 \quad (9)$$

(for all adjacent nodes i and j)

In this traditional form, the model has 15 variables and 26 constraints. To recast this problem in the form of UQP, it suffices to use Transformation 1 on the equations of (8) and Transformation 2 on the inequalities of (9). Arbitrarily choosing the penalty P to be 4, the equivalent problem in unified form is given by

$$\text{UQP}(Pen) : \min x \hat{Q} x$$

where the \hat{Q} matrix is

$$\hat{Q} = \begin{bmatrix} -4 & 4 & 4 & 4 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 4 & 0 & 0 \\ 4 & -4 & 4 & 0 & 4 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 4 & 0 \\ 4 & 4 & -4 & 0 & 0 & 4 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 4 \\ 4 & 0 & 0 & -4 & 4 & 4 & 4 & 0 & 0 & 4 & 0 & 0 & 4 & 0 & 0 & 0 & 0 \\ 0 & 4 & 0 & 4 & -4 & 4 & 0 & 4 & 0 & 0 & 4 & 0 & 0 & 0 & 4 & 0 & 0 \\ 0 & 0 & 4 & 4 & 4 & -4 & 0 & 0 & 4 & 0 & 0 & 4 & 0 & 0 & 0 & 0 & 4 \\ 0 & 0 & 0 & 4 & 0 & 0 & -4 & 4 & 4 & 4 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 4 & 0 & 4 & -4 & 4 & 0 & 4 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 4 & 4 & 4 & -4 & 0 & 0 & 4 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 4 & 0 & 0 & 4 & 0 & 0 & -4 & 4 & 4 & 4 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 4 & 0 & 0 & 4 & 0 & 4 & -4 & 4 & 0 & 4 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 4 & 0 & 0 & 4 & 4 & 4 & 4 & -4 & 0 & 0 & 0 & 4 \\ 0 & 0 & 0 & 0 & 0 & 0 & 4 & 0 & 0 & 4 & 4 & 4 & 4 & -4 & 0 & 0 & 4 \\ 4 & 0 & 0 & 4 & 0 & 0 & 0 & 0 & 0 & 4 & 0 & 0 & 0 & -4 & 4 & 4 & 4 \\ 0 & 4 & 0 & 0 & 4 & 0 & 0 & 0 & 0 & 0 & 4 & 0 & 4 & 0 & 4 & -4 & 4 \\ 0 & 0 & 4 & 0 & 0 & 4 & 0 & 0 & 0 & 0 & 0 & 4 & 4 & 4 & 4 & 4 & -4 \end{bmatrix}$$

Solving this unconstrained model, $x\hat{Q}x$, yields the feasible coloring:

$$x_{11}, x_{22}, x_{33}, x_{41}, x_{53}, = 1 \text{ all other } x_{ij} = 0$$

This approach to coloring problems has proven to be very effective for a wide variety of coloring instances from the literature as disclosed in [41].

2 Solving UQP

Employing the UQP unified framework to solve combinatorial problems requires the availability of a solution method for xQx . The recent literature reports major advances in such methods involving modern metaheuristic methodologies. The reader is referred to references [6–9, 14, 16, 24–26, 37, 45, 49, 50, 53, 54] for a description of some of the methods that have provided valuable contributions to the area. The pursuit of further advances in solution methods for xQx remains an active research arena.

The computational work reported later in this chapter derives from previous studies of three methods: a basic tabu search method due to Glover, Kochenberger, and Alidaee [23–25], a tabu search method due to Lewis [47], and the more recent tabu search method of Glover, Jin-Kao, and Lu [29]. For convenience these methods will be referred to as methods 1, 2, and 3 respectively. A brief overview of each approach is given below. Complete details are provided in the aforementioned references.

Method 1 Overview: This tabu search metaheuristic for UQP is centered around the use of strategic oscillation, which constitutes one of the primary strategies of tabu search. The method alternates between constructive phases that progressively

set variables to 1 (whose steps are called “add moves”) and destructive phases that progressively set variables to 0 (whose steps are called “drop moves”). To control the underlying search process, the method uses a memory structure that is updated at *critical events*, identified by conditions that generate a subclass of locally optimal solutions. Solutions corresponding to critical events are called *critical solutions*.

A parameter SPAN is used to indicate the amplitude of oscillation about a critical event. To begin *span* is set equal to 1 and then is gradually increased until reaching some limiting value. For each value of *span*, a series of alternating constructive and destructive phases is executed before progressing to the next value. At the limiting point, *span* is gradually decreased, allowing again for a series of alternating constructive and destructive phases. When *span* reaches a value of 1, a *complete span cycle* has been completed and the next cycle is launched. The search process is typically allowed to run for a preset number of SPAN cycles.

Information stored at critical events is used to influence the search process by penalizing potentially attractive add moves (during a constructive phase) and inducing drop moves (during a destructive phase) associated with assignments of values to variables in recent critical solutions. Cumulative critical event information is used to introduce a subtle long-term bias into the search process by means of additional penalties and inducements similar to those discussed above. Other standard elements of tabu search such as short- and long-term memory structures are also included.

Method 2 Overview: This method is a modification of the previous method that implements a basic multi-start, tabu search procedure with path-relinking. A local search is performed using a 1-opt mechanism. When no improvements to the current solution can be found using 1-opt local search, including tabu aspiration possibilities, a path-relinking procedure is initiated between the current solution and an elite set of diverse solutions saved during the search process. After relinking, a random portion of the current solution is perturbed and testing continues. If after a number of iterations (specified by the restart limit) no improvements are found, then a larger perturbation is invoked based on long-term memory.

Method 3 Overview: The DDTs method repeatedly alternates between a simple version of tabu search (TS) and a diversification phase founded on a memory-based perturbation operator. Starting from an initial random solution, DDTs uses the TS procedure to reach a local optimum. Then, the perturbation operator is applied to displace the solution to a new region, whereupon a new round of TS is launched. To facilitate achieving effective diversification, the perturbation operator is guided by information from a special memory structure.

This tabu search procedure uses a neighborhood defined by the single 1-flip moves, which consists of changing (flipping) the value of a single variable x_j to its complement value $1 - x_j$. The implementation of this neighborhood uses a fast incremental evaluation technique to calculate the cost of candidate moves. The diversification strategy utilizes a memory-based perturbation operator composed of three parts: a flip frequency memory, an elite solution memory, and an elite value frequency memory. These memory structures are used jointly by the perturbation operator to enhance the diversification of the search process. This method has proven

to be highly effective for solving large instances of UQP. Complete details of this method are given in Glover, Lu, and Hao [29].

3 Applications

To date several important classes of combinatorial problems have been successfully modeled and solved by employing the unified framework. Results with the unified framework applied to these problems have been uniformly attractive in terms of both solution quality and computation times. While the three solution methods described above are designed for the completely general form of UQP, without any specialization to take advantage of particular types of problems reformulated in this general representation, the outcomes typically prove competitive with or even superior to those of specialized methods designed for the specific problem structure at hand. The broad base of experience with UQP as a modeling and solution framework obtained by applying the three methods above includes a substantial range of problem classes including quadratic assignment problems, capital budgeting problems, multiple knapsack problems, task allocation problems (distributed computer systems), maximum diversity problems, p-median problems, asymmetric assignment problems, symmetric assignment problems, side constrained assignment problems, quadratic knapsack problems, constraint satisfaction problems (CSPs), set partitioning problems, fixed charge warehouse location problems, maximum clique problems, maximum independent set problems, maximum cut problems, graph coloring problems, graph partitioning problems, number partitioning problems, and-linear ordering problems.

Additional test problems representing a variety of other applications have also been reformulated and solved via UQP. The section below reports specific computational experience with some large-scale applications. [Section 5](#) then suggests promising new applications areas for UQP.

4 Illustrative Computational Experience

The following summarizes results obtained on large-scale test problems of a variety of well-known problem classes from combinatorial optimization. Because methods 1, 2, and 3 were developed at different points in time, and each has been applied to classes of problems different from those treated by the other two, outcomes for these classes of problems are reported by describing the findings for the three methods in the sequence in which they have been applied.

4.1 The Task Allocation Problem

The task allocation problem, which consists of assigning tasks to processors, can be described as follows: Let $P = \{P_1, P_2, \dots, P_m\}$ be a set of distributed processors

and $T = \{T_1, T_2, \dots, T_n\}$ be a set of tasks to be run on the processors. Let c_{ij} be the communications cost between tasks T_i and T_j and q_{tp} be the execution cost of task t on processor p . Then stipulating that x_{tp} equals 1 if task T_t is assigned to processor P_p and is otherwise equal to 0, the model becomes

$$\begin{aligned} & \min \sum_{t=1}^n \sum_{p=1}^m q_{tp} x_{tp} + \sum_{i < j} \sum_{p=1}^m c_{ij} x_{ip} (1 - x_{jp}) \\ & \text{st} \\ & \quad \sum_{p=1}^m x_{tp} = 1 \quad \text{for } t = 1, \dots, n \end{aligned}$$

which is of the form

$$\min x'Qx$$

st

$$Ax = b$$

Applying Transformation 1 of Sect. 1.2 yields a model in the form of UQP. In a study [46] comparing CPLEX 8.1 and method 1 on 16 large test problems ranging in size from 1,000 to 3,000 variables, CPLEX was unable to prove optimality on any of the problems (within a 48-h limit). Running method 1 for a total of 300 SPAN cycles took less than 12 min on the largest of the problems. Across all 16 problems, the best solutions produced by CPLEX had objective function values that were, on average, 52 % inferior to those produced by method 1, in spite of being allowed to run 240 times longer.

4.2 The Max 2-Sat Problem

It is well known (see for instance [13] and [33]) that the Max 2-Sat problem can be formulated as an unconstrained binary quadratic program of the form $\min x'Qx$. Yet little computational experience treating the Max 2-Sat problem as an instance of UQP has appeared in the literature prior to the computational study of [42] which reports on the successful application of the tabu search Method 1 to a variety of old and new test problems from this class. In all cases, method 1 was run for 50 SPAN cycles. Applied to a public data set with 16 problems ranging from 50 variables and 100 clauses to 150 variables and 600 clauses, method 1 found best known solutions in less than 3 s while more than half of these problem instances could not be solved within a 12-h limit by the well-known Maxsat [10] procedure.

On another publicly available set of 20 problems with 200 variables and 1,000–2,000 clauses, method 1 again found best known solutions in less than 3 s. On a third data set of 17 problem instances ranging in size from 100 to 1,000 variables and 626 to 22,883 clauses, method 1 was tested against CPLEX 8.0 by applying the latter to the classical MIP formulation of Max 2-Sat. CPLEX was only able to solve and terminate naturally on the smallest of these problems, requiring 147 s in

this case. Method 1 by contrast found the optimal solution for this problem in less than 1 s. On the other 16 problems, CPLEX was unable to terminate naturally within a 10-h time limit while the UQP approach of method 1 obtained solutions within 50 SPAN cycles in an average of less than 9 s. For these problems, the best solutions found in the 10-h time limit by CPLEX had objective function values on average 20 % inferior to those produced by the method 1 tabu search approach. Full details of these results are given in [42].

4.3 The Group Technology Problem

The group technology (GT) problem is concerned with clustering machines and parts together in a manner that facilitates economies in time and cost. From a graph theoretic point of view, nodes in a graph can be taken to represent machines and parts, which are connected by edges denoting the association of each pair of nodes in the network. The GT problem then becomes one of partitioning the nodes into cliques with similar characteristics. Thus, the GT problem can be modeled by the standard IP formulation for clique partitioning:

$$\begin{aligned} & \max \sum_{(i,j) \in E} w_{ij} x_{ij} \\ \text{st} \quad & x_{ij} + x_{ir} - x_{jr} \leq 1 \quad \forall \text{ all distinct } i, j, r \in V \\ & x_{ij} \in \{0, 1\} \text{ for all } \{i, j\} \in E \end{aligned}$$

The variable x_{ij} is equal to 1 if machine (or part) i and machine (or part) j are assigned in a cell and is equal to 0 otherwise. The coefficient w_{ij} is the weight of the edge (i, j) in the graph.

Since the variables are associated with edges in the graph, the model has many variables and constraints. In practice even modest-sized GT problems give rise to extraordinarily large IP models and often are beyond the capability of modern MIP solvers to handle. As an alternative to the standard IP model for clique partitioning, it is shown in [6] that the GT problem can be solved by employing the following quadratic model for clique partitioning:

$$\begin{aligned} & \max \sum_{i=1}^{n-1} \sum_{j=i+1}^n w_{ij} \sum_{k=1}^{K_{\max}} x_{ik} x_{jk} \\ \text{st} \quad & \sum_{k=1}^{K_{\max}} x_{ik} = 1 \quad \text{for } i = 1, n \end{aligned}$$

In this formulation n is the number of nodes, w_{ij} again denotes the weight of edge (i, j) , K_{\max} is an upper bound on the number of groups to be formed, and $x_{ik} = 1$

if node i is assigned to clique k and otherwise equals zero. It is to be noted that variables are associated with nodes rather than edges in this model. Thus, in spite of being nonlinear, the model is much smaller than the standard IP model and is readily approached via the unified framework. Specifically, the problem has the form

$$\begin{aligned} \max \quad & x'Qx \\ \text{st} \quad & \\ & Ax = b \end{aligned}$$

and thus can be recast in the form of UQP using Transformation 1 of [Sect. 1.2](#).

To test the effectiveness of the UQP approach for modeling GT, experiments were conducted on 36 standard test problems of modest size ranging from graphs with 46 nodes and 1,035 edges to 71 nodes and 2,485 edges. Each problem was solved with method 1 running for 100 SPAN cycles, with the largest problem taking slightly more than 1 min. To provide a benchmark for comparison, each problem was solved in its standard MIP formulation by CPLEX 6.5. CPLEX's time performance on these problems was very erratic. The average solution time was 1.2 days, and 4 problems required more than 4 days. Nonetheless, CPLEX terminated naturally on all 36 problems and thus confirmed the optimality of the solutions obtained by the UQP approach although requiring running times that were 1,500–6,000 times longer. Complete details are given in Wang et al. [61].

4.4 The Set Packing Problem

[Example 1](#) of [Sect. 1](#) of this chapter presented a small example of a set packing problem, illustrating how this class of problems can easily be reformulated as an unconstrained quadratic binary program. In general, this class of problems is given by

$$\begin{aligned} \max \quad & \sum_{j=1}^n w_j x_j \\ \text{st} \quad & \\ & \sum_{j=1}^n a_{ij} x_j \leq 1 \quad \text{for } i = 1, \dots, m \end{aligned}$$

where the a_{ij} are 0/1 coefficients, the w_j are weights, and the x_j variables are binary. Each constraint can alternatively be enforced by subtracting one or more quadratic penalties from the objective function, thus producing an equivalent problem in the form of an unconstrained quadratic binary program. Note that this recasting takes place without the introduction of new variables. Moreover, the size of the equivalent UQP model depends only on the number of original variables and is independent of the number of constraints in the original set packing problem.

Computational results are given in [4] for applying method 1 to a set of publicly available set of 16 test problems containing 1,000–2,000 variables and 2,000–10,000 constraints. Best known results for these problems reported in the literature

are obtained by a leading heuristic (see [19]) specially designed for set packing problems. This special procedure was allowed to run for 5 h on each problem. For each problem, method 1 was run for 1,000 SPAN cycles, taking 20 min for the largest instance and 7 min on average. For the 16 test problems, method 1 quickly found the best known solutions for 13 of the 16 problems and produced solutions whose objective function values were more than 99 % of the best known values for the other 3 problems. To provide additional comparison, these problems were also solved using CPLEX 8.1 which consumed on average 38 h of computer run time before terminating due to reaching memory limitations. The reader is referred to [4] for complete details of these runs as well as additional computational experience.

4.5 The Set Partitioning Problem

As noted in [Example 2](#) of [Sect. 1](#), the set partitioning problem can be formulated as

$$\begin{aligned} \max \quad & \sum_{j=1}^n c_j x_j \\ \text{st} \quad & \sum_{j=1}^n a_{ij} x_j = 1 \quad \text{for } i = 1, \dots, m \end{aligned}$$

where the a_{ij} are 0/1 coefficients, the c_j are objective function coefficients, and the x_j variables are binary. Computational experience with a wide variety of solution methods has shown that even modest-sized instances of these problems are extraordinarily difficult to solve and become increasingly difficult as density grows. Applying Transformation 1, the set partitioning problem becomes a UQP problem without introducing new variables and whose size is independent of the number of constraints in the original problem.

An equivalent but simpler alternative to Transformation 1 is presented in [47] for re-expressing set partitioning problems as UQP models. Computational experience is reported with a set of 31 test problems ranging in size from 600 to 15,000 variables and 100 to 5,000 constraints. CPLEX 8.1, applied to the classical formulation given above, was used to provide a benchmark for comparison with the basic tabu search and path relinking approach of method 2. For each problem, CPLEX was run until optimality was proven or until reaching 12 h of processing time (or until the run was terminated by an “out of memory” error). For the first 21 problems, CPLEX terminated naturally with an optimal solution. Method 2 quickly found an optimal solution to these problems as well with a time performance that was on average 270 times faster than CPLEX. (This excludes the time it took CPLEX to prove the optimality of the solutions it found).

For the largest problem (15,000 variables and 5,000 constraints), CPLEX terminated with a memory fault and no solution while method 2 found a feasible solution in less than 20 min. For the other problems, CPLEX terminated due to the

12-h time limit, giving a “best solution found so far.” On these problems, method 2 obtained solutions with objective functions approximately 2 % superior to those obtained by CPLEX while running more than 100 times faster.

4.6 The Linear Ordering Problem

The linear ordering problem (LOP) is a particularly hard problem defined by an n-by-n matrix of weights $C = \{c_{ij}\}$ where the goal is to find a permutation, p , of columns (and rows) that maximizes the sum of the weights in the upper triangular matrix. Such problems arise in a variety of settings (such as finding an acyclic tournament of maximum weight, or the aggregate ordering of paired observations) but are most often associated with the triangulation of input-output matrices in economics where the data in question often refer to sectors. The problem can be modeled utilizing the decision variable: $x_{ij} = 1$ if sector i goes before sector j in the permutation; and $x_{ij} = 0$ otherwise. Taking advantage of the fact that $x_{ij} + x_{ji} = 1$ for all i and j , a standard integer programming formulation for the problem is given by

$$\begin{aligned} & \text{Max } \sum_{i < j} c_{ij} x_{ij} + \sum_{j < i} c_{ij} (1 - x_{ji}) \\ & \text{st} \\ & x_{ij} + x_{jk} - x_{ik} \leq 1 \quad \forall (i, j, k) : i < j < k \\ & x_{ij} + x_{jk} - x_{ik} \geq 0 \quad \forall (i, j, k) : i < j < k \\ & x_{ij} \in \{0, 1\} \quad \forall (i, j) : i < j \end{aligned}$$

This model can be recast into the form of UQP by employing a specially crafted quadratic penalty, a penalty that is unique to the structure of the linear ordering problem. To see how this special penalty arises, note that for a particular set $i < j < k$, the pair of constraints shown above allows 6 of the 8 possible solutions, excluding only $x_{ij} = 1$, $x_{jk} = 1$, and $x_{ik} = 0$ and $x_{ij} = 0$, $x_{jk} = 0$, and $x_{ik} = 1$. It is easy to see that an exact quadratic penalty that precludes these same two solutions, while allowing the others, is given by

$$P \{x_{ik} + x_{ij}x_{jk} - x_{ij}x_{ik} - x_{jk}x_{ik}\}$$

Thus, without introducing additional variables, this special penalty can be used to easily transform the linear ordering problem into an equivalent UQP. For a problem with n sectors, both the IP formulation and the equivalent UQP model will have $n(n - 1)/2$ variables. Again the size of the UQP model is independent of the number of constraints in the original IP model.

An application of this UQP approach is reported in [48] for a set of 11 test problems ranging in size from 190 variable and 2,280 constraints (a LOP instance with $n = 20$) to 19,900 variables and 2,626,800 constraints (a LOP instance with $n = 200$). As before, experience with CPLEX was reported on these problems to provide a benchmark of comparison. Both CPLEX and method 2 were given a time

limit of 1 h. Best known solutions, obtained from a specially crafted Scatter Search method for LOP problems, are also available for purposes of benchmarking.

Due to the large size of the IP models, CPLEX was able to find and prove optimality for only the two smallest problems. Method 2 found these same optimal solutions within the 1-h time limit. For the four largest problems (more than 4,000 variables and 234,960 constraints), CPLEX was unable to find a feasible solution within the 1-h time limit while the UQP approach readily found feasible solutions. For the other problems, CPLEX reported solutions that were inferior to those produced by the tabu search/path-relinking approach of method 2. Across the entire set of test problems, solutions were produced using the UQP model whose objective function values were at least 95 % of the best known values obtained by any method in the literature specialized for solving LOP problems. See [48] for a complete discussion of these results.

4.7 The Max-Cut Problem

Given an undirected graph $G(V,E)$ with edge weights w_{ij} , the Max-Cut (MC) problem seeks a partition $S_1 \subset V$ and $S_2 = V|S_1$ such that the weight of the cut, defined as the sum of the weights on the edges connecting the two sets, is maximized. MC is another classic problem in combinatorial optimization. This problem has a natural quadratic structure and with a simple change of variables, it can be readily put into the form of UQP. The common formulation from the literature is

$$\max \frac{1}{2} \sum_{1 \leq i < j \leq n} w_{ij}(1 - y_i y_j)$$

subject to

$$y_i \in \{-1, 1\} \quad \forall i \in V$$

The change of variables $y_i = 2x_i - 1$ yields the unconstrained quadratic binary program

$$\max \sum_{i < j} w_{ij}(x_i + x_j - 2x_i x_j); \quad x_j \in \{0, 1\}$$

which is of the form $\max x'Qx$. This class of problems is described in detail in [28] together with reporting computational experience for 69 test problems from the literature ranging in size from 800 variables to 10,000 variables. Most articles in the literature addressing MC only consider problems with up to a few thousand variables.

This study employed the tabu search approach of method 3. Depending on the problem size, run time limits ranged from one half hour for small problems to 24 h for the 10,000 variable problems. The results obtained were highly attractive compared to previously published results in the literature, as evidenced by the fact that, over the entire test bed of 69 problems, method 3 matched best known solutions on 19 problems, found new best known solutions on 46 problems, and failed to find best known solutions on just 4 problems.

4.8 Comments on Computational Experience

The computational experience reported above is intended to demonstrate the viability and breadth of applicability of the unified framework. This framework has been successfully applied to many other problem classes as well. While the intention of the present chapter is to disclose the general applicability of the unified modeling and solution methodology, and not to provide a comprehensive comparison of this approach with the best-performing specialized methods for each class of problems at this time, it should nonetheless be emphasized that the results presented clearly establish that the reformulation approach not only works across a wide array of problem classes but works very well. The approach finds best known solutions for many problems, regardless of problem class, in modest computer times. As future studies take advantage of the opportunity to apply more advanced UQP algorithms such as method 3 across a wider range of applications, additional records will undoubtedly be set for finding best known solutions to test problems from a variety of sources.

4.9 Important Alternative Model for Assignment Problems

Many important classes of problems have assignment constraints where, generally, agents of some kind are assigned to tasks. For such problems, Transformation 1 can be used to enforce the assignment constraints via quadratic penalties as illustrated earlier in this chapter. For such problems, however, a slightly different manner of constructing the quadratic penalty matrix, Q , has proven to be attractive in certain cases provided that resulting quadratic optimization problem is carried out subject to a cardinality constraint rather than being unconstrained. Recall that Transformation 1 results in an additive constant and a modification of the elements on the main diagonal of the Q matrix. With the alternative method, neither the additive constant nor modified diagonal elements are employed. The idea is illustrated by the following example:

Suppose the goal is to obtain solutions that satisfy

$$\begin{aligned}x_{11} + x_{12} + x_{13} &= 1 \\x_{21} + x_{22} + x_{23} &= 1 \\x_{31} + x_{32} + x_{33} &= 1\end{aligned}$$

Clearly exactly three variables will be equal to one and the other six variables will be zero. Finding solutions that satisfy the above assignment constraints is equivalent to solving the problem

$$\begin{aligned}\min x_0 &= x'Qx \\ \text{st} \\ \sum_{i=1}^3 \sum_{j=1}^3 x_{ij} &= 3\end{aligned}$$

where

$$\mathbf{x} = (x_{11}, x_{12}, x_{13}, x_{21}, \dots, x_{33})$$

and the Q matrix is given by

$$Q = \begin{bmatrix} 0 & P & P & 0 & 0 & 0 & 0 & 0 & 0 \\ P & 0 & P & 0 & 0 & 0 & 0 & 0 & 0 \\ P & P & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & P & P & 0 & 0 & 0 \\ 0 & 0 & 0 & P & 0 & P & 0 & 0 & 0 \\ 0 & 0 & 0 & P & P & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & P & P & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & P & P & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & P & 0 & P \\ 0 & 0 & 0 & 0 & 0 & 0 & P & P & 0 \end{bmatrix}$$

where P is a positive scalar penalty. Note that the block diagram structure along the main diagonal makes this penalty matrix particularly easy to construct.

The cardinality constraint requires exactly three of the nine variables to be equal to 1. The penalty structure of Q, given the goal of forcing x_0 to zero, will not allow, say, x_{12} or x_{13} to be 1 in the event that x_{11} is equal to one. In this manner, all three assignment constraints are enforced via the penalties.

In applications involving assignment constraints, there are typically additional constraints (besides the assignment constraints), and these need to be “folded” into the Q matrix as well. This approach is particularly well suited for quadratic assignment problems where facilities are assigned to locations, clustering problems where data are assigned to clusters, coloring problems where colors are assigned to nodes, clique partitioning problems where nodes are assigned to cliques, and so forth.

5 Promising New Application Areas

This combined modeling/solution approach provides a unifying theme that can be applied in principle to all linearly constrained quadratic and linear programs in bounded integer variables, and the computational findings for a broad spectrum of problem classes raises the possibility that similarly successful results may be obtained for even wider ranges of problems. The generality of the approach of modeling and solving problems using the UQP formulation invites additional applications to be pursued via this unified framework. Promising applications that are part of current work in progress include:

1. *The variable (feature) selection problem:* This important problem in linear regression concerns choosing a set of independent variables that are strongly correlated with the independent variable and weakly correlated with one another. One model for this, given by Eksioglu et al. [20], takes the form of a

two-objective IP model that can be easily recast into the unified $x'Qx$ framework. Tests are currently underway applying this alternative approach to a variety of data sets and making comparisons with standard statistical approaches.

2. *Clustering*: Clustering is an important data mining tool with applications in many important areas from medicine to marketing. Taking a graph-theoretical perspective, clustering can be viewed as a clique partitioning problem, and thus the quadratic model presented in Sect. 4.3 can be used to cluster data. In this setting too, tests are in process to extend the encouraging early results from this approach reported in Kochenberger et al. [43] and in Wang et al. [62].
3. *Computational biology*: Several important problems arising in biology can be modeled and solved as combinatorial optimization problems. Of particular interest are the multiple sequence alignment problem, the lattice protein folding problem, the rotamer assignment problem and the contact map optimization problem. Each of these problems, as explained in Forrester and Greenberg [21], can be modeled as a constrained quadratic optimization problem in zero-one variables, thus permitting them to be transformed into the $x'Qx$ framework and solved by solution methods designed for the unified framework. Early testing of this approach is underway.
4. *General linear 0/1 programming*: The general 0/1 linear programming problem can be represented by

$$\begin{aligned} & \max cx \\ & \text{st} \\ & Ax = b \\ & x \text{ binary} \end{aligned}$$

By using Transformation 1 it is possible to recast the problem in the form of

$$\begin{aligned} & \max x_0 = x^t Qx \\ & \text{st } x \text{ binary} \end{aligned}$$

For problems with inequality constraints, slack variables, via a binary expansion, can always be introduced to create the system of constraints $Ax = b$. This procedure is illustrated by the following example:

$$\begin{aligned} & \max 6x_1 + 4x_2 + 8x_3 + 5x_4 + 5x_5 \\ & \text{st} \\ & 2x_1 + 2x_2 + 4x_3 + 3x_4 + 2x_5 \leq 7 \\ & 1x_1 + 2x_2 + 2x_3 + 1x_4 + 2x_5 = 4 \\ & 3x_1 + 3x_2 + 2x_3 + 4x_4 + 4x_5 \geq 5 \\ & x \in \{0, 1\} \end{aligned}$$

Adding slack variables for the 1st and 3rd constraints

$$\begin{aligned} 0 \leq s_1 \leq 3 &\Rightarrow s_1 = 1x_6 + 2x_7 \\ 0 \leq s_3 \leq 6 &\Rightarrow s_3 = 1x_8 + 2x_9 + 4x_{10} \end{aligned}$$

gives the system $Ax = b$ with A given by

$$A = \begin{bmatrix} 2 & 2 & 4 & 3 & 2 & 1 & 2 & 0 & 0 & 0 \\ 1 & 2 & 2 & 1 & 2 & 0 & 0 & 0 & 0 & 0 \\ 3 & 3 & 2 & 4 & 4 & 0 & 0 & -1 & -2 & -4 \end{bmatrix}$$

For a scalar penalty $P=10$, applying Transformation 1 gives the equivalent problem

$$\max x_0 = x'Qx$$

with an additive constant of -900 and a Q matrix

$$Q = \begin{bmatrix} 526 & -150 & -160 & -190 & -180 & -20 & -40 & 30 & 60 & 120 \\ -150 & 574 & -180 & -200 & -200 & -20 & -40 & 30 & 60 & 120 \\ -160 & -180 & 688 & -220 & -200 & -40 & -80 & 20 & 40 & 80 \\ -190 & -200 & -220 & 645 & -240 & -30 & -60 & 40 & 80 & 160 \\ -180 & -200 & -200 & -240 & 605 & -20 & -40 & 40 & 80 & 160 \\ -20 & -20 & -40 & -30 & -20 & 130 & -20 & 0 & 0 & 0 \\ -40 & -40 & -80 & -60 & -40 & -20 & 240 & 0 & 0 & 0 \\ 30 & 30 & 20 & 40 & 40 & 0 & 0 & -110 & -20 & -40 \\ 60 & 60 & 40 & 80 & 80 & 0 & 0 & -20 & -240 & -80 \\ 120 & 120 & 80 & 160 & 160 & 0 & 0 & -40 & -80 & -560 \end{bmatrix}$$

Solving $\max x_0 = x'Qx$ gives the nonzero values

$$x_1 = x_4 = x_5 = x_9 = x_{10} = 1$$

for which $x_0 = 916$. Adjusting for the additive constant gives an objective function value of 16 which is optimal. Note that any linear problem in bounded integer variables, through a binary expansion, could be converted into $\max x_0 = x'Qx$ as illustrated here. Note also, though, that the elements of the Q matrix can, for some problems, get unacceptably large and may require suitable scaling to mitigate this problem.

5. *The Max 3-Sat Problem:* Section 4.2 discusses the Max 2-Sat problem, showing how it can be reformulated and solved as $\min x^t Qx$. The penalty approach adopted for the Max 2-Sat problem can be expanded to address the Max 3-Sat problem. In this case, however, the penalty function that results is a cubic rather than a quadratic function. Nonetheless, by a simple transformation, the cubic function can be recast as a quadratic and thus the Max 3-Sat problem, like

the Max 2-Sat problem, can also be modeled and solved using the $\min x^T Qx$ formulation.

In particular, the Max 3-Sat problem gives rise to four possible clause types. A linear constraint is associated with each which can be carried into the problem objective by a cubic penalty function which is equal to zero when the constraint is satisfied and otherwise equal to one. Finding solutions that maximize the number of clauses satisfied then corresponds to minimizing the penalty function that results by summing the individual penalties. The procedure is illustrated below.

The four clause types together with their associated constraint and penalty are:

1. *No negations*:

Linear constraint: $x_i + x_j + x_k \geq 1$

Cubic penalty: $(1 - x_i x_j x_k - x_i - x_j - x_k + x_i x_j + x_i x_k + x_j x_k)$

2. *One negation*:

Linear constraint: $x_i + x_j + \bar{x}_k \geq 1$

Cubic penalty: $(x_k - x_i x_k - x_j x_k + x_i x_j x_k)$

3. *Two negations*:

Linear constraint: $x_i + \bar{x}_j + \bar{x}_k \geq 1$

Cubic penalty: $(x_j x_k - x_i x_j x_k)$

4. *Three negations*:

Linear constraint: $\bar{x}_i + \bar{x}_j + \bar{x}_k \geq 1$

Cubic penalty: $(x_i x_j x_k)$

The conversion of the cubic penalty function to an equivalent quadratic function is carried out by the reduction procedure of Boros and Hammer [11] by replacing a product term xy by a new binary variable z and adding the penalty term $P(xy - 2xz - 2yz + 3z)$ to the objective function as illustrated in the following example with $n=5$ variables and 12 clauses.

Clause #	Clause
1	$x_1 \vee x_2 \vee x_3$
2	$x_1 \vee \bar{x}_2 \vee x_3$
3	$\bar{x}_1 \vee x_2 \vee \bar{x}_3$
4	$x_2 \vee \bar{x}_3 \vee x_4$
5	$\bar{x}_2 \vee x_3 \vee x_4$
6	$\bar{x}_2 \vee \bar{x}_3 \vee \bar{x}_4$
7	$x_2 \vee x_4 \vee x_5$
8	$\bar{x}_2 \vee x_3 \vee x_5$
9	$x_2 \vee \bar{x}_3 \vee x_5$
10	$x_3 \vee x_4 \vee x_5$
11	$x_3 \vee \bar{x}_4 \vee \bar{x}_5$
12	$\bar{x}_3 \vee \bar{x}_4 \vee \bar{x}_5$

Introducing the penalty functions for these clauses gives the following cubic penalty function to minimize:

$$\begin{aligned} x_0 = & 3 - x_1 + x_2 - 2x_4 - 2x_5 + 2x_1 x_3 - 4x_2 x_3 + 3x_4 x_5 \\ & - x_1 x_2 x_3 + 3x_2 x_3 x_4 - x_2 x_4 x_5 - x_3 x_4 x_5 + 2x_2 x_3 x_5 \end{aligned}$$

Note that this function has five cubic terms. Introducing two new binary variables, $x_6 = x_2x_3$ and $x_7 = x_4x_5$ along with the associated quadratic penalties yield the equivalent quadratic penalty function:

$$\begin{aligned} x_0 = & 3 - x_1 + x_2 - 2x_4 - 2x_5 + 2x_1x_3 - 4x_2x_3 + 3x_4x_5 \\ & - x_1x_6 + 3x_4x_6 - x_2x_7 - x_3x_7 + 2x_5x_6 \\ & + P(x_2x_3 - 2x_2x_6 - 2x_3x_6 + 3x_6) \\ & + P(x_4x_5 - 2x_4x_7 - 2x_5x_7 + 3x_7) \end{aligned}$$

which is of the form

$$x_0 = 3 + (xQx)/2$$

Taking (arbitrarily) the penalty P to be 10, the 7-by-7 Q matrix is

$$Q = \begin{bmatrix} -2 & 0 & 2 & 0 & 0 & -1 & 0 \\ 0 & 2 & 6 & 0 & 0 & -20 & -1 \\ 2 & 6 & 0 & 0 & 0 & -20 & -1 \\ 0 & 0 & 0 & -4 & 13 & 3 & -20 \\ 0 & 0 & 0 & 13 & -4 & 2 & -20 \\ -1 & -20 & -20 & 3 & 2 & 60 & 0 \\ 0 & -1 & -1 & -20 & -20 & 0 & 60 \end{bmatrix}$$

Minimizing xQx yields $x_1 = x_2 = x_3 = x_6 = 1$, $x_4 = x_5 = x_7 = 0$ for which $xQx = -6$. Thus, $x_0 = 0$ implying that all 12 clauses are satisfied at this solution. Note that in carrying out the reduction from the cubic penalty function to the quadratic several choices for variable substitutions were available. In general it is desirable to make these choices in a manner that minimizes the number of new variables that are introduced.

The preceding discussion and illustrations disclose that the unified unconstrained approach offers a fresh and promising alternative method of attack for these important problems. As additional research is conducted to provide enhanced methods for solving the UQP model, the benefits of recasting diverse problems into this general framework will become even greater.

6 Conclusion

A variety of disparate combinatorial optimization problems can be treated by first reexpressing them within the common modeling framework of the unconstrained quadratic binary program. Once in this unified form, the problems can be solved effectively by recently developed solution approaches for UQP.

The empirical findings from extensive testing challenge the conventional wisdom that places high priority on preserving linearity and exploiting specific structure. Although the merits of such a priority are well-founded in many cases, experience with a large variety of problem classes suggests that an unflinching adoption of

the conventional *linear* approach may preclude obtaining the best outcomes in a number of cases. In making use of the UQP model, any linearity that the original problem may have exhibited is destroyed. Moreover, any exploitable structure that may have existed originally is “folded into” the \hat{Q} matrix, and a general UQP solution procedure takes no advantage of it. Nonetheless, the use of such procedures has been remarkably successful, yielding results that rival the effectiveness of the best specialized methods.

Acknowledgments The authors would like to acknowledge the contributions of their coworkers Drs. Bahram Alidaee, Jin-Kao Hao, Mark Lewis, Karen Lewis, Zhipeng Lu, and Cesar Rego whose work contributed to the results appearing in this chapter.

Abstract

Identification of targets, generally virus or bacteria, in a biological sample is a relevant problem in medicine. Biologists can use hybridization experiments to determine whether a specific DNA fragment, that represents the virus, is present in a DNA solution. A probe is a segment of DNA or RNA, labeled with a radioactive isotope, dye, or enzyme, used to find a specific target sequence on a DNA molecule by hybridization. Selecting unique probes through hybridization experiments is a difficult task, especially when targets have a high degree of similarity, for instance, in case of closely related viruses.

The nonunique probe selection problem is a challenging problem from a biological and computational point of view; a plethora of methods have been proposed in literature ranging from evolutionary algorithms to mathematical programming approaches.

In this study, we conducted a survey of the existing computational methods for probe design and selection. We introduced the biological aspects of the problem and examined several issues related to the design and selection of probes: oligonucleotide fingerprinting, maximum distinguishing probe set, minimum cost probe set, and nonunique probe selection.

1 Introduction

The discovery of the DNA has been defined as the most important biological research in the last century, thus a new era started for biology, medicine, and all genetic researches. These advances in genomic research showed the necessity of implementing efficient methodologies for genome analysis and classification. In this scenario, *in silico* design has become an effective approach to model complex systems, due to the several advantages that computer-aided design holds; in particular, computational approaches for biological problems allow one to reduce the time and cost required for performing experiments, by decreasing the number of wet experiments needed or by speeding up the experimentation process.

Deoxyribonucleic acid (DNA) is a nucleic acid that carries genetic information in the cells that can be passed from one generation to the next [4]. DNA was first observed by Frederich Miescher in the late 1800s, and its structure was discovered in the 1950s by James Watson, Francis Crick, Maurice Wilkins, and Rosalind Franklin. In 1953 James Watson and Francis Crick presented the double-helix model of DNA [83]. Nine years later, Watson, Crick, Wilkins, and Franklin shared the Nobel Prize for their discoveries concerning the molecular structure of nucleic acids and its significance for information transfer in living material.

The structure of the DNA helix consists of two antiparallel complementary strands of simple units, called nucleotides, which represent the genetic material of all living organisms. Each nucleotide comprises three components:

two-deoxyribose, which is a five-carbon sugar; a phosphate group; and a nitrogen-containing base attached to the sugar. In particular, DNA nucleotides have four bases: adenine (A), cytosine (C), guanine (G), and thymine (T).

The sugars in nucleic acids are linked one another by phodiester bridges between the 3' and 5' carbon atoms of adjacent sugar rings. The asymmetric ends of DNA are called the 5' end and 3' end: the 5' end contains a terminal phosphate group, and the 3' end contains a terminal hydroxyl group [4].

According to the Watson-Crick base pairing, the end of one strand in a DNA molecule lines up with the beginning of the other: each adenine on one strand pairs with a thymine on the other and in the same way each guanine pairs with a cytosine base [40].

Ribonucleic acid (RNA) consists of a long chain of nucleotide units. The structure of RNA is usually single stranded; each nucleotide in a RNA chain consists of three chemical units: a nitrogenous base, a ribose sugar, and a phosphate. RNA nucleotides contain ribose while DNA contains deoxyribose and the base uracil rather than the thymine. Some viruses use RNA as their genetic material.

After the description of the double helix by Watson and Crick [83], it was shown that the two DNA strands could be separated by heat or treatment with alkali. Marmur and Doty [47] described the reconstitution process of double-stranded DNA molecule, which underlies all the methods based on DNA renaturation or molecular hybridization. These methods exploit the technology offered by DNA microarrays to monitor thousands of genes at the same time: the basic mechanism behind microarrays is hybridization between two DNA strands, according to the Watson-Crick complementary pairing of nucleotide bases. The results of hybridization experiments can be used to infer the presence of specific targets, and find applications in many areas of biomedicine, such as gene expression profiling, disease diagnosis, drug discovery and development, and therapy planning.

2 Microarrays and Applications

One of the most important recent development in biology is the success of The Human Genome Project (HGP). The principal goal of this project was to sequence the entire human genome. This project was completed in 2003 after 13 years effort. Nevertheless, due to the great amount of data collected, the data analysis will continue for years.

The first step towards mapping a genome is to break down the DNA into segments: this is achieved by making a genomic library. A *DNA library* can be made by fragmenting large pieces of DNA with a restriction enzyme and cloning these fragments randomly into a suitable vector [72]. Given a DNA library, the problem is how to identify specific probes in a clone.

A *probe* is a segment of DNA or RNA, labeled with a radioactive isotope, dye, or enzyme and used to find a specific sequence of nucleotides or gene on a DNA

molecule by hybridization. A clone is said to be positive if it contains a given probe; otherwise, it is negative.

DNA microarray technology provides a fast approach to monitor the entire genome on a single chip and to perform hybridization experiments. A DNA microarray or DNA chip is a glass or nylon slide, onto which single strands of DNA sequences are fixed, called probes. The foundation of microarray technology lies in the Watson-Crick base pairing: two DNA strands, the probe and the target, hybridize if they are complementary to each other. The amount of hybridized target represents the gene expression level.

The two most important DNA microarray platforms are the c-DNA based-platform, and the oligonucleotide microarrays [11].

Some important DNA microarray applications are [76]:

- *Gene identification:* microarrays are used to identify functionality and phenotypes from DNA sequences. Levels and patterns obtained from microarray experiments provide a measure of cell- and tissue-specific gene expression.
- *Diagnosis of genetic diseases:* Genetic diseases are caused by an abnormality in an individual's genome. Common aberrations involved in cancer disease include gene amplifications, nonreciprocal translocations, and interstitial deletions. Microarray technology (i.e., comparative genomic hybridization) can be used to detect and map these changes in copy number of DNA sequences [1].
- *Study of cell cycle variation:* Microarrays are well suited for the analysis of temporal changes in gene expression during cellular events [20].
- *Drug discovery and toxicological research:* DNA microarrays can be used to identify appropriate targets for therapeutic intervention and to monitor changes in gene expression in response to drug treatments [15].
- *Forensic identification:* Microarrays can also be used to identify individuals within forensics [33]. Scientists can use microarrays to find markers in a DNA sample in order to create a profile of an individual.

3 Probe Design and Selection

Probe design involves the selection of probes to be used in microarray experiments. To be effective, each DNA microarray probe should meet the following criteria: specificity, sensitivity, and homogeneity. Additionally, “space and time search” efficiency should be taken into account.

3.1 Specificity

The specificity criterion identifies probes that are unique to each gene in the genome, minimizing the chance cross hybridization [76]. Specificity can be measured by

the Hamming distance metric¹ and BLAST (Basic Local Alignment Search Tool) search.

Libson et al. [44] developed a specificity search algorithm to handle the probe specificity property, under a stochastic model assumption.

Sung and Lee [76] used the Hamming distance metric to check for specificity criterion: if the Hamming distance between a probe and every subsequence in the genome is greater than some constant, the probe is said to be specific enough.

3.2 Sensitivity

According to the sensitivity criterion, probes with high self-complementariness and minimal secondary structure should not appear in microarrays.

Gasieniec et al. [22, 23] adopted free energy to measure sensitivity, where the total difference in the free energy of the folded and unfolded states of a DNA duplex is approximated by using a nearest-neighbor model.

3.3 Homogeneity

Temperature is one of the most important experimental conditions to take into account when performing hybridization experiments. The homogeneity filter aims to discard probes which hybridize at a temperature out of the experiment temperature range [76]. Several studies have derived accurate equations for the melting temperature T_m .

In 1996 SantaLucia et al. [71] calculated the T_m for individual melting curves from the fitted parameters.

In their model each probe should be in a predefined melting temperature range. The melting temperature T_m for a length- m probe p is given by

$$T_m(p) = \frac{\Delta H(p)}{\Delta S(p) + R \times \log(C_T)} - 273.15 + 16.6 \log(\text{Na}^+) \quad (1)$$

where R is the molar gas constant ($1.987 \text{ cal/C}^\circ \times \text{mol}$) and C_T is the total molar concentration of the annealing oligonucleotides when oligonucleotides are self-complementary. For non-self-complementary oligonucleotides, C_T is replaced by $\frac{C_T}{4}$. Na^+ is the salt concentration of the solution in which the oligomers are dissolved. $\Delta H(p)$ and $\Delta S(p)$ are the enthalpy and entropy for helix formation of p respectively. They then calculated the optimal hybridization temperature T_h of p as

$$T_h(p) = T_m(p) - 25 - 0.62(C_F) \quad (2)$$

where C_F is the formamide concentration of the solution.

¹For two strings s and t , the Hamming distance $H(s, t)$ is the number of positions where the characters of the two strings differ.

Wang and Seed [82] calculated the median temperature (T_m) for probes as follows:

$$\text{Median } T_m = 64.6 + 41 \times \frac{\text{gcCount}}{\text{probeLength}} - \frac{600}{\text{probeLength}} \quad (3)$$

where gcCount is the number of all *G*s and *C*s in a probe and the molar sodium concentration is taken to be 0.1 M. A probe candidate is discarded if its T_m is not within 5 C° of the median T_m .

In [22, 23], the melting temperature T_m is calculated as

$$T_m = \frac{\Delta H}{\Delta S + R \times \ln(c/4)} - 273.15 \quad (4)$$

where ΔH and ΔS are the enthalpy and entropy for helix formation respectively, R is the molar gas constant (1.987 cal/C° × mol), and c is the total molar concentration of the annealing oligonucleotides when oligonucleotides are not self-complementary.

3.4 Literature Review for Probe Design and Selection

A plethora of methods and softwares has been presented to design and select “effective” probes for microarrays. In this paragraph, we provide the reader a short summary of some of the most known methodologies.

In 1996 Lockhart et al. [45] proposed a program for designing oligo probes. Their approach is based on hybridization to small, high-density arrays containing tens of thousands of synthetic oligonucleotides.

Xu et al. [86] developed a method useful in selecting gene-specific fragments, which can be used as the input to design PCR primer pair for PCR amplification and microarrays.

Li and Stormo [42] developed a heuristic approach to optimize the selection of specific probe for each gene in an entire genome.

Rouillard et al. [69] presented the Oligoarray software that computes gene-specific and secondary structure-free oligonucleotides for genome-scale oligonucleotide microarray construction. They used BLAST for avoiding cross hybridization.

Kaderali and Schliep [35] proposed an algorithm for the probe design problem. Melting temperatures are calculated for all possible probe target interactions using an extended nearest-neighbor model.

Libson et al. [44] addressed the probe specificity properties under a stochastic model assumption.

Mrowka et al. [53] presented a web-based system for interactive design of suitable oligos, for transcription profiling experiments with user-defined parameters. The web interface allows the user to retrieve oligos for human transcripts in a

flexible manner. Criteria for selecting the oligos are low similarity to all other known human genes, the absence of stable secondary structures, the length of the oligo, and the absence of low-complexity regions. The user may select oligos corresponding to the desired position in the 5'-3' direction of the transcript and based on the melting temperature.

Chen and Sharp [10] provided a suite of Perl scripts that facilitates the search for gene-specific oligonucleotides for microarray experiments. Genes of interest are first identified in the form of UniGene clusters. The sequences of these clusters are extracted and assembled into contigs to increase their accuracy. The 3'-untranslated region (3'UTR) of the contig is parsed. Then, multiple 50 mer oligonucleotide sequences with similar melting temperature are obtained from each 3'UTR. These sequences are analyzed for gene specificity.

Sung and Lee [76] proposed an algorithm to select good probes based on the criteria of homogeneity, sensitivity, and specificity. They used the pigeonhole principle to speed up the specificity filter. Their algorithm is based on probe elimination and includes three steps: first, it filters oligo probes in the genome which fail to satisfy homogeneity criterion, then, it filters oligo probes in the genome which fail to satisfy sensitivity criterion, and finally filters oligo probes based on the specificity criterion using the pigeonhole principle. This is done to remove probes that might cross hybridize with any of the subsequences in the whole genome.

Wang and Seed [82] described the results of studies on the impact of various design criteria on the fraction of candidate probes qualified for microarray interrogation of RNA coding regions. They built the OligoPicker design software that evaluates specificity primarily for the occurrences of contiguous perfect matches. Moreover, they developed an algorithm to cluster redundant mouse and human genes; the resulting unique sequences were used for probe design.

Emrich et al. [19] designed a software tool that enables optimal oligos to be designed for a single or a group of target nucleic acid sequences.

Bozdech et al. [6] developed a software package, ArrayOligoSelector, to design an open reading frame (ORF)-specific DNA microarray using the publicly available *P. falciparum* genome sequence.

Tolstrup et al. [78] presented, OligoDesign, which provides optimal design of LNA (locked nucleic acid)-substituted oligonucleotides for functional genomics applications. OligoDesign features recognition and filtering of the target sequence by genome-wide BLAST analysis in order to minimize cross hybridization with nontarget sequences, and it includes routines for predicting melting temperature, self-annealing, and secondary structure for LNA-substituted oligonucleotides, as well as secondary structure prediction of the target nucleotide sequence. Individual scores for all these properties are calculated for each possible LNA oligonucleotide in the query gene, and the OligoDesign program ranks the LNA probes according to a combined fuzzy logic score, finally returns the top scoring probes to the user. OligoDesign has been used to design a *Caenorhabditis elegans* LNA oligonucleotide microarray, which allows monitoring the expression of a set of 120 potential marker genes for a variety of stress and toxicological processes and toxicologically relevant pathways.

Nielsen et al. [55] presented a program for designing optimal oligonucleotides for microarrays, OligoWiz. The program implements the design of highly specialized arrays, as well as general use arrays. OligoWiz evaluates and graphically presents all the potential oligonucleotides in the input sequences, according to a collection of parameters, each of which can be assigned a different weight.

Gordon and Sensen [26] developed a software package called Osprey for the calculation of optimal oligonucleotides for DNA sequencing and the creation of microarrays based on either PCR-products or directly spotted oligomers. It incorporates a novel use of position-specific scoring matrices, for the sensitive and specific identification of secondary binding sites, anywhere in the target sequence. Osprey consists of a module for target site selection based on user input, novel utilities for dealing with problematic sequences such as repeats, and a common code base for the identification of optimal oligonucleotides from the target list.

Chou et al. [12] implemented an oligo microarray design tool for large genomes, which integrates novel computer science techniques and the best-known nearest-neighbor parameters to quickly identify sequence similarities, and estimate their hybridization properties. The designed oligos are computationally optimized to guarantee the best specificity, sensitivity and uniformity, under the given design constrains.

Reymond et al. [67] developed a software to design optimal oligonucleotide probe sets for microarrays. Selected probes show no significant cross hybridization and no stable secondary structures, and their melting temperature (T_m) is chosen to minimize the T_m variability of the probe set.

Li et al. [43] presented a tool that uses sequence identity, free energy, and continuous stretch for selection of optimal oligonucleotide probes. This approach implements a series of filters to check every oligonucleotide. A sequence identity based on gapped global alignments is identified, and a traversal algorithm is used to generate alignments for free energy calculation. The optimal T_m interval determined is based on probe candidates that have passed all other filters. Final probes are picked using a combination of user-configurable piecewise linear functions and an iterative process. The thresholds for identity, stretch, and free energy filters are automatically determined from experimental data by an accessory software tool, CommOligo-PE (CommOligo Parameter Estimator).

Rimour et al. [68] compared the existing oligo design softwares under certain experimental conditions. They proposed a new approach to design oligonucleotides, which combines good specificity with a potentially high sensitivity. They also presented an experimental validation of their strategy by comparing results obtained with standard oligos and with their composite oligos.

Charbonnier et al. [9] described a procedure for selecting 40–60 mer oligonucleotide probes combining optimal thermodynamic properties with high target specificity, suitable for genomic studies of microbial species. The algorithm for filtering probes from extensive oligonucleotide libraries includes positional information of predicted target-probe binding regions. The validity of potential microarray probes is tested by considering the possibility of cross hybridization

with nontarget coding sequences. This analysis can be performed within a single genome or between several different organisms.

Nordberg [56] presented an application for assisting biological researchers in selecting signature sequences. It incorporates a custom sequence similarity search to find potential cross hybridizing non-target sequences. The tool supports multiple probe design goals, including single-genome, multiple genome, pathogen host, and species/strain identification.

4 Probe Selection Problems

The choice of the oligonucleotide probe sets plays an important role in hybridization experiments: the optimal probe set should contain a minimal number of oligonucleotides in order to minimize the number of hybridization experiments, since this affects the experimental costs [5]. Due to the importance of an efficient design and selection, this subject has attracted increasing attention in the last 20 years. Therefore, a plethora of approaches has been proposed in literature, ranging from specific software tools and web-based applications to select oligonucleotides having specific features, such as low similarity, absence of secondary structure, as already seen in the previous sections, [6, 12, 19, 26, 53, 55, 56, 67, 69, 78, 82], to algorithms that optimize the design [9, 35, 43, 45, 68, 76].

Informally, the probe selection problem involves the selection of a small set of probes to analyze a population of unknown clones [59]. The basic (binary) probe selection problem can be formally stated as follows [5]:

Definition 1 Let $C = \{c_1, \dots, c_m\}$ be a set of unknown clones (or *targets*) and $P = \{p_1, \dots, p_n\}$ a set of oligonucleotide probes of preselected length l . The objective is to find a *smallest* set P of probes such that any two distinct clones $c, d \in C$ are distinguished by at least one probe $p \in P$, where a probe p is said to *distinguish* two clones c, d if it is a substring of exactly one of c or d .

This problem can be classified into two main categories: oligonucleotide fingerprinting and nonunique probe selection problem.

5 Oligonucleotide Fingerprinting

Oligonucleotide fingerprinting is a technique to identify unique probes by performing hybridization experiments: hybridization signals are evaluated and a vector of numerical values, the *fingerprint*, is assigned to each probe. Essentially, a fingerprint is a sequence of m numbers, that are signals from an image, which represents the interaction of the clone sequence with the probe set. For the sake of simplicity, it can be assumed that a fingerprint is a binary vector where the value 1 at a given position j , $1 \leq j \leq m$, means that the j th probe hybridizes to that clone, whereas a 0 means

that it does not. The fundamental hypothesis in this approach is the uniqueness of the fingerprint for each probe [29, 30].

The oligonucleotide fingerprinting method was first developed in 1986 for analyzing the mammalian genome. From then on, since many computational challenges arise in this method, several algorithmic approaches have been developed; in particular, two main issues have been handled: clone classification and probe selection.

5.1 Clone Classification

The classification of oligonucleotide fingerprints finds application in analysis of bacterial community composition and expression levels of genes. This process comprises several steps, starting with the creation of clones to perform hybridization, to the analysis of the fingerprints resulting from the experiment. Once this analysis is completed, clones are classified according to their characteristics and the results of the hybridization; two classes are therefore constructed, representing the clones that hybridize to probes and those that do not [21]. Unfortunately, the step of translating hybridization signals into two groups is not easy to perform, especially due to the intensity values of hybridization array [21]. Most of the existing approaches to classify clones are based on clustering methods.

Clustering can be informally defined as the classification of patterns into groups, the clusters, according to a similarity measure. Intuitively, patterns belonging to a specific cluster present more similarity to each other than to patterns within a different cluster. Typically, a clustering procedure comprises several steps [34]: pattern representation, definition of the similarity measure used to cluster the domain into groups, the clustering of data, and the evaluation of the output.

One of the most known clustering method is the k -means algorithm [46], where the underlying idea is to partition the pattern into k clusters, by minimizing the sum of squares of distances between data and the corresponding cluster centroid. Briefly, the k -means procedure works as follows: k cluster centers are chosen; therefore, the patterns are assigned to the closest cluster centroid. The centroids are recomputed using the current cluster memberships, and at each iteration, a new binding is done between the same dataset points and the nearest new centroid. This process ends when a specific convergence criterion is met.

In [29], Herwig et al. proposed a clustering procedure based on a sequential k -means algorithm to classify clone fingerprints. The clustering algorithm groups similar fingerprints together, according to a pairwise similarity measure. This measure is based on mutual information and takes into account the total number of matched similarities, whereas the commonly used metric distances, like the Euclidean distance, do not. An important assumption is that hybridization signals in clones are independent; mutual information measures the mutual dependence of two signals: it tends to zero if there is no correlation between the fingerprints $x = (x_1, \dots, x_p)$ and $y = (y_1, \dots, y_p)$; it is maximal if x and y are equal (perfect correlation). Given two fingerprints x and y , the mutual information is given by

$$H(x; y) = \sum_{i=1}^K \sum_{j=1}^K \frac{n_{ij}^{xy}}{n^{xy}} \log_2 \frac{n_{ij}^{xy} n^{xy}}{n_i^x n_j^y} \quad (5)$$

where K represents the number of intervals used to digitalize signals, n_{ij}^{xy} is the number of pairs where x falls in interval i and y falls in interval j , n_i^x and n_j^y are the respective marginal frequencies of x and y , and n^{xy} is the number of pairs where signals are present in both vectors [29]. To select pairs that are close to each other, the value $t(x, y) = \sum_{i=1}^K (n_{ii}^{xy}) / (n^{xy})$ is computed for each pair of data points.

In order to compare different pairwise clone similarities, the value of mutual information is normalized as follows:

$$s(x, y) = \frac{2H(x; y)}{H(x) + H(y)} \quad (6)$$

where $H(x) = -\sum_{i=1}^K K \frac{n_i^x}{n^{xy}} \log_2 \frac{n_i^x}{n^{xy}}$ represents the entropy value for x and $H(y)$ the entropy value for y .² Since

$$H(x; y) \leq \min\{H(x), H(y)\} \quad (7)$$

as reported in [14], s lies in the interval $[0,1]$. If $s = 1$, x and y are perfectly correlated; otherwise, no correlation is found.

For clustering fingerprints, two parameters are introduced: γ is the minimal similarity threshold to merge two clusters, and ρ is the maximal admissible similarity of a data point to a cluster centroid. A random sample of data pairs is selected to adjust the threshold according to the dataset, and a distribution of pairwise similarity is derived from this sample. The median m and the standard deviation s computed from the obtained distribution are used to compute the threshold values γ and ρ .

The clustering procedure guarantees that cluster centroids are sufficiently separated, because their pairwise similarity at each step is less than γ ; moreover, centroids that have similarity with a data point greater or equal than ρ are replaced by this point. To validate the clustering, a measure of quality is computed: let us assume to know the true clustering T for a data structure of N data points, x_1, \dots, x_n . Let $t_{ij} = 1$ if x_i and x_j are in the same cluster; otherwise, $t_{ij} = 0$, where $1 \leq i, j \leq N$. For a calculated cluster C , c_y is defined in the same way: it is equal to 1 if x_i and x_j belongs to the same cluster, 0 if not. To evaluate the clustering quality, a 2×2 contingency table is computed (see Table 1), where columns correspond to the true clustering and rows correspond to the calculate clustering.

²Entropy measures the information content of a probe with respect to the set of sequences. Shannon entropy is introduced in [74].

Table 1 Contingency table for clustering validation

	0	1	Total
0	N_{00}	N_{01}	$N_{0\cdot}$
1	N_{10}	N_{11}	$N_{1\cdot}$
Total	$N_{\cdot 0}$	$N_{\cdot 1}$	$N_{\cdot \cdot}$

In **Table 1**, $N_{kl} = \#\{(i, j); t_{ij} = l, c_{ij} = k, l \leq i, j \leq N\}$, $0 \leq k, l \leq 1$. $N_{\cdot k}$ and $N_{l\cdot}$ represent the respective marginal frequencies. The number of diagonal pairs in the table ($N_d = N_{00} + N_{11}$) indicates the number of correct clustered data pairs. To measure the clustering quality, the relative mutual information coefficient (RMIC) is computed as

$$\rho(C, T) = \text{sgn}(N_d - N^2/2) \frac{H(C; T)}{H(T)} \quad (8)$$

where C and T represent, respectively, calculated and true clustering; $\text{sgn}(y) = 1$ if $y \geq 0$, -1 otherwise. The number K of intervals considered for $H(C; T)$ and $H(T)$ is 2. RMIC represents the amount of information that calculated clustering contains about true clustering, and its value is negative if there are more pairs incorrectly clustered than correctly.

In a later work [30], the described clustering method is implemented in a data-analysis pipeline, where the probe set is a simulation parameter. An initial set of sequences is divided into two parts: a training set, and a part used to derive test sets for clustering. Probe sets are constructed by iteratively choosing probes that partition the training sequences into subsets that are as equal in size as possible. Binary fingerprints are computed from sequences in the test sets. Since the number of possible fingerprints increases as 2^p for p probes, computing all the possibilities is computationally infeasible. Then an approximation is applied [48]: in the first step, the probe that best partitions the sequences into two groups having the same size is found. Then, the algorithm selects the second probe that, together with the first one, partitions the training set into four groups that are as equal in size as possible. This process is iterated until the number of selected probes is equal to a threshold, or each partition contains only one probe, condition defined as complete partitioning.

Another clustering procedure is introduced in [28]. The proposed algorithm works on a similarity graph, constructed from a similarity matrix S as follows: given an $n \times p$ matrix H , where n is the number of clones and p the number of probes, H_{ij} represents the intensity level of hybridization of clone i with probe j , for $i \leq n, j \leq p$. The similarity matrix S , where $S_{ij} = \sum_k H_{ik} \cdot H_{jk}$, is constructed from H . The similarity graph G_θ is a graph with vertices corresponding to the clones and whose edges connect clones having pairwise similarity greater or

equal to the threshold θ [52]. The idea behind this approach is to identify cliques³ in the similarity graph (because they represent similar fingerprints), by recursively searching for highly connected subgraphs.⁴

5.2 Probe Selection

Selecting optimal probes for oligonucleotide fingerprinting is a difficult task, since the “quality” of probes affects the final design. From this perspective, effective and efficient computational methods have been developed to provide a fast and accurate set of probes. These approaches range from exact methods to heuristic algorithms. In particular, two variations of the original probe selection problem have been introduced by Borneman et al. in [5], where the objectives are to maximize the number of clones distinguished (*maximum distinguishing probe set*) and to minimize the number of probes needed to distinguish all the clones (*minimum cost probe set*). We will discuss these problems later in this section.

A randomized algorithm for probe selection is proposed in [23], whose underlying idea is to explore randomization to reduce the computational time needed for selecting probes. In this approach, every substring of a gene of a specific length m is referred to as a *candidate*. For each candidate, the algorithm verifies if it satisfies the following criteria: quantitative criteria, concerning the size of the bases and the length contiguous regions of bases [45]; homogeneity, concerning the melting temperature; and sensitivity. Candidates that do not meet such standards are filtered out whereas candidates that pass the filtering step are called probes. Once the probes are produced, the optimal among them are selected from this pool by applying a randomized procedure, that guarantees a faster selection and assures unique probes for up 99 % of genes in the whole genome. The time complexity of the algorithm is $\mathcal{O}(kmn)$, where k (usually smaller than n) is the number of genes in the whole genome, m is the length of probes, and n the length of the whole genome, versus the $\mathcal{O}(mn^2)$ complexity of the brute-force approach.

In [65], Rash and Gusfield introduced the barcoding problem, where the notion of barcode is equivalent to the concept of oligonucleotide fingerprint. In their approach, the problem is formulated as an integer linear programming (ILP) model, and suffix trees are used to reduce the number of variables by selecting substrings, the probes, from strings that represent the target sequences.

Let c_1, \dots, c_k represent the set of all substrings for each pair of clones (C_1, C_2). For each substring c_i , $1 \leq i \leq k$, a corresponding binary variable v_i is assigned. The goal of the mathematical formulation is to minimize the sum of v_i , subject to

³We recall that a clique in a graph $G = (V, E)$ is a subset $C \subseteq V$, such that each pair of vertices in C is connected by an edge.

⁴A graph G with $n > 1$ vertices is said highly connected if the minimum size of a cut, $k(G)$, is $> n/2$. A highly connected subgraph is an induced subgraph that is highly connected.

$$v_1 + \dots + v_k \geq 1. \quad (9)$$

In this approach, a method to identify virus mutations is introduced: instead of requiring that each pair of clones is distinguished by only one probe, the constraint of having pairs distinguished by at least r probes is imposed. Therefore, (9) becomes

$$v_1 + \dots + v_k \geq r. \quad (10)$$

Using $r = 5$ ensures with high confidence that a signature would remain valid under reasonably high mutation rates and short generation time. A second constraint imposes a minimum edit distance between pairs of clones:

$$v_i + v_j \leq 1. \quad (11)$$

According to (11), if a pair of substrings v_i and v_j does not satisfy the constraint, only one of the strings is allowed to be in the solution set. The result of the analysis shows that using 2 or 4 as edit distance results in added confidence that mutations in nature not invalidate the signatures.

The choice of addressing an optimal design, by maximizing the quality of probes or minimizing the cost of selecting probe, is addressed in two variations of the oligonucleotide fingerprinting problem introduced in [5]: the *maximum distinguishing probe set (MDPS, for short)* and the *minimum cost probe set (MCPS, for short)*. Some basic notations are now introduced to define the problems.

Definition 2 Let $C = \{c_1, \dots, c_m\}$ be the set of clones (or *targets*) and $P = \{p_1, \dots, p_n\}$ the set of probes of preselected length l .

Let $C^2 = \{(c, d) : c, d \in C, c < d\}$ be the set of all pairs of different clones of C , where “ $<$ ” denotes an arbitrary ordering of C ; $\text{occ}(c, p)$ is the number of occurrences of the probe p in the target c .

R denotes the threshold for the number of occurrences of each probe in a clone.

The P -fingerprint of c , denoted by $\text{fingerprint}_P(c)$, is a vector of length m which contains one entry for each probe p ; $\text{fingerprint}_P(c)$ is the value $\min\{R, \text{occ}(p, c)\}$, $\forall p \in P$.

If $R = 1$, the fingerprint is just a binary vector with a 1 in position i if probe p_i is a substring of clone c , and a 0 otherwise.

A set of probes P distinguishes two clones c and d , if $\text{fingerprint}_P(c) \neq \text{fingerprint}_P(d)$.

$\Delta_P \subseteq C^2$ is the set of pairs of clones distinguished by P .

In *MDPS*, the problem is to find a set of k probes, where k is a known parameter, that maximizes the number of distinguished pairs of clones. Formally,

Problem 1 (Maximum Distinguishing Probe Set) Given a set C of clones, a set P of probes, and an integer k , find a subset $S \subseteq P$, with $|S| = k$, where $|\Delta_S|$ is maximized.

In *MCPS*, the objective is to find a minimal number of probes that distinguishes all the clones. Formally,

Problem 2 (Minimum Cost Probe Set) Given a set C of clones and a set P of probes, find a subset $S \subseteq P$, such that $\Delta_P = C^2$ and $|S|$ is minimized.

In particular, the *MCPS* problem can be considered as a special case of the set-cover problem [31], and *MDPS* as a special case of maximum coverage [31]. *MCPS* and *MDPS* are NP-hard, when the length of probes is unbounded [5]. To overcome such NP-hardness, some heuristic methods have been introduced in literature: in [5], a heuristic method based on a Lagrangian relaxation is applied to solve the *MCPS* problem, since this approach performs good for the set cover problem [7]. The *MCPS* problem is formulated as a constrained integer linear program, as follows:

$$\min |S| = \sum_{p \in P} x_p \quad (12)$$

subject to

$$\sum_{p \in P} \delta_{p,c,d} \cdot x_p \geq 1 \quad \forall (c, d) \in C^2 \quad (13)$$

$$x_p \in \{0, 1\} \quad \forall p \in P \quad (14)$$

where $x_p \in \{0, 1\}$ indicates whether the probe p is in a feasible solution S or not; $\delta_{p,c,d} = 1$ if $(c, d) \in \Delta_p$. This formulation is solved by using a Lagrangian relaxation algorithm. Since the solutions obtained can be infeasible, a greedy strategy is applied to ensure their feasibility.

The *MDPS* problem is addressed by applying a simulated annealing algorithm: it starts with an initial random solution and moves to neighbors characterized by values that are better than the current one. Two sets of probes are said neighbors if one can be obtained from the other by substituting exactly one probe.

At each iteration of the algorithm, a new random neighbor S' is generated from the current solution S . S' is chosen as new solution according to a probability $\text{pr} = \min\{1, \exp \frac{|\Delta_S| - |\Delta_{S'}|}{t}\}$, where t represents the temperature parameter. The temperature value is decreased at each iteration according to $t = \beta t / (\beta + t)$; the value of β has been set empirically to 2,000.

Experimental results show that both methods presented in [5] are able to find satisfactory probe sets for real instances.

In [8], the *MDPS* several approaches for solving the *MDPS* problems have been proposed. The quality of the results is estimated in [8] by using four different measures: entropy; number of sets that measure the number of sets of undistinguishable clones; largest set, which considers the cardinality of the largest set; and number of pairs, counting the number of clones distinguished by the probe set.

Entropy is defined as follows:

$$E = - \sum_{i=1}^k \frac{|C_i|}{m} \log_2 \left(\frac{|C_i|}{m} \right), \quad (15)$$

where C_i , $1 \leq i \leq k$, represent the sets of undistinguishable clones for the given probe set and m is the number of clones. The entropy value for the optimal solution is $\log_2 m$. Two kinds of neighbors are exploited: augmented and pivot neighbors. Two solutions S_i , S_{i+1} are said to be augmented neighbors if and only if $|S_i| + 1 = |S_{i+1}|$ and $S_i \subset S_{i+1}$.

S_i , S_{i+1} are pivot neighbors if and only if $|S_i| = |S_{i+1}| = k$ and $|S_i \cap S_{i+1}| = k - 1$, that is, S_i and S_{i+1} differ for exactly one element. k is the parameter representing the number of probes.

The first approach presented in [8] is an affinity-based algorithm: a square matrix of the affinity is computed for each pair of probes, and the two probes having the best value are selected. At each step the probe that together with the former ones generates a better affinity score is picked, until the number of selected probes is equal to k . The greedy algorithm proposed in [8] moves from a solution set to its augmented neighbors, by selecting a probe that together with the previously selected ones partitions the clone set better, according to the quality measures, until the number of selected probes is equal to k . The pivot-last algorithm and pivot-greedy algorithm combine the greedy strategy with pivot steps. Furthermore, two heuristic approaches, a genetic algorithm [32] and a simulated annealing method [36], are proposed.

All the proposed methods for the *MDPS* problem are tested on real and synthetic data; it turns out that the best approach is the pivot greedy algorithm. Moreover, the entropy measure is recognized as the best estimation measure, since it represents the most global and exhaustive criterion with respect to the others.

In [51], an efficient Asynchronous Teams technique [17] is applied to find near-optimal solutions for the *maximum distinguishing probe set* and the *minimum cost probe set* problems. An A-Team can be viewed as a collection of autonomous agents, each of which representing a heuristic strategy. Agents can read and write to shared memory without any synchronization among them. The details of this approach for the *MDPS* and the *MCPS* problems can be found in Figs. 1 and 2, respectively. $C1$, $C2$, and $C3$ are independent agents that create the probe set, compute the fingerprint for each probe, and construct a feasible solution. Agents $CB1$ and $CB2$ work together with $C2$ for creating new solutions starting from the “old” ones. $M1$ and $M2$ represent the shared memory. Agents $I1$ and $I2$ improve the current solutions, by implementing a 1-neighbor and 2-neighbors strategy for *MDPS* and a 2,1-exchange for *MCPS*, where, if possible, two probes are substituted by one.

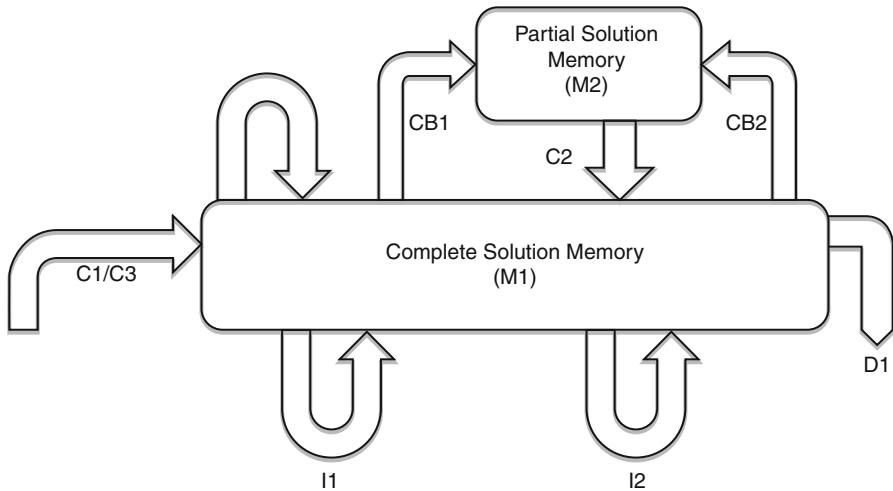

Fig. 1 A-Team for the *MDPS*: agents and shared memories

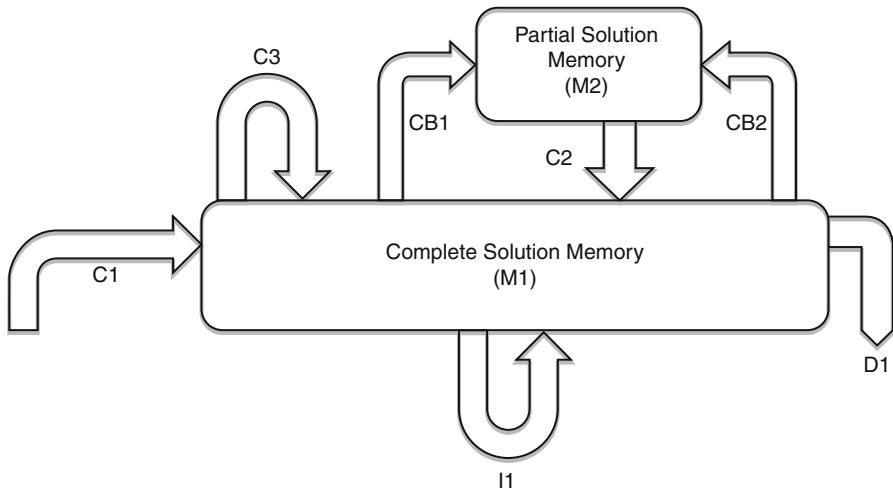

Fig. 2 A-Team for the *MCPS*: agents and shared memories

The A-Team strategy produces results comparable to [5]; moreover, this approach is able to find near-optimal probe sets with probes of both fixed and variable lengths.

6 The Nonunique Probe Selection Problem

Finding probes that are unique through hybridization experiments is difficult, especially when targets have a high degree of similarity, as in the case of closely related viruses. An alternative approach consists on the selection of *nonunique* probes, characterized by the hybridization to more than one target. In addition to the intrinsic complexity of this task, the presence of errors can affect the results of the experiments: false hybridizations can occur (*false positive*), or experiments might not report their presence (*false negative*). A remedy is introducing redundancy into the design, by requiring that targets have to be separated by more than one probe (*separation constraint*) and that each target has to hybridize to more than one probe (*coverage constraint*). The formal definition of the Nonunique probe selection problem (*NUPS*, for short) requires some additional definitions.

Definition 3 (Target-Probe Incidence Matrix) Given m target sequences t_1, \dots, t_m , and n candidate probes p_1, \dots, p_n , a target-probe incidence matrix $H = (h_{ij})$ is defined by $h_{ij} = 1$ if target t_i hybridizes to probe candidate p_j , and $h_{ij} = 0$ otherwise.

An example of target-probe incidence matrix can be found in [Table 2](#).

Definition 4 (Probe Coverage) Given m target sequences t_1, \dots, t_m , and n candidate probes p_1, \dots, p_n , a probe p_j , $1 \leq j \leq n$, is said to be covered by the target t_i , $1 \leq i \leq m$, if the target t_i hybridizes to the probe p_j or, equivalently, if $h_{ij} = 1$.

Definition 5 (Probe Separation) Given m target sequences t_1, \dots, t_m , and n candidate probes p_1, \dots, p_n , a probe p_j , $1 \leq j \leq n$, is said to distinguish or separate two target sequences t_a and t_b , if it is a substring of exactly one of t_a or t_b , that is, if $|h_{aj} - h_{bj}| = 1$.

As an example, given the targets $t_a = AGGCAATT$ and $t_b = CCATATTGG$, for the probe $p_j = GCAA$, $h_{aj} = 1$, $h_{bj} = 0$; therefore, p_j distinguishes t_a and t_b . On the contrary, for the probe $p_k = ATT$, we have $h_{ak} = h_{bk} = 1$, so that it follows p_k does not distinguish the target-pair t_a, t_b .

Informally, the goal of the nonunique probe selection problem is to select a minimum set of probes such that the presence or absence of a single target can be univocally determined. In order to reduce the presence of experimental errors, each pair of targets should be distinguished by at least h_{\min} probes; these requirements are called *Hamming distance constraints*⁵ or *separation constraints*. The *coverage constraint* requires that each target has at least c_{\min} probes hybridizing to it.

⁵Recall that the Hamming distance between two strings of equal length is defined as the number of positions at which the strings differ.

Table 2 Target-probe incidence matrix

	p_1	p_2	p_3	p_4	p_5	p_6
t_1	1	1	0	1	0	1
t_2	1	0	1	0	0	1
t_3	0	1	1	0	1	1
t_4	0	0	1	1	1	0

It can be shown that the problem is NP-hard, using a reduction from the set-cover problem as a special case for $h_{\min} = 1$ and $c_{\min} = 0$ [37, 38].

6.1 State-of-the-Art Methods

Due to its importance in genomic applications, the nonunique probe selection problem has been broadly studied, and a great number of mathematical and algorithmic approaches has been proposed. In particular, we distinguish between exact and heuristic methods.

6.1.1 Exact Methods

Many combinatorial formulations of the nonunique probe selection problem, have been presented in literature. In [37, 38], after a preliminary reduction of the numbers of candidate probes, the problem is modeled as a variation of a set-cover integer linear programming problem.

Let $N = \{p_1, \dots, p_n\}$ denote the set of candidate probes, $M = \{t_1, \dots, t_m\}$ denote the set of targets, and $P = \{(i, k) | 1 \leq i < k \leq m\}$ denote the set of all combinations of target indices. Let x_j , $j \in N$, be the binary-valued decision variables, with $x_j = 1$ if the probe j is chosen, 0 otherwise.

The problem is formulated as follows:

$$\min \sum_{j=1}^n x_j \quad (\text{master ILP}) \quad (16)$$

subject to

$$\sum_{j=1}^n h_{ij} x_j \geq c_{\min} \quad \forall i \in M \quad (17)$$

$$\sum_{j=1}^n |h_{ij} - h_{kj}| x_j \geq h_{\min} \quad \forall (i, k) \in P \quad (18)$$

$$x_j \in \{0, 1\} \quad \forall j = 1, \dots, n. \quad (19)$$

The objective function (16) minimizes the number of probes; the constraints in (17) require that at least c_{\min} selected probes hybridize to each target, and (18) represents the Hamming distance constraints. Finally, (19) restricts the variables to binary values.

When h -separation cannot be ensured for all target pairs with the given set of probes, the solutions of the above ILP formulation are empty. As a remedy, a large number $l = m \cdot h$ of unique virtual probes are added to the initial set of available probes. It is important to note that such “artificial” probes are chosen only if the separation constraint does not hold the original set of candidate probes. In this scenario, the objective function coefficients of the virtual probes are set to a large number M ; the original master ILP is hence reformulated as follows:

$$\min \sum_{j=1}^n x_j + M \sum_{k=n+1}^{n+l} x_k, \quad (20)$$

with n replaced by $n + l$ in the constraints of the original master ILP formulation.

The master ILP formulation presented in (16)–(19) guarantees separation between pairs of single targets. In some circumstances, however, separation between groups of targets is desirable, since this approach can take into account cross hybridization and error tolerance. A group testing approach for this case has been already introduced in [73], where separation is defined also among pairs of small target groups.

For the mathematical formulation, group-separability is considered in a new model, the slave ILP. Given a set of targets S , let $\omega_j^S = \max_{i \in S} h_{ij}$ the signature of S , resulting from applying the logical *OR* to the rows in S , with $j = 1, \dots, n$. S and T are d -separable if and only if the Hamming distance between ω^S and ω^T is at least d . A cutting-plane approach is proposed to solve this problem: the idea is to iteratively construct a most violated group constraint by looking at the current solution.

Let x^* be a solution vector and $X = \{j | x_j^* = 1\}$ the index set of probes included in x^* . For a target set S , let $\omega_{|X}^S$ be the restriction of ω^S to the columns in X . The following slave ILP is solved to find target groups S and T such that the Hamming distance between $\omega_{|X}^S$ and $\omega_{|X}^T$ is less or equal than d :

$$\max \sum_{j \in X} (\sigma_j^0 + \sigma_j^1) \quad (\text{slave ILP}) \quad (21)$$

subject to

$$\sigma_j^0 \leq 1 - s_i \quad \forall (i, j) \in M \times X \quad \text{with } h_{ij} = 1 \quad (22)$$

$$\sigma_j^0 \leq 1 - t_i \quad \forall (i, j) \in M \times X \quad \text{with } h_{ij} = 1 \quad (23)$$

$$\sigma_j^1 \leq \sum_{i \in M} h_{ij} s_i \quad \forall j \in X \quad (24)$$

$$\sigma_j^1 \leq \sum_{i \in M} h_{ij} t_i \quad \forall j \in X \quad (25)$$

$$\sum_{i \in M} s_i \geq 1 \quad (26)$$

$$\sum_{i \in M} t_i \geq 1 \quad (27)$$

$$s_i + t_i \leq 1 \quad \forall i \in M \quad (28)$$

$$\sum_{i \in M} s_i \leq c \quad (29)$$

$$\sum_{i \in M} t_i \leq c \quad (30)$$

$$0 \leq \sigma_j^0 \leq 1 \quad \forall j \in X \quad (31)$$

$$0 \leq \sigma_j^1 \leq 1 \quad \forall j \in X \quad (32)$$

$$s_i \in \{0, 1\} \quad \forall i \in M \quad (33)$$

$$t_i \in \{0, 1\} \quad \forall i \in M \quad (34)$$

Variables σ_j^0 and σ_j^1 model the similarity between S and T for the probe j : $\sigma_j^0 = 1$ if and only if ω_j^S and ω_j^T are equal to 0, and $\sigma_j^1 = 1$ if and only if both variables are equal to 1. Constraints (22) and (23) express that $\sigma_j^0 = 0$ if S or T contains a target that hybridizes to probe j ; due to the constraints (24) and (25), $\sigma_j^1 = 1$ if at least one target in both S and T hybridizes to probe j .

Finally, constraints (26) and (27) avoid that $S = \emptyset$ and $T = \emptyset$, while (28) and (29) control the size of S and T .

A new formulation that does not require virtual probes is modeled in [38]. Here, the maximal possible separation between two groups of targets S and T is defined as

$$h(S, T) = \sum_{j \in N} |\omega_j^S - \omega_j^T|. \quad (35)$$

Therefore, the following model is introduced:

$$\min \sum_{j=1}^n x_j \quad (36)$$

subject to

$$x_j \in \{0, 1\} \quad \forall j \in N \quad (37)$$

$$\sum_{j \in N} |\omega_j^S - \omega_j^T| \cdot x_j \geq \min\{d, h(S, T)\} \quad \forall S, T \subseteq M, \quad (38)$$

$$|S| \leq c, \quad |T| \leq c, \quad S \neq T.$$

Inequalities (38) ensure that coverage constraints are satisfied; since the number of constraints in (38) is exponential, a branch-and-bound approach is applied to solve the relaxed version of the problem.

In [16], an algorithm based on the previous ILP formulations is proposed to solve the nonunique probe selection problem using a d -disjunct matrix. A matrix is d -disjunct if and only if the union of any d columns does not contain any other column, formally:

Definition 6 (d -Disjunct Matrix) H is a d -disjunct matrix if and only if for any $(d + 1)$ columns t_0, t_1, \dots, t_d , there exists a row p_i such that $H[i, 0] = 1$ and $H[i, j] = 0, \forall j = 1, \dots, d$.

Row p_i is said to cover the pair $(t_0, \langle t_1, \dots, t_d \rangle)$. The problem is hence reformulated as follows:

Problem 3 (Minimum- d -Disjunct Submatrix (MIN- d -SD)) Given m nonunique probe candidates and an $m \times n$ target-probe incidence matrix M , select a minimum set of the probe candidates such that the $h \times n$ submatrix H is d -disjunct, where $h \leq n$.

Naturally, the new defined problem is also NP-hard [77]. This problem is addressed by reformulating the ILP models proposed in [38]. The first new ILP formulation is based on the following definition:

Definition 7 H is called (d, k) -disjunct if each column has at least $(k + 1)$ 1-entries not contained in the union of other d columns.

The following mathematical formulation is used to construct a $(1, d - 1)$ -disjunct submatrix.

$$\min \sum_{i=1}^m x_j \quad (39)$$

subject to

$$\sum_{i \in M} |M_{ij} - M_{ij} M_{ik}| x_i \geq d \quad \forall j, k \in N, \quad j \neq k \quad (40)$$

$$x_j \in \{0, 1\} \quad \forall i \in M, \quad (41)$$

where M is the target-probe incidence matrix; m and n are, respectively, the number of probes and targets; and $x_i = 1$ if probe p_i is chosen for the submatrix H , otherwise is 0. The first constraint guarantees that any column in M has at least a number d of one-components not contained in any other column.

A second ILP formulation recalls the slave ILP proposed in [38]; it finds the target sets R and S that violate d -disjunctness.

In order to detect errors in hybridization experiments, a new ILP problem is modeled that is able to identify at most d targets when at most k errors occur, by constructing a $(d, 2k)$ -disjunct matrix [18].

$$\min \sum_{i=1}^m x_j \quad (42)$$

subject to

$$\sum_{i \in M} |M_{ij} - M_{ij} M_{ik}| x_i \geq d + 2k \quad \forall j, k \in N, \quad j \neq k \quad (43)$$

$$x_j \in \{0, 1\} \quad \forall i \in M \quad (44)$$

The algorithm for the error tolerance case uses this formulation to construct the $(1, d + 2k - 1)$ -disjunct matrix and the second one to find the target sets that violate $(d, 2k)$ -disjunctness.

6.1.2 Heuristic Methods

Though exact methods are able to locate solutions with a guarantee of optimality, these approaches require an exact knowledge of the domain; moreover, in some cases, finding a solution via integer programming software is intractable, due to the large number of variables and constraints within the problem [49]. Heuristic algorithms allow to overcome these difficulties, by implementing search strategies that speed up the location of optimal solutions, even if without any guarantee of optimality.

A two-phases heuristic algorithm for the nonunique probe selection problem has been presented in [50]. It consists of a construction phase, which builds a feasible solution when possible, and a reduction phase that reduces the number of probes while maintaining feasibility. To begin with, candidate probes are selected according to the number of targets to which each probe binds, until the minimum coverage constraint is satisfied for each target. The algorithm next focuses on satisfying the minimum Hamming distance constraint: probes that are not included in the current solution are sorted in decreasing order by the number of target pairs they separate; then probes are selected from the ordered list and added to the solution until the number of Hamming distance violated constraints is reduced to a predefined threshold. The remaining probes are found using a local search. The reduction phase

iteratively deletes two probes at a time and verifies if the solution is still feasible or if it can be made feasible by adding just one probe to the solution.

A cutting-plane algorithm is presented in [60]: this method relaxes a large subset of Hamming distance constraints, in order to find and improve the lower bound on the number of probes required in an optimal solution. Relaxed constraints are reinstated only if it is needed to maintain feasibility. Results provided by this approach are compared to the values computed by the heuristic algorithm implemented in [50] and the ILP approach presented in [37]: the cutting-plane algorithm outperforms the two approaches; in particular it is able to find solutions that are about 20 % better than the previous best ones provided by the other two methods.

A model-based approach is discussed in [79], where a greedy heuristic uses a Bayesian model [57] for guiding the search towards the probes that satisfy separation and coverage constraints. In general, a Bayesian optimization algorithm generates an initial population of solutions randomly, according to a uniform distribution. Therefore, the current population is updated for a number of iterations, by selecting the best solutions using methods inspired to genetic algorithms. This allows one to construct a Bayesian network representing the population of promising solutions, and new solutions are generated by sampling the defined probabilistic model. The new candidate solutions replace some of the old ones in the original population, in order to obtain in-silicon evolutionary pressure.

The model-based approach proposed in this work is similar to a Bayesian algorithm, but it does not consider any evolution mechanism. It represents a modification of the heuristic presented in [50]: the idea is to prefer probes that appear in the largest number of minimal sets, by distinguishing between *good* and *bad* ones. Good probes are those with the highest degree of contribution to minimal solutions, whereas bad probes have the lowest degree of contribution. In order to include good probes in a feasible candidate solution, a coverage and a separation probabilistic models are implemented as follows.

Given the target-probe incidence matrix H , a candidate probe set $P = \{p_1, \dots, p_n\}$, and a target set $T = \{t_1, \dots, t_m\}$, let the function $\text{cov}_{\text{drc}} : P \times T \rightarrow [0, 1]$ be defined as follows:

$$\text{cov}_{\text{drc}}(p_j, t_i) = h_{ij} \times \frac{c_{\min}}{|P_{t_i}|}, \quad p_j \in P_{t_i}, \quad t_i \in T \quad (45)$$

where P_{t_i} is the set of probes hybridizing to target t_i . Notice that $\text{cov}_{\text{drc}}(p_j, t_i)$ is the amount that p_j contributes to satisfy the coverage constraint for target t_i . Additionally, we have $0 \leq \text{cov}_{\text{drc}}(p_j, t_i) \leq 1$. The coverage function $C_{\text{drc}} : P \rightarrow [0, 1]$ is then defined as follows:

$$C_{\text{drc}}(p_j) = \max_{t_i \in T_{p_j}} \{\text{cov}_{\text{drc}}(p_j, t_i) \mid 1 \leq j \leq n\}, \quad (46)$$

where T_{p_j} is the set of targets covered by p_j . $C_{\text{drc}}(p_j)$ is the maximum amount that p_j can contribute to satisfy the minimum coverage constraints. Function C_{drc}

favors the selection of probes that c_{\min} -cover targets t_i that have the smallest subsets P_{t_i} ; these are the essential or near-essential covering probes. In particular, C_{drc} guarantees the selection of near-essential covering probes that c_{\min} -cover *dominated targets*, where t_i dominates t_k if $P_{t_k} \subset P_{t_i}$.

Similarly, the function $\text{sep}_{\text{drc}} : P \times T^2 \rightarrow [0, 1]$ is defined as

$$\text{sep}_{\text{drc}}(p_j, t_{ik}) = |h_{ij} - h_{kj}| \times \frac{h_{\min}}{|P_{t_{ik}}|}, \quad p_j \in P_{t_{ik}}, \quad t_{ik} \in T^2 \quad (47)$$

where $P_{t_{ik}}$ is the set of probes separating target-pair t_{ik} ; $\text{sep}_{\text{drc}}(p_j, t_{ik})$ is what p_j can contribute to satisfy the separation constraint for target-pair t_{ik} . We have $0 \leq \text{sep}_{\text{drc}}(p_j, t_{ik}) \leq 1$. The separation function $S_{\text{drc}} : P \rightarrow [0, 1]$ is

$$S_{\text{drc}}(p_j) = \max_{t_{ik} \in T_{p_j}^2} \{\text{sep}_{\text{drc}}(p_j, t_{ik}) \mid 1 \leq j \leq n\}, \quad (48)$$

where $T_{p_j}^2$ is the set of target pairs separated by p_j . $S_{\text{drc}}(p_j)$ is the maximum amount that p_j can contribute to satisfy the minimum separation constraints. Function S_{drc} favors the selection of essential or near-essential probes that h_{\min} -separate *dominated target pairs*; these probes h_{\min} -separate target-pairs t_{ik} that have the smallest subsets $P_{t_{ik}}$.

Now, cover and selection functions are combined together into the selection function that allows to choose the minimum number of probes such that coverage and separation constraints are satisfied:

$$D_{\text{drc}}(p_j) = \max\{(C_{\text{drc}}(p_j), S_{\text{drc}}(p_j)) \mid 1 \leq j \leq n\}. \quad (49)$$

$D_{\text{drc}}(p_j)$ represents the degree of contribution of p_j , that is, the maximum amount required for p_j to satisfy all constraints; D_{drc} ensures that all essential probes p_j will be selected for inclusion in the subsequent candidate solution, since $C_{\text{drc}}(p_j) = 1$ or $S_{\text{drc}}(p_j) = 1$.

The model-based algorithm uses the above-introduced functions to create a feasible set of probes, according to the constraints of coverage and separation. This algorithm consists of three phases: the initialization phase creates an initial solution; since this solution can be infeasible, the construction phase repeatedly inserts high-degree probes into the initial solution in order to maintain feasibility; finally, the reduction phase removes low-degree probes to reduce the cardinality of the solution set. This heuristic is called *dominated row covering* heuristic. Results provided by the described model are compared with the ones obtained by applying the ILP method [37] and the heuristic algorithm presented in [50]: the Bayesian algorithm obtains comparable results for the artificial data and better results on real instances.

The selection strategy introduced in [79] is combined with an evolutionary approach in [80], where a genetic algorithm, already proposed for the set-cover problem in [3], is adapted to the nonunique probe selection problem. After the creation of a random population, two solutions are selected, by using fitness scaling and binary tournament. Therefore, a fusion crossover is used to create a

new solution, to which a mutation operator is applied. In order to guarantee the feasibility, the heuristic presented in [79] is applied to the generated solution. At this point, a new solution has been generated from the pool of “parents,” and it is used to replace a randomly selected solution with an above-average fitness in the population. This process will be iterated until a stopping criterion is met.

Each solution is modeled as an n -bit binary string $s = s_1 \dots s_n$, where $s_j = 1$ if $p_j \in S$ and $s_j = 0$ if $p_j \notin S$, $1 \leq j \leq n$. The fitness of an individual s is directly related to its objective value, which corresponds to the number of probes in its associated subset S . That is, the fitness of s is defined as

$$f(s) = \sum_{j=1}^n s_j. \quad (50)$$

To create a new population from the current one, crossover and mutation operators are applied. The crossover operator used to create a new individual from two parental ones is a generalized fitness-based crossover: it considers the differences between the parents and is more capable of generating new solutions when the parents are similar; also, the fittest parent influences more the “child” solution. Let f_{P_1} and f_{P_2} be the fitness values of the parents P_1 and P_2 respectively, and let C denote the child solution. Then for $1 \leq j \leq n$, $C_j = P_{1j} = P_{2j}$, provided that $P_{1j} = P_{2j}$; otherwise, $C_j = P_{1j}$, with probability $p = f_{P_2}/(f_{P_1} + f_{P_2})$, and $C_j = P_{2j}$, with probability $1 - p$.

After the crossover, the algorithm applies the mutation operator by randomly altering a number of bit positions, in order to introduce diversity and prevent the stagnation into local optima. The number of positions to mutate for a given solution depends on the mutation rate, which is correlated to the convergence rate of the algorithm; it is defined as

$$B = \left\lceil \frac{m_f}{1 + \exp \frac{-4m_g(t-m_c)}{m_f}} \right\rceil, \quad (51)$$

where t is the current number of child solutions generated, m_f specifies the final stable mutation rate, m_c is the number of solutions that should be generated such that the mutation rate is $\frac{m_f}{2}$, and m_g specifies the gradient at $t = m_c$. The value of m_f is user defined and the values of m_c and m_g are problem-dependent parameters.

The initial population is generated with a high probability of being feasible, by putting

$$s_{cj} = \begin{cases} 1 & \text{if } r \leq D_{\text{drc}}(p_j) \\ 0 & \text{otherwise} \end{cases} \quad 1 \leq j \leq n \quad (52)$$

where $r \in [0, 1]$ is randomly chosen.

If the solution is infeasible, a heuristic feasibility operator, consisting of the construction and reduction phase of the model presented in [79], is applied to maintain feasibility. In order to replace solutions in the current population, a steady-state replacement strategy is implemented: a new solution replaces a randomly chosen individual of the population having a higher fitness value. This strategy is elitist since the best solutions are picked and they replace always the worst ones; in this way the population will converge quicker. This method allows one to create high quality solutions; in fact it outperforms all the previous implemented methods, by constructing probe set with minimum cardinality.

Though the dominated row covering heuristic presented in [79] guarantees the selection of near-essential probes that c_{\min} -cover and h_{\min} -separate dominated targets, it is not able to distinguish among targets having the same values for C_{drc} or S_{drc} . To address this task, a dominated probe selection heuristic is introduced in [81]. Here, the coverage and separation functions penalize each probe p by an amount that is proportional, respectively, to the number of targets that it covers or separates.

In order to guarantee separation not only between target pairs but also between pairs of small groups of targets, a subset selection criterion is introduced in [81]. This criterion is used by a sequential forward algorithm [58] to select the best subset of probes; in particular, it iteratively selects the probe that maximizes the dominant probe selection criterion and adds it to the current probe set. When a feasible solution is found, a reduction phase based on [79] is applied. This method performs better than the approaches proposed in [50, 73]; nevertheless, the genetic algorithm proposed in [80] and the cutting-plane method developed in [60] provide better results for all the tested datasets.

In [54], the two heuristics presented so far, the dominated row covering and the dominated probe selection, are modified in order to consider, at each step, the knowledge about the probes that are already selected in the previous iterations. In fact, these methods compute coverage and separation values during the initialization phase, and their values remain unchanged for the rest of the computation. Three new heuristics are introduced: the dynamic dominated row covering heuristic, the dynamic dominant probe selection heuristic and the normalized dynamic dominant probe selection heuristic. The first takes into account the information about selected probes: if a probe q is selected for a given target or target-pair, coverage and separation are recomputed only for those rows affected by this selection.

In a further work [24], the dominated row covering heuristic, the dominated probe selection heuristic, and a new one, the sum of dominated row covering, are combined with a Bayesian optimization algorithm [41]. The new heuristic introduced in [41] is capable to distinguish among probes that have the same score for the coverage of the dominated targets and the same score for the separation of the dominated target pairs. This new approach outperforms the other methods in some test instances.

In [25], a multiobjective optimization method is combined with the Bayesian algorithm presented in [24] to solve the nonunique probe selection problem for

the multiple targets case. The two objectives for this problem are minimizing the number of probes involved in a solution and maximizing the ability of recognizing multiple targets. In order to evaluate the fitness functions, a modified version of the weighted average ranking (WAR, for short) is computed. In WAR, each objective is evaluated separately and the fitness values of the solutions for each objective are sorted. Solutions are then ranked according to their fitness; finally the ranks obtained by sorting each list of objectives are averaged. This approach guarantees successful results for the simple cases of 5 and 10 targets in the sample, and good results for the case of 15 in almost all the instances considered in the dataset. When 20 targets are considered, it is able to find good solutions for some of the real and artificial datasets.

7 Datasets and Experimental Comparisons for the Nonunique Probe Selection Problem

The experiments for all the methods presented in the previous section were conducted on the same groups of data: it includes ten artificial datasets ($a_1, \dots, a_5, b_1, \dots, b_5$) and three real datasets (*meiobenthos*, *HIV-1*, and *HIV-2*).

To generate the artificial data, the Random Evolutionary FORest Model (REFORM) software was used with two different forest models. From each model, five independent test sets were generated. The test sets generated from the first model (a_1-a_5) contain 256 targets each; from the second one, five test sets (b_1-b_5) with 400 targets each are constructed.

The described two model topologies were chosen because they were able to produce sets of target sequences having a high degree of similarity, so that they cannot be easily separated using unique probes.

The probe candidates for each of the ten artificial test sets were generated using Promide software [61, 62].

For the real datasets, three groups of sequences are constructed. Benthos are organisms that live in the sea floor. They are categorized according to their size; meiobenthos are those having size between 100 and 500 μm [2]. In order to obtain the target sequences, 1,230 28S rDNA sequences from different organisms present in the meiobenthos were clustered in 149 groups. Clusters were representative of approximately 56 % of all *meiobenthos* sequences [73]. A test set of 679 targets was obtained by arbitrarily selecting a representative from each cluster. The corresponding probe set contained 15,139 probes.

The second and the third group of real data consisted of 200 each *HIV-1* and *HIV-2* sequences downloaded from the National Center for Biotechnology Information, having high similarity [50]. Candidate probes for the sequences were generated using Primer3 [70] with default input parameters. The default parameters include length between 18 and 27 nucleotides, melting temperature between 57 and 63°C, and GC content between 20 and 80 % for each HIV sequence.

Properties of the datasets are presented in Table 3: the second and third columns are the number of targets and number of probes of each dataset, respectively. Since

most of the datasets used are not able to satisfy the minimum Hamming distance constraint for every pair of targets, even if the entire set of candidate probes is chosen for the solution, artificial probes are added to the final solution set. Column $|V|$ represents the number of these virtual probes.

All the experiments were performed with parameters $c_{\min} = 10$ and $s_{\min} = 5$.

Tables 4 and **5** show the number of probes included in the final solution ($|P_{\min}|$), for the methods described in the previous section. The best solutions found are reported in bold face. As shown in **Tables 4** and **5**, the genetic and the Bayesian approaches guarantee to find the best solutions for $a1, \dots, a5$ datasets and on the real instances *HIV-1* and *HIV-2*, although they are computationally expensive and slower than the other methods: genetic algorithm runs for at least 2 h for the a datasets [80] on the other hand, the optimal cutting-plane algorithm runs for at most 851 s [60].

For the *Meiobenthos* dataset, genetic and optimal cutting-plane methods find the optimal solution.

Genetic and Bayesian algorithms have difficulties in optimizing the sets $b1, \dots, b5$; for these datasets, the optimal cutting-plane method performs better.

As described in the previous section, genetic and Bayesian algorithms use the DRC heuristic presented in [79] for selecting the probes. It can be noticed that $a1-a5$ contain a greater percentage of probes having a higher heuristic value respect to $b1-b5$ sets. Moreover, $b5$ contains many probes with the same heuristic value, and the DRC heuristic is not able to distinguish between these probes. On the other hand, the optimal cutting plane algorithm focuses first on probes that cover the largest number of rows [80]; hence, it does better on the $b1-b5$ sets.

8 Conclusion

The complexity in designing and selecting optimal probes for hybridization experiments makes this subject an interesting problem from a computational perspective. Specifically, a plethora of methods have been proposed in literature to address several issues related to the selection and design of probes, ranging from exact approaches to heuristic algorithms. After introducing the biological aspects of hybridization procedures, this chapter illustrates the state-of-the-art methods for the described problems.

In particular, the nonunique probe selection problem represents a challenging problem from a biological and computational point of view.

It is our opinion that there is still a lot of work to be done on this emerging and interesting research field: firstly, target-group separation for the nonunique probe selection problem represents a new field, that has not yet been well investigated.

From a biological point of view, it is important to note that the experiments conducted for the nonunique probe selection problem are focused on identifying

five targets in the sample; it can be interesting to extend the existing approaches for the case of more targets since this is more realistic. A new approach for the problem could concern the reformulation of separation and coverage constraints in a unique metric, since the resulting problem could be easier to solve. Moreover, the intrinsic characteristics of the datasets used for the experiments are not well explored. Since they affect the computational results, it would be desirable taking into account the biological information contained in the sequences, in order to better explore the search space and deeply understand the results. An interesting idea could be the application of a multiobjective optimization strategy for the problem, where the constraints are treated as conflicting objective functions; in this way we aim to provide to biologists a better way to analyze the computational results from a biological perspective. Also, a crucial point for understanding the effectiveness of the existing methods for this class of problem is to provide new real-world datasets; for this sake, interdisciplinary efforts between biologists and computer scientists should be encouraged in the future.

Abstract

This chapter presents data mining techniques that are formulated as combinatorial optimization problems together with their applications. There are a number of cases where fundamental data mining tool is not combinatorial in nature, yet widely used special-purpose combinatorial extensions exist. For the sake of completeness, these fundamental tools are also discussed in detail before the extensions with underlying combinatorial optimization problems. A number of computationally challenging data mining algorithms that have non-convex formulations are also explored.

1 Introduction

Data mining is defined as the practice of searching through large amounts of computerized data to find useful patterns or trends [101]. Being closely related to statistics and machine learning, data mining has been referred to as statistical learning and learning from the data. Different classifications of data mining methods exist in the literature [24], but one of the most commonly used classifications is based on the type of input data. Other than the features (attributes), input data can contain information on classes data instances belong to or responses of the underlying system, or it may contain no additional prior information. If information on classes or responses are available, the data is considered as *labeled*, and *supervised learning techniques* would be appropriate. Conversely, *unlabeled* data consists of only features with no class or response information, where *unsupervised learning techniques* attempt to identify patterns in data. *Semi-supervised learning*, which can be considered as halfway between supervised and unsupervised learning, utilizes both labeled and unlabeled data.

Regardless of the data mining tool employed, a data instance belongs to one of the two sets: *training set* or *test set*. Training set contains data instances that are used to train the data mining tool. That includes discovering patterns and relationships. Test set contains data instances that are used to assess the success of the predictions on relationships, which shed a light on the generalization performance of the employed tool.

Generalization performance of a model is its capability to find a more general classification based on given instances, i.e., how accurate the model can classify independent sample sets. To evaluate the generalization performance of a mining model, *cross validation* methods are used. Two widely used cross validation methods are *k-fold cross validation* and *leave-one-out cross validation (jackknife)*. In *k*-fold cross validation, all available data is randomly partitioned into *k* approximately equal subsets. Then, one of the *k* subsets is chosen as test set and the rest of the subsets are used as training set. This process is repeated *k* times in a way that each subset is chosen as test set once. The *k* results obtained will be averaged to find the generalization performance of the classification method. Leave-one-out cross validation (LOOCV), also known as jackknife, is a special case of *k*-fold where *k* is equal to the number of data instances.

In this chapter, methods to learn from data are explored in three main sections: supervised, unsupervised, and semi-supervised, with an emphasis on underlying combinatorial optimization problems. Discrete decision making based on analysis of data is the goal of fundamental problems in data mining (e.g., class assignment, feature selection, data categorization, identifying outlier instances). These problems are combinatorial in nature and can be formulated and solved by combinatorial approaches [33]. Last two sections are devoted to combinatorial ranking and feature selection problems.

2 Supervised Learning

Supervised learning refers to data mining tools that utilize *labeled* data. These labels can be *discrete* categories or *continuous* responses where the corresponding techniques are called *classification* or *regression*, respectively. Labels are input to the data mining tool during the training stage by a *supervisor*, hence the name supervised learning. In this section, combinatorial optimization problems are investigated in the context of classification and regression.

2.1 Support Vector Machines

Support vector machines (SVMs) are the state-of-the-art supervised machine learning methods that are initially introduced to classify pattern vectors that belong to two different classes (see [136]). Although there are multi-class generalizations, hyperplane-based methods have major drawbacks in classifying data from multiple classes (see [19]). Besides, classification of two classes has a wide variety of applications in image and voice recognition, text mining, healthcare, and clinical data mining.

The SVM classification function is a hyperplane that separates given two classes. The desired hyperplane maximizes the distance from the convex hulls of both classes. This problem can be formulated as a quadratic (and convex) optimization problem. SVM classifiers' success relies on strong fundamentals from the statistical learning theory, implementation advantages due to regularization (hence sparsity), and their generalization performance. When misclassified instances are penalized in the linear form, SVM classifiers are proven to be universally consistent (see [130]). A classifier is *consistent* if the probability of misclassification (in expectation) converges to a Bayes optimal rule when the number of data instances increases. A classifier is *universally consistent* if it is consistent for all distributions of data. SVMs can also perform nonlinear classification utilizing separating curves by implicitly embedding the original data in a nonlinear space using *kernel functions* (see, e.g., [121]).

The training is performed by minimizing a quadratic convex function that is subject to linear constraints. Although minimizing a convex function has a polynomial worst-case complexity, the general purpose methods are not practical for

large problems. SVM Light [78] and LIBSVM [71] are among the most frequently used implementations that use chunking [107] and decomposition [110] methods efficiently and use subsets of points to find a near-optimal hyperplane. Recently, Shalev-Shwartz et al. [120] propose a stochastic sub-gradient descent algorithm (Pegasos), whose run-time does not depend directly on the size of the training set but the bound on the number of nonzero features in each data instance. Experimental results show that Pegasos is especially successful for linear kernels.

SVM classifiers have a wide spectrum of application areas ranging from pattern recognition [92] and text categorization [77] to biomedicine [26, 43, 106, 109], cell death [112], nanotoxicology [113], brain-computer interface [60, 89], and financial applications [72, 134].

Based on SVM classifiers, support vector regression (SVR) is an optimization-based regression framework for solving machine learning problems. SVR approach is based on estimation of a linear function in a kernel-induced feature space. The objective is to optimize a certain boundary to the optimal regression line; therefore, errors within a certain distance (ε) of predicted value are disregarded. The learning algorithm minimizes a convex functional with sparse solution comparable to classification technique. For improved illustration, this can be considered a hyper-tube (insensitive band) about a linear function in the kernel-induced nonlinear space, such that pattern vectors in this tube are assumed not to contribute any error. This form of regression is called ε -insensitive because any point within ε distance of the anticipated regression function does not contribute an error. An important advantage for considering the ε -insensitive loss function is the sparseness of the dual variables similar to the case with SVM classifiers. Representing the solution by a small subset of training points has computational advantages. Furthermore, ε -insensitive regression ensures the existence of a global minimum and minimization of a reliable generalization error bound (see [45]).

SVR has various applications in numerous technological [15, 116], analytical [73, 91], and scientific fields [131, 145]. Wu et al. [142] perform location estimation using the Global System for Mobile communication (GSM) based on an SVR approach which demonstrates promising performances, especially in terrains with local variations in environmental factors. SVR method is also used in agricultural schemes in order to enhance output production and reduce losses [42, 108, 143]. Based on statistical learning theory, SVR has been used to deal with forecasting problems. Performing structural risk minimization rather than minimizing the training errors, SVR algorithms have better generalization ability than the conventional artificial neural networks [70].

2.1.1 SVM Classifiers: Mathematical Formulation

In a typical *binary classification* problem, class S^+ and S^- are composed of pattern vectors $\mathbf{x}_i \in \mathbb{R}^d$, $i = 1, \dots, n$. If $\mathbf{x}_i \in S^+$, it is given the label $y_i = 1$; if $\mathbf{x}_i \in S^-$, then it is given the label $y_i = -1$. The ultimate goal is to determine which class a new pattern vector $\mathbf{x}_i \notin \{S^+ \cup S^-\}$ belongs to. SVM classifiers solve this problem by finding a hyperplane (\mathbf{w}, b) that separates instances in classes S^+ and S^- with the maximum interclass margin.

A hyperplane in the feature space $\langle \mathbf{w}, \mathbf{x} \rangle + b = 0$ is represented as the normal vector \mathbf{w} and the offset parameter b . The *geometric distance* to be maximized between a data point \mathbf{x}_i and the hyperplane is given by $(\langle \mathbf{w}, \mathbf{x}_i \rangle + b) / \|\mathbf{w}\|$. Instead of maximizing the geometric distance fixing $\|\mathbf{w}\|$, the approach is minimizing $\|\mathbf{w}\|$ fixing $\langle \mathbf{w}, \mathbf{x}_i \rangle + b$, which is referred to as the *functional distance*.

In practice, many real-life problems are composed of nonseparable data which is generally due to noise. In this case, *slack variables* ξ_i are introduced for each pattern vector \mathbf{x}_i in the training set. Slack variables allow misclassifications for each pattern vector, but they are subject to a penalty to avoid trivial solutions. Therefore, the SVM classifier formulation is given as

$$[\text{SVM}] \quad \min_{\mathbf{w}, b, \xi} \quad \frac{1}{2} \|\mathbf{w}\|^2 + \frac{C}{2} \sum_{i=1}^n \xi_i^2 \quad (1a)$$

$$\text{subject to } y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b) \geq 1 - \xi_i \quad i = 1, \dots, n, \quad (1b)$$

where nonnegativity of the slack variables is assured implicitly since the solution cannot be optimal when $\xi_i < 0$ for any pattern vector.

Using the optimal solution (\mathbf{w}^*, b^*) for (1), a new pattern vector \mathbf{x}' can be classified as positive if $\langle \mathbf{w}^*, \mathbf{x}' \rangle + b^* > 0$ and negative if $\langle \mathbf{w}^*, \mathbf{x}' \rangle + b^* < 0$ (see Fig. 1). It is common to penalize the two-norm of the slack in the objective of SVM classifiers. Alternative formulations exist with one-norm penalization of the slack vector in the objective function, which is commonly referred to as the *hinge loss function* [45].

Lagrangian dual formulation of (1) and optimality conditions lead to an optimization problem where input vectors only appear in the form of dot products. Therefore, *kernel trick* can be introduced for nonlinear classification [45]. The dual problem is a concave maximization problem, which can also be solved efficiently. However, when the number of data points increases for better generalization performance, the dual tends to get harder to solve compared to the primal. The dual for two-norm soft margin formulation in (1) is given as

$$[\text{Dual - SVM}] \quad \max_{\alpha} \quad \sum_{i=1}^n \alpha_i - \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n y_i y_j \alpha_i \alpha_j \langle \mathbf{x}_i, \mathbf{x}_j \rangle - \frac{1}{2C} \sum_{i=1}^n \alpha_i^2 \quad (2a)$$

$$\text{subject to } \sum_{i=1}^n y_i \alpha_i = 0 \quad (2b)$$

$$\alpha_i \geq 0 \quad i = 1, \dots, n. \quad (2c)$$

When the dual formulation is used, b^* is calculated as follows using Karush-Kuhn-Tucker complementarity conditions:

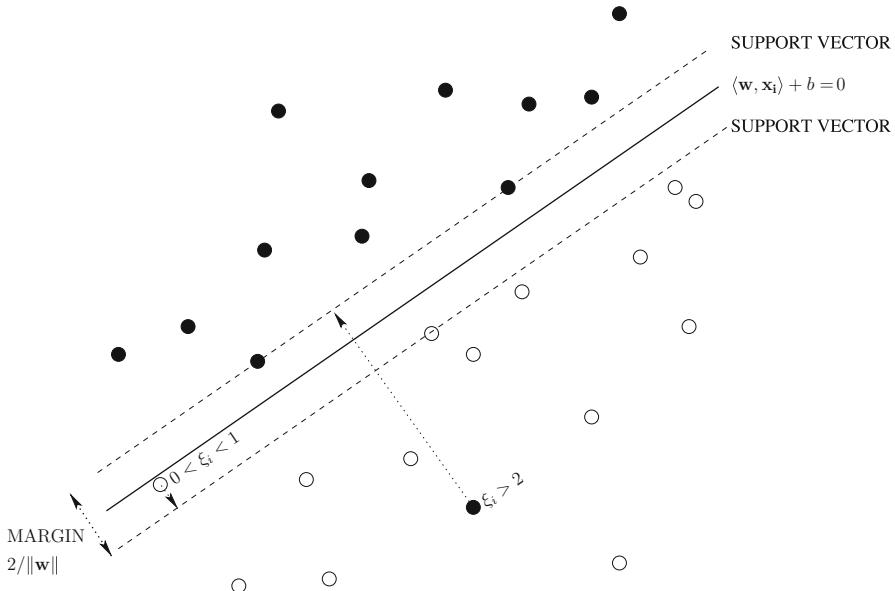

Fig. 1 Illustration of linear support vector machine classifiers

$$b^* = \sum_{i:\alpha_i^*>0} y_i - \sum_{j=1}^n y_j \alpha_j^* \langle \mathbf{x}_j, \mathbf{x}_i \rangle, \quad (3)$$

and a new pattern vector, \mathbf{x}' , can be classified as positive if $\sum_{j=1}^n y_j \alpha_j^* \langle \mathbf{x}_j, \mathbf{x}' \rangle + b^* > 0$, and negative otherwise. Note that dot products in (2) and (3) can be substituted with a suitable kernel function. The kernel function transforms the original *input space*, \mathcal{X} to a usually higher dimensional dot product space \mathcal{H} called the *feature space*, with a map $\Phi : \mathcal{X} \rightarrow \mathcal{H}$, such that $\mathbf{K}(\mathbf{x}_i, \mathbf{x}_j) = \langle \Phi(\mathbf{x}_i), \Phi(\mathbf{x}_j) \rangle$. The function must satisfy conditions for Mercer's theorem which are equivalent to the requirement that the corresponding matrix is positive semidefinite for any finite subset of \mathcal{X} . Further information on the kernel trick can be found in [45, 117].

2.1.2 SVM Regressors: Mathematical Formulation

There are many reasonable choices of loss function for regression. SVR uses ε -insensitive loss function to ensure that the solution is characterized as the minimum of a convex functional. Another motivation for considering the ε -insensitive loss function is that it will ensure sparseness of the dual variables similar to SVM classifiers.

The linear ε -insensitive loss function $L^\varepsilon(\mathbf{x}, y, f)$ is defined by

$$L^\varepsilon(\mathbf{x}, y, f) = |y - f(\mathbf{x})|_\varepsilon = \max(0, |y - f(\mathbf{x})| - \varepsilon),$$

where f is a real-valued function on a domain X , $\mathbf{x} \in X$, and $y \in \mathbb{R}$. The quadratic ε -insensitive loss function $L_2^\varepsilon(\mathbf{x}, y, f)$ is similarly

$$L_2^\varepsilon(\mathbf{x}, y, f) = |y - f(\mathbf{x})|_\varepsilon^2.$$

Let \mathbf{X} be a set of pattern vectors $\mathbf{x}_i \in \mathbb{R}^d$, with dependent variable values (i.e., real-valued response) $y_i \in \mathbb{R}$. The problem of finding a regression function $f(\cdot)$ for these pattern vectors is minimizing the sum of ε -insensitive losses over all pattern vectors \mathbf{x} . Let the distance between the regression hyperplane and the closest pattern vector \mathbf{x}^* be $|(\langle \mathbf{w}, \mathbf{x}^* \rangle) + b|$. Then, the solution to the following quadratic programming problem finds the regression hyperplane with the minimum sum of quadratic ε -insensitive losses. Similar to the goal programming approach in SVM classifiers, there is an associated penalty of C for outliers. Therefore, the primal SVR problem is as follows:

$$[\text{SVR}] \quad \min_{\mathbf{w}, b, \xi, \hat{\xi}} \quad \frac{1}{2} \|\mathbf{w}\|^2 + \frac{C}{2} \sum_{i=1}^n (\xi_i^2 + \hat{\xi}_i^2) \quad (4a)$$

$$\text{subject to } (\langle \mathbf{w}, \mathbf{x}_i \rangle + b) - y_i \leq \varepsilon + \xi_i \quad i = 1, \dots, n \quad (4b)$$

$$y_i - (\langle \mathbf{w}, \mathbf{x}_i \rangle + b) \leq \varepsilon + \hat{\xi}_i \quad i = 1, \dots, n. \quad (4c)$$

The main idea is to create a linear function in the kernel-induced space such that the quadratic loss function for regression from the generalization theory is minimized. First component of the objective function deals with minimizing the squared norm of the regression hyperplane ($\|\mathbf{w}\|^2$). The goal here is to enclose all pattern vectors with the ε -insensitive band of the regression hyperplane. Second component of the objective introduces penalty cost for instances outside the ε boundaries. Note that both ξ_i and $\hat{\xi}_i$ will be zero for all points inside the limits. The objective function seeks to minimize this penalty cost to reveal the best regression fit to the model. Constraints (4b)–(4c) imply that the pattern vectors are allowed to be ε below or above the target value without penalty. All pattern vectors outside the ε range are still allowed; however, they incur a cost of C [121].

The dual can be found using the Lagrangian function for the primal problem, differentiating this function with respect to the primal variables, and substituting equivalent expression for the primal variables back in the Lagrangian function. The resulting dual formulation is given as

$$[\text{Dual - SVR}] \quad \max_{\alpha, \hat{\alpha}} \quad -\frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n (\hat{\alpha}_i - \alpha_i)(\hat{\alpha}_i - \alpha_i) \langle \mathbf{x}_i, \mathbf{x}_j \rangle \quad (5a)$$

$$-\varepsilon \sum_{i=1}^n (\alpha_i + \hat{\alpha}_i) + \sum_{i=1}^n y_i (\hat{\alpha}_i - \alpha_i)$$

$$\text{subject to } \sum_{i=1}^n (\alpha_i - \hat{\alpha}_i) = 0 \quad (5b)$$

$$0 \leq \alpha_i, \hat{\alpha}_i \leq C \quad i = 1, \dots, n. \quad (5c)$$

From the solution α^* and $\hat{\alpha}^*$, the regression function can be written as $f(\mathbf{x}) = \sum_{i=1}^n (\hat{\alpha}_i^* - \alpha_i^*) \langle \mathbf{x}_i, \mathbf{x} \rangle + b^*$, where b^* is chosen such that $f(\mathbf{x}_i) - y_i = -\varepsilon$ for any i with $0 < \hat{\alpha}_i^* < C$.

2.1.3 Combinatorial Extensions of Support Vector Machines

Recently proposed combinatorial optimization problems related to SVMs are based on penalization of different loss functions and generalizations of traditional classification problem. Integer programming formulations for SVM classifiers with the ramp loss (6) and hard margin loss (7) are proposed in [25]. Facet-defining inequalities are presented and both ramp loss and hard margin loss SVM classifiers are proven to be universally consistent. The idea behind these combinatorial formulations is to obtain classifiers that are more robust to the outliers compared to hinge or smooth loss functions:

$$[\text{RL - SVM}] \quad \min_{\mathbf{w}, b, \xi, \mathbf{z}} \quad \frac{1}{2} \|\mathbf{w}\|^2 + C \left(\sum_{i=1}^n \xi_i + 2 \sum_{i=1}^n z_i \right) \quad (6a)$$

$$\text{subject to } y_i (\langle \mathbf{w}, \mathbf{x}_i \rangle + b) \geq 1 - \xi_i \quad \text{if } z_i = 0, \quad i = 1, \dots, n \quad (6b)$$

$$z_i \in \{0, 1\} \quad i = 1, \dots, n \quad (6c)$$

$$0 \leq \xi_i \leq 2 \quad i = 1, \dots, n \quad (6d)$$

$$[\text{HML - SVM}] \quad \min_{\mathbf{w}, b, \mathbf{z}} \quad \frac{1}{2} \|\mathbf{w}\|^2 + C \sum_{i=1}^n z_i \quad (7a)$$

$$\text{subject to } y_i (\langle \mathbf{w}, \mathbf{x}_i \rangle + b) \geq 1 \quad \text{if } z_i = 0, i = 1, \dots, n \quad (7b)$$

$$z_i \in \{0, 1\} \quad i = 1, \dots, n. \quad (7c)$$

Seref et al. [118] introduce novel *selective* linear and nonlinear classification methods, in which sets of pattern vectors sharing the same label are given as input. One pattern vector is *selected* from each set in order to maximize the classification margin with respect to the selected positive and negative pattern vectors. The problem of selecting the best pattern vectors is referred to as the *hard selection* problem. Kernelized hard selection problems are also developed for classification. However, these combinatorial problems cannot be solved in polynomial time unless $\mathcal{P} = \mathcal{NP}$ [119]. Alternative approaches are proposed with relaxed formulations. The selective nature of these formulations is satisfied by the restricted free slack

concept. The intuition behind this concept is to reverse the combinatorial selection problem by detecting influential pattern vectors which require free slack to decrease their effect on the classification functions. Iteratively removing problematic pattern vectors, better classification results can be found.

Two variations of the free slack method, namely, pooled free slack (PFS) and free slack per set (FSS), are introduced for selective linear classification together with kernelized dual formulations for selective nonlinear classification. These methods are further extended to direct separation by increasing the total free slack to diminish the effect of multiple pattern vectors per set and provide more flexibility for the hyperplane to reorient itself with respect to well-separated pattern vectors. The performance of iterative elimination and direct selection algorithms is compared with each other, as well as with a naïve elimination algorithm that uses standard SVM method and ideas from the proposed methods. Results are reported for linear and nonlinear simulated data.

Kundakcioglu et al. [88] consider the margin maximization problem within the multiple instance learning (MIL) context. Training data is composed of labeled bags of instances. Despite the large number of margin maximization-based classification methods, there are only a few methods that consider the margin for MIL problems in the literature. A combinatorial margin maximization problem (8) is formulated for multiple instance classification which is proven to be \mathcal{NP} -hard. Kernel trick is applied on this formulation to classify nonlinear MIL data. A branch and bound algorithm is proposed that outperforms a leading commercial solver in terms of the best integer solution and optimality gap in a majority of image annotation and molecular activity prediction test cases. The major difference between the MIL setting and the selective setting is the interpretation of negative bags. In selective learning, a selection is performed on negative bags as well as positive bags. In MIL, on the other hand, only actual positives are to be discovered where all negative instances must be kept. The mixed-integer nonlinear programming (MINLP) formulation for this problem is as follows:

$$[\text{MI - SVM}] \quad \min_{\mathbf{w}, b, \xi, \eta} \quad \frac{1}{2} \|\mathbf{w}\|^2 + \frac{C}{2} \sum_{i=1}^n \xi_i^2 \quad (8a)$$

$$\text{s.t.} \quad \langle \mathbf{w} \cdot \mathbf{x}_i \rangle + b \geq 1 - \xi_i - M(1 - \eta_i) \quad i \in I^+ \quad (8b)$$

$$- \langle \mathbf{w} \cdot \mathbf{x}_i \rangle - b \geq 1 - \xi_i \quad i \in I^- \quad (8c)$$

$$\sum_{i \in I_j} \eta_i \geq 1 \quad j \in J^+ \quad (8d)$$

$$\eta_i \in \{0, 1\} \quad i \in I^+. \quad (8e)$$

In this formulation, $I^+ = \{i : i \in I_j \wedge y_j = 1\}$ is the index set for instances that are in a positive bag, $I^- = \{i : i \in I_j \wedge y_j = -1\}$ is the index set for instances that are in a negative bag (negative instances), and $J^+ = \{j : y_j = 1\}$ is the index set for positive bags. Note that M is a sufficiently large number that ensures that

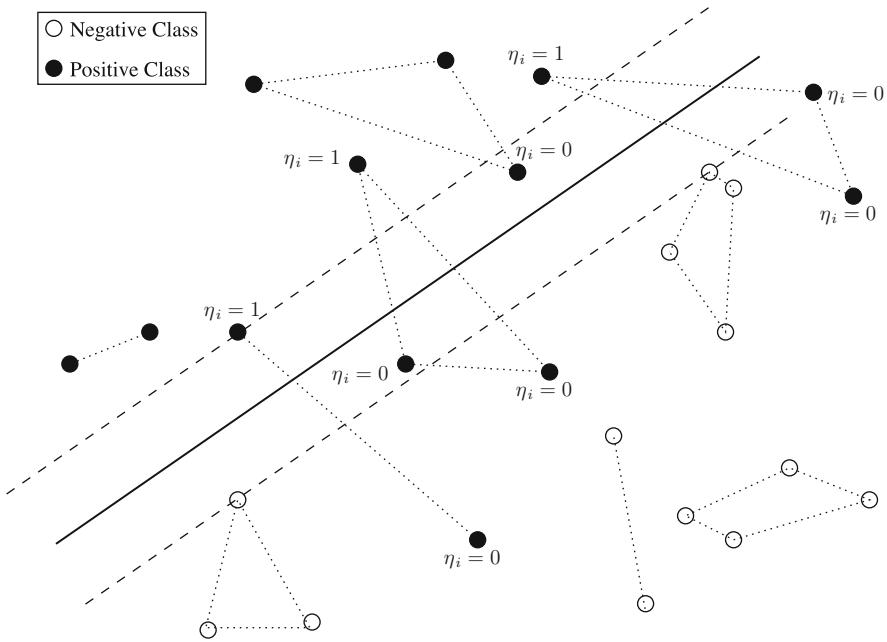

Fig. 2 Multiple instance support vector machine classifiers

the constraint is active if and only if $\eta_i = 1$. η_i is a binary variable that is 1 if i th instance is one of the actual positive examples of its bag (see Fig. 2).

Recently, Poursaeidi and Kundakcioglu [111] propose a hard margin loss formulation for multiple instance learning. The main idea is to avoid the dependency of the classifier in (Eq. 8) to the number of negative instances and make it dependent on the number of negative bags. Proposed formulations in [111] are also less sensitive to outliers, showing better generalization performance.

Next, *consistent biclustering* is introduced, another classification technique that employs combinatorial optimization formulations.

2.2 Consistent Biclustering

The concept of *consistent biclustering* is introduced by Busygin et al. [29]. In this method, a classification of features as well as data instances are needed as input. Formally, a biclustering \mathcal{B} is consistent if in each instance (feature) from any set S_r (set F_r), the average expression of features (instances) that belong to the same class r is greater than the average expression of features (instances) from other classes. The model for supervised biclustering involves solution of a special case of fractional 0–1 programming problem whose consistency is achieved by feature

selection. Computational results on microarray data mining problems are obtained by reformulating the problem as a linear mixed 0–1 programming problem.

An improved heuristic procedure is proposed in [103], where a linear programming problem with continuous variables is solved at each iteration. Numerical experiments on the data, which consists of instances from patients diagnosed with *acute lymphoblastic leukemia (ALL)* or *acute myeloid leukemia (AML)* diseases (see [10, 11, 64, 141, 144]), confirm that the algorithm outperforms the previous results in the quality of solution as well as computation time. Busygin et al. [30] use consistent biclustering to analyze scalp EEG data obtained from epileptic patients undergoing treatment with a vagus nerve stimulator (VNS).

Given an $m \times n$ data matrix A , each column represents a data instance and each row represents a feature. Formally, $A = (a_{ij})_{m \times n}$, where a_{ij} is the expression of i th feature of j th instance. A classification of instances is provided through a 0–1 matrix $S = (s_{jr})_{n \times k}$, where $s_{jr} = 1$ if instance j is classified as a member of the class r (i.e., $a^j \in S_r$), and $s_{jr} = 0$ otherwise. Similarly, given a classification of the features, F_r , let $F = (f_{ir})_{m \times k}$ denote a 0–1 matrix where $f_{ir} = 1$ if feature i belongs to class r (i.e., $a_i \in F_r$), and $f_{ir} = 0$ otherwise. Corresponding *centroids* are constructed as follows:

$$C_S = AS(S^T S)^{-1} = (c_{i\xi}^S)_{m \times r}, \quad (9)$$

$$C_F = A^T F(F^T F)^{-1} = (c_{j\xi}^F)_{n \times r}. \quad (10)$$

The elements of the matrices, $c_{i\xi}^S$ and $c_{j\xi}^F$, represent the average expression of the corresponding instance and feature in class ξ , respectively:

$$c_{i\xi}^S = \frac{\sum_{j=1}^n a_{ij} s_{j\xi}}{\sum_{j=1}^n s_{j\xi}} = \frac{\sum_{j|a^j \in S_\xi} a_{ij}}{|S_\xi|},$$

and

$$c_{j\xi}^F = \frac{\sum_{i=1}^m a_{ij} f_{i\xi}}{\sum_{i=1}^m f_{i\xi}} = \frac{\sum_{i|a_i \in F_\xi} a_{ij}}{|F_\xi|}.$$

Using the elements of matrix C_S , one can assign a feature to a class where it is overexpressed. Therefore, feature i is assigned to class \hat{r} if $c_{i\hat{r}}^S = \max_\xi \{c_{i\xi}^S\}$. Similarly, one can use the elements of matrix C_F to classify the instances. Data instance j is assigned to class \hat{r} if $c_{j\hat{r}}^F = \max_\xi \{c_{j\xi}^F\}$. Formally,

$$a_i \in \hat{F}_{\hat{r}} \implies c_{i\hat{r}}^S > c_{i\xi}^S, \quad \forall \xi, \xi \neq \hat{r}, \quad (11)$$

$$a^j \in \hat{S}_{\hat{r}} \implies c_{j\hat{r}}^F > c_{j\xi}^F, \quad \forall \xi, \xi \neq \hat{r}. \quad (12)$$

Note that the constructed classification of the features and instances \hat{F}_r and \hat{S}_r are not necessarily the same as classifications F_r and S_r , respectively.

Biclustering \mathcal{B} is referred to as a *consistent biclustering* if relations (11) and (12) hold for all elements of the corresponding classes, where matrices C_S and C_F are defined according to (9) and (10), respectively. A data set is *biclustering-admitting* if some consistent biclustering for it exists. Furthermore, the data set is called *conditionally biclustering-admitting* with respect to a given (partial) classification of some instances and/or features if there exists a consistent biclustering preserving the given (partial) classification. Busygin et al. [29] prove conic separability which also indicates convex hulls of classes do not intersect.

By definition, a biclustering is consistent if $F_r = \hat{F}_r$ and $S_r = \hat{S}_r$. However, a given data set might not have these properties. In such cases, one can remove a set of features and/or instances from the data set so that there is a consistent biclustering for the truncated data. This feature selection process may incorporate various objective functions depending on the desirable properties of the selected features. One general choice is to select the maximal possible number of features in order to lose minimal amount of information provided by the training set:

$$[\text{CB}] \quad \max_{\mathbf{x}} \quad \sum_{i=1}^m x_i \quad (13a)$$

$$\text{subject to} \quad \frac{\sum_{i=1}^m a_{ij} f_{i\hat{r}} x_i}{\sum_{i=1}^m f_{i\hat{r}} x_i} > \frac{\sum_{i=1}^m a_{ij} f_{i\xi} x_i}{\sum_{i=1}^m f_{i\xi} x_i} \quad \hat{r}, \xi = 1, \dots, k, \hat{r} \neq \xi, j \in S_{\hat{r}} \quad (13b)$$

$$x_i \in \{0, 1\} \quad i = 1, \dots, m. \quad (13c)$$

In this formulation, x_i , $i = 1, \dots, m$ are the decision variables. $x_i = 1$ if i th feature is selected, and $x_i = 0$ otherwise. $f_{ik} = 1$ if feature i belongs to class k , and $f_{ik} = 0$ otherwise. The objective is to maximize the number of features selected and (13b) ensures that the biclustering is consistent with respect to the selected features.

The goal of the CB problem is to find the largest set of features that can be used to construct a consistent biclustering. A problem with selecting the most representative feature set is the following. Assume that there is a consistent biclustering for a given data set, and there is a feature, i , where the difference between the two largest values of c_{ir}^S is negligible. For such cases, *additive* and *multiplicative consistent biclustering* are introduced in [103] by relaxing (11)–(12) with (14)–(15) and (16)–(17), respectively:

$$a_i \in F_{\hat{r}} \implies c_{i\hat{r}}^S > \alpha_i^S + c_{i\xi}^S, \quad \forall \xi, \xi \neq \hat{r} \quad (14)$$

$$a^j \in S_{\hat{r}} \implies c_{j\hat{r}}^F > \alpha_j^F + c_{j\xi}^F, \quad \forall \xi, \xi \neq \hat{r} \quad (15)$$

$$a_i \in F_{\hat{r}} \implies c_{i\hat{r}}^S > \beta_i^S c_{i\xi}^S, \quad \forall \xi, \xi \neq \hat{r} \quad (16)$$

$$a^j \in S_{\hat{r}} \implies c_{j\hat{r}}^F > \beta_j^F c_{j\xi}^F, \quad \forall \xi, \xi \neq \hat{r}. \quad (17)$$

Using these relaxations, α -consistent and β -consistent biclustering problem formulations are obtained as follows:

$$[\alpha\text{-CB}] \quad \max_{\mathbf{x}} \quad \sum_{i=1}^m x_i \quad (18a)$$

$$\text{subject to} \quad \frac{\sum_{i=1}^m a_{ij} f_{i\hat{r}} x_i}{\sum_{i=1}^m f_{i\hat{r}} x_i} > \alpha_j + \frac{\sum_{i=1}^m a_{ij} f_{i\xi} x_i}{\sum_{i=1}^m f_{i\xi} x_i} \quad \forall \hat{r},$$

$$\xi = 1, \dots, k, \hat{r} \neq \xi, j \in S_{\hat{r}} \quad (18b)$$

$$x_i \in \{0, 1\} \quad i = 1, \dots, m \quad (18c)$$

$$[\beta\text{-CB}] \quad \max_{\mathbf{x}} \quad \sum_{i=1}^m x_i \quad (19a)$$

$$\text{subject to} \quad \frac{\sum_{i=1}^m a_{ij} f_{i\hat{r}} x_i}{\sum_{i=1}^m f_{i\hat{r}} x_i} > \beta_j \frac{\sum_{i=1}^m a_{ij} f_{i\xi} x_i}{\sum_{i=1}^m f_{i\xi} x_i} \quad \forall \hat{r},$$

$$\xi = 1, \dots, k, \hat{r} \neq \xi, j \in S_{\hat{r}} \quad (19b)$$

$$x_i \in \{0, 1\} \quad i = 1, \dots, m. \quad (19c)$$

The information obtained from these solutions can be used to classify additional instances in the *test set*. These solutions are also useful for adjusting the values of vectors α and β to produce more characteristic features and decrease the number of misclassifications. Feature selection for consistent (13), α -consistent (18), and β -consistent biclustering (13) is proven to be \mathcal{NP} -hard [86].

2.3 Other Classification Approaches

A special case of biclustering introduced by Ben-Dor et al. [12] is the order-preserving submatrix problem, which is proven to be \mathcal{NP} -hard. The goal of this problem is to select a subset of rows and columns from the original data matrix in which there exists a permutation of columns such that in each row the values are strictly increasing. Trapp and Prokopyev [135] propose a general linear mixed 0–1 programming formulation and an iterative algorithm that makes use of a smaller linear 0–1 programming formulations. The proposed solution algorithm enhanced by a number of enhancements including valid inequalities and bounding schemes is able to solve problems with approximately 1,000 rows and 50 columns to optimality.

Bertsimas and Shioda [16] introduce mixed-integer linear methods to the classical statistical problems of classification and regression and construct a software

package called *classification and regression via integer optimization* (CRIo). CRIo separates data points into different polyhedral regions. In classification, each region is assigned a class, while in regression, each region has its own distinct regression coefficients. Computational experimentations show that CRIo is comparable to the leading methods in classification and regression.

Logical analysis of data is a technique that is used for risk prediction in medical applications [2]. This method is based on combinatorial optimization and boolean logic. The goal is essentially classifying groups of patients at low and high mortality risk, and LAD is shown to outperform standard methods used by cardiologists.

Kundakcioglu and Ünlüyurt [87] consider the problem of generating the sequence of tests required to reach a diagnostic conclusion with minimum average cost, which is also known as a test-sequencing problem. In this setting, the training data consists of asymmetrical tests (i.e., a probabilistic outcome for a feature or test) and the decision rule is obtained using an optimal binary AND/OR decision tree. An efficient bottom-up tree construction algorithm is developed based on fundamental ideas of Huffman coding. Computational results show that the algorithm outperforms previously proposed heuristic algorithms in reasonable time.

3 Unsupervised Learning

Unsupervised learning can be defined as finding patterns in unlabeled data. The goal is finding similarities among instances that belong to same class, where no class information is available. In this group of methods, N instances (x_1, x_2, \dots, x_N) of a random p -vector \mathbf{X} having joint density $Pr(\mathbf{X})$ are given and a decision is to be made based on representation of instances. Unlike the supervised methods that are trying to minimize some external error criterion, in unsupervised methods, calculating the difference between the target and input data instances is not possible. This results in different methods that are not relying on any outside information. It should be noted that unsupervised methods are particularly useful since unlabeled data is usually less costly compared to labeled data. Two widely used applications of unsupervised learning are clustering and dimensionality reduction.

Clustering (or cluster analysis) is defined as finding a convenient and valid organization of the data to establish rules for separating future data into categories [75]. Clustering algorithms can be divided into two major groups: *partitional* and *hierarchical* [74]. In partitional clustering, all clusters are found simultaneously as partitions of the data. In hierarchical clustering, nested clusters are found recursively. This can be done by one of the following two approaches. *Agglomerative methods* initially consider each data point as the head of its own cluster and try to merge the most similar pair of clusters successively to form a cluster hierarchy. On the contrary, *divisive methods* initially assign all data instances in one cluster and divide each cluster into smaller clusters (see [62]).

Another useful application of unsupervised learning is dimensionality reduction. These techniques aim to find a lower dimensional representation of the original data, which captures the content of the original data based on some criterion. A lower

dimensional representation of data is desired mainly because the computational advantage of handling a smaller data set outweighs the loss of information. Frequently used in the preprocessing stage, dimensionality reduction helps mitigate computational limitations of data mining algorithms for large data sets.

3.1 Latent Variable Models

In this section, probabilistic methods that utilize *latent variables* are introduced. Latent variable (or hidden variable) is a statistical variable that is not observed directly but can be estimated based on its relation with an observed variable. Latent variable models can be used to perform dimensionality reduction and clustering, the two cornerstones of unsupervised learning. Clustering problems that are addressed in this section are hard clustering problems and fuzzy clustering problems (FCP). In hard clustering problems, each data point needs to be assigned to one and only one cluster. On the other hand, in fuzzy clustering, each data point is a member of all clusters and it has a membership grade for each cluster showing its likelihood of belonging to that cluster.

3.1.1 k -Means

k -means is a hard clustering problem that has been introduced by several researchers across different disciplines, most notably Lloyd [95], Forgy [54], Friedman and Rubin [58], Ball and Hall [6], and MacQueen [96]. Given a data set of n vectors $x_j \in \mathbb{R}^d$, $j = 1, \dots, n$, the goal is to find a partition $S = \{S_1, S_2, \dots, S_k\}$ that minimizes the expected loss (see [96]). A random point $z \in \mathbb{R}^d$ with a known distribution p generates a loss proportional to the square of the error resulting from the choice of clusters, formally $\|z - \hat{z}\|^2$, where \hat{z} is the cluster centers or *exemplars*. The goal is to minimize the expected loss over possible choices of clusters, which is formally defined as

$$w^2(S) = \sum_{i=1}^k \int_{S_i} \|z - \hat{z}\|^2 dp(z). \quad (20)$$

Given a selection of cluster members from the data, it is easy to see that the cluster mean minimizes the squared error term. Therefore, the problem reduces to selection of cluster members, which can be formulated as the following mixed-integer programming (MIP) problem:

$$[k-\text{means}] \quad \min_{\mu, r} \quad \sum_{i=1}^k \sum_{j=1}^n r_{ij} \|x_j - \mu_i\|^2 \quad (21a)$$

$$\text{subject to} \quad \sum_{i=1}^k r_{ij} = 1 \quad j = 1, \dots, n \quad (21b)$$

$$r_{ij} \in \{0, 1\} \quad i = 1, \dots, k, \quad j = 1, \dots, n. \quad (21c)$$

This problem is proven to be \mathcal{NP} -hard [3]. One of the most widely used iterative heuristic approaches is the k -means algorithm, also known as Lloyd's algorithm [95], which can be considered as an expectation-maximization algorithm. Initially, k initial exemplars are randomly selected. Next, by repeating the following two steps, the clusters will be iteratively refined. In the first (i.e., *expectation*) step, each instance will be temporarily associated with the cluster whose exemplar is the closest. In the second (i.e., *maximization*) step, based on the temporary cluster assignment, each exemplar is updated as the mean of instances in its cluster. The algorithm terminates when no exemplar can be further updated. The convergence is guaranteed since the objective is finite and an improvement is assured in each step.

It should be noted that the term k -means is used to define the problem of minimizing the within-cluster sum of squares (i.e., (21)) as well as Lloyd's expectation-maximization algorithm defined above.

One observation is that k -means algorithm is sensitive to the initial set of exemplars especially when k is large. Thus, random initialization of exemplars is acceptable for relatively small values of k . There are alternative approaches, especially useful when number of clusters is increased, including, but not limited to, heuristic initialization schemes and parallel implementations with multiple initial exemplars.

Typically, k -means problem considers spherical clusters by minimizing Euclidean distance between points and cluster centers, as presented in formulations (20) and (21). Other distances that are used in k -means are mahalanobis distance metric [99], Itakura-Saito distance [93], L1 distance [81], and Bregman distance [7].

It has been proven that the worst-case complexity of the k -means algorithm is $O(kn^2\Delta^2)$ [4]. Although it is introduced over 50 years ago, k -means is still one of the most widely used algorithms for clustering. This algorithm is particularly useful due to its simplicity, ease of implementation, efficiency, and success in practice.

3.1.2 Message Passing

In order to overcome difficulties associated with the sensitivity of k -means to the initialization process, Frey and Dueck [57] propose a message-passing method where every data instance is a potential exemplar. The problem to be solved is the \mathcal{NP} -hard k -median problem. For computational tractability, an *affinity propagation* scheme is proposed, where data instances are nodes of a network, real-valued messages are transmitted along edges, and the magnitude of each message is updated based on the current affinity that one data instance has for choosing another data instance as its exemplar. Two types of messages are transmitted: First, *responsibility*, $r(i, j)$, sent from data instance i to candidate exemplar j , is a cumulative variable for how appropriate instance j is to be the exemplar

for instance i . Second, *availability*, $a(i, j)$, sent from potential exemplar j to data instance i , reflects the accumulated evidence for how good it is for instance i to select instance j as its exemplar. Availability includes support from other instances that instance j is an exemplar. Formally, responsibility and availability are defined as

$$r(i, j) \leftarrow s(i, j) - \max_{j' \text{ s.t. } j' \neq i} \{a(i, j') + s(i, j')\} \quad (22)$$

$$a(i, j) \leftarrow \min \left\{ 0, r(j, j) + \sum_{i' \text{ s.t. } i' \notin \{i, j\}} \max\{0, r(i', j)\} \right\}, \quad (23)$$

where $s(i, j)$ is the similarity between instances i and j . The objective is to minimize the total squared error; thus, $s(i, j)$ is defined as $-\|x_i - x_j\|^2$. Since availabilities are zero in the first iteration, $r(i, j)$ is equal to the input similarity between instance i and instance j as its exemplar minus the largest of the similarities between instance i and other potential exemplars. In the subsequent iterations, when an instance is effectively assigned to an exemplar, its updated availabilities will become below zero. This negative availability removes some of the exemplars from candidate exemplars of that data instance. If availability of some other instances becomes negative for that exemplar, the exemplar is out of competition.

When $j = i$, the responsibility $r(j, j)$ equals $s(j, j)$, minus the largest of the similarities between instance i and all other candidate exemplars. If $r(j, j)$ (i.e., self-responsibility) is negative at any iteration, it is more appropriate for instance j to belong to another exemplar rather than being an exemplar itself. This transmission continues until a good set of exemplars and corresponding clusters are obtained.

3.1.3 Fuzzy Clustering

Fuzzy clustering is an extension of k -means problem, in which instances have a degree of membership for *all* clusters. In this setting, a data instance is not designated to a specific cluster, but it belongs to each cluster to a certain extent, referred to as the *membership grade*. To solve this problem, different nonexact (i.e., soft computing) approaches have been introduced in the literature (see [8, 17, 82, 102]). An exact reformulation-linearization technique (RLT)-based approach has been introduced by Sherali and Desai [123], where the objective is to minimize the total degree-2 fuzzifier weighted squared Euclidean distance. Formally, given a data set of n vectors $a_j \in \mathbb{R}^d$, $j = 1, \dots, n$, the problem is

$$[\text{FCP}] \quad \min_{\mathbf{w}, \mathbf{z}} \quad \sum_{i=1}^n \sum_{j=1}^c w_{ij}^2 \|a_i - z_j\|^2 \quad (24a)$$

$$\text{subject to } \sum_{j=1}^c w_{ij} = 1 \quad \forall i = 1, \dots, n \quad (24b)$$

$$w_{ij} \geq 0 \quad \forall (i, j), \quad (24c)$$

which is essentially a weighted version of (21). Since the objective function (24a) is nonlinear, RLT is used to relax (24) as a linear programming problem and a specialized branch and bound algorithm is employed. To further speed up the process, data reduction is performed on instances by replacing group examples with their centroids [53].

3.2 Network-Based Models

In the last few decades, network-based data mining models have received increasing attention for their capability of extracting useful information from large-scale data sets that are widely available in network structure. Boginski [22] presents a wide variety of applications for network-based data mining models.

One use of networks is finding the structural properties of a data set by *degree* (i.e., number of edges emanating from a node) distribution of constructed graphs, which is a representation of large-scale pattern of connections in the graph. This leads to the fact that graphs that are related to completely different data sets might have a similar well-defined power-law structure. Power-law structure states that the probability that a vertex of a graph has degree k is $P(k) \propto k^{-\gamma}$ [22].

Network-based models are widely used in clustering. Finding *cliques* and *independent sets* in a network is synonymous with discovering clusters in that data set. Given a graph $G = (V, E)$, a subgraph whose vertices are pairwise adjacent is called a clique or complete subgraph. On the contrary, an independent set or stable set is a set of vertices none of which are adjacent. Therefore, maximum clique in a graph gives the maximum possible size of a group of similar objects, whereas maximum independent set leads to the largest group of essentially different objects. It should be noted that a clique in graph is an independent set in the complement graph and vice versa. Maximum clique problem and the maximum independent set problem are proven to be \mathcal{NP} -hard [61].

These two problems are extended to find the minimum number of distinct cliques for clustering purposes [22]. There also exist relaxations of clique problems such as quasi-clique problems ensuring a lower bound on the total number of edges within the subgraph [1] and k -plex problems ensuring a lower bound on the number of adjacent nodes for each selected node within the subgraph [5]. See [125] for a detailed survey on combinatorial optimization techniques for network-based data mining.

3.3 Biclustering

Biclustering is simultaneous partitioning of data instances and their features into classes. Instances and features classified together are expected to have a high relevance with each other (i.e., similar data values).

Given an $m \times n$ data matrix A , each column represents a data instance and each row represents a feature. Formally, $A = (a_{ij})_{m \times n}$, where a_{ij} is the expression of i th feature of j th instance. Biclustering is applied by simultaneous partitioning of the instances and features into k classes. Let S_1, S_2, \dots, S_k denote the classes of the instances (columns) and F_1, F_2, \dots, F_k denote the classes of features (rows). Biclustering is defined as a collection of pairs of instance and feature subsets $\mathcal{B} = \{(S_1, F_1), (S_2, F_2), \dots, (S_k, F_k)\}$ such that

$$S_1, S_2, \dots, S_k \subseteq \{a^j\}_{j=1,\dots,n},$$

$$\bigcup_{r=1}^k S_r = \{a^j\}_{j=1,\dots,n},$$

$$S_\zeta \cap S_\xi = \emptyset \Leftrightarrow \zeta \neq \xi,$$

$$F_1, F_2, \dots, F_k \subseteq \{a_i\}_{i=1,\dots,m},$$

$$\bigcup_{r=1}^k F_r = \{a_i\}_{i=1,\dots,m},$$

$$F_\zeta \cap F_\xi = \emptyset \Leftrightarrow \zeta \neq \xi,$$

where $\{a^j\}_{j=1,\dots,n}$ and $\{a_i\}_{i=1,\dots,m}$ denote the set of columns and rows of the matrix A , respectively. The ultimate goal in a biclustering problem is to find a partitioning scheme for which instances from the same class have *similar* values for that class' characteristic features. One of the early algorithms to obtain an appropriate biclustering is [69], which is known as *block clustering*. Given a biclustering \mathcal{B} , the variability of the data in the block (S_r, F_r) is used to measure the quality of partitions. A lower variability in the resulting problem is desired. The number of classes should be fixed in order to avoid a trivial, zero variability solution in which each class consists of only one instance. A more sophisticated approach for biclustering is introduced in [40], where the objective is to minimize the mean squared residual. In this setting, the problem is proven to be \mathcal{NP} -hard and a greedy algorithm is proposed to find an approximate solution. A simulated annealing algorithm is proposed in [27]. Dhillon [49] proposes another biclustering method for text mining using a bipartite graph. In the graph, the nodes represent features and instances, and each feature i is connected to an instance j with a link (i, j) ,

which has a weight a_{ij} . The total weight of all links connecting features and instances from different classes is used to measure the quality of a biclustering. A lower value corresponds to a better biclustering. A similar method for microarray data is suggested in [83].

Dhillon et al. [50] treat input data as a joint probability distribution between two discrete sets of random variables. The goal of the method is to find disjoint classes for both variables. A Bayesian biclustering technique based on Gibbs sampling can be found in [122]. A detailed survey on biclustering techniques can be found in [31, 97].

4 Semi-supervised Learning

Semi-supervised learning is a branch of machine learning that utilizes both labeled and unlabeled data to improve generalization performance. Since unlabeled data is relatively easier to collect, these methods are less expensive than supervised learning methods. Moreover, these methods are more accurate than unsupervised learning because they are using information obtained from labeled data as well.

Data used in these methods are comprised a set to be used for training and a set to be used for testing. Let $X = (x_1, \dots, x_n)$ be a set that consists of l labeled examples $\{(x_i, y_i)\}_{i=1}^l$, $y_i = \pm 1$ and of u unlabeled examples $\{x_i\}_{i=l+1}^n$. In the literature, u unlabeled examples are referred to as the *working set* and l labeled examples are referred to as the *training set* [14]. Both training set and working set in this definition are used during the training process. Test set is used to test the accuracy of the learning method as usual.

Based on definition of semi-supervised learning, two types of data are available: the similarity distances for the training and working set and class labels of training set. According to the capability of an algorithm to handle unseen data instances (in the test set), semi-supervised methods can be classified as *transductive* or *inductive*. In transductive learning, training, and working sets are processed but test set cannot be used during the algorithm. The early graph-based methods in semi-supervised learning are transductive. On the other hand, inductive learning algorithms can handle test set as well. Semi-supervised learning algorithms can be divided into three main groups based on the data representation considered. These groups are *manifold assumption*, *cluster assumption*, and *manifold-cluster assumption*. In manifold assumption, the data instances lie on a low-dimensional manifold in the input space. These algorithms generally represent data as a graph, instances as vertices, and pairwise similarities between instances as edge weights. In cluster assumption, decision boundaries between classes must lie in low-density regions as the aim of these algorithms is placing instances with high similarities in the same cluster. Manifold-cluster assumption proposed by Mallapragada et al. [98] uses both manifold and cluster assumptions to overcome weaknesses of both approaches.

One of the earliest semi-supervised learning methods proposed in the literature is *self-training*. This method initially constructs a temporary classifier using only

labeled data. Using this classifier, labels are predicted for the instances in the working set and the classifier is progressively updated [150]. Next, some of the most notable methods for semi-supervised learning are introduced.

4.1 Semi-supervised Support Vector Machines ($S^3\text{VM}$)

The idea of using SVMs to solve semi-supervised learning problems is introduced by Vapnik and Sterin [138]. The combinatorial formulation for semi-supervised support vector machines is as follows (see [37]):

$$[\text{S}^3\text{VM}] \quad \min_{\mathbf{w}, b, \xi, \mathbf{y} \in \mathbb{R}^u} \frac{1}{2} \|\mathbf{w}\|^2 + C \left[\sum_{i=1}^l \xi_i \right]^p + C^* \left[\sum_{j=l+1}^{l+u} \xi_j \right]^p \quad (25a)$$

$$\text{subject to } y_i(\mathbf{w} \cdot \mathbf{x}_i + b) + \xi_i \geq 1 \quad i = 1, \dots, l+u \quad (25b)$$

$$\xi_i \geq 0 \quad i = 1, \dots, l+u \quad (25c)$$

$$\frac{1}{u} \sum_{i=l+1}^{l+u} y_i = 2r - 1 \quad (25d)$$

$$y_i \in \{-1, 1\} \quad i = l+1, \dots, l+u. \quad (25e)$$

In this formulation, y_i are given as input for $i = 1, \dots, l$ (i.e., training set) and are decision variables for $i = l+1, \dots, l+u$ (i.e., working set). Equation (25d) is called the *balancing constraint* since it enforces the solutions to be balanced by assigning specified percentages of unlabeled data to positive and negative classes [133]. r is the ratio of positive labels to be assigned to the number of instances in the working set.¹ Usually, r is hard to predict; thus, it is assumed to be equal to the ratio of positive labels in the training set. C and C^* represent the penalty weight for labeled (training) and unlabeled (working) data, respectively. To obtain a good generalization performance, ideally C and C^* should be different (see [38]); however, they are usually assumed equal for the sake of simplicity. Some common penalty functions for the objective are linear (i.e., $p = 1$) and quadratic (i.e., $p = 2$) functions.

Bennett and Demiriz [14] introduce a 0–1 variable d_j for each instance x_j in working set to formulate (25) as a MINLP problem. An instance belongs to positive class if $d_j = 1$ and negative class if $d_j = 0$. With this change, $S^3\text{VM}$ can be formulated as

¹An exact equality for balancing constraint is likely to lead to infeasible solutions depending on the number of instances and ratios. Therefore, a subtle adjustment is usually necessary to ensure feasibility.

$$[\mathbf{S}^3\mathbf{VM - MINLP}] \quad \min_{\mathbf{w}, b, \eta, \xi, \mathbf{z}} \quad C \left[\sum_{i=1}^l \eta_i + \sum_{j=l+1}^{l+u} (\xi_j + z_j) \right] + \|\mathbf{w}\| \quad (26a)$$

$$\text{subject to } y_i(\mathbf{w} \cdot \mathbf{x}_i - b) + \eta_i \geq 1 \quad i = 1, \dots, l \quad (26b)$$

$$\mathbf{w} \cdot \mathbf{x}_j - b + \xi_j + M(1 - d_j) \geq 1 \quad j = l+1, \dots, l+u \quad (26c)$$

$$-(\mathbf{w} \cdot \mathbf{x}_j - b) + z_j + Md_j \geq 1 \quad j = l+1, \dots, l+u \quad (26d)$$

$$\eta_i \geq 0 \quad i = 1, \dots, l \quad (26e)$$

$$\xi_j \geq 0 \quad j = l+1, \dots, l+u \quad (26f)$$

$$z_j \geq 0 \quad j = l+1, \dots, l+u \quad (26g)$$

$$d_j \in \{0, 1\} \quad j = l+1, \dots, l+u \quad (26h)$$

where M is a large enough number that ensures $\xi_j = 0$ when $d_j = 0$ and $z_j = 0$ when $d_j = 1$. It should be noted that Bennett and Demiriz [14] assume $C = C^*$, ignore balancing constraint, and use one-norm of \mathbf{w} in the objective function.

A number of methods have been introduced to solve non-convex problem (25) (see [38]). These methods typically utilize continuous relaxations or heuristics except one hard approach solving (25) directly.

4.1.1 Branch and Bound

Proposed briefly as a framework in [137], this method is used to find the global optimum for (25). Chapelle et al. [37] implemented a branch and bound algorithm that performs a search over y_u 's. This approach is particularly useful for relatively smaller data sets due to its complexity. Based on empirical evidence, the generalization performance of the global optimum solution can be significantly better than nonexact solutions.

The initial solution for the root node of branch and bound tree is the SVM solution for labeled training data. Branching is performed on unlabeled instances in the working set. To achieve optimal solution quickly, unlabeled instance x^* to be labeled next is selected in a way that its label (y^*) assignment has a high potential to improve the objective function. To formulate this concept, let $s(L)$ be the SVM objective function trained on labeled set that is formally defined as

$$s(L) = \min_{\mathbf{w}, b} \frac{1}{2} \|\mathbf{w}\|^2 + C \sum_{(x_i, y_i)} \max(0, 1 - y_i(\mathbf{w} \cdot \mathbf{x}_i + b))^2. \quad (27)$$

The branching is performed on the following unlabeled instance:

$$\arg \max_{x \in U, y \in \pm 1} s(L \cup \{x, y\}). \quad (28)$$

The lower bound for each node will be the objective function value after optimizing a standard SVM on instances that have been labeled so far, i.e., $s(L)$ introduced in (27). The incumbent solution will set the upper bound; thus, exploration strategy in the tree is depth first search. This approach promotes reaching leaves frequently and having tight upper bounds to perform aggressive pruning.

4.1.2 Continuous Relaxations

To solve the problem by continuous optimization methods, integer variables y_i for $i = l+1, \dots, l+u$ should be relaxed. Chapelle et al. [36, 38] introduce a soft computing approach that balances the distance of unlabeled instances from the hyperplane instead of the number of instances as in (25d). The problem is formulated as

$$[\text{S}^3\text{VM} - \mathbf{R}] \quad \min_{\mathbf{w}, b, \xi, z} \quad \frac{1}{2} \|\mathbf{w}\|^2 + C \sum_{i=1}^l \xi_i^p + C^* \sum_{j=l+1}^{l+u} z_j^p \quad (29a)$$

$$\text{subject to} \quad y_i(\mathbf{w} \cdot \mathbf{x}_i + b) \geq 1 - \xi_i \quad i = 1, \dots, l \quad (29b)$$

$$\xi_i \geq 0 \quad i = 1, \dots, l \quad (29c)$$

$$|\mathbf{w} \cdot \mathbf{x}_j + b| \geq 1 - z_j \quad j = l+1, \dots, l+u \quad (29d)$$

$$z_j \geq 0 \quad j = l+1, \dots, l+u \quad (29e)$$

$$\frac{1}{u} \sum_{j=l+1}^{l+u} \mathbf{w}^T \mathbf{x}_j = \tilde{r} - 1. \quad (29f)$$

Note that (29f) balances the sum of distances for the working set, given \tilde{r} . This constraint is first proposed in [35], and the problem with and without the balancing constraint is solved in [36, 38], respectively.

The problem can be solved via a concave convex-procedure, where the non-convex objective function is rewritten as the sum of a convex component and a concave component [148]. At each iteration of this algorithm, concave part is estimated by its tangent and the convex part is minimized using traditional algorithms. This type of methods to minimize the concave function is discussed by Fung and Mangasarian [59] and improved in [44, 139] to handle larger data sets.

$\nabla \text{S}^3\text{VM}$ method [35] minimizes the objective function by gradient descent. Since the objective function is not smooth, z_j^p in the objective function is replaced by an exponential function $\exp(-s(\mathbf{w} \cdot \mathbf{x}_j + b)^p)$, where s is a parameter. Furthermore, an annealing procedure is performed by increasing C^* at each iteration. Chapelle et al. [36] propose a continuation technique to solve the S^3VM problem. In this method, a system of nonlinear equations is solved through a simpler system of equations

by smoothing the objective function. Annealing is performed without increasing C^* , but instead keeping it fixed, and continuation technique is used to transform the objective function. Chapelle [34] later introduces Newton S³VM that is more efficient compared to ∇ S³VM and Continuation S³VM. This technique utilizes a new loss function for unlabeled instances in the primal problem and an associated Newton method.

Bie and Cristianini [18] propose a convex relaxation using the dual of (25) and solve through semidefinite programming (SDP). The dual formulation also allows kernel trick to be used for nonlinear classification and classification of nonvectorial data. The dual problem can be formulated as

$$\min_{\mathbf{Y}} \max_{\alpha} 2\alpha^T \mathbf{1} - \alpha^T (K \odot \mathbf{Y}\mathbf{Y}^T)\alpha \quad (30a)$$

$$\text{subject to } 0 \leq \alpha_i \leq C \quad i = 1, \dots, l+u \quad (30b)$$

$$\mathbf{Y}_u \in \{-1, 1\}^u. \quad (30c)$$

In this formulation, $\alpha = (\alpha_1, \dots, \alpha_{l+u})$ is a vector of dual variables α_i , K is the complete kernel matrix, and $\mathbf{Y} = \begin{bmatrix} \mathbf{Y}_l \\ \mathbf{Y}_u \end{bmatrix}$ is the complete label vector. The optimization problem (30) can be reformulated as follows by introducing the outer product of labels $\Gamma = \mathbf{Y}\mathbf{Y}^T$:

$$\min_{\Gamma} \max_{\alpha} 2\alpha^T \mathbf{1} - \alpha^T (K \odot \Gamma)\alpha \quad (31a)$$

$$\text{subject to } 0 \leq \alpha_i \leq C \quad i = 1, \dots, l+u \quad (31b)$$

$$\mathbf{Y}_u \in \{-1, 1\}^u. \quad (31c)$$

In (31), $\Gamma = \mathbf{Y}\mathbf{Y}^T = \begin{bmatrix} \mathbf{Y}_l \mathbf{Y}_l^T & \mathbf{Y}_l \mathbf{Y}_u^T \\ \mathbf{Y}_u \mathbf{Y}_l^T & \mathbf{Y}_u \mathbf{Y}_u^T \end{bmatrix}$, objective function is linear in Γ , concave in α , and constraints are linear. The problem is not convex due to (31c); therefore, a relaxation is proposed as

$$[\mathbf{S}^3\mathbf{VM} - \mathbf{SDP}] \quad \min_{\Gamma} \max_{\alpha} 2\alpha^T \mathbf{1} - \alpha^T (K \odot \Gamma)\alpha \quad (32a)$$

$$\text{subject to } 0 \leq \alpha_i \leq C \quad i = 1, \dots, l+u \quad (32b)$$

$$\text{diag}(\Gamma) = 1 \quad (32c)$$

$$\Gamma \succeq 0, \quad (32d)$$

where $\Gamma = \begin{pmatrix} \mathbf{Y}_l \mathbf{Y}_l^T & \Gamma_{lu} \\ \Gamma_{ul} & \Gamma_{uu} \end{pmatrix}$. In (32), \mathbf{Y}_u 's lie in the interval $[-1, 1]$. Furthermore, rank of Γ is not necessarily 1. Although the problem is convex, this method is not widely used due to its high time complexity $O((1 + u^2)^2(l + u)^{2.5})$ [38].

4.1.3 Heuristics

Introduced by Thorsten [133], S^3VM^{light} is an S^3VM implementation within the SVM^{light} software package. It is based on local combinatorial search guided by a label-switching procedure. In this method, the labels of test instances are switched in a way that improves the objective function. In an outer loop, the value of C^* is gradually increased. This temporary adjustment of C^* helps algorithm avoid suboptimal local minima.

Deterministic annealing (DA) is a metaheuristic that has been used to solve hard combinatorial or non-convex problems. Sindhiani and Keerthi [127] use DA for S^3VM s by relaxing discrete label variables y_u to real-valued variables $p_u = (p_{l+1}, \dots, p_{l+u})$, where p_i is interpreted as the probability that $y_i = 1$. Based on these new variables, an easier reformulation is solved.

4.2 Expectation-Maximization (EM) Method

The expectation-maximization (EM) algorithm is first introduced by Dempster et al. [48] as an iterative procedure for estimating parameter values that maximize the likelihood function, when there is missing data. This method has two steps: *expectation* (E-step) and *maximization* (M-step). E-step calculates the expected values of the sufficient statistics given the current parameter estimates. M-step sets parameters to their maximum likelihood estimates given the estimated values of the sufficient statistics. Starting with a randomly generated set of parameter estimates, these steps are repeated either for a predefined number of steps or more commonly until the difference between parameter estimates in two consecutive iterations is negligible. In this setting, labels for working set are considered as missing data and EM method attempts to label these instances [100].

4.3 Graph-Based Methods

Graph-based semi-supervised methods define an empirical graph $G = (V, E)$. In this graph, nodes $V = 1, \dots, n$ are instances given in training and working sets, and edges E represent the similarity between these instances. A weight matrix $W = [w_{ij}]$ is also defined in a way that $w_{ij} \neq 0$ if there is an edge between i and j . Weight matrix can be introduced in a number of different ways. For example, W can be a k -nearest neighbor matrix, i.e., $w_{ij} = 1$ if i is among the k -nearest neighbors of j . The way the weight matrix is defined affects the performance of graph-based semi-supervised learning [41].

These methods rely on the geometry of data induced by labeled and unlabeled instances and usually assume a smooth distribution of labels over the graph. Graph-based methods are nonparametric, discriminative, and transductive in nature, yet they can be modified to be inductive. Goal of a graph-based method can be *label propagation* on a similarity graph or minimization of a *quadratic cost criterion*.

In label propagation, known labels are used to spread information through the graph in order to label unlabeled nodes [151]. Szummer and Jaakkola [132] propose a Markov random walk algorithm based on label propagation on similarity graph. In this method, labeling is performed based on how easy it gets to move from one node to the other via a random walk.

In quadratic cost criterion-based methods, rapid changes of estimated labels (i.e., \hat{Y}) between close instances are penalized. The penalty term is defined as follows:

$$\begin{aligned} \frac{1}{2} \sum_{i,j=1}^n W_{i,j} (\hat{y}_i - \hat{y}_j)^2 &= \frac{1}{2} \left(2 \sum_{i=1}^n \hat{y}_i^2 \sum_{j=1}^n W_{ij} - 2 \sum_{i,j=1}^n W_{ij} \hat{y}_i \hat{y}_j \right) \\ &= \hat{Y}^T (D - W) \hat{Y} \\ &= \hat{Y}^T L \hat{Y}. \end{aligned} \quad (33)$$

In (33), $L = D - W$ is an un-normalized graph laplacian. In [153], the penalty term is minimized over \hat{Y}_u . Other methods considering quadratic cost criterion can be found in [9, 47, 79]. Bengio et al. [13] show that minimizing quadratic cost criterion is equivalent to label propagation.

4.4 Co-training

In co-training, two learners are iteratively combining their outputs to increase size of the training set, which is reused for training and generating more labeled data automatically. Co-training is proposed by Blum and Mitchell [21] for semi-supervised learning. This technique assumes features are separable into two sets that are conditionally independent given the classes. In first step, two classifiers are trained with the labeled data using subfeature sets. Then, each classifier is used to designate labels to unlabeled instances. Each classifier is retrained by the most confident predictions given by the other classifier. This process is repeated until all instances in the working set are labeled [149].

5 Ranking

Ranking is one of the fastest growing areas in machine learning. In ranking, a group of alternatives are ranked based on aggregate scores assigned by voters. Some of the most popular applications are internet databases, search engines, and e-commerce sites. A number of algorithms have been proposed for ranking in the literature [28, 52, 56] with different limitations.

Recently, Jiang et al. [76] propose a model called HodgeRank using graph Helmholzian. Alternatives to be ranked by voters are vertices of a graph, where preferences are quantified and aggregated into an edge flow. Hodge theory yields an orthogonal decomposition of the edge flow known as the Hodge or

Helmholtz decomposition and analyzes pairwise rankings represented as edge flows. HodgeRank uses combinatorial Hodge theory to reduce rank aggregation to a linear least squares regression and avoids usual \mathcal{NP} -hard combinatorial optimization problems. HodgeRank outperforms classical ranking methods due to its ability to handle incomplete and imbalanced data as well as large complex network data. Furthermore, although this method is designed for cardinal data (i.e., each alternative is given a score), it can also give insights about ordinal data sets (i.e., a set of alternatives is compared and ranked by each voter).

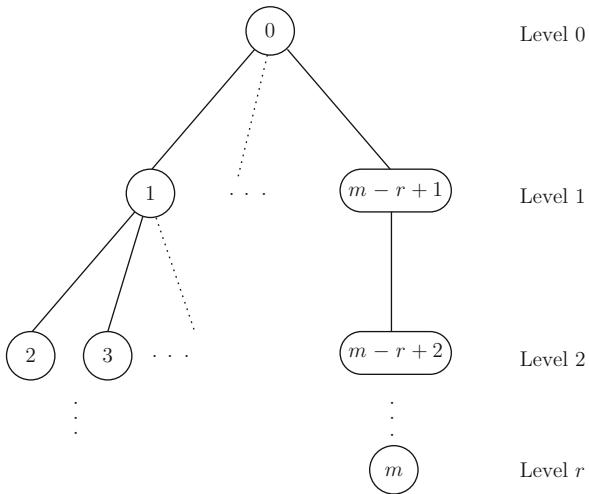

6 Feature Selection

Feature selection has been studied since the 1970s in statistical pattern recognition, machine learning, and data mining [94]. Feature selection is applied in a variety of fields such as text categorization, gene expression array analysis, combinatorial chemistry, and bioinformatics [66, 115] and is one of the key techniques in data preprocessing for data mining [20]. Feature selection is the process of removing irrelevant (features that do not affect the underlying target concept) and redundant features (features that do not add any information to the target concept) [46, 80]. Feature selection's role is more significant in real-world problems in which the data set is large (i.e., larger than the desired learning tool can handle). The idea with feature selection is to decrease running time of the learning process without decreasing the accuracy of the result significantly. It is needed because of generalization performance, running time requirements, constraints, and interpretational issues imposed by the problem itself. Further benefits of feature selection include facilitating data visualization and data understanding, reducing the measurement and storage requirements, reducing training and utilization times, and defying the curse of dimensionality to improve prediction performance [66]. Problem of selecting the optimal subset of features is proven to be an \mathcal{NP} -complete problem [63].

Based on availability of class information, feature selection methods can be divided into three groups: supervised feature selection (feature selection for classification), unsupervised feature selection (feature selection for clustering), and semi-supervised feature selection. Feature selection methods can also be categorized based on role of the mining algorithm: the filter model, the wrapper model, and the hybrid model. *Filter models* start with an empty set of features and add features until a combination consistent with the training data is found. Mining method is applied next based on the selected features. On the other hand, *wrapper models* need a predefined mining method to use as evaluation criterion. Generally, wrapper methods are more accurate than filter methods due to the interaction between a mining algorithm and its training data [84, 90]. Wrapper methods are also computationally more expensive as they run the mining algorithm repeatedly during the evaluation process.

Feature selection in classification is defined as methods that select minimal sized subset of features based on two criteria. First, classification accuracy should

Fig. 3 Illustration of a branch and bound algorithm for feature selection

not notably decrease. Second, the resulting class distribution based on selected features should be as close as possible to the original class distribution based on all features. There are a number of studies in the literature (e.g., [51, 126]) that explore stages of feature selection methods. Dash and Liu [46] breaks down a typical feature selection method into four basic steps: generation, evaluation, stopping criterion, and validation. Generation procedure is a search approach that generates subsets for evaluation. When number of features is N , order of search space is $O(2^N)$. The search approach can be complete, heuristic, or random. Using complete methods guarantees optimality of the feature subset because they do backtracking. Backtracking is done by using techniques such as branch and bound, best first search, and beam search. Stopping criterion can be based on generation (predefined number of features/iterations) or evaluation procedure (optimal subset is obtained or addition/deletion of any feature does not result in a better subset).

Basic branch and bound algorithm omits r out of m features by producing r levels as shown in Fig. 3. At each level, one of the features is discarded. The level number indicates the number of features that have been omitted at that level. The root of the tree (at level 0) refers to the set of all m features. The leaves at the bottom of the tree correspond to all possible subsets of size $m - r$ features. The paths in this tree denote all combinations of r -eliminated features. Numbers in the nodes correspond to omitted features. The problem is selecting the best path through the tree that yields the best criterion function result. Ideally, this path should be achieved with the fewest number of calculations.

Branch and bound is first used for solving feature selection problem by Narendra and Fukunaga [105]. This algorithm assumes *monotonicity* of criterion function to find optimal feature subset without evaluating all possible feature subsets. Monotonicity property states that a subset of features is not better than any larger set

that contains the subset. A criterion function that satisfies the monotonicity property helps to cut off some subtrees and decreases the search area in the branch and bound algorithm. Generally, all branch and bound algorithms used for feature selection fall into two groups based on monotonicity assumption. Hamamoto et al. [68] show that criterion function is not monotonic, branch and bound still can result in a good recognition rate. A more efficient branch and bound algorithm with same assumption is introduced by Yu and Yuan [147]. This method can handle high-dimensional data by dynamically searching for the optimal solution on a minimum solution tree which is a subtree of the traditional solution tree. Another high-dimensional branch and bound algorithm (HDBB) that assumes monotonicity is introduced in [32]. To improve the speed of branch and bound, right-left search strategy is employed in addition to top-down strategy and backtracking in [39]. Frank et al. [55] propose a branch and bound algorithm using Bhattacharyya distance which is monotonic and additive. This method finds a feature subset of a given size with the lowest Bayesian classification error. A branch and bound method that can give a large initial bound using a floating search method is introduced in [104]. This model can order the tree nodes by the significance of features and has a jump search strategy to avoid redundant criterion function calculations. There are a number of methods that utilize monotonicity assumption (see [85, 128, 140, 146]). Recently, Ris et al. [114] introduce a branch and bound algorithm, which bases the representation and exploration of the search space on new lattice properties and the criterion function is not monotonic.

Another widely used approach in feature selection is the use of SVMs. Combined with filter methods, SVMs can be used after features are selected. SVMs can also be used in wrapper strategies, where one-norm SVM is used for automatic feature selection [23, 129, 152]. It is shown that the one-norm SVM has advantages over the two-norm SVM when there are features that present noise [152]. Having more spare solutions implies w has more zero components; thus, less features could be chosen. An extension of one-norm SVM is used in [154]. This method generates groups among features by clustering and uses F_∞ -norm SVM. Shi et al. [124] introduce a feature selection strategy using l_p -norm support vector classification (l_p -SVC) and l_p -norm proximal support vector machine (l_p -PSVM) where $0 < p < 1$. Guyon et al. [67] have proposed a recursive feature elimination (RFE) method. Adaptive scaling methods can be used for feature selection in SVMs [65]. For scaling, a linear transformation is done within the input space.

7 Conclusion

This review presents the numerous applications in data mining, which have benefited from the theory of combinatorial optimization. Combinatorial optimization improves quality and robustness of numerous applications and will certainly continue to support the constantly growing field of data mining.

Abstract

The matters of discussion are combinatorial optimization aspects, concepts, and applications arising in the broad area of network-based data mining. The approach of representing real-world datasets as large-scale networks (graphs) has become increasingly popular during recent years. The purpose of this chapter is to briefly review the graph-theoretic and combinatorial optimization concepts that are important in the context of data mining, as well as to discuss the interpretation of these concepts from mathematical modeling perspective.

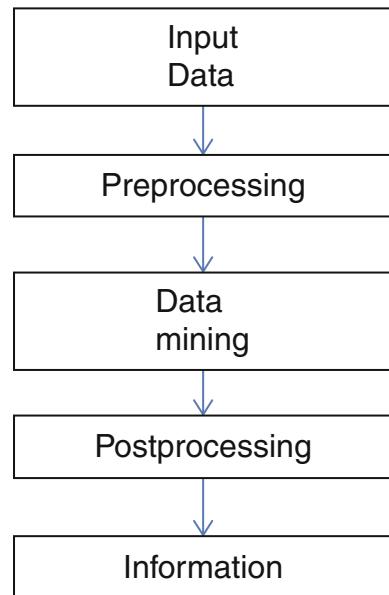

1 Introduction

The process of studying real-life complex systems often deals with large datasets arising in diverse applications including telecommunications, biotechnology, medicine, finance, physics, ecology, and geographical information systems [2, 21]. Understanding the structural properties of a certain dataset is in many cases the task of the crucial importance. To extract useful information from data, one often needs to apply advanced mathematical modeling techniques to summarize, visualize, and process the information contained in a dataset. *Data mining* problems deal with multiple aspects of information retrieval from datasets, and a variety of techniques has been developed to address different types of tasks arising in this area. Data mining is a part of *knowledge discovery in databases (KDD)* [81]. This is the process of converting data into useful information, which includes several main steps summarized in Fig. 1. The purpose of preprocessing is to transform input data to a proper format for further analysis. An example of postprocessing is visualization, which allows to research and explore data and data mining results from different viewpoints. One can also apply statistical measures and hypothesis testing techniques at the postprocessing step to potentially eliminate inconsistent data mining results. However, data mining itself is a crucial step in the KDD process. The purpose of this chapter is to review possible methods of utilizing combinatorial optimization and network-based tools to extract information from real-world datasets.

During the past several years, *optimization-based approaches* have received increased attention in the context of data mining problems [27]. Moreover, along with classical data mining techniques (e.g., support vector machines, artificial neural networks, decision trees, K-means/K-median clustering, and fuzzy C-means clustering), many recent studies deal with *network (graph)-based representations* of large real-world datasets and utilize graph-theoretic and network optimization concepts to extract useful and nontrivial information from these datasets. In this approach, a dataset is represented as a *graph (network)* with certain attributes associated with its vertices and edges. As it will be discussed later, combinatorial optimization problems often arise in this analysis, and solving these problems is an integral part of network-based data mining.

Studying the structure of a graph representing a dataset is often important for understanding the internal properties of the application it represents, as well as for

Fig. 1 Knowledge discovery in databases

improving storage organization and information retrieval. One can visualize a graph as a set of dots and links connecting them, which often makes this representation convenient and easily understandable.

The main concepts of graph theory were founded several centuries ago, and many network optimization algorithms have been developed since then. However, the trend of applying graph models to represent various real-life massive datasets has started relatively recently. Graph theory and related operations research techniques are quickly becoming a field with a strong practical impact. The expansion of graph-theoretical approaches in various applications gave birth to the terms “graph practice” and “graph engineering” [47]. Graph (network)-based data mining techniques have gained significant popularity in the recent years. Various aspects of this emerging field are addressed in [32, 84]. The term “network science” referring to a broad variety of network-based modeling approaches has also been widely used recently. In [10] potential relevance between “network science” and operations research is discussed. Although potential applications of operations research in this broad field can be diverse, network-based data mining is among the areas where optimization-based techniques can provide valuable contributions.

Network-based models allow one to extract information from real-world datasets using various standard concepts from graph theory. In many cases, one can investigate specific properties of a dataset by detecting special formations in the corresponding graph, for instance, *connected components*, *spanning trees*, *cliques*, and *independent sets*. In particular, connected components, cliques, and independent sets can be used to address the important *clustering* problems arising in many data mining applications. This problem essentially represents partitioning the set of elements of a certain dataset into a number of subsets (clusters) of objects according

to some *similarity* (or *dissimilarity*) criterion. These concepts are associated with a number of network optimization problems that will be discussed below.

Another aspect of investigating network models of real-world datasets is studying the global organization and structural properties of these networks, which are reflected by *degree distributions* of the constructed graphs. The degree distribution represents the large-scale pattern of connections in the graph, which reflects the global properties of the dataset. One of the important results discovered during the last several years is the observation that many graphs representing the datasets from diverse areas (Internet, telecommunications, biology, sociology) obey the *power-law* model [5]. The fact that graphs representing completely different datasets have a similar well-defined power-law structure has been widely reflected in the literature [4, 8, 16, 17, 21, 31, 47]. It indicates that global organization and evolution of datasets arising in various spheres of life follow similar laws and patterns. This fact served as a motivation to introduce a concept of “self-organized networks.” The information about the degree distribution of a graph that represents a certain dataset can be significant in the data mining context, since it may allow one to analytically predict the size of certain types of clusters in this graph (e.g., connected components, cliques, and other structures). In particular, the size of connected components (clusters) in very large power-law graphs has been studied in [5].

Further in this chapter, the main issues and concepts arising in network-based data mining will be addressed: specifically, the process of representing a dataset as a graph using appropriate similarity (proximity) measures, which serves as a basis for applying graph-theoretic and network optimization techniques. These concepts and techniques are discussed later in this chapter. Finally, there will be given several examples of popular recent application areas of network-based data mining.

2 Similarity Measures Used in Graph-Based Data Mining

As indicated above, the essence of network-based data mining is representing a dataset under consideration as a network (graph) where vertices and edges are constructed according to certain principles that may depend on the structure and the origin of this dataset. The vertices of the graph usually represent data records (objects), whereas the edges that connect the vertices are constructed using an appropriate *similarity criterion*. That is, two data objects (vertices) are connected if they are “similar enough” to each other. However, there are a lot of different ways to quantify the degree of similarity. In this section, possible types of *similarity measures* (also referred to as *proximity measures*) will be discussed. More precisely, those are proximity measures between data objects that can be used for constructing the corresponding graph representations of datasets.

Usually, the *similarity* between two objects is a numerical measure of the degree to which the two objects are alike. It can often be scaled between 0 (no similarity) and 1 (complete similarity). The *dissimilarity* between two objects is a numerical measure of the degree to which the two objects are different. Also, the term *distance* is used to measure the degree of similarity/dissimilarity. Dissimilarities sometimes occupy the interval $[0, 1]$, but it is usual for them to belong to the range $[0, \infty)$.

Transformations are used to convert similarity to dissimilarity and vice versa. First of all, proximity measures should be converted to the interval $[0, 1]$. For instance, if the grade has a range from 1 to 5, it makes sense to use the formula $\hat{s} = (s - 1)/4$ to replace the initial proximity measure s by standard \hat{s} that belongs to the interval $[0, 1]$. Generally, the transformations of similarities to the interval $[0, 1]$ are given by the formula

$$\hat{s} = \frac{s - \min s}{\max s - \min s}.$$

Analogously, dissimilarity measures with a finite range can be mapped to the interval $[0, 1]$ by transformation

$$\hat{d} = \frac{d - \min d}{\max d - \min d}.$$

In other cases, when values of the original proximity measure fill the interval $[0, \infty)$, a nonlinear conversion is necessary. As an example, the formula $\hat{d} = \frac{d}{1+d}$ can be utilized. The dissimilarities $0, \frac{1}{3}, \frac{2}{3}, 1, 5, 10, 100, 1,000$ will be converted to the new dissimilarities $0, 0.25, 0.4, 0.5, 0.833, 0.909, 0.99, 0.999$. Transforming dissimilarities into similarities and vice versa is rather straightforward too. If the similarity falls in the interval $[0, 1]$, then the dissimilarity can be defined by the formula $d = 1 - s$. For $d \in [0, \infty)$, various nonlinear transformations can be employed. Consistent examples are $s = 1/(d + 1)$ and $s = e^{-d}$.

In the standard setup of many data mining problems, one deals with a dataset of N data records that can be represented by vectors $x^i = (x_1^i, x_2^i, \dots, x_n^i)$, $i = 1, \dots, N$, where every vector x^i has n components that are referred to as the *features*, or *attributes*, of the data record. The similarity/dissimilarity measure between any two data records would be defined by the corresponding values of their attributes. The following similarity/dissimilarity measures are commonly used in practice.

- *Distance metrics:* Generally it can be expressed in the form of Minkowski distance metric

$$d(x, y) = \left(\sum_{k=1}^n |x_k - y_k|^r \right)^{1/r},$$

where r is a parameter that defines different types of metrics. The most commonly used distance metrics are L_1 norm for $r = 1$ (*Manhattan distance*, *city block distance*), L_2 norm for $r = 2$ (*Euclidean distance*), and L_∞ norm for $r = \infty$ (*supremum distance*) that signifies

$$d(x, y)_{L_\infty} = \max_{i=1, \dots, n} |x_k - y_k|.$$

A common particular instance of Manhattan distance is the *Hamming distance*, which is the number of bits that are different between two objects that have only binary attributes (i.e., between two binary vectors). In Fig. 2, the difference

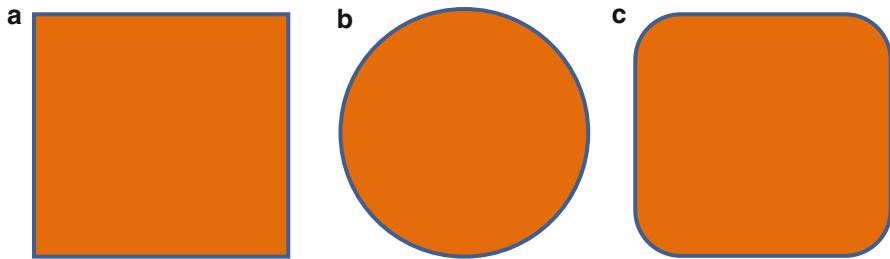

Fig. 2 Circumferences in different L_p norms. (a) Standard circle in L_1 norm. (b) Standard circle in L_2 norm. (c) Standard circle in L_4 norm

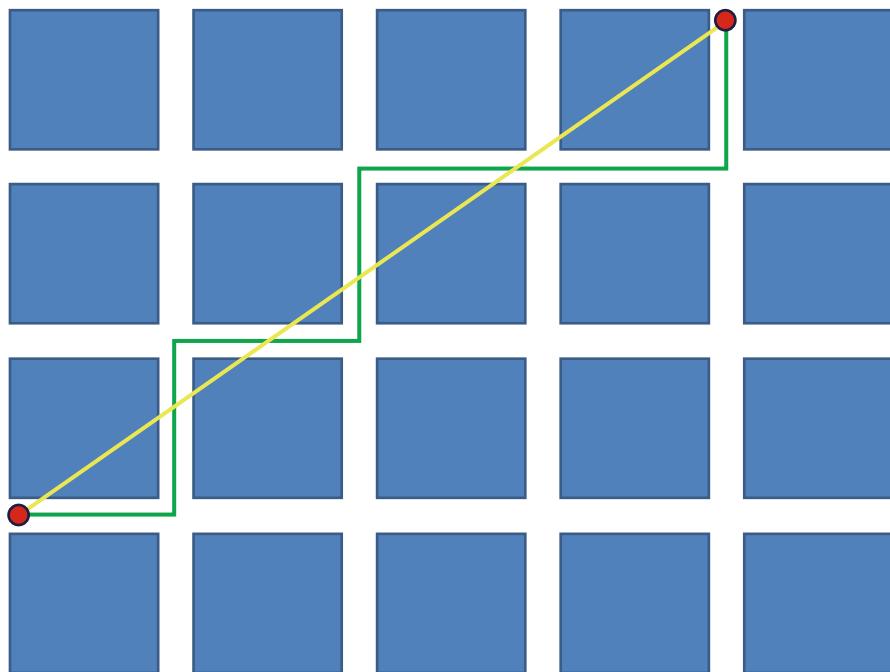

Fig. 3 Comparison of city block distance and Euclidean distance

between L_1 , L_2 , and L_4 can be observed graphically on the example of the standard circle presented in all these metrics. The norms L_1 and L_2 are compared visually in Fig. 3.

Supremum (L_{\max} or L_{∞} norm) distance is the maximum difference between any attribute of two objects. More rigorously, L_{∞} is defined by the limit

$$d(x, y) = \lim_{r \rightarrow \infty} \left(\sum_{k=1}^n |x_k - y_k|^r \right)^{1/r}.$$

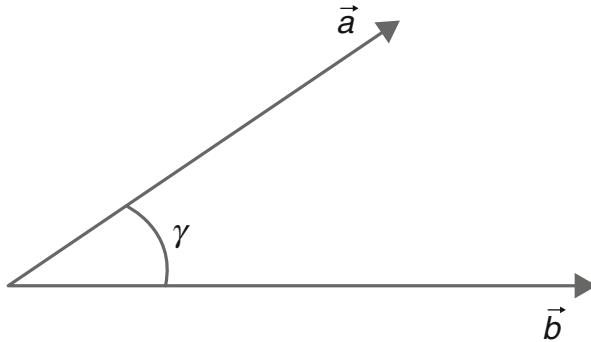

Fig. 4 Geometric representation of cosine similarity

To add more flexibility in the situations when the values of some attributes have substantially different importance levels or orders of magnitude, the formulas of proximity can be modified by weighting the contribution of each attribute. In the case of the distance metrics, the Minkowski distance can be modified as follows:

$$d(x, y) = \left(\sum_{k=1}^n \omega_k |x_k - y_k|^r \right)^{1/r},$$

where ω_k is the relative weight of the k th component in the considered vector space.

- *Cosine similarity:* This measure is often used to characterize text document similarity (e.g., documents represented as vectors with attributes denoting the frequency of each word in the considered document) and can be expressed as

$$\cos(a, b) = \frac{a \cdot b}{\|a\| \|b\|},$$

where $a \cdot b$ is a scalar product of vectors a and b . Even though documents have thousands of attributes, each document is sparse because there is a few nonzero attributes. Thus, similarity should not depend on the number of shared zero values. Therefore, a proximity measure for documents must ignore 0–0 matches like *Jaccard measure*. The cosine similarity is one of the useful measures in this case (Fig. 4).

- *Correlation:* The standard correlation measure is commonly used to characterize the similarity between different types of data, for instance, time series data, where the attributes represent the values of a certain parameter for different time moments. A well-known example that the correlation measure can be effectively used is the analysis of stock market data, where high correlation would mean high degree of similarity between a given pair of stocks.

The *general correlation coefficient* is given by the formula

$$\bar{r} = \frac{\sum_{i < j} c_{ij}(x)c_{ij}(y)}{\sqrt{\sum_{i < j} c_{ij}^2(x) \cdot \sum_{i < j} c_{ij}^2(y)}},$$

where x and y are two samples of comparable data and c_{ij} is some function measuring relative distance between x_i and x_j (i th and j th coordinates of the sample vector x). Three particular examples of the general correlation coefficient are given below.

Pearson's correlation coefficient is the most widely used correlation measure. It is defined by the formula

$$\text{corr}(x, y) = \frac{\text{covariance}(x, y)}{\text{standard deviation}(x) * \text{standard deviation}(y)},$$

where from statistics theory it is known that

$$\begin{aligned} \text{covariance}(x, y) &= \sum_{k=1}^n (x_k - \bar{x})(y_k - \bar{y}), \\ \text{standard deviation}(x) &= \sqrt{\frac{1}{n-1} \sum_{k=1}^n (x_k - \bar{x})^2}, \\ \text{standard deviation}(y) &= \sqrt{\frac{1}{n-1} \sum_{k=1}^n (y_k - \bar{y})^2}. \end{aligned}$$

Using standard notations, \bar{x} and \bar{y} are means of two samples x and y , respectively. Notice that Pearson's correlation coefficient could be easily derived from the general correlation coefficient if it is assigned that $c_{ij} = x_j - x_i$. Also, Spearman's rank correlation coefficient [79] and Kendall's tau (τ) rank correlation coefficient [55] are frequently utilized for peculiar statistical tests and hypotheses.

If it is assigned that $c_{ij} = R_j - R_i$ where R_k is the rank of x_k in the given sample vector $x = (x_1, \dots, x_n)$ for each $k = 1, \dots, n$, then the formula below for *Spearman's rank correlation coefficient* can be derived:

$$\rho_S = \frac{\sum_{i=1}^n (R_i - \bar{R})(S_i - \bar{S})}{\sqrt{\sum_{i=1}^n (R_i - \bar{R})^2 \sum_{i=1}^n (S_i - \bar{S})^2}},$$

where R_k and S_k are the ranks of x_k and y_k in the samples x and y , correspondingly. Also, it should be pointed out that always $\bar{R} = \bar{S} = (n+1)/2$.

Having assigned $c_{ij} = \text{sgn}(x_j - x_i) = \text{sgn}(R_j - R_i)$, the formula for *Kendall's tau (τ) rank correlation coefficient* is obtained:

$$\tau = \sum_{i < j} \text{sgn}(R_i - \bar{R}) \cdot \text{sgn}(S_i - \bar{S}),$$

where R_k and S_k are ranks of the given samples as in the previous notations.

Regarding binary data, other definitions of similarity (proximity) measures are also used in practice [81]. For instance, simple matching coefficient, Jaccard coefficient, and extended Jaccard coefficient can be efficiently used to measure the similarity between data objects of aforementioned kind. Let x and y be two objects that consist of n binary attributes. Comparing of binary data x and y induces the following qualities:

- f_{00} = the number of attributes where $x_i = 0$ and $y_i = 0$
- f_{01} = the number of attributes where $x_i = 0$ and $y_i = 1$
- f_{10} = the number of attributes where $x_i = 1$ and $y_i = 0$
- f_{11} = the number of attributes where $x_i = 1$ and $y_i = 1$.

Simple matching coefficient (SMC) is commonly used similarity measure for binary data. It does not pay attention to elimination of 0–0 matches from consideration. SMC reflects both presences and absences equally. For instance, it can be utilized to find respondents who had answered questions on a test similarly.

$$SMC = \frac{f_{00} + f_{11}}{f_{00} + f_{01} + f_{10} + f_{11}}$$

Jaccard coefficient can be employed for sparse data. The idea is to compare nonzero elements belonging to two samples. Consequently, it makes little sense to use SMC coefficient in such a case because samples will be always similar because of the large number of zeros. In this case, 0–0 matches must not be counted. That is why under such conditions, Jaccard coefficient is more reasonable than simple matching coefficient.

$$J = \frac{f_{11}}{f_{01} + f_{10} + f_{11}}$$

Extended Jaccard coefficient is an expansion of Jaccard coefficient to real data. In the binary case, it is equal to a regular Jaccard coefficient. The extended Jaccard coefficient can be used for document data and also known as Tanimoto coefficient.

$$EJ(x, y) = \frac{x \cdot y}{||x||^2 + ||y||^2 - x \cdot y}$$

A significant issue related to distance measures is how to handle the situation when attributes do not have the same range of values. Often there is some correlation between some of attributes. In this case, a generalization of Euclidean distance referred to as *Mahalanobis distance* can be applied to measure similarity.

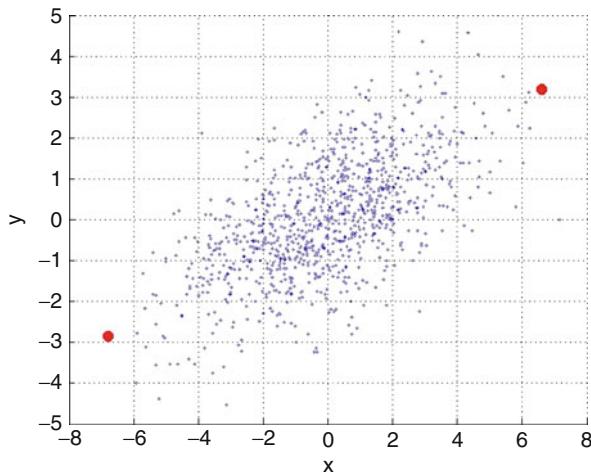

Fig. 5 Mahalanobis distance versus Euclidean distance [81]. The Mahalanobis distance between these two points are represented by *large dots* is 6. The corresponding Euclidean distance is 14.7. The correlation between axes causing distortion of data is equal to 0.6

The Mahalanobis distance between two objects x and y is defined as follows:

$$\text{mahalanobis}(x, y) = (x - y)\Sigma^{-1}(x - y)^T,$$

where Σ is the covariance matrix of the given data that reflects dependence between some attributes. The good example [81] is provided in Fig. 5. In practice, computing the Mahalanobis distance is worth doing it for correlated points in spite of its expensive cost.

Moreover, besides defining the similarity between data objects, in some cases, it is also needed to quantify the *dissimilarity*. The aforementioned proximity measures can be also used to define the pairwise dissimilarity. Therefore, all further discussion is applicable to clustering applications based on either similarity or dissimilarity. Without loss of generality, the term “similarity” will mostly be used throughout this chapter.

Determining an appropriate similarity measure is often a nontrivial task. However, if a suitable similarity measure is determined for a given dataset, this gives one the information about pairwise proximities for all pairs of data objects. Based on this information, one can easily construct the $N \times N$ proximity matrix and then use the proximity matrix to create a graph with N vertices and $N(N - 1)/2$ weighted edges, where the weights $w_{ij} = d(x^i, x^j)$ are equal to the corresponding proximity measures between data objects x^i and x^j .

Note that this simple procedure would produce a complete weighted graph (with all possible edges), which can be challenging to analyze from both theoretical and computational perspectives. To reduce the edge density of the obtained graph, one can use an appropriate *sparsification* procedure that can substantially reduce the number of edges in the graph while still preserving valuable information about the dataset. The following simple principles can be used to achieve this:

- *k-nearest neighbor approach*: For every vertex i , keep only the edges that connect it to its k -nearest neighbors, that is, preserve k edges (i, j) with the smallest values of w_{ij} (as determined by an appropriate proximity measure) and delete the remaining edges.
- *Threshold approach*: For every edge (i, j) , delete it if the corresponding similarity measure w_{ij} is below (or above) a specified threshold.

Applying one or both of these approaches can, in many cases, eliminate most of the edges in the constructed graph and make sure that the remaining edges preserve the most meaningful similarity relationships between the data objects in the considered dataset. It should be noted that the similarity measures between each pair of vertices can be further updated to incorporate the idea of *shared nearest neighbors*. That is, if two vertices i and j are both connected to certain number of other vertices, the weight of the edge (i, j) is increased by the number of these shared neighbors. This idea can be used for constructing the *shared nearest neighbor (SNN) similarity graph*. In particular, the concept of SNN graph has been used in the Jarvis-Patrick clustering algorithm, which essentially performs clustering on the considered dataset by identifying connected components in the corresponding SNN graph [49].

Finalizing this section, it should be emphasized that in many real-world situations, one of the most crucial problems is to choose a suitable proximity measure which is the best fit for the considered type of data. For many cases with dense continuous data, metric distance measures such as Euclidean distance are appropriate and often used. On the contrary, for sparse data, measures that disregard 0–0 matches are frequently utilized. The cosine similarity, Jaccard, and Extended Jaccard measures are typically used for such data. For comparing time series, Euclidean distance or various correlation coefficients depending on the given data should be employed. If the time series contain similar quantities, then Euclidean distance can be used. On the contrary, if the time series represent different quantities (for instance, quantities of various substances in human organism in different biomedical studies), then one should use the one of aforementioned definitions of correlation coefficients.

In general, after the graph representing a dataset has been constructed and sparsified, one can use a variety of graph-theoretic concepts and techniques to extract useful information about the considered dataset and divide the dataset into a number of meaningful clusters according to the specified similarity criterion. The next section discusses relevant concepts, definitions, and optimization problems arising in this analysis.

3 Basic Concepts from Graph Theory and Their Data Mining Interpretation

To facilitate further discussion, several formal basic definitions and notations from graph theory will be presented, and the interpretation of the introduced concepts from the perspective of data mining and information retrieval will be discussed.

Let $G = (V, E)$ be an undirected graph with the set of N vertices V and the set of edges $E = \{(i, j) : i, j \in V\}$. Directed graphs, where the head and tail of each edge are specified, are considered in some applications. The concept of a *multigraph* is also sometimes used. A multigraph is a graph where multiple edges connecting a given pair of vertices may exist. A directed multigraph is a directed graph in which loops and multiple edges between any two vertices are permitted. Examples of different types of graphs are given in Fig. 6.

One of the important characteristics of a graph is its *edge density*: the ratio of the number of edges in the graph to the maximum possible number of edges. A *dense graph* is a graph in which the number of edges is close to the maximum possible number of edges. A *sparse graph* is a graph in which the number of edges is substantially smaller than maximum possible number of edges. In undirected graphs, edge density formally defined as

$$D = \frac{2|E|}{|V|(|V| - 1)}, \quad (1)$$

where $|E|$ denotes the number of edges and $|V|$ denotes the number of vertices in graph G . Clearly, the maximum number of edges is $\frac{1}{2}|V|(|V| - 1)$, so the highest possible edge density is 1 (for complete graphs) and the lowest edge density is 0. As indicated in the previous section, one often needs to eliminate a substantial number of edges from a graph representing a real-life dataset, so that the edge density is reduced and only the most meaningful connections are preserved.

Often, a real-world dataset can be represented as a graph with the particular structure, and the examined properties of such graphs can be used for data mining. Some examples of well-known graph structures are:

- *Complete graph*: a graph, which contains all possible edges, that is, any two vertices are adjacent.
- *Bipartite graph*: a set of graph vertices decomposed into two disjoint sets such that no two graph vertices within the same set are adjacent.
- *Complete bipartite graph*: a bipartite graph such that every pair of graph vertices in the two sets are adjacent.
- *Linear (path) graph*: a graph, which vertices can be listed in order, v_0, v_1, \dots, v_n , so that the edges are $(v_{i-1}, v_i) \in E$ for each $i = 1, 2, \dots, n$. If a linear graph occurs as a subgraph of another graph, it is a *path* in that graph.
- *Cycle graph*: a graph containing a single cycle through all nodes.
- *Planar graph*: a graph whose vertices and edges can be drawn in a plane such that no two of the edges intersect.

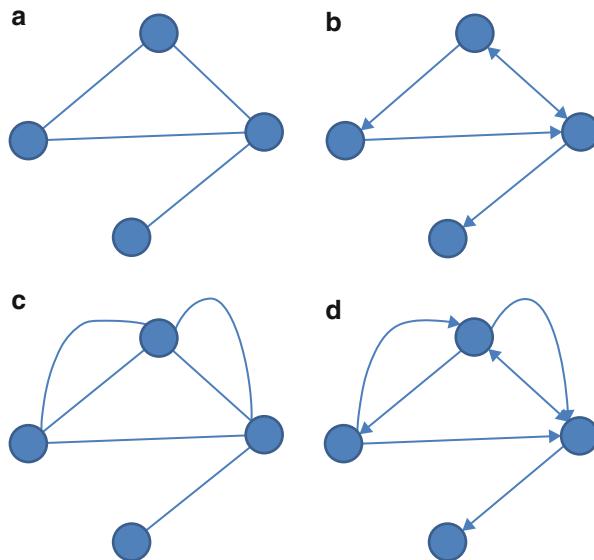

Fig. 6 Examples of different concepts of graphs. (a) Undirected graph. (b) Directed graph. (c) Multigraph. (d) Directed multigraph

- *Tree*: a connected graph with no cycles.
- *Forest*: a graph with no cycles, that is, the disjoint union of one or more trees.

3.1 Connected Components and Degree Distributions

The graph $G = (V, E)$ is *connected* if there is a path from any vertex to any vertex in the set V . If the graph is disconnected, it can be decomposed into several connected subgraphs, which are referred to as the *connected components* of G . A graph is called *K-vertex-connected* or *K-edge-connected* if there is no set of $K - 1$ vertices (edges, respectively) that disconnects the graph. A *K-vertex-connected* graph is often simply called *K-connected*. In many clustering techniques, distinct connected components are interpreted as distinct *clusters* in the corresponding dataset. It should be noted that although using connected components for clustering is rather common in a variety of applications, there are alternative graph-theoretic concepts that can be utilized in clustering problems. These concepts will be discussed in further sections.

The *degree* of a vertex is the number of edges emanating from it. For every integer k , one can calculate the number of vertices $n(k)$ with a degree equal to k , and then get the estimate of the probability that a vertex has the degree k as $P(k) = n(k)/n$, where n is the total number of vertices. The function $P(k)$ is referred to as the *degree distribution* of the graph. In the case of a directed graph, the concept of degree distribution is generalized: one can distinguish the distribution of *in-degrees*

and *out-degrees*, which deal with the number of edges ending at and starting from a vertex, respectively.

Degree distribution is an important characteristic of a dataset represented by a graph. It reflects the overall pattern of connections in the graph, which in many cases reflects the global properties of the dataset this graph represents. As mentioned above, many real-world graphs representing the datasets coming from diverse areas (Internet, telecommunications, finance, biology, chemistry, sociology) have degree distributions that follow the *power-law* model, which states that the probability that a vertex of a graph has a degree k (i.e., there are k edges emanating from it) is $P(k) \propto k^{-\gamma}$. Equivalently, one can represent it as $\log P \propto -\gamma \log k$, which demonstrates that this distribution forms a straight line in the logarithmic scale, and the slope of this line equals the value of the parameter γ . Figures 7 and 8 illustrate the power-law distribution in a regular and logarithmic scale.

An important characteristic of the power-law model is its *scale-free* property. This property implies that the power-law structure of a certain network should not depend on the size of the network. Clearly, real-world networks dynamically grow over time; therefore, the growth process of these networks should obey certain rules in order to satisfy the scale-free property. The necessary properties of the evolution of the real-world networks are *growth* and *preferential attachment* [17]. The first property implies the obvious fact that the size of these networks grows continuously (i.e., new vertices are added to a network, which means that new elements are added to the corresponding dataset). The second property represents the idea that new vertices are more likely to be connected to old vertices with high degrees. It is intuitively clear that these principles characterize the evolution of many real-world complex networks and massive datasets they represent.

From another perspective, some properties of graphs that follow the power-law model (and the corresponding datasets) can be predicted theoretically. Interesting properties of power-law graphs were studied using the theoretical *power-law random graph model* [5, 31]. Among these results, one can mention the existence of a giant connected component (i.e., a giant cluster that contains $\Theta(N)$ vertices) in a power-law graph with $\gamma < \gamma_0 \approx 3.47875$ and the fact that all connected components (clusters) are small ($o(N)$ vertices) otherwise.¹ The emergence of a giant connected component (or a giant connected cluster) at the point $\gamma_0 \approx 3.47875$ is often referred to as a *phase transition*.

The size of connected components of the graph may provide useful information about the structure of the corresponding dataset, since, as indicated above, the connected components would normally represent clusters of “similar” objects. In many applications, decomposing the graph into a set of connected components can provide a reasonable solution to the clustering problem. From the computational perspective, identifying all connected components in a graph is a *polynomially*

¹These results are valid *asymptotically almost surely* (a.a.s.), which means that the probability that a given property takes place tends to 1 as the number of vertices N goes to infinity.

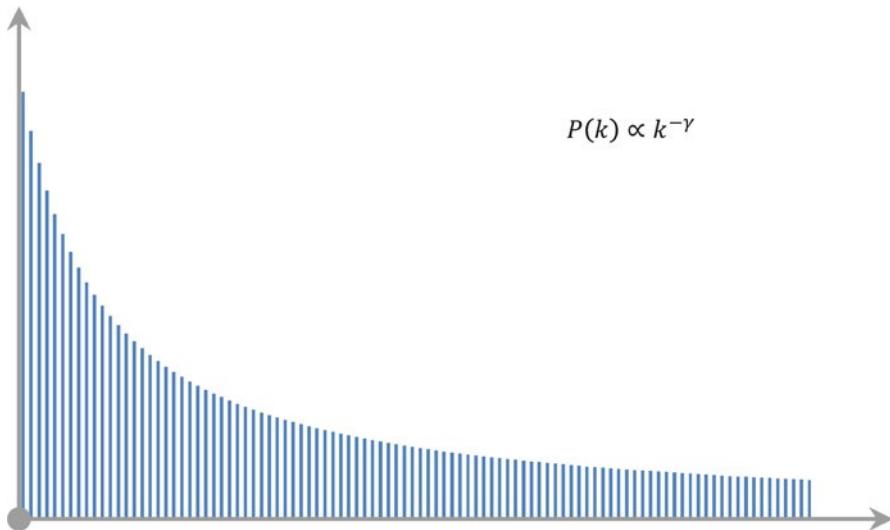

Fig. 7 A power-law distribution in the regular scale. The *horizontal axis* represents node degrees, and the *vertical axis* represents the corresponding probabilities (frequencies)

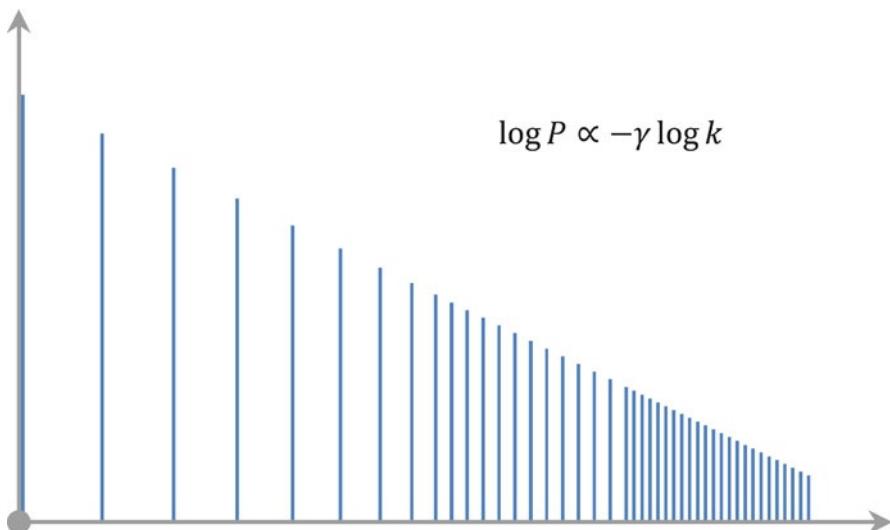

Fig. 8 A power-law distribution in the log-log scale. The interpretation of the axes is the same as in the previous figure

solvable problem, which is especially important when the considered graphs and datasets are very large.

However, in some situations, clusters based on connected components can be extremely large (e.g., comparable with the size of the whole graph, as indicated above),

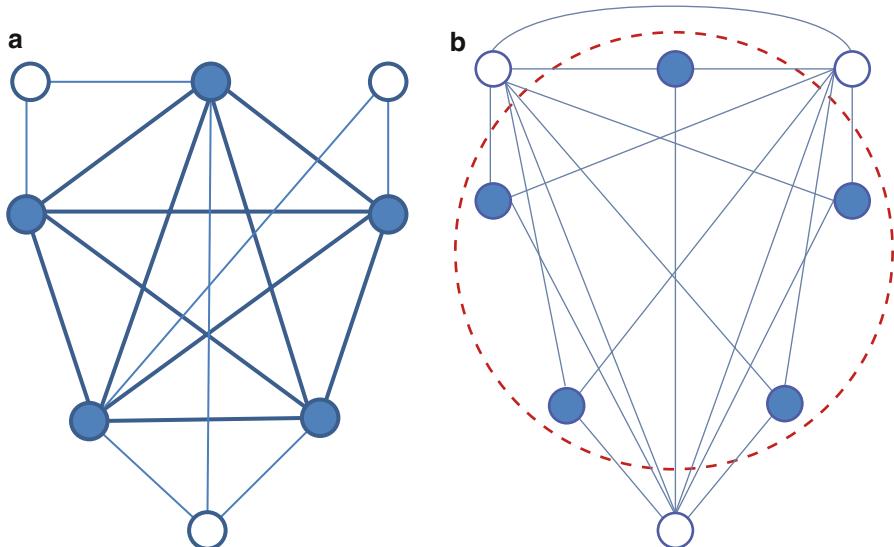

Fig. 9 Correspondence between the maximum clique and the maximum independent set in the complementary graph. (a) Clique in the graph (size 5). (b) Independent set in the complement graph (size 5)

and/or they may not be “tight enough,” that is, the degree of connectivity within a cluster may not be sufficient to make reliable conclusions regarding the similarity of the data objects. This motivates one to look for substantially more “robust” clusters that have specific properties of their connectivity patterns. The corresponding graph structures that address these issues are discussed in the next subsections.

3.2 Cliques and Independent Sets

Given a subset $S \subseteq V$, $G(S)$ is denoted as the subgraph induced by S . A subset $C \subseteq V$ is a *clique* if $G(C)$ is a complete graph (i.e., it has all possible edges). Figure 9a shows an example of a clique in the graph.

One of the most well-known problems in combinatorial optimization, the *maximum clique problem* [26], is to find the largest clique in a graph. The maximum clique problem has several equivalent formulations as an integer programming (IP) problem, or as a continuous nonconvex optimization problem.

The simplest formulation of maximum clique problem is the following edge formulation [70]:

$$\max \sum_{i=1}^N x_i \quad (2)$$

s.t.

$$\begin{aligned} x_i + x_j &\leq 1, \forall (i, j) \in \bar{E} \\ x_i &\in \{0, 1\}, i = 1, \dots, N. \end{aligned}$$

In the above formulation, \bar{E} is the set of edges in the *complementary graph* $\bar{G}(V, \bar{E})$, defined as follows. If an edge $(i, j) \in E$, then $(i, j) \notin \bar{E}$, and if $(i, j) \notin E$, then $(i, j) \in \bar{E}$. Decision variables x_i defined as

$$x_i = \begin{cases} 1, & \text{if vertex } i \text{ is in the clique} \\ 0, & \text{otherwise.} \end{cases}$$

The objective (2) is to maximize the number of vertices, which are in the clique. The maximum clique problem finds a clique of maximum cardinality. It can be easily transformed into the *maximum-weight clique problem*, which finds a clique of maximum weight, by introducing positive weights w_i associated with node i . Clearly, the objective of formulation (2) in the weighted case will be of the form

$$\max \sum_{i=1}^N w_i x_i$$

with the same set of constraints as in (2).

An *independent set* is a subset $I \subseteq V$ such that the subgraph $G(I)$ has no edges. Figure 9b shows an example of an independent set in the graph. The maximum independent set problem can be easily reformulated as the maximum clique problem in the *complementary graph* $\bar{G}(V, \bar{E})$. A maximum clique in \bar{G} is a maximum independent set in G , so the maximum clique and maximum independent set problems can be easily transformed to each other and are essentially equivalent. Let \mathcal{I} denote the set of all maximal independent sets of G . An alternative formulation is the following independent set formulation [70]:

$$\max \sum_{i=1}^N x_i \tag{3}$$

s.t.

$$\begin{aligned} \sum_{i \in S} x_i &\leq 1, \forall S \in \mathcal{I} \\ x_i &\in \{0, 1\}, i = 1, \dots, N, \end{aligned}$$

where $S \subseteq V$ is a subset of graph G .

The advantage of formulation (3) over (2) is the fact that it is a tighter formulation, that is, the gap between the optimal values of (3) and its linear programming relaxation is smaller [70].

Clearly, locating cliques and/or independent sets in a graph representing a dataset provides important information in terms of identifying completely connected (or, on the contrary, completely disconnected) clusters. Therefore, cliques would naturally represent very *dense* clusters of similar objects. On the contrary, independent sets can be treated as groups of objects that differ from every other object in the group. This information may be important in some applications. In particular, it is often useful to find a *maximum clique or independent set* in the graph, since it would give the maximum possible size of the groups of “similar” or “different” objects.

Although finding large cliques in a graph representing a dataset may be useful in terms of identifying large tightly connected clusters, an important computational disadvantage of this approach is that the maximum clique problem (as well as the maximum independent set problem) is known to be NP-hard [44]. Moreover, it turns out that these problems are difficult to approximate [11, 46]. This makes these problems especially challenging in large graphs.

3.3 Clustering via Clique Partitioning

The problem of locating cliques and independent sets in a graph can be naturally extended to finding an optimal *partition* of a graph into a minimum number of distinct cliques or independent sets. These problems are referred to as *minimum clique partition* and *graph coloring* [43], respectively. Pardalos et al. [71] give various mathematical programming formulations of these problems. Clearly, as in the case of maximum clique and maximum independent set problems, minimum clique partition and graph coloring are reduced to each other by considering the complimentary graph, and both of these problems are NP-hard [44]. The example of optimal graph coloring is represented in Fig. 10. The simplest formulation of graph coloring for graph $G(V, E)$ is given below. Solving these problems for graphs representing real-life datasets is important from a data mining perspective, especially for addressing the clustering problem.

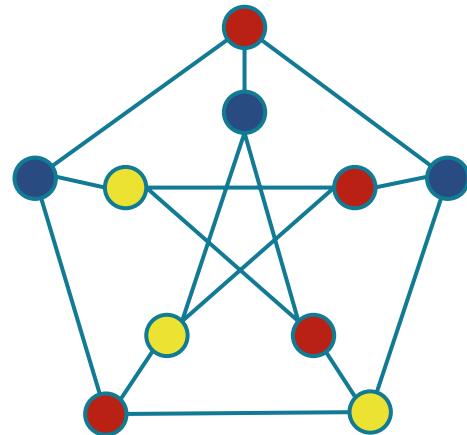

$$\min \sum_{k=1}^N y_k \quad (4)$$

s.t.

$$\sum_{k=1}^N x_{ik} = 1, \forall i \in V \quad (5)$$

$$x_{ik} + x_{jk} \leq 1, \forall (i, j) \in E \quad (6)$$

Fig. 10 Vertex coloring of the Petersen graph (minimum number of colors – 3)

$$y_k \geq x_{ik}, \forall i \in V, k = 1, \dots, N \quad (7)$$

$$y_k, x_{ik} \in \{0, 1\}, \forall i \in V, k = 1, \dots, N. \quad (8)$$

In the above model, decision variables x_{ik} and y_k defined as

$$x_{ik} = \begin{cases} 1, & \text{if color } k \text{ is assigned to vertex } i \\ 0, & \text{otherwise} \end{cases}$$

$$y_k = \begin{cases} 1, & \text{if color } k \text{ is used} \\ 0, & \text{otherwise.} \end{cases}$$

Constraints (5) ensure that exactly one color is assigned to each vertex. Constraints (6) prevent adjacent vertices from having the same color. Constraints (7) ensure that no x_{ik} can be 1 unless color k is used. The optimal objective value gives the chromatic number of a graph ($\chi(G)$), and the sets $S_k = \{i | x_{ik} = 1\}, \forall k$, comprise a partition of the vertices the minimum number of independent sets.

Since the data elements assigned to the same cluster should be similar to each other, the goal of clustering is achieved by finding a clique partition of the graph, and the number of clusters will equal the number of cliques in the partition.

Similar arguments hold for the case of the graph coloring problem which should be solved when a dataset needs to be decomposed into the clusters of “different” objects (i.e., each object in a cluster is different from all other objects in the same cluster) that can be represented as independent sets in the corresponding graph. The number of independent sets in the optimal partition of graph G is referred to as the *chromatic number* ($\chi(G)$) of the graph.

3.4 Using Clique Relaxations for Graph-Based Clustering

Although cliques and independent sets address the issue of “robust” tightly connected clusters, a significant practical drawback of these structures is that they are often *too restrictive*, that is, all pairs of vertices need to be connected (disconnected). On the contrary, as mentioned above, a simple connectivity requirement is not restrictive enough to guarantee sufficient tightness of a cluster. In an attempt to provide a tradeoff between the clique-based and sparse connected component-based clusters, the concepts of *clique relaxations* are introduced.

Several concepts of clique relaxations first appeared in studying cohesive subgroups in social networks and were based on relaxing some of the desirable properties that a clique idealizes. For instance, instead of cliques and independent sets, one can consider *quasi-cliques* and *quasi-independent sets* and partition the graph on this basis. Quasi-cliques are subgraphs that are *dense enough* (i.e., they have a sufficiently high edge density, but the edge density does not have to be 1 as in the case of cliques). Formal definitions of a quasi-clique and other clique relaxations will be given below.

It is often reasonable to relate clusters to quasi-cliques, since they still represent sufficiently dense clusters of similar objects [50, 88]. Obviously, in the case of partitioning a dataset into clusters of “different” objects, one can use quasi-independent sets (i.e., subgraphs that are sparse enough) to define these clusters.

Other types of clique relaxations have also been introduced. Many of these definitions come from the studies of social networks; however, these concepts clearly have important data mining interpretations. The main idea behind these concepts is to “relax” certain properties of a clique while still maintaining sufficient connectivity and robustness characteristics of the obtained network structures. Note that in many cases, the size of these clique relaxations is substantially larger than the size of cliques, which provides a significant advantage in situations when a *large tightly connected cluster* needs to be identified. In addition, an important factor that motivates the use of these clusters instead of cliques is the fact that they are not as sensitive to potential errors in data collection and measurement. For instance, if one link in a clique-based cluster is missing because of an error, the structure of the clique is violated, and the corresponding cluster may not be adequately reflected in data mining results. However, if one uses quasi-clique-based clusters, the absence of several edges due to such errors is usually not as critical, since it will likely not have a significant effect on the required edge density of the cluster.

The ideas for the clique relaxation concepts discussed below originally come from the study of social networks; however, these definitions can be efficiently utilized in the data mining context. More specifically, there are three main directions for possible relaxations of the clique definition:

1. *Density-based relaxations* – relaxing the requirement for the edge density of a clique to be 1: *quasi-cliques* (γ -dense subgraphs) [3]

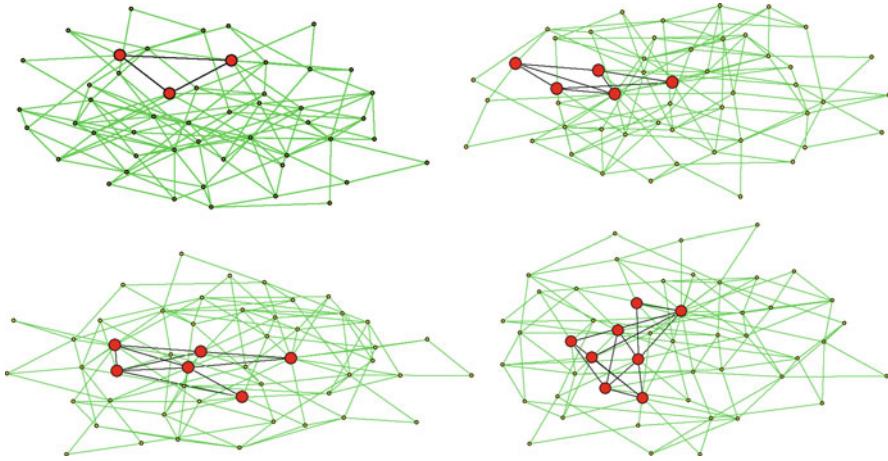

Fig. 11 Visual comparison of maximum clique ($\gamma = 1$) versus maximum quasi-clique ($\gamma = 0.7, 0.6, 0.5$) in the same uniform random graph $G(50, 0.1)$

2. *Degree-based relaxations* – relaxing the requirement that the degree of each node in a clique of size q to be $q - 1$: k -plexes [78]
3. *Path (diameter)-based relaxations* – relaxing the requirement that the length of the path between any two nodes in a clique to be 1: k -cliques [59], k -clubs, and k -clans [66]

As mentioned above, a *quasi-clique* (also referred to as a γ -clique or a γ -dense subgraph) is a subgraph that has the edge density of at least γ , where $\gamma \in (0, 1]$. Clearly, a quasi-clique becomes a clique when $\gamma = 1$. A more rigorous definition is provided below. Let $G = (V, E)$ be the graph with the set of vertices G and the set of nodes E . Denote the graph induced by the vertex subset $S \subseteq G$ by G_S . Under these notations, G_S is a quasi-clique (γ -dense subset) if $|E(G_S)| \geq \gamma \binom{|V(G)|}{2}$ (recalling that $\binom{|V(G)|}{2} = \frac{|V(G)|(|V(G)|-1)}{2}$) and it is connected. The illustrative example is shown in Fig. 11. The given graph $G(50, 0.1)$ is a random graph on 50 vertices with probability $p = 0.1$ that each edge exists. The size of the maximum clique is equal to 3, and the size of the maximum quasi-clique with $\gamma = 0.7$ is equal to 5, with $\gamma = 0.6$ is equal to 6 and with $\gamma = 0.5$ is equal to 8. As one can observe, the sizes of quasi-cliques are substantially larger than the size of the maximum clique, whereas the density of these clusters is still high. Therefore, clusters based on quasi-cliques may be more meaningful as they include a larger number of data elements, which are still “similar enough” to be included in the same cluster.

A k -plex is a subgraph in which the degree of each node is at least $q-k$ (assuming that q is the number of nodes in this subgraph). Figure 12 presents an illustrative example of k -plexes in a small graph on 7 vertices.

A k -clique is a subgraph where the length of the path between any two nodes is at most k (note that other nodes in this path are *not required* to belong to the k -clique). Consider the graph $G = (V, E)$ as in the previous definition and the subset $S \subseteq G$

Fig. 12 Maximum k -plexes in the graph for different k .

- (a) Maximum 1-plex (clique) subgraph in the given graph.
- (b) Maximum 2-plex subgraph in the given graph.
- (c) Maximum 3-plex subgraph in the given graph.
- (d) Maximum 4-plex subgraph in the given graph

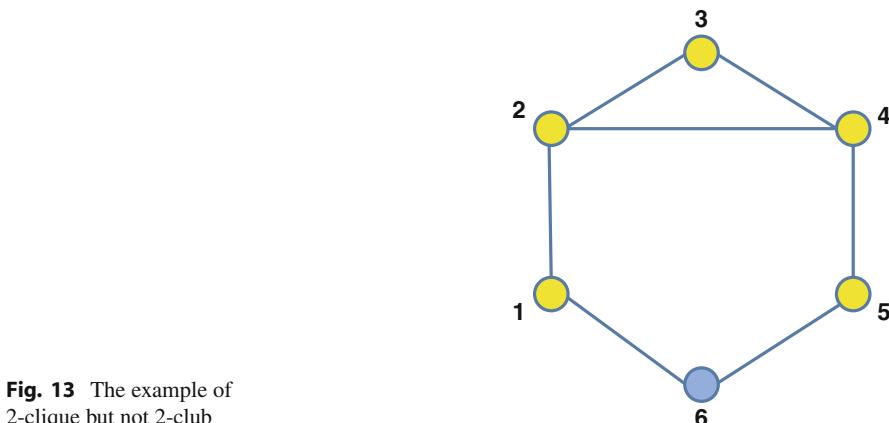

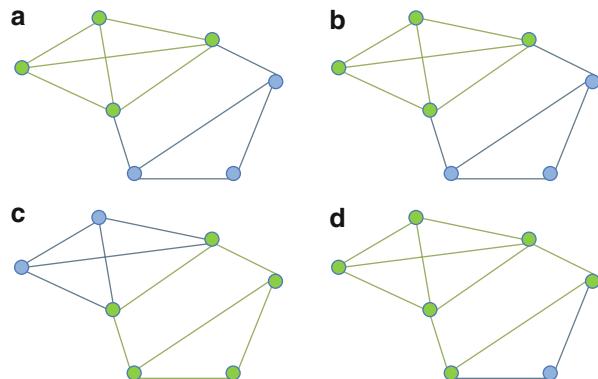

Fig. 13 The example of 2-club but not 2-clique

denoted by G_S . Then, G_S is a k -clique if $\forall i, j \in V$ it is given that $d_G(i, j) \leq k$. Note that distances between any two points in k -clique can be greater than k because some paths might pass through the complementary graph $G \setminus G_S$ to the k -clique. An example illustrating this fact is mentioned in [7] and given in Fig. 13. As one can see, there is the set $L = \{1, 2, 3, 4, 5\}$ that forms a 2-clique, but the diameter of this cluster is equal to 3. Therefore, the concept of k -clique does not necessarily embody the idea of “tightness” of the corresponding cluster of points in a graph. In order to ensure a higher level of tightness and low diameter of a cluster, the concept of a k -clique can be “upgraded” to a k -club (Fig. 14).

A k -club is a subgraph that has a *diameter* of at most k (note that in this definition, all the nodes in the shortest path that connects any pair of nodes within a k -club have to also belong to this k -club). Using the same notations as in previous definitions, it can be pointed out that G_S is a k -club if $\forall i, j \in V$ it is given that $d_{G_S}(i, j) \leq k$. Thus, k -club can be viewed as a “tighter” structure than a k -clique. It is more applicable for connectivity and clustering problems on networks where cluster “cohesiveness” and “robustness” issues play an important role.

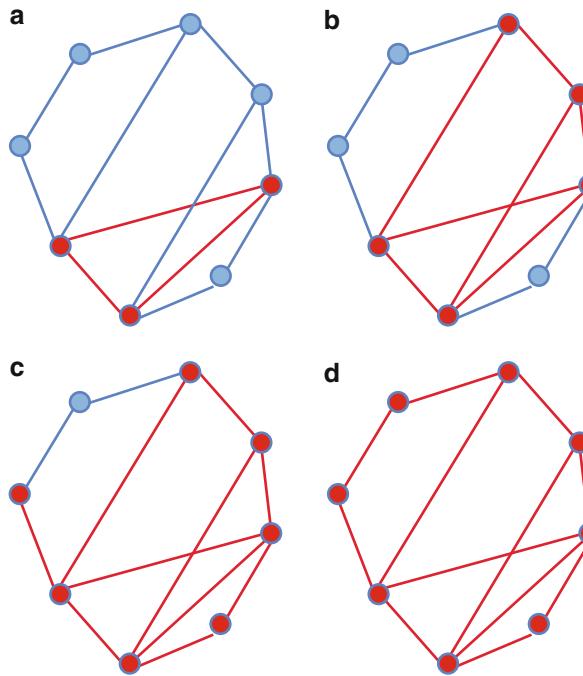

Fig. 14 Maximum k -clubs in the graph for different k . (a) Maximum 1-club (clique) subgraph in the given graph. (b) Maximum 2-club subgraph in the given graph. (c) Maximum 3-club subgraph in the given graph. (d) Maximum 4-club subgraph in the given graph

Although the given definitions are rather straightforward and intuitively clear, mathematically rigorous studies on related optimization aspects (e.g., mathematical programming formulations for finding the largest clique relaxation-based clusters in graphs) have started to appear only within the past few years.

For instance, an important combinatorial optimization problem associated with quasi-cliques is the maximum γ -clique problem. Pattillo et al. [72] proved that the decision version of the γ -clique problem is NP-complete for any fixed positive $\gamma \in (0, 1)$.

Furthermore, linear 0–1 formulations for the maximum γ -clique problem were proposed in [72]. Consider the problem of finding a maximum γ -clique in the graph $G = (V, E)$. If for some subgraph G_S one wants to check whether this subgraph is a γ -clique, one can define $x = (x_1, \dots, x_N)$ as a 0–1 vector with $x_i = 1$ if node i belongs to G_S , or zero otherwise. Since $x_i^2 = x_i \quad \forall i$, then the subgraph G_S is a γ -clique if it consists of $\frac{1}{2}\gamma \sum_{i,j=1, i \neq j}^N x_j x_i$ arcs. The number of arcs in the subgraph G_S can be calculated as

$$\frac{1}{2}x^T Ax = \sum_{i,j=1,i \neq j}^N a_{ij} x_j x_i.$$

Therefore, the problem of finding the maximum γ -clique in the graph G can be formulated as follows:

$$\max \sum_{i=1}^N x_i.$$

subject to

$$\sum_{i,j=1,i \neq j}^N a_{ij} x_j x_i \geq \gamma \sum_{i,j=1,i \neq j}^N x_j x_i.$$

This is the problem with a linear objective and one quadratic constraint. In [72], two possible linearizations of this problem were proposed.

The simplest linearization is rather straightforward with the main idea of introducing new variables $w_{ij} = x_i x_j$. The constraint $w_{ij} = x_i x_j$ is equivalent to

$$\begin{aligned} w_{ij} &\leq x_i, \\ w_{ij} &\leq x_j, \\ w_{ij} &\geq x_i + x_j - 1. \end{aligned}$$

Now, the problem can be formulated as the following linear 0–1 problem:

$$\max \sum_{i=1}^N x_i$$

subject to

$$\begin{aligned} \sum_{i,j=1,i < j}^N a_{ij} w_{ij} &\geq \gamma \sum_{i,j=1,i < j}^N w_{ij}, \\ w_{ij} &\leq x_i, \\ w_{ij} &\leq x_j, \\ w_{ij} &\geq x_i + x_j - 1. \end{aligned}$$

This problem contains $N(N - 1)/2$ variables and $\frac{3}{2}N(N - 1) + 1$ constraints, that is, it has $O(N^2)$ entities. Besides this formulation, the problem of finding a maximum γ -clique can also be represented by the linear 0–1 formulation with $O(N)$ variables and constraints as described in [72], although this linearization is not as straightforward as the one mentioned above, since it explicitly uses the special structure of the considered problem. Despite the fact that the second linearization is more compact, it does not always provide better computational performance

compared to the $O(N^2)$ linearization, although it does perform faster on sparse graphs and relatively high values of γ , which is a typical setup in many situations that deal with finding dense clusters in sparse networks representing real-world datasets.

Besides the maximum quasi-clique problem, similar problems for other types of clique relaxations representing tight clusters (in particular, k -plexes and k -clubs) have been considered in the recent literature from the combinatorial optimization perspective. The maximum k -plex problem has been addressed by Balasundaram et al. in [15], where they provide the most compact formulation with N variables and constraints. It has also been proven in [15] that the decision version of this problem is NP -complete for any fixed positive integer k .

The maximum k -club problem was considered in several previous studies. The first mathematical programming formulations (linear 0–1 formulations containing $O(N^k)$ variables and constraints) and complexity analysis of this problem were addressed in [14]. In a recent study, Veremyev and Boginski in [82] developed a new compact linear 0–1 programming formulation for finding maximum k -clubs that substantially reduces the number of entities compared to the known formulations with $O(kN^2)$ entities and allows one to find exact solutions to problems with larger values of k , which can provide more flexibility in terms of modeling k -club-based clusters.

In conclusion, utilizing clique relaxations in the context of clustering in data mining appears to be a promising approach with attractive characteristics, since it provides sufficient flexibility in terms of the tightness and size of the obtained clusters. The chapter describes more details on clique relaxation models in graph theory.

4 Examples of Real-World Applications

The aforementioned network-based data mining techniques have been used in a variety of real-world applications during recent years. Although it is impossible to describe all the applications in detail within one chapter, several examples of networks and datasets that have been addressed in the recent literature will be briefly discussed.

4.1 Biological Networks

Nowadays, representing complex biological systems as networks and studying the properties of these networks has become a very popular tool in computational biology and biomedical applications. For instance, an overview of graph-based molecular data mining approaches is presented in [41]. An extensive recent volume [30] covers many topics related to clustering problems in biological network applications, such as the analysis of regulatory and interaction networks from clusters of

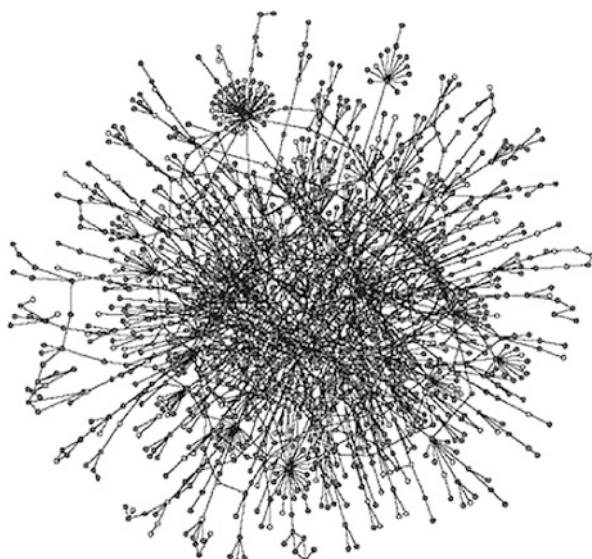

co-expressed genes, graph-based approaches for motif discovery, identifying critical nodes in protein-protein interaction networks, genetic graph partitioning algorithms, and so on. The most recent review of network-based approaches in biomedical applications is presented in [18].

As new advances in experimental design produce a large amount of data to describe biological interactions at a genome scale, this data is increasingly being deposited into biological databases. These interaction networks include, among others, protein interaction networks [54, 77], metabolic networks [33, 69], gene regulatory networks [6], and signal transduction networks [80]. Since there is evidence that preserved interaction pathways exist across organisms, efficient algorithms to analyze common pathways in these networks can make significant contributions to understanding of these networks. The most common representation of such networks is a graph with vertices representing biological entities and edges representing interactions between them. With this representation, one can look for the presence of special substructures in these graphs to answer various questions. By studying paths in these graphs, one can investigate the properties of pathways and their relationships, and by finding similar subgraphs, one can search for *network motifs* and study common substructures embedded in these networks. While path matching allows the study of individual “linear” paths or chains, graph matching allows one to investigate entire “nonlinear” pathways or functional modules. Efficient algorithms for solving these problems give biologists an opportunity to study evolutionary mechanisms such as pathway conservation, duplication, and specialization. Thus, one important strategy is to start from a given pathway of interest and find related pathways within the same organism. By comparing proximities and differences in the returned pathways, it is possible to evaluate various hypotheses concerning evolution. Although the path matching problem models linear interaction chains well, many biological pathways are more complex and may consist of multiple interacting components [86].

To solve the problem of finding similar paths in two graphs, a combined graph from the two given graphs should be constructed, so that each vertex in the combined graph represents a pair of related vertices, one from each of the two given graphs, and each pathway alignment is represented as a simple path in the combined graph. A randomized algorithm for finding simple paths by imposing acyclic edge orientations may be useful in this case. The main difficulty here arises from the presence of cycles in the given graphs. To avoid substantial repetitions of vertices in a path, the problem of finding similar paths in two graphs has been reduced to the NP-hard problem of finding high-scoring simple paths of a given length in a combined graph (see [54]).

In contemporary post-genomic era, protein interactions are well captured by so-called protein-protein interaction networks. In particular, protein-protein interaction networks (see Fig. 15) have been experimentally constructed for many known organisms. A protein interaction network is represented by a graph with the proteins as nodes, and an arc exists between two nodes if the proteins are known to interact. Also, it has been discovered that the degree distribution of many of these complex protein interaction networks follows a power law. For instance, the protein

Fig. 15 A cluster in the protein-protein interaction network of the yeast [87]

interaction network of *S. cerevisiae*, as well as many other networks of this type, has been experimentally shown to have a power-law degree distribution. Due to the power-law structure, an average node degree is no longer representative, and the majority of nodes have few neighbors, while a smaller number of nodes have very high degrees. Many problems for biological networks can be solved via identification of large clusters or functional modules. Cliques have formed the basis for several studies that attempt to decompose a protein interaction network into functional modules and protein complexes. Protein complexes are groups of proteins that interact with each other at the same time and place, while functional modules are groups of proteins that are known to have pairwise interactions by binding with each other to participate in different cellular processes at different times. Clique models have been popular in this area as they represent tight clusters in a network, but sometimes they are too restrictive, as indicated earlier in this chapter. Therefore, employing clique relaxations instead of cliques may be useful in this case. Network-based clustering techniques utilizing clique relaxations (e.g., k -clubs) have been applied to studying those networks in [13] and [14].

There are several computational methods to measure sequence similarities between proteins. Some homology search algorithms capture similar database sequences to a query from a database and calculate the statistical significance of their similarities. However, retrieved proteins with evident similarities are often uninformative from a practical perspective. To cope with this problem, it is important to consider alternative approaches, such as signature identification and sequence clustering. Functionally or structurally related proteins often have locally conserved regions, referred to as functional motifs or signatures. Proteins sharing the same signatures do not always exhibit apparent similarities between

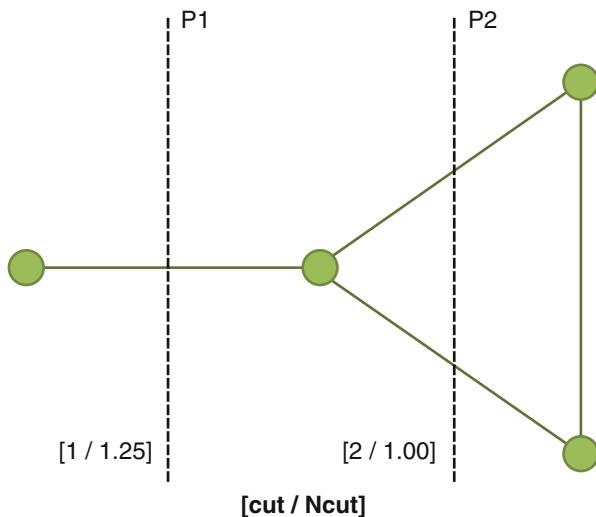

Fig. 16 An instance of a graph representation of protein sequence similarities. Graph partitions are shown by *dashed lines* P_1 and P_2 relatively. Each of these lines partitions vertices of the graph into two distinct sets. Numbers below the *dashed lines* show the capacities of their cuts and normalized cuts

their sequences. Therefore, they are referred to as *distantly related proteins*. Massive amounts of signature data have been accumulated in special signature databases. These databases enable one to accurately find proteins that share signatures and their relative positions on the protein sequences. Clustering protein sequences is an important approach to finding distant relationships. Distantly related proteins may be grouped together into a cluster even though they do not show apparent similarities. The most well-known and simplest method for clustering proteins is *single linkage* (SL). A detailed description of SL method can be found in [57]. Although the method is simple, fast, and widely used, it has difficulty in detecting an appropriate cutoff score for sequence similarity. More advanced algorithms employ a graph representation of a given set of proteins. Such algorithms are *SL-based clustering method*, named SL-KL (see [52]), and *p-quasi complete linkage algorithm* (see [61]). They allow some proteins to overlap between two or more groups. However, such clustering techniques usually carry high computational costs. Therefore, in order for the algorithms to be applicable to a large number of proteins, attention should be focused on approximate distantly related proteins without overlapping groups. This approach to clustering proteins is based on iterative partitioning. The key concept of graph partitioning is a “cut,” which is a set of edges between two distinct sets of nodes (or proteins). When the sum of edge weights in a cut (referred to as the cut capacity) is small, the two sets are considered to be dissimilar.

Figure 16 shows a very simple example of graph representation of protein similarities, where for simplicity all edges have unit weights. The proteins are

naturally grouped into two sets on the left and right side of the cut P2. However, P1 is a partition with the lowest capacity of the cut, called the *minimum cut*, due to the sparseness of the set of edges (e.g., one edge) connecting the proteins on the left side of P1. Unfortunately, it is difficult for applications to find distant relationships in a protein set containing various kinds of signatures using minimum-cut partitioning. The *normalized cut partitioning* is proposed to avoid the tendency of inaccurate clustering by the minimum-cut partitioning. It uses the normalized cut capacity (N_{cut}) criterion, which is the ratio of the capacity of a cut to the sum of similarities in each of the two distinct sets. In the context of the graph in Fig. 16, P2 is a partition with the minimum normalized cut. In addition, a locally minimal cut criterion can also be used. All the aforementioned methods are described in detail in [53].

The genome is also a highly interactive system, and the expression of a gene depends on the activity of other genes. Gene expression data is often represented in a network format. Cliques are widely used for gene co-expression networks' clustering. In the case of gene expression data, nodes represent the genes and arcs represent the relations between co-expressed genes with correlation higher than a specified threshold (see [51]) based on microarray experiments. Quasi-clique-based clusters can also be identified in these networks [73].

The main challenge in the analysis of this data is to understand biological functions from the topology of the network. There is a rather useful approach based on efficient *sequence alignment* algorithms and a statistical theory to assess the significance of the results (see [35]). Another way to address these challenges leads to an algorithmic procedure referred to as *local graph alignment*, which is conceptually similar to sequence alignment. It is based on a scoring function measuring the statistical significance for families of mutually similar subgraphs. This scoring involves quantifying the significance of the individual subgraphs, as well as their mutual similarity. As a computational problem, graph alignment is more challenging than sequence alignment. Sequences can be aligned in polynomial time by using dynamic programming algorithms. For graph alignment, the existence of a polynomial-time algorithm is unlikely. Thus, an important issue for graph alignment is the construction of efficient heuristic search techniques, such as those described in [19].

4.2 Chemical Networks

Chemical datasets are often represented as graphs, since they are natural representations of chemical compounds. Such graphs can be used to model topological and geometric characteristics of chemical structures. The nodes correspond to atoms, and the edges correspond to bonds connecting the atoms. For instance, Fig. 17 shows ball-and-stick diagrams of chemical compounds pentacene (Fig. 17a) and lysozyme (Fig. 17b).

Chemical graph mining techniques have many applications in the drug discovery procedure that include structure-activity-relationship (SAR) model construction and bioactivity classification. Many data mining algorithms are based on the assumption

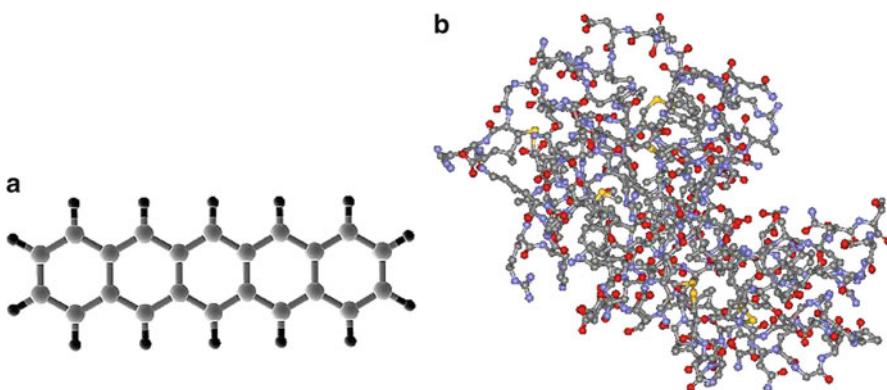

Fig. 17 Representation of chemical data. (a) Pentacene molecule. (b) Lysozyme molecule

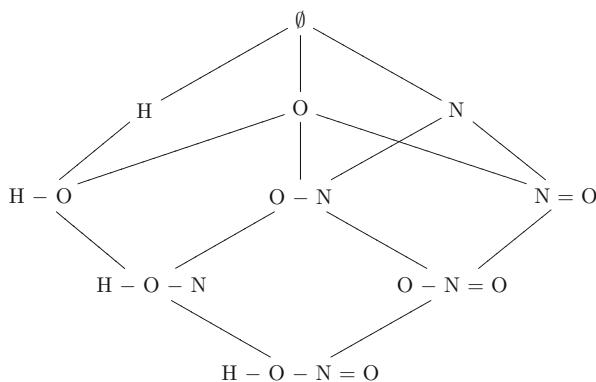

that the properties of a chemical element are related to its structure. For further details, see [83]. Studying and mining chemical graphs can provide new perspectives to chemistry, biology, and toxicology.

In recent years, a lot of algorithms on frequent graph pattern mining and related chemical graph mining problems have been published. The amount and complexity of the available data is steadily increasing. Within molecular databases, it is interesting to find patterns (fragments) that appear at least in a certain percentage of graphs. Another problem is to find fragments that are frequent in one part of the database but infrequent in the other. Recently developed approaches for chemical graph data mining include *Subdue* (see [32]), *inductive logic programming* (see [40]), and *Gaston* (see [68]).

Chemical graph data mining can be considered in the context of search in the lattice of all possible subgraphs. In Fig. 18, a small example is shown based on a small molecule of nitrous acid (shown in the bottom of the figure). The four nodes are labeled corresponding to their atom types (H, N, and O), and the edges are labeled with their corresponding bond types (single and double bonds). All possible subgraphs of this small graph are shown in the figure. At the top, the empty graph is denoted by \emptyset . In the next row, all possible fragments containing just one atom are listed and so on. At the bottom of the figure, the complete molecule with three bonds is given. Many chemical graph mining algorithms are based on the common idea of performing search this subgraph lattice. They are interested in finding a subgraph (or several subgraphs) that is the most frequent in the considered graph. Building this lattice of frequent subgraphs involves two main steps: *candidate generation*, where new subgraphs are created out of smaller ones, and *support computation* where the frequency or support of the new subgraphs in the database is determined. Both steps are computationally challenging, and various algorithms and techniques have been developed to find frequent subgraphs in reasonable time. For more details, see [42].

Another approach utilized in chemical graph data mining is based on kernels. Kernel methods have emerged as an important class of machine-learning methods

Fig. 18 The lattice of all subgraphs in nitrous acid HNO_2

suitable for variable-size structured chemical data (see [76]). Applications of kernel methods to molecular bond graphs require the construction of graph kernels, that is, functions that measure the similarity between graphs with labeled nodes and edges. Also, kernel methods can be applied to molecular clustering and regression problems, such as predicting the boiling point of alkanes and other organic substances [12].

4.3 Brain Networks

One more interesting application of network-based data mining is associated with studying human brain. It is a significant practical task since the results of this analysis are important in medical practice, especially studying brain diseases. The analysis of connectivity patterns of the brain function is extremely challenging because of the complex structure with the huge numbers of neurons and dynamic nature of connections between them. According to [67], the number of neurons is estimated to be 8.3×10^9 , and the number of connections is approximately 6.6×10^{13} . The empirical analysis of such structures represented as a graph with neurons as nodes is computationally prohibitive.

Several aspects of the analysis of brain connectivity are studied in [48]. One can potentially use the following technique to analyze the graph representing the brain. Different functional units of the brain containing a large number of neurons can be considered as a nodes in the graph. This approach enables the use of different algorithms proposed for much smaller graphs. This method can be applied in order to study properties of the connections between these functional units. In [37], the authors applied this approach to study the cortical visual system of a macaque monkey represented by a graph.

A similar approach can also be applied to study some properties of the human brain. The major areas of the human brain and their functions are represented on Fig. 19. In [36], the authors investigated a graph corresponding to 147,456

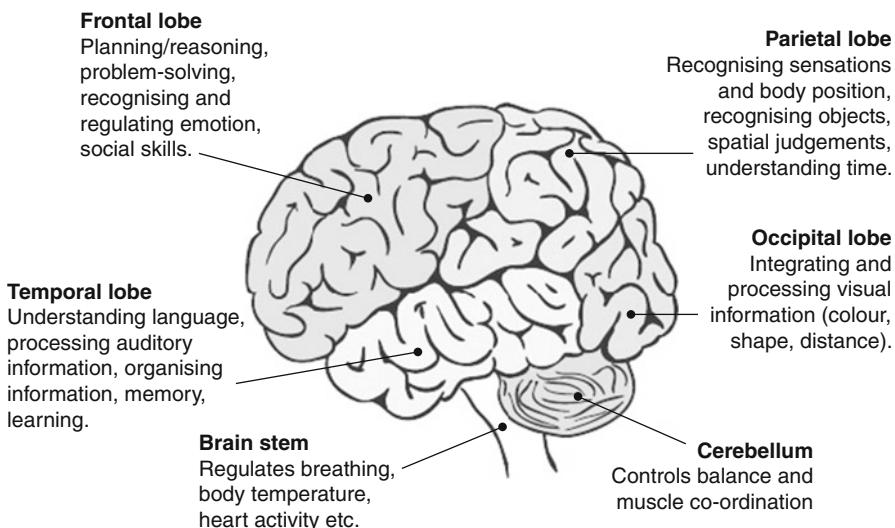

Fig. 19 Functional areas of the human brain

functional units of the human brain, which were selected by dividing the entire brain into a set of $64 \times 64 \times 36$ voxels of a small size. The set of edges of this graph were constructed using the time series defined by the recorded signals representing the activity of each functional unit. The correlation coefficients were calculated according to the formula similar to (9) using the time series representing the signals obtained from functional units, and the corresponding nodes were connected if the correlation exceeded a certain threshold value. It turned out that the resulting brain graphs also follow the power-law distribution with the parameter $\gamma \approx 2$ [36].

Investigating different characteristics of brain networks is a crucial practical task. One can study various structures (network motifs) in the brain networks as spanning trees, cliques/independent sets, clique relaxations, etc., which may provide a new insight into the process of signal propagation between the functional brain units and neurons. This information could potentially be very useful in studying brain disorders. More detailed information on network models in brain dynamics is given in the chapters [75].

4.4 Telecommunication/Information Exchange Networks

Large-scale information exchange networks arise in a great variety of areas, including large-scale wireless communication/sensor networks, the Internet/World Wide Web, and telephone traffic networks. The Internet, the World Wide Web, and the telephone call networks (also referred to as call graphs) were experimentally shown to have a power-law structure. Studying the structural properties and the global

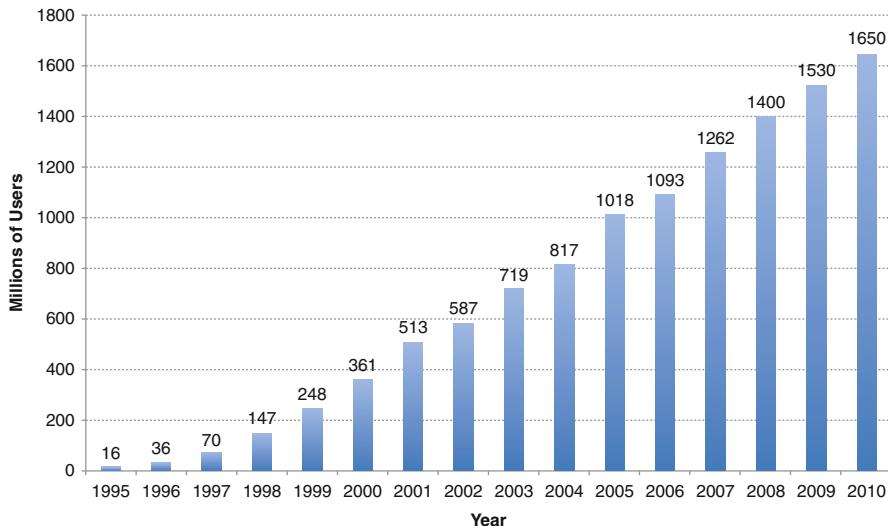

Fig. 20 Internet users in the world. Growth 1995–2010 [65]

organization of these networks has been addressed in recent literature. Graph theory has been applied for web search [28, 56], web mining [63, 64], and other problems arising in the Internet and World Wide Web [9]. In an interesting experimental study of the World Wide Web, Broder et al. [29] used two Al tavista crawls, each with about 200 million pages and 1.5 billion links and identified certain properties of the connected components of this graph. Studying the structural properties of the Internet is an exciting area of ongoing research [85]. The necessity of such research is justified because the usage of the Internet increases very rapidly in the world over years. The graph on the Fig. 20 represents the growth of number of Internet users through 1995–2010 [65]. The overall structural characteristics of the Internet are sometimes referred to as “robust yet fragile” [34], which implies the overall robustness with respect to random disruptions/errors, but potential vulnerability to targeted attacks on “hubs” (i.e., high-degree vertices).

Another well-known experimental study of a large communication network was conducted on the “call graph” representing daily telephone traffic data from AT&T telephone billing records [1]. The call graph is also very large, and the considered instance contained 53,767,087 vertices and over 170 million edges. The size of cliques and quasi-cliques in this graph was investigated, and it turned out that the size of the largest clique did not exceed 32, and the size of the largest quasi-clique with $\gamma \geq 0.5$ did not exceed 96. Since the size of the considered graphs is extremely large, the problems of identifying tight clusters, such as cliques and quasi-cliques, cannot be solved exactly due to computational challenges. Therefore, appropriate heuristic algorithms need to be applied to tackle these problems. For instance, in [1], the greedy randomized adaptive search procedure (GRASP) [38, 39] was successfully used.

4.5 Financial Networks

Stock market data can also be represented as a network and analyzed using combinatorial optimization techniques. One can represent each traded stock by a node in a network, and a given pair of nodes will be connected by an edge if the corresponding stocks exhibit a similar behavior over a certain period of time (this similarity can be measured as a correlation between the corresponding time series, and a threshold can be set, so that an edge would be placed if this threshold is exceeded) [23].

Boginski et al. [24, 25] have previously done the work on studying the behavior of the US stock market and modeling the corresponding massive dataset as a large-scale network (referred to as the *market graph*).

It is possible to construct the market graph in a relatively simple way [23]. As it was mentioned, the set of nodes of such graphs corresponds to the set of stocks. For each pair of stocks i and j , the correlation coefficient C_{ij} is calculated using the following procedure. Let $P_i(t)$ denote the price of the instrument i at time t . Then,

$$R_i(t, \Delta t) = \log \frac{P_i(t + \Delta t)}{P_i(t)}$$

defines the natural logarithm of return of the stock i over the certain period of time $[t, t + \Delta t]$.

Correlation coefficients C_{ij} between all pairs of stocks i and j are calculated as

$$C_{ij} = \frac{\mathbb{E}[R_i R_j] - \mathbb{E}[R_i] \mathbb{E}[R_j]}{\sqrt{\text{Var}[R_i] \text{Var}[R_j]}}, \quad (9)$$

where $\mathbb{E}[R_i]$ is the average return of the instrument i over T considered time units [58, 60, 74]:

$$\mathbb{E}[R_i] = \frac{1}{N} \sum_{t=1}^T R_i(t).$$

If one defines a threshold $\theta \in [-1, 1]$, then an undirected edge between the nodes i and j is added to the graph if the corresponding coefficient $C_{ij} \geq \theta$. Usually, the value of θ is chosen to be significantly larger than zero, and therefore, an edge between two nodes reflects the fact that stocks i and j are significantly correlated.

The values of the correlation threshold θ can be changed in order to construct market graphs where the edges between the nodes reflect different correlation between the corresponding stocks. As the threshold value θ increases, the number of edges in the market graph decreases.

The edge density (as defined in Sect. 3) of the market graph is a measure of the fraction of pairs of stocks exhibiting a similar behavior over some certain time period. One can define different “levels” of this similarity by specifying different

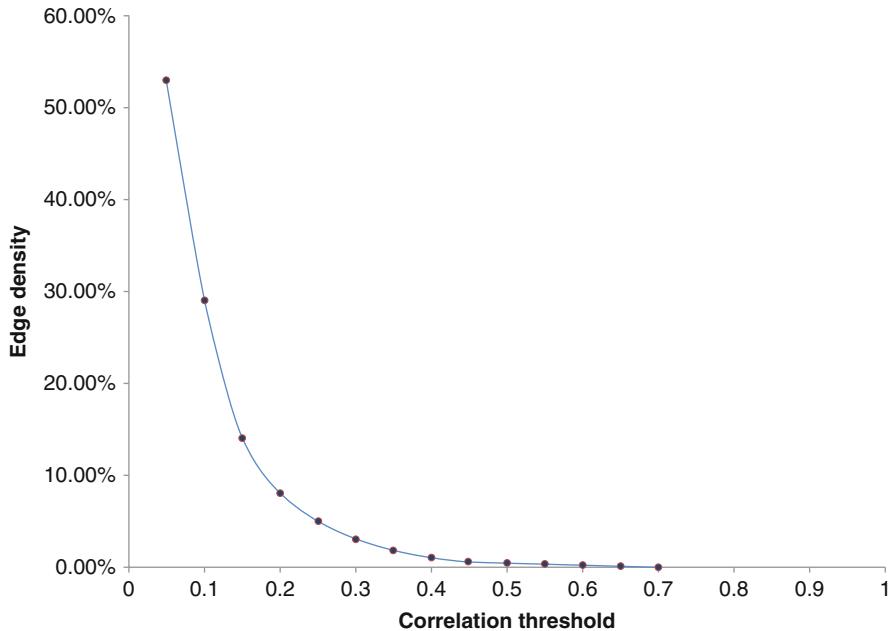

Fig. 21 Edge density of the market graph for different values of the correlation threshold

values of θ . Figure 21 represents the plot of the edge density of the market graph as a function of θ [23].

In [20], the authors also looked at the changes of the edge density of the market graph over time. The authors analyzed these dynamics for 11 overlapping 500-day period in 2000–2002 (the 1st period was the earliest, and the 11th period was the latest). A relatively large value of θ ($\theta = 0.5$) was chosen in order to consider only highly correlated stocks. It turned out that the edge density of the market graph corresponding to the 11th period was more than 8 times higher than for the first period. The corresponding plot is shown in Fig. 22. This jump of the edge density suggests that there is a trend to the globalization of the modern stock market. It means that the number of stocks that significantly affect the behavior of the others was consistently increasing during the considered time period, and it is possible to derive some regularities in the structure of the market.

In order to define the pattern of connections between stocks, the concept of degree distribution defined above in the previous sections can be utilized. It turns out that the degree distribution of the market graph has a well-defined power-law structure [23].

In [22], the authors proposed to relate combinatorial properties of the market graph to some properties of the stock market. For instance, one can apply algorithms for finding cliques or quasi-cliques in the market graph and relate them to groups of highly correlated stocks (the market graph should be constructed using a relatively

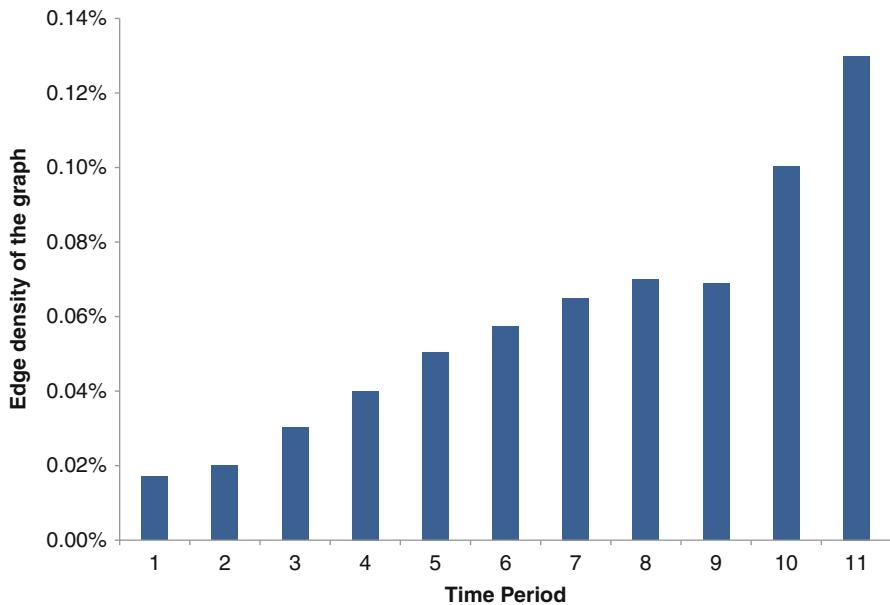

Fig. 22 Evolution of the edge density of the market graph during 2000–2002

large value of θ). A clique and quasi-clique (as defined in Sects. 3.2 and 3.4) of the graph are subsets of the this graph which are complete or “almost” complete graphs itself, respectively (i.e., has all possible edges or needed edge density is satisfied). Also, one can define the minimum clique partition problem for the market graphs, which solution (the minimum number of distinct cliques that the market graph) would represent the minimum number of clusters in the partition of the set of financial instruments.

It is worth mentioning that even though the problem of finding maximum clique in the graph is NP-hard, the exact solutions of this problem were found for different instances of the market graph, which was possible because the market graph is clustered (i.e., it contains dense groups of connected nodes).

Recall from Sect. 3.2 that an independent set is a subset of nodes which are not connected with any other node in this set. Therefore, this notion can be utilized for the market graphs in order to partition these graphs into clusters with stocks whose price fluctuations are not correlated or negatively correlated. It is rather important because finding independent sets in market graphs gives a method of choosing fully diversified portfolios. Partitioning the market graph in such a way that the number of clusters containing distinct diversified portfolios is minimal would represent the optimization problem of partitioning this graph to minimal number of independent sets. The optimal solution to this problem is a chromatic number corresponding to the graph coloring problem. As it was mentioned above, modern stock markets are usually highly correlated, so it is

much more likely to observe a relatively large cliques and quasi-cliques which represent correlated sets of the stocks in the market graph than a large independent sets which represent diversified portfolios in the modern stock market. These results are interesting since they support the idea of the globalization of the stock market.

Overall, finding cliques (as well as quasi-cliques, k -plexes, and other clique relaxations) and independent sets, along with the extensions similar to clique relaxations, in the market graph provides an efficient tool of performing data mining based on the stock market data, that is, partitioning the set of stocks into clusters of “similar” or “dissimilar” objects.

4.6 Social Networks

The process of formation of new communities, their integration and disintegration, attracting new members and their interaction with each other, and growth of the network and its progress, is among the most important research problems in social sciences. Political, religious, professional, and other forms of social organizations provide examples of such communities. A social network is a structure of people related directly or indirectly to each other through a common relation or interest. Therefore, it is very natural to represent these systems as graphs: the nodes are the people, groups, organizations, or other social entities and links represent relationships or flows between the nodes.

A number of recent studies have focused on the statistical properties of social networks. Researchers have concentrated particularly on a few properties that seem to be common to many social networks: the small-world property, power-law degree distribution (which was mentioned earlier in this chapter), and network transitivity. “Small-world effect” is the name given to the finding that the average distance between vertices in a network is short, usually scaling logarithmically with the total number of vertices. A characteristic that many networks have in common is clustering, or network transitivity, which is the property that two vertices that are both neighbors of the same third vertex have a higher probability of also being neighbors of each other. In the language of social networks, two of one’s friends will have a greater probability of knowing each other than two people chosen at random from the population. Another important property that appears to be common in many networks is the property of community structure. Consider the case of social networks of friendships or other acquaintances between individuals. It is intuitively clear that such networks would contain “communities”: subsets of vertices, within which vertex-to-vertex connections are dense, but between which connections are not as dense. A visual sketch of a network with such a community structure is shown in Fig. 23. The ability to detect community structures in a network clearly has practical applications. Detection of community structures can be performed using different approaches. A traditional method is hierarchical clustering that constructs a measure that tells one which edges are most central to communities. An alternative approach to the detection of communities is focused on the edges

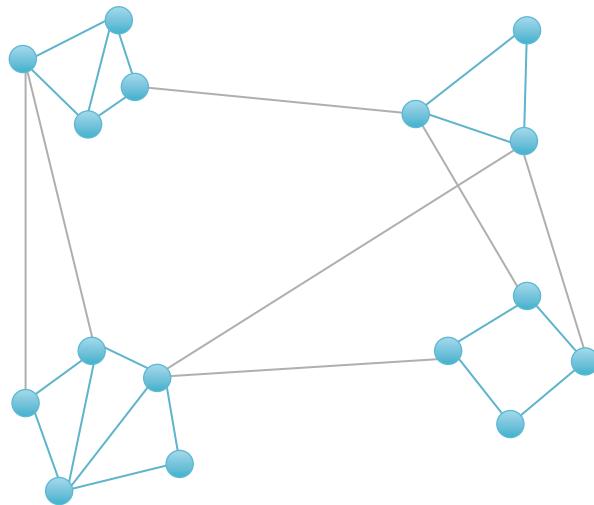

Fig. 23 A representation of a network with community structure. In this network, there are four communities of densely connected nodes (*circles with solid blue lines*), with a much lower density of connections (*gray lines*) between them

that are most “between” communities and strongly connected cores of communities (see [45]). In addition, the aforementioned concepts of clique relaxations (k -cliques, k -clubs, k -plexes) have their origins in the context of communities (tightly knit clusters) in social networks; therefore, efficient combinatorial algorithms for identifying these structures in networks have significant implications in this important application area.

Nowadays, social online communities are growing extensively, and the number of people using such services is increasing very fast; therefore, the necessity of social science research and related data mining techniques is unquestionable. More details on this emerging application of network-based data mining techniques can be found in [62].

5 Conclusion

Network-based data mining and related combinatorial optimization techniques are promising in a variety of applications, which have been demonstrated by multiple recent studies. In this chapter, several graph-theoretic concepts and problems have been discussed in the context of their interpretation from both data mining and combinatorial optimization perspectives. In addition, important real-world application areas have been briefly described, including biological/medical, chemical, telecommunication, financial, and social networks. Clearly, the research in this broad area is far from complete, and new methodological and application aspects will likely continue to be developed in the near future.

Abstract

Transportation and logistic networks have always been offering significant practical applications for optimization and operations research techniques. Especially in the last two decades, numerous success stories for large-scale, realistic networks have attracted the interest of the scientific and research society. A typical example of such a success story is the vehicle routing problem, where recent advancements have made it possible for large, complex problems to be solved to optimality. This chapter is designed so as to introduce the reader in the notions tackled by important problems in transportation and logistics engineering and the algorithms that have been devised over the years to solve them. The problems presented and studied in this contribution include the traffic assignment, the vehicle routing problem, and the toll pricing among others.

1 Introduction

1.1 Transportation

Transportation has always been an important society factor. To fully satisfy the needs and the desires of society, it has proven very important to analyze the mathematical models of transportation networks. In order to make the required decisions which help to meet the requirements of an enterprise, a city, and a country, certain optimization techniques have been proposed and explored over the years. In the following sections, the prevalent techniques are described and analyzed.

A formal definition of transportation can be traced back to Steenbrink [109]. Transportation is defined as the transfer of persons and/or goods, in a vehicle or otherwise, between geographically separate places. The collective movement of these vehicles or persons between two places or within an area is called traffic. In order for the movement to take place, the *transportation infrastructure* is used. The infrastructure can be characterized as:

- Fixed objects, describing highways, routes, railways, airports, pipelines, and so on
- Vehicles using the fixed infrastructure
- Organizational infrastructure vital to ensure the well-being and well utilization of the above objects

Let us now focus on the demand for transport. There have been extensive surveys on the models built; however, the bases of the models used in modern transport networks can be found in the works of Hamerslag [50], Overgaard [97], and Steenbrink [109], whereas readers interested in recent advancements based on the models mentioned above are directed to Hensher and Button [59] and Hoogendoorn and Bovy [61]. First of all, it is important to distinguish between the costs and benefits to the trip maker and to those of the society, which are not necessarily the same, as noted by Hamerslag [50] and Henderson and Quandt [58]. When moving from a place-node a to another b , there exist certain benefits (e.g., necessary presence at b) and costs (e.g., time consumption) with that trip which are specific

and particular to the trip maker. However, it can be easily assumed that every one using the transport network for their needs has the objective of maximizing the difference between their benefits and costs as shown in P .

$$P : \max_{m,p,b} u^{ab} - t^{mpab},$$

where

- u^{ab} are the benefits gained by moving from a to b .
- t^{mpab} are the costs incurred when moving from a to b using vehicle (mode) m by route p .

1.2 Logistics

Logistics and logistic networks are widely considered to be closely related to transportation networks. That is why notorious problems such as the traveling salesman or the vehicle routing problems are also tackled in logistic operations research.

One of the first logistic network problems tackled in literature can be tracked back to Fulkerson and Ford [37] and is the famous Hitchcock transportation problem. The statement is pretty simple, yet has immense practical applications:

Given m customers (retailers) and n production plants (factories), find the optimal allocation of shipments that minimize the total costs of transporting the commodities, satisfying the offer and demand restrictions imposed by the production plants and the customers accordingly.

This problem shows the close relation of the fields of transportation and logistics. However, logistics is much more than just optimizing the transportation of commodities and vehicle scheduling. Timetabling is also an important aspect, the problem of determining whether there exists a timetable or schedule that can explicitly satisfy a set of pairing and distributing constraints. Applications extend from the vehicle routing problem and the crew scheduling problem to the most recent ones of sports timetabling [82, 90]. The problem is defined as follows:

- There are N teams and every two teams must play against each other exactly once.
- Hence, the full season will have $N - 1$ game days.
- Every team plays each game day.
- There are also $\frac{N}{2}$ available periods and each period can be used to accommodate one game.
- A team cannot use the same period again in the whole season.

Even though the problem definition is simple and it is true that problems of size less than or equal to 8 can be solved easily by brute force, the combinatorics of the problem increase extremely fast. For that reason, algorithms for the solution of this problem behave poorly and are considered inefficient [47].

In general, logistics engineering and optimization have vast applications, including supply chain management and evacuation planning. In this chapter, the focus is primarily on the transportation network problems involved in logistics such as the vehicle routing problem which is discussed in Sect. 4.

1.3 Chapter Overview

The chapter is structured as follows. First, a small introduction is presented in order to accommodate the reader with useful information on the reasons why transportation and logistics are vital social factors. Then, the traffic assignment problem is described with special focus on the techniques that are widely used to solve the system optimum and the user equilibrium formulations. After the notions of the traffic assignment problem are established, the toll pricing problem is presented along with the recent developments in solving it for large-scale transportation networks. Next, the vehicle routing problem and the vehicle fleet management problems, which are the problems that connect the transportation and logistics frameworks, are presented. Last, conclusions are given so as the reader obtains a better understanding of the state of the art and can apply this information to advance scientific interest in transportation and logistics optimization.

2 Combinatorial Optimization in Traffic Assignment

2.1 Introduction

According to Patriksson [99], there has been an extensive interest in mathematical models and optimization methods in traffic planning for about 45 years now. Operations research techniques have been proposed over the years in order to solve real-life traffic assignment problems, a solution that will provide individual travelers, and the society in general, with a traffic system of a much better performance.

It is important to elaborate first on the notion of congestion which is fundamental to transportation analysis. As traffic volumes grow, the speed on a link of the infrastructure tends to decrease. At first, average speed decreases slowly, however with significant queuing effects tends to decrease more rapidly, as noted by Vickrey [116].

In addition to the above, it is of utmost importance to point out an obvious assumption. Kohl [66] had recognized as soon as 1841 that alternate route choice behaviors are to be encountered concerning different trip makers and their perspective of the shortest one under the current traffic conditions.

In a seminal contribution, which is respected by most transport researchers as the first attempt to state the behavioral assumptions, Wardrop [119] presented the two principles that formalize the notion of user equilibrium (UE) and the alternative

Table 1 Notation used in the branch-and-bound algorithms

Notation	Description
f_{ij}	Traffic flow on arc $(i, j) \in A$
f_a	Traffic flow on arc $a \in A$
t_{ij}	Travel time on arc $(i, j) \in A$
t_a	Travel time on arc $a \in A$
$G = (N, A)$	Transport network G , where N is the set of the nodes and A is the set of the directed arcs
d_{pq}	Demand of travel between two nodes of the graph, p and q
R_{pq}	Set of routes connecting nodes p and q
h_{pqr}	Flow on route $r \in R_{pq}$
c_{pqr}	Travel cost on route r between nodes p and q
\bar{c}_{pqr}	Marginal cost on route r between nodes p and q
π_{pq}	Cost of the shortest route between p and q at equilibrium

of minimizing the total travel costs or system optimal (SO). The two principles are cited by Wardrop:

Wardrop's first principle: "The journey times on all the routes actually used are equal, and less than those which would be experienced by a single vehicle on any unused route."

Wardrop's second principle: "The average journey time is a minimum."

These two principles had already been noted by Pigou [100] in 1920. Moreover, Wardrop's principles will be the central focus of all the algorithms and methods that will be presented in this section of the chapter.

2.2 Branch-and-Bound Methods for Traffic Assignment and Infrastructure Investment

The branch-and-bound optimization technique remains a very useful tool in the hands of optimization researchers in the fields of combinatorial optimization problems. This subsection presents the algorithms presented by Ridley [102] and Chan [21]. These techniques are widely considered to be very important since they were the first attempts to provide useful ideas on how in reality transportation and logistic networks are interconnected. The insight of using optimal flows in order to detect bottlenecked arcs in the transportation network and, therefore, try to invest in these links to provide better quality service was firstly tackled by Ridley and followed by Chan. Their work has immensely contributed in combining the economic world with known combinatorial optimization problems (Table 1).

A good description of the branch-and-bound technique can be found in Lawler and Wood [70] and in Coffman [24]. One of the first researchers to use

branch-and-bound methods for transport networks was Ridley. The formulation of Ridley [102] is the following:

$$\min_{y_{ij}} F = \sum_{ij \in A} f_{ij} t_{ij} \quad (1)$$

$$\text{s.t. } \sum_i f_{ij}^{ab} - \sum_k f_{jk}^{ab} \begin{cases} = 0 & \forall j \neq a \text{ or } b; j \in N \\ = -f^{ab} & \text{if } j=a \\ = f^{ab} & \text{if } j=b \end{cases} \quad (2)$$

$$f_{ij}^{ab} \geq 0, \quad \forall ab \in N, \quad \forall ij \in A \quad (3)$$

$$x_{ij} = \sum_{ab \in N} x_{ij}^{ab}, \quad \forall ij \in A \quad (4)$$

$$x^{ab} = x^{0ab} \quad \forall ab \in N \quad (5)$$

$$\begin{aligned} t^{ai} + t_{ij} &= t^{aj} && \text{if } x_{ij}^{ab} > 0 \\ t^{ai} + t_{ij} &> t^{aj} && \text{if } x_{ij}^{ab} = 0 \end{aligned}, \quad \text{for all } ij \in A, ab \in N \quad (6)$$

$$t_{ij} = a_{ij} - b_{ij} y_{ij} \quad \text{for all } ij \in A \quad (7)$$

$$y_{ij} = 0 \quad \text{for } ij \in \bar{L}_I \quad \text{and } y_{ij} = 0 \text{ or } 1 \quad \text{for } ij \in L_I \quad (8)$$

$$\sum_{ij \in L} y_{ij} i_{ij} \leq I^0 \quad (9)$$

$$i_{ij} = 1 \quad \text{for } ij \in L. \quad (10)$$

Ridley's purpose was to find an investment algorithm that minimizes the time each traveler has to spend while using a link of the infrastructure (denoted as L). Then Eqs. (4)–(6) refer to the network constraints. More specifically, Eq. (4) represents the conservation law in the network flows, (5) ensures the nonnegativity of the number of trips a link can accommodate, and (6) generalizes the algorithm for different sets of commodities. Moreover, Eq. (6) declares the fixed trip matrix, while (7) is the shortest-route principle as shown by Wardrop.

For Eqs. (8)–(10), the reader needs the following notations used:

- y_{ij} —boolean variable which indicates whether an investment is made on link ij or not
- L_I —the set of links where an investment can be made
- \bar{L}_I —the set of links where an investment cannot be made
- I^0 —the budget available for investments.

In the beginning, minimization of F takes no consideration for the budget constraint. Therefore, the initial total investment is equal to I^{\max} . Next, Ridley's approach attempts to minimize the objective function with a virtual budget of $I^{\max} - 1$. This bounding procedure is continued until the true budget I^0 is reached.

In the effort spent to compute the optimal network for a given budget, the method helps find interesting by-products, such as all the intermediate optimal networks for possible budgets $I^0 + 1$ up to I^{\max} . The algorithm can be described as follows:

1. Initialize $m = I^{\max}$.
2. Set $m = m - 1$.
3. Generate all A_m and compute $F^l(A_m)$. Then, compute $F_m^U = F_m^{U(0)}$.
4. For all A_m , check if $F^l(A_m) < F_m^U$. If yes, then compute $F(A_m)$. If this is also less than F_m^U then substitute F_m^U with $F(A_m)$. Otherwise, proceed to the next A_m .
5. If $m = I^0$, then stop. Otherwise return to Step 2.

However, only the bounding process is well developed, thus making this method inefficient. It has thoroughly been studied until recently, providing significant insight to other researchers. Some of them were Ochoa-Rosso [94], Ochoa-Rosso and Silva [95], and Chan [21]. The common drawback these techniques have is the same branch-and-bound feature: a complete assignment is required at every step for the calculation of the total users' costs. That makes the methods mentioned here extremely costly, and it seems prohibitive to use them for even medium sized networks.

2.3 Equilibrium Models

Before proceeding to analyzing the state of the art combinatorial optimization techniques that are used in practice, it is a good idea to consider the most common model formulations. The first mathematical model was provided by Beckmann [9] in 1956 and led to a number of publications on the field. Analytically the topics covered by this very important contribution are presented by Patriksson [99] and Hearn and Florian [38]. According to Florian and Hearn [39], the major formulations are:

1. *Deterministic models*
2. *Stochastic models*

First of all, let us consider the deterministic traffic assignment model. The notation that will be used is presented in [Table 2](#).

It follows clearly that all the flows on paths k add up to the overall demand of the particular origin–destination pair or, more formally,

$$\sum_{k \in K_i} h_k = g_i, \forall i \in I, h_k \geq 0, k \in K. \quad (11)$$

In addition to that, the flow of a specific arc α can be calculated by

$$v_\alpha = \sum_{k \in K} h_k \delta_{\alpha k}, \alpha \in A. \quad (12)$$

Table 2 Notations used for the deterministic mathematical model

Notation	Description
$G = (N, A)$	The transportation network G , where N is the set of the nodes and A is the set of the directed arcs
I	The set of origin–destination pairs in the network
K_i	The set of paths connecting the origin–destination pair i
v	The vector of vehicle flows on the network
v_α	The number of vehicles on a specific arc $\alpha \in A$
$s_\alpha(v)$	The cost of using arc α as a function of vector v
g_i	The demand of the origin–destination pair $i \in I$.
$\delta_{\alpha k}$	Binary variable equal to 1 if arc $\alpha \in A$ and 0 otherwise

Now, by considering Wardrop’s user equilibrium principle, the conclusion that

$$s_k(v^*) - v_i^* \begin{cases} = 0 & \text{if } h_k^* > 0 \\ \geq 0 & \text{if } h_k^* = 0 \end{cases} \quad (13)$$

can be reached.

After several modifications [39], the Pareto optimality condition that is most commonly used in practical applications can be reached as

$$s(v)(v - v^*) - w(g^*)(g - g^*) \geq 0. \quad (14)$$

can be obtained.

Stochastic models are more realistic approaches to the traffic assignment problem, since they take into consideration the fact that travelers systematically make false decisions based on the wrong cost perceptions they assume during their trips. According to Florian and Hearn [39], it is vital to introduce the probability pr_k that an individual will choose path $k \in K_i$ during the trip which is defined as

$$pr_k = pr_k(Z_i), \forall k \in K_i, \forall i \in I, \quad (15)$$

where Z_i represents the vector of perceived times of all the paths k that can be formed for a specific origin–destination pair. These perceived travel times are considered to be represented by a probability density function

$$z_\alpha D(s_\alpha, \theta s_\alpha). \quad (16)$$

Now, the probability that a user will choose path k as they perceive it to be the shortest can be computed as

$$pr_k = Pr[z_k = \min_{k' \in K_i} (z_{k'})], \forall k \in K_i, \forall i \in I. \quad (17)$$

Finally, it has been shown by Evans [35] that the stochastic network optimum model is summarized by the optimization model presented here:

$$\min_v \left(\sum_{i \in I} g_i E\{\min_{k \in K_i} [z_k | s^k(v)]\} \right) + \sum_{\alpha \in A} v_\alpha s_\alpha(v_\alpha) - \sum_{\alpha \in A} \int_0^{v_\alpha} s_\alpha(x) dx \quad (18)$$

subject to the nonnegativity constraints. This objective function is clearly not convex; however, by Evans [35] it has been shown that there exists one stationary point in the neighborhood of which it is strictly convex.

2.4 Decomposition Methods

One important historical reference in the evolution of algorithms for the traffic assignment problem is the Frank–Wolfe method [40]. This method originally appeared in order to solve quadratic problems. Soon though, it became evident that easily it can be suited to solve any pseudoconvex linearly constrained problem such as the traffic assignment as shown by Hearn [56].

The traffic assignment model on which the Frank–Wolfe method can be deployed is the *user equilibrium* model, shown in standard form:

$$\min T(f) = \sum_{a \in A} \int_0^{f_a} t_a(s) ds \quad (19)$$

$$\text{s.t. } \sum_{r \in R_{pq}} h_{pqr} = d_{pq}, \forall (p, q) \in C \quad (20)$$

$$h_{pqr} > 0, \forall r \in R_{pq}, \forall (p, q) \in C \quad (21)$$

$$\sum_{(p,q) \in C} \sum_{r \in R_{pq}} \delta_{pqr\alpha} h_{pqr} = f_a, \forall \alpha \in A. \quad (22)$$

The insight behind the Frank–Wolfe method can be summed up to the following:

- *Initialization:* Let $f^{(0)}$ be an initial feasible solution. Then, set the iteration counter $k = 0$ and $\varepsilon_1, \varepsilon_2$, and ε_3 to be positive parameters.
- *Linearization of the objective:* Approximation of the objective function by a first-order Taylor series
- *Lower-bound search:* Solve the linear program presented in Eqs. (3)–(6). The solution $\hat{y}^{(k)}$ yields a new lower bound (LBD).
- *Check criterion:* If $\frac{T(f^{(k)}) - LBD}{LBD} < \varepsilon_1$, then the method terminates.

Table 3 Notations used for the Frank–Wolfe method

Notation	Description
f_{ij}	Traffic flow on arc $(i, j) \in A$
f_a	Traffic flow on arc $a \in A$
t_{ij}	Travel time on arc $(i, j) \in A$
t_a	Travel time on arc $a \in A$
$G = (N, A)$	Transport network G , where N is the set of the nodes and A is the set of the directed arcs
C	Set of commodities, characterized as pairs of origins and destinations (O–D pairs)
d_{pq}	Demand of travel between two nodes of the graph, p and q
R_{pq}	Set of routes connecting nodes p and q
h_{pqr}	Flow on route $r \in R_{pq}$
c_{pqr}	Travel cost on route r between nodes p and q
\bar{c}_{pqr}	Marginal cost on route r between nodes p and q
π_{pq}	Cost of the shortest route between p and q at equilibrium

- *Solve the line search problem:* The line search problem can be described as follows:

$$\min_{l \in [0,1]} \bar{T}(l) = T(f^{(k)} + l(\hat{y}^{(k)} - f^{(k)})) \quad (23)$$

in order to find the $l^{(k)}$.

- *Next iteration or stop criterion:* For the new iteration, update the solution-flow

$$f^{(k+1)} = f^{(k)} + l^{(k)}(\hat{y}^{(k)} - f^{(k)}).$$

In the case of nonlinear network flows, the Frank–Wolfe method can be efficiently used in order to decompose the problem of traffic assignment into $|C|$ shortest-route problems, which are more easily tackled (Table 3). The costs considered during the shortest-route problems are for each arc:

$$\frac{\partial}{\partial t} T(f^{(k)}) = t_\alpha(f_\alpha^{(k)}), \quad (24)$$

which present the travel times of each arc as perceived by the traveler. Thus, it is easy to see that this method resembles a real-life iterative procedure where the decision makers of the travel routes chosen adjust their decisions based on the prevailing conditions.

The method has been successfully applied to transportation management by several researchers during the 1970s and 1980s. The most noted ones are LeBlanc et al. [72–75], Golden [45, 46], and Nguyen [91, 92]. This research has enabled the

method to reach commercial software designed and programmed to solve instances of traffic flow networks, such as the TRAFFIC by Nguyen and James [93] and EMME/2 by Babin et al. [4].

However, not everything is satisfactory as far as the efficiency of the algorithm in traffic assignment problems is concerned, a result that was early extracted by Zangwill in 1969 [122]. Zangwill proved that the convergence rate of the Frank–Wolfe method can be quite slow. Although this has rendered the method inapplicable to practical applications, still transportation researchers are developing more efficient algorithms based on the method.

That is the main reason why researchers went on to propose several more efficient decomposition methods, mostly simplicial and cyclic, for solving the traffic assignment problem. The first transportation researcher who discussed the simplicial decomposition is Murchland [86], followed by Holloway [60] and Cantor and Gerla [18] who were the pioneers for implementing a simplicial decomposition algorithm for nonlinear commodity flows. The method is common in computer network optimization as the *extremal flows method*.

In general, simplicial decomposition is based on the Caratheodory theorem, stating that any point in the convex hull of a set X can be represented as a convex combination of at most $\dim(X)+1$ points and directions. Therefore, if the set of the extreme points is denoted as $\hat{y}^{(k)}$ and as $\hat{z}^{(j)}$ the corresponding set of directions of the polyhedron X for all $k = 1, \dots, m$ and $j = 1, \dots, l$, then any point $\bar{x} \in X$ can be represented as

$$\bar{x} = \sum_{k=1}^m \bar{\lambda}^{(k)} \hat{y}^{(k)} + \sum_{j=1}^l \bar{\mu}^{(j)} \hat{z}^{(j)} \quad (25)$$

where

$$\sum_{k=1}^m \bar{\lambda}^{(k)} = 1$$

and

$$\bar{\lambda}^{(k)}, \bar{\mu}^{(j)} \geq 0, \forall k, j.$$

When applying simplicial decomposition to a problem, the same problem as in the Frank–Wolfe method is actually being solved, that is,

$$\hat{y}^{(k)} \in \arg \min_{y \in X} \nabla T(x^{(k)})^T y. \quad (26)$$

In the Frank–Wolfe method, the next step would be to find the solution to the line search problem, as described in a previous paragraph. This is where the simplicial decomposition method differs: all the extreme points and directions obtained by

Table 4 Notations used for the simplicial decomposition

Notation	Description
$G = (N, A)$	The transportation network G , where N is the set of the nodes and A is the set of the directed arcs
I	The set of origin–destination pairs in the network
K_i	The set of paths connecting the origin–destination pair i
v	The vector of vehicle flows on the network
v_α	The number of vehicles on a specific arc $\alpha \in A$
$s_\alpha(v)$	The cost of using arc α as a function of vector v
g_i	The demand of the origin–destination pair $i \in I$
$\delta_{\alpha k}$	Binary variable equal to 1 if arc $\alpha \in A$ and 0 otherwise

previous iterations of the method are stored. Then, a master problem is solved using simplex. The master problem would be:

$$\min T(\bar{x}) \text{ s.t. the conditions of Eq. (20).}$$

The solution of the master problem leads to a new iteration point $x^{(k+1)}$.

Very important publications in the scientific field of simplicial decomposition are considered the ones by Hearn et al. [51, 52, 113], where a special version of the decomposition is shown. More specifically, the maximum number of extreme points stored is specified by the user as $r \leq |A| + 1$. That way, Hearn et al. managed to prove convergence within finite number of steps if r is greater than the optimal face dimension. Therefore, the result helped store less extreme points, which in turn implies that the number of variables required decreases. Von Hohenbalken [117] had noted that when the transportation network is rather small, then even Newton-type methods can converge quickly to an optimal solution. The drawback of the restricted simplicial decomposition algorithm proposed by Hearn is that the optimal choice for parameter r is unknown a priori, since the dimension of the optimal face is also unknown.

A restricted simplicial decomposition method is presented in [39]. The notation used can be found at **Table 4**. The algorithm begins ($k := 0$) from a feasible starting point (let v_0) and sets $\Theta_x = \emptyset$, $\Theta_v = v_0$. At each iteration the following problem is solved:

$$\min \sum_{\alpha \in A} (s_\alpha(v_\alpha^k)) x_\alpha \quad (27)$$

$$\text{s.t. } \sum_{k \in K_i} x_k = g_i, \quad i \in I, \quad x_k \geq 0, \quad k \in K \quad (28)$$

$$z_\alpha = \sum_{k \in K} \delta_{\alpha k} x_k. \quad (29)$$

The solution x_k is then checked. If

$$s(u^k)(x^k - v^k) \geq 0 \quad (30)$$

then an optimal solution has been reached as shown in Eq. (14). Otherwise, proceed to update the sets Θ_z and Θ_v . The updating process is as follows:

- If $|\Theta_x^k| < q$
 $\Theta_x^{(k+1)} = \Theta_x \cup x^k$ and $\Theta_v^{(k+1)} = \Theta_v^k$.
- If $|\Theta_x^k| = q$
Replace the minimally weighted extreme point with the solution found x_k to update the set $\Theta_x^{(k+1)}$ and $\Theta_v^{(k+1)} = v^k$.

It is clear to all transportation researchers that decomposition of real-life large-scale traffic assignment problems is more than vital. As it has been discussed by the author, the Frank–Wolfe method has been proven to achieve tractability while remaining economic resource-wise. However, its behavior near the optimal solution and its convergence rate made it an unlikely candidate for practical problems. Therefore, researchers have been looking for years for algorithms of much smaller dimension (i.e., requiring less resources) and which manage to preserve the original problem's special structure. The subproblems produced are then to be solved iteratively, while the rest of the problem, including its values and parameters, are discarded.

Because of the independence between commodity flows, they have been the natural choice for approaching a decomposition. This happens since there exist efficient algorithms for solving single commodity network flows. Let us consider again now the subproblem shown in Eq. (20), where $X = \{x : Ax = b; x \geq 0\}$, and let also $x = (x_1, x_2, \dots, x_n)$ be a variable vector where $x_i \in X_i$ is the feasible region for each x_i . There are two decomposition methods for the solution of the subproblem of Eq. (20). They are:

- *Gauss–Seidel*
- *Jacobi*

The subproblems that are solved according to each of the methods mentioned are:

- *Gauss–Seidel*

$$x_i^{(k+1)} \in \arg \min_{x_i \in X_i} T(x_1^{(k+1)}, x_2^{(k+1)}, \dots, x_{i-1}^{(k)}, x_i^{(k)}, x_{i+1}^{(k)}, \dots, x_n^{(k)}). \quad (31)$$

This approach is regarded as the *method of successive replacements* and *cyclic decomposition*, because the newest information from the most recent subproblems is used in the subproblem i .

- *Jacobi*

$$x_i^{(k+1)} \in \arg \min_{x_i \in X_i} T(x_1^{(k)}, x_2^{(k)}, \dots, x_{i-1}^{(k)}, x_i^{(k)}, x_{i+1}^{(k)}, \dots, x_n^{(k)}). \quad (32)$$

In contrast to the previous technique, this one is called the *method of simultaneous replacements*.

The convergence rates of the algorithms based on those decomposition techniques, as well as their special structure for the interested reader, can be found in the studies by Bertsekas and Tsitsiklis [12].

The application of cyclic decomposition methods in traffic assignment was first encountered in Dafermos [26] and has, thereafter, been successfully applied [69]. Moreover, scientific research on cyclic decomposition offered the bases on which modern heuristics advancements were founded. These subjects are treated in the following sections.

2.5 Heuristics and Recent Advancements

As the problem sizes increase, the traffic assignment becomes computationally intractable. This leads to approaches that attempt to tackle the problem by detecting a near-optimal or even just a feasible solution. Heuristics that are famous for their capability to solve hard discrete problems have been implemented in order to solve the traffic assignment problem. These heuristics include:

- Greedy randomized adaptive search procedure (GRASP)
- Simulated annealing
- Tabu search
- Genetic algorithms

Especially genetic algorithms, coupled with a random search procedure, seem to be obtaining high quality solutions in reasonable computational times.

Based on the previous work of Merchant and Nemhauser [83, 84] and Carey [19, 20], Waller and Ziliaskopoulos presented the DUO algorithm in 2006 [120] for dynamic traffic assignment. Their combinatorial approach required the discretization of the network arcs into smaller segments chosen so as to prevent a vehicle of traversing more than one “cell” at a single time unit. Then, they divided the aforementioned cells into five subcategories:

- Ordinary
- Merging
- Diverging
- Source
- Sink

More information on the cell transmission model that the authors adopted can be found at the work of Daganzo [27, 28].

To sum up, the algorithm they devised is at first calculating all the time-dependent shortest paths from every origin to the destination and then choosing the one shortest path with the smallest expected time of arrival and assigning it to a vehicle. Then, the capacities along the links of that path are decreased. In case now there exist more vehicles to be routed, the method is repeated. Otherwise, the allocation of vehicles to paths is optimal.

The algorithm is simple and can be implemented in an easy way. It is, also, very efficient since it is taking into consideration the special structure of the problem. However, it is limited to work under the assumption that there is only one destination in the network.

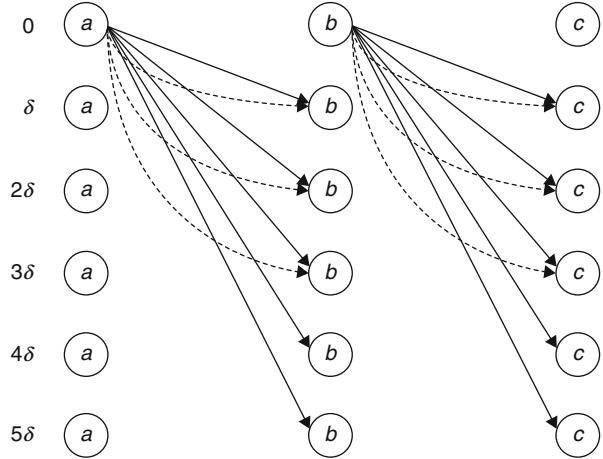

Another important advancement in the last years is the attempts to represent the problems arising in a more realistic approach. In their work, Zheng and Arulselvan [123] take into consideration the notion of the managed lanes and the dynamic and continuous nature of traffic assignment and try to implement techniques that make use of these special characteristics. According to the authors, managed lanes are lanes with restricted access to a subset of the vehicles currently using the infrastructure. So the lanes in a traffic system can be, more easily, distinguished into two major categories:

- Unmanaged (unrestricted, free) lanes
- Managed (restricted) lanes

In their work, they use the time-expanded network and the dynamic traffic assignment model and formulation presented in the work of Nahapetyan and Langpopanich [88]. In that, the planning time horizon is continuous, but is discretized into a set $\Gamma = \{0, \delta, 2\delta, \dots, C\delta\}$. Then, the time-expanded network can be modeled by copying each node in the original static network $C + 1$ times. One such time-expanded network can be found in Fig. 1.

G	The set of all group users, defined by the set (a, b, r, d)
(a, b)	The origin–destination pair
r	The desired starting time of the trip
d	The expected arriving time of the trip
$\Delta_{p,q}$	The set of all possible discrete travel times of path (p, q)
$M_{p,q}$	The capacity of the path (p, q)
$\phi()$	Penalty function for late/early departure
$\psi()$	Penalty function for late/early arrival
$r_{p,q}$	Maximum outflow rate for arc (p, q)
$h_{a,b,r,d}$	The demand for each of the groups $(a, b, r, d) \in G$
$v_t^{(a,b,r,d)}$	Vehicle flow starting at time t for group (a, b, r, d)
$w_t^{(a,b,r,d)}$	Vehicle flow arriving at time t for group (a, b, r, d)
$y_{p_t, q_{t+\tau}}^{(a,b,r,d)}$	The flow on the expanded arc $(p_t, q_{t+\tau})$ for group (a, b, r, d)
D_1, D_2, D_3	The arc-node incidence matrices
$\Gamma_{p,q}$	The set of all possible times of departure for arc (p, q)

Fig. 1 An example of a time-expanded network

Finally, the formulation of the problem based on the notation presented and the notions behind the time-expanded network, described previously, is the following:

$$\min \sum_{(a,b,r,d) \in G} \left\{ \sum_s \phi(s-r) w_s^{(a,b,r,d)} \right\} \quad (33)$$

$$+ \sum_s \psi(s-r) v_s^{(a,b,r,d)} \quad (34)$$

$$+ \sum_{(p,q) \in A} \sum_{t \in \Gamma_{p,q}} \phi_{p,q}(x_t^{p,q}) \sum_{\tau \in \Delta_{p,q}} y_{p_t, q_{t+\tau}}^{(a,b,r,d)} \quad (35)$$

$$\text{s.t. } \sum_t w_t^{(a,b,r,d)} = h_{(a,b,r,d)}, \quad \forall (a,b,r,d) \in G \quad (36)$$

$$\sum_t v_t^{(a,b,r,d)} = h_{(a,b,r,d)}, \quad \forall (a,b,r,d) \in G \quad (37)$$

$$D_1 w + D_2 y + D_3 v = 0 \quad (38)$$

$$x_t^{p,q} = \sum_{(a,b,r,d) \in G} \sum_{\alpha \leq t, \beta \geq t} \frac{\beta - t}{\beta - \alpha} y_{p_\alpha, q_\beta}^{(a,b,r,d)}, \quad \forall t \in \Gamma_{p,q}, (p,q) \in A \quad (39)$$

$$x_t^{p,q} \geq \sum_{\tau \in \Delta_{p,q}} \phi_{p,q}^{-1}(\tau - \delta) z_{p_t, q_{t+\tau}}, \quad \forall t \in \Gamma_{p,q}, (p,q) \in A \quad (40)$$

$$x_t^{p,q} \leq \sum_{\tau \in \Delta_{p,q}} \phi_{p,q}^{-1}(\tau) z_{p_t, q_{t+\tau}}, \quad \forall t \in \Gamma_{p,q}, (p,q) \in A \quad (41)$$

$$\sum_{(a,b,r,d) \in G} y_{p_t,q_{t+\tau}}^{(a,b,r,d)} \leq M_{p,q} z_{p_t,q_{t+\tau}}, \quad \forall \tau \in \Delta_{p,q}, t \in \Gamma_{p,q}, (p,q) \in A \quad (42)$$

$$\sum_{\tau \in \Delta_{p,q}} z_{p_t,q_{t+\tau}} = 1, \quad \forall t \in \Gamma_{p,q}, (p,q) \in A \quad (43)$$

$$\sum_{(a,b,r,d) \in G} \sum_{\tau \in \Delta_{p,q}} y_{p_{t-\tau},q_t}^{(a,b,r,d)} \leq r_{p,q} \delta, \quad \forall t \in \Gamma_{p,q}, (p,q) \in A \quad (44)$$

$$v, w, x, y \geq 0 \quad (45)$$

$$z_{p_t,q_{t+\tau}} \in \{0, 1\}, \quad \forall \tau \in \Delta_{p,q}, t \in \Gamma_{p,q}, (p,q) \in A. \quad (46)$$

Constraints (36)–(38) are ensuring that the flow in the network is balanced after the time expansion modification. Then, the weighted flows are modeled by the set of constraints in Eq. (39), while the travel times are taken care of by Eqs. (40)–(41). Last, the uniqueness of the travel time for each static arc and the capacity constraints are ensured by (42)–(43) and (44) accordingly.

The authors then proceed to introduce a formulation that can be decomposed into a master problem and a series of relaxed subproblems. This way, they can exploit a series of properties that they prove the new problems possess in order to show the effectiveness of their heuristic approach. The master problem is defined in Eqs. (47)–(49):

$$\min H(z) = \min \{c_1^T w + c_2^T v + c_3^T y | (w, v, y) \in S(z)\} \quad (47)$$

$$\text{s.t. } \sum_{\tau \in \Delta_{p,q}} z_{p_t,q_{t+\tau}} = 1 \quad \forall t \in \Gamma_{p,q}, (p,q) \in A \quad (48)$$

$$z_{p_t,q_{t+\tau}} + z_{p_s,q_{s+\tau}} \leq 1 \quad \forall t < s, s > \beta, (p,q) \in A, \quad (49)$$

while the relaxed subproblem is presented in Eqs. (50)–(59):

$$\tilde{H}(z^k) = \min c_1^T w + c_2^T v + c_3^T y + m^T \gamma \quad (50)$$

$$\text{s.t. } \sum_t w_t^{(a,b,r,d)} = h_{(a,b,r,d)} \quad \forall (a,b,r,d) \in G \quad (51)$$

$$\sum_t v_t^{(a,b,r,d)} = h_{(a,b,r,d)} \quad \forall (a,b,r,d) \in G \quad (52)$$

$$D_1 w + D_2 y + D_3 v = 0 \quad (53)$$

$$x_t^{p,q} = \sum_{(a,b,r,d) \in G} \sum_{\alpha \leq t, \beta \geq t} \frac{\beta - t}{\beta - \alpha} y_{p_\alpha, q_\beta}^{(a,b,r,d)} \quad \forall t \in \Gamma_{p,q}, (p,q) \in A \quad (54)$$

$$x_t^{p,q} \geq \sum_{\tau \in \Delta_{p,q}} \phi_{p,q}^{-1}(\tau - \delta) z_{p_t,q_{t+\tau}}^k, \quad \forall t \in \Gamma_{p,q}, (p,q) \in A \quad (55)$$

$$x_t^{p,q} \leq \sum_{\tau \in \Delta_{p,q}} \phi_{p,q}^{-1}(\tau) z_{p_t, q_t + \tau}^k, \quad \forall t \in \Gamma_{p,q}, (p, q) \in A \quad (56)$$

$$\sum_{(a,b,r,d) \in G} y_{p_t, q_t + \tau}^{(a,b,r,d)} \leq M_{p,q} z_{p_t, q_t + \tau}^k, \quad \forall \tau \in \Delta_{p,q}, t \in \Gamma_{p,q}, \\ (p, q) \in A \quad (57)$$

$$\sum_{(a,b,r,d) \in G} \sum_{\tau \in \Delta_{p,q}} y_{p_t - \tau, q_t}^{(a,b,r,d)} \leq r_{p,q} \delta, \quad \forall t \in \Gamma_{p,q}, (p, q) \in A \quad (58)$$

$$v, w, y, \gamma \geq 0 \quad (59)$$

The heuristic approach adopted needs some operations that are defined by the authors and are the following:

- *Shrinking* reduces the carrying capability of the expanded network associated with the value of z^k . It is defined by Eqs. (60)–(62):

$$z_{\hat{p}_u, \hat{q}_{u+\tau}}^{k+1} = \mathbf{1}_{[\tau=\pi-\delta]} \quad \forall \tau \in \Delta_{\hat{p}, \hat{q}} \quad (60)$$

$$z_{\hat{p}_t, \hat{q}_{t+\tau}}^{k+1} = z_{\hat{p}_t, \hat{q}_{t+\tau}}^k \quad \forall \tau \in \Delta_{\hat{p}, \hat{q}}, t \in \Gamma_{\hat{p}, \hat{q}} / \{u\} \quad (61)$$

$$z_{p_t, q_{t+\tau}}^{k+1} = z_{p_t, q_{t+\tau}}^k \quad \forall \tau \in \Delta_{p,q}, t \in \Gamma_{p,q}, (p, q) \in A / (\hat{p}, \hat{q}). \quad (62)$$

- *Expanding* increases the carrying capability of the network of z^k and is described in (63)–(65):

$$z_{\hat{p}_u, \hat{q}_{u+\tau}}^{k+1} = \mathbf{1}_{[\tau=\pi+\delta]} \quad \forall \tau \in \Delta_{\hat{p}, \hat{q}} \quad (63)$$

$$z_{\hat{p}_t, \hat{q}_{t+\tau}}^{k+1} = z_{\hat{p}_t, \hat{q}_{t+\tau}}^k \quad \forall \tau \in \Delta_{\hat{p}, \hat{q}}, t \in \Gamma_{\hat{p}, \hat{q}} / \{u\} \quad (64)$$

$$z_{p_t, q_{t+\tau}}^{k+1} = z_{p_t, q_{t+\tau}}^k \quad \forall \tau \in \Delta_{p,q}, t \in \Gamma_{p,q} / \{u\}, (p, q) \in A / (\hat{p}, \hat{q}). \quad (65)$$

After a solution has been obtained by the relaxed subproblem, a set $\Omega = \{(t, p, q)\}$ is created with the candidate time-expanded arcs. The basic operations of shrinking and expanding are then performed to detect if a better solution can be obtained.

So the heuristic can be summed up to the following. First, an initial binary solution z^0 which has the lowest carrying capacity. This happens because of the fact that all time-expanded arcs are associated with the least travel times. However, this initial solution can very well be infeasible, hence an expanding operation as described above needs to take place. When feasibility is achieved, implying that now the constraint (55) is binding, then a better solution can be searched for hence requiring the execution of a shrinking operation. According to the state of constraints (55)–(56), different actions are to be taken (Fig. 2). In order to deal with this fact, the authors decided to partition the set $\Omega = \{(t, p, q) | t \in \Gamma_{p,q}, (p, q) \in A\}$ into a number of different subsets defined below:

```

procedure DTA-UB Heuristic
1   Set  $z^0$  as defined in equation (21)
2   Solve RSP0 associated with  $z^0$ , and get the solution  $(w^0, v^0, x^0, y^0, \gamma^0)$ .
3   Set the incumbent solution,  $(\bar{w}, \bar{v}, \bar{x}, \bar{y}, \bar{\gamma}) = (w^0, v^0, x^0, y^0, z^0, \gamma^0)$ .

Fig. 2 The heuristic introduced by Zheng and Arulselvan [123]

$$\begin{aligned}
\Omega_0 &= \{(t, p, q) | \bar{x}_t^{p,q} = \sum_{\tau \in \Delta_{p,q}} \phi_{p,q}^- 1(\tau - \delta) \bar{z}_{p_t, q_{t+\tau}}, (t, p, q) \in \Omega\} \\
\Omega_1 &= \{(t, p, q) | \bar{y}_t^{p,q} > 0, (t, p, q) \in \Omega\} \\
\Omega'_2 &= \{(t, p, q) | \bar{\mu}_t^{p,q} < 0, (t, p, q) \in \Omega\} \\
\Omega_2 &= \Omega'_2 \setminus \Omega_1 \\
\Omega_3 &= \Omega \setminus \Omega'_2,
\end{aligned}$$

where $\bar{\mu}_t^{p,q}$ is the optimal dual multiplier of constraint (56).

3 Combinatorial Optimization in Toll Pricing

3.1 Introduction

As noted in the previous section, Wardrop's principles [119] have played a very important role in shaping transportation engineering. The two principles seem and are incompatible with each other in practice. The insight to have a solution that is simultaneously system and user optimal is what led to more advanced techniques in toll pricing.

One of the main objectives of transportation engineering is to figure ways to achieve unique solutions in order to solve both problems of traffic assignment and toll pricing. The second problem is clearly solved in conjunction with data derived from the traffic assignment problem and consists of the determination of fares and tariffs that would lead the users to select a network optimal route rather than a "selfish" route.

In the last years, there has been an extensive interest in the toll pricing problem due to the recurrent congestion that appears especially in urban and metropolitan areas. As was noted by Arnott and Small [2], trying to maximize a driver's convenience may result in deteriorating the overall congestion level.

In addition to the above, in the last two decades, a significant change in federal management of transportation is noticed [121]. Instead of focusing on construction and upgrading infrastructure, the key to successful utilization is now lying with the optimal management of the existing infrastructure. Hence, it is implied that new policy makers are actually trying to improve efficiency. One way to do so is by deciding on a congestion pricing scheme that leads to a system optimal solution, through appropriate toll pricing.

Numerous practical applications of toll pricing schemes have been presented along the years. The most noted ones in literature are according to Tsekeris and Voß [111]:

- Travel demand and congestion management
- Toll revenues used to construct or improve infrastructures
- Environmental management

Especially important is congestion management. A big variety of European cities have adopted tolls as a means to control and improve congestion levels. The studies in literature usually focus on optimizing toll fares in London [48, 71, 103] and Stockholm [1, 33, 79].

3.2 First-Best vs Second Best Frameworks

The first-best principle in toll pricing is based on the cost of marginal social cost [65]. More specifically, it consists of the unconstrained marginal-cost pricing, where the cost for the traveler is equal to the marginal cost of the road use as perceived by the infrastructure manager plus the cost incurred because of the delay imposed to the rest of the network users.

The notion of a second-best solution is becoming more and more applicable as the problems become more large scale and realistic [81]. As was noted by Luenberger [78], the optimal solution for a toll pricing problem would be to price all possible links on the network. As the reader can immediately realize, this approach is highly ineffective and expensive. Therefore, recent studies in the past 15 years have focused on second-best approaches for toll pricing. In addition to that, new optimization problems have been proposed, such as the toll booth location problem, which take into consideration the minimization of the number of toll booths installed in a network.

The insights of first-best toll pricing stated by Pigou in 1920 [100] are recognized by all researchers to be [114] the best benchmark available for toll pricing. However, it is also a fact that the Pigou assumptions are unrealistic, meaning that:

- The regulator is able to place toll booths in all arcs of a network.
- All network users and the regulator have full and accurate knowledge of the traffic and infrastructure conditions at all times.

From the economic point of view, the assumptions made are strong; hence, unconstrained maximization ends up being unrealistic and therefore only used as a benchmark and often infeasible solution.

That is the main reason why second-best toll pricing policies have prevailed in literature receiving much scientific interest. For instance, as early as 1968, Lévy-Lambert [76] studied the second-best regulation problem concerning the problem where there exist two routes parallel to each other; however, one of them is untolled.

Increasingly used are some game-theoretic modelings of the toll pricing problem. Because of the large-scale nature of a typical transportation network, there have appeared noncooperative game theoretic models [111] where management is considered to come from a higher federal power. Examples of such models include but are not limited to the works of Chau and Sim [22], Correa et al. [25], Roughgarden [104], and Roughgarden and Tardos [105]. The above models consider a set of selfish players that aim to minimize their total costs while also minimizing the price of anarchy [22]. The price of anarchy is calculated by measuring the network inefficiency levels when the users are let to decide their own selfish routes compared to the ones imposed by a central management system.

3.3 Modern Optimization Techniques

Recent computational methods for toll pricing in order to control and adapt congestion levels in metropolitan areas have been studied extensively by Hearn et al. [53]. Especially in the journal article published in 2002 by Hearn et al. [54], they focus on a fixed demand toll pricing framework and benchmark two approaches. The first method is based on a toll set approximation, while the second one makes use of a cutting plane methodology ([Table 5](#)).

Then, using the principles of traffic assignment presented in [Sect. 2.3](#), which state that a feasible network flow v is tolled-user optimal if and only if

Table 5 Notations used in the toll pricing methodology presented

Notation	Description
G	The transportation network
N	The set of nodes
A	The set of arcs
p	An origin node
q	A destination node
K	The set of all $k = (p, q)$ representing o-d pairs
\bar{t}_k	The demand of a specific o-d pair k
x_k	The commodity flow of o-d pair k
v	The aggregate flow vector
$s(v)$	The cost function for the current flow
$s_\alpha(v)$	The cost function for a specific link $a \in A$

$$(s(\bar{v}) + \beta)^T (v - \bar{v}) \geq 0, \forall v \in V \quad (66)$$

The authors begin by using the very useful lemma proved by Hearn and Ramana [55]:

Lemma 1 For a given optimal system optimum solution flow v^* , let T be the set of all tolls that ensure that $v^* \in V$ is also a tolled user equilibrium optimal flow. Then, $T = W_{FD}(v^*)$ is the polyhedron given by the β variable part of the following system

$$s(v^*) + \beta \geq A^T \rho^k \quad \forall k \in K \quad (67)$$

$$(s(v^*) + \beta)^T v^* = \sum_{k \in K} \bar{t}_k E_k^T \rho^k. \quad (68)$$

Then, by imposing other constraints or choosing different objective functions an alternative tolls set can be obtained. The most common objective functions used can be summed up to the following:

- Minimize the total tolls collected (**MINSYS**)
- Minimize the number of toll booths installed
- Minimize the largest toll fare collected

The MINSYS problem as studied by Hearn and Ramana [55] is then transformed by penalizing the aggregate complementarity constraint in order to find an approximate toll vector solution. The problem becomes then

$$\min u_1 Z + u_2 ((s(v^*) + \beta)^T v^* - b^T \rho) \quad (69)$$

$$\text{s.t. } s(v^*) + \beta \geq A^T \rho^k, \quad \forall k \in K \quad (70)$$

$$(\beta, \rho, y, z) \in \hat{T}, \quad (71)$$

where u_1 and u_2 are positive scalars and Z is the objective of the MINSYS problem, that is, $\beta^T v$ and \hat{T} are the constraints that $\beta \geq 0$.

After these notes, the authors proceed to formalize their algorithmic idea. It can be described as follows:

1. Solve the system optimal problem to obtain an approximate optimal flow v^* and the corresponding cost $s(v^*)$.
2. Solve the MINSYS problem presented above by penalizing the complementarity constraint in Eq. (68). Let the violation be denoted by

$$\bar{\varepsilon} = (s(v^*) + \bar{\beta}_{\text{MINSYS}})^T v^* - b^T \bar{\rho}.$$

3. Compute the approximation toll set as $W_{\text{FD}}(\bar{v}, \bar{\varepsilon})$.
4. Define and optimize one of the toll pricing problems with the current toll set $W_{\text{FD}}(\bar{v}, \bar{\varepsilon})$.

Then, the authors proceed with the proposal of a new cutting plane algorithm to solve the MINSYS problem. They decompose the initial problem into a master linear problem and a subproblem which consists of $|K|$ shortest-path detections. The steps of the cutting plane algorithm proposed are described as follows:

1. Obtain an aggregate vector flow v^* and the corresponding costs $s(v^*)$.
2. Begin choosing an approximate toll vector T^0 and setting the iteration counter $l = 0$.
3. Solve the LP

$$\min\{\beta^T v^* | \beta \in T^l\}. \quad (72)$$

4. Compute the shortest paths as $s(v^*) + \beta_l$. Also, obtain the extreme point solution $v_l = \sum_{k \in K} x_l^k$.
5. Check the condition with a tolerance ε . If

$$(s(v^*) + \beta)^T (v_l - v^*) \geq -\varepsilon$$

then the user equilibrium condition is approximately satisfied.

6. Otherwise, the constraint is added to the set of constraints T^l to obtain the new set T^{l+1} .
7. Increase the iteration counter $l = l + 1$ and go to Step 3.

3.4 A Generalized Second-Best Congestion Pricing Model

In this seminal publication, Verhoef [114] derives a second-best tax rule and shows that many known problems and tax rules can be considered as special cases to the general solution obtained. First of all, let us introduce the notation of the model in the following table (Table 6).

First of all, the basic assumption of the toll pricing model presented is that the regulator sets tolls on arcs according to the maximization of social welfare,

Table 6 Notation used for the second-best toll pricing problem

Notation	Description
G	Transport network
N	Set of nodes of the network
J	Set of the arcs of the network
I	Set of origin–destination pairs
N_i	Number of users for each pair i
N_j	Number of users of arc j
$D_i(N_i)$	Inverse demand function for each pair i
P	Set of paths (noncyclical) of the network
N_p	Number of users for path p
P_i	Set of noncyclical paths connecting origin–destination pair i
δ_{jp}	Binary parameter equal to 1 if arc j belongs to path p and 0 otherwise
δ_j	Binary parameter equal to 1 if it is possible to place a toll booth in arc j and 0 otherwise
f_j	Fee charged at toll on arc j

that is, total benefits minus total costs. That can be stated mathematically as follows:

$$\max_{f_j \forall j: \delta_j = 1} \quad W = \sum_{i=1}^I \int_0^{N_i} D_i(x_i) dx_i - \sum_{j=1}^J N_j c_j(N_j) \quad (73)$$

$$\text{s.t.} \quad N_p \geq 0 \quad (74)$$

$$\sum_{j=1}^J \delta_{jp}(c_j + \delta_j f_j) - D_i \geq 0 \quad (75)$$

$$N_p \left(\sum_{j=1}^J \delta_{jp}(c_j + \delta_j f_j) - D_i \right) = 0, \forall p \in P_i, \forall i \in I. \quad (76)$$

This model is maximizing an objective, based on the conditions that each trip decision maker is aiming to maximize their own objectives represented by Wardrop's principles. Then, Verhoef had the insight of discarding all irrelevant paths in order to transform the Wardrop conditions involved in the model to strict equalities. Therefore, the problem can be represented by the Lagrangian:

$$\begin{aligned} \Lambda = & \sum_{i=1}^I \int_0^{\sum_{p=1}^P \delta_{ip} N_p} D_i(x_i) dx_i - \sum_{j=1}^J \sum_{i=1}^I \sum_{p=1}^P \delta_{jp} \delta_{ip} N_p c_j \left(\sum_{k=1}^I \sum_{q=1}^P \delta_{jq} \delta_{kq} N_q \right) \\ & + \sum_{i=1}^I \sum_{p=1}^P \delta_{ip} \lambda_p \left[\sum_{j=1}^J \delta_{jp} \left(c_j \left(\sum_{k=1}^I \sum_{q=1}^P \delta_{jq} \delta_{kq} N_q \right) + \delta_j f_j \right) - D_i \left(\sum_{q=1}^P \delta_{iq} N_q \right) \right] \end{aligned}$$

Then, based on this equation, the first-order conditions can be computed:

$$\begin{aligned} \frac{\partial \Lambda}{\partial N_p} &= \sum_{i=1}^I \delta_{ip} D_i - \sum_{j=1}^J \delta_{jp} \left(c_j + \sum_{k=1}^I \sum_{q=1}^P \delta_{jq} \delta_{kq} N_q c'_j \right) \\ &\quad + \sum_{k=1}^I \sum_{q=1}^P \delta_{kq} \lambda_q \left(\sum_{j=1}^J \delta_{jp} \delta_{jq} c'_j \right) - \sum_{i=1}^I \sum_{q=1}^P \delta_{ip} \delta_{iq} \lambda_q D'_i = 0, \\ \forall p : \delta_{ip} &= 1 \\ \frac{\partial \Lambda}{\partial f_j} &= \sum_{i=1}^I \sum_{p=1}^P \delta_{ip} \delta_{jp} \lambda_p = 0, \forall j : \delta_j = 1 \\ \frac{\partial \Lambda}{\partial \lambda_p} &= \sum_{j=1}^J \delta_{jp} (c_j + \delta_j f_j) - \sum_{i=1}^I \delta_{ip} D_i = 0, \forall p : \delta_{ip} = 1. \end{aligned}$$

Substituting the last of the first-order conditions in the first one, the Lagrange multipliers can be calculated. The multipliers that are nonzero are the factors that cause the second-best optimal solution found (the one that does not allow a toll to be placed on all arcs) to be always inferior to the first-best framework. It can be verified that if it was permitted to use tolls in all the arcs of the network, then the second first-order condition would yield $\lambda_p = 0$.

After these important findings, Verhoef went along to compare his interesting results to earlier research outcomes on the field. First of all, the comparison with the first-best toll pricing framework, which implies that $\delta_j = 1, \forall j$, proves that the results obtained by the author are consistent with the Pigou tax rule [100], as expected. Then, the author performs another important comparison to the standard two-route problem. As mentioned in the introduction, this problem was initially studied by Lévy-Lambert [76] in 1968, to be followed by Verhoef et al. [115] in 1996.

Both studies concluded that the optimal second-best toll for the tolled route in the problem can be calculated by:

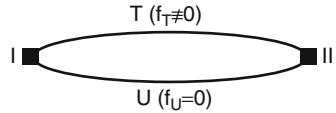

$$f_T = N_T c'_T - N_U c'_U \frac{-D'}{c'_U - D'}. \quad (77)$$

This can be shown when substituting the first-order conditions:

$$\frac{\partial \Lambda}{\partial N_T} = D - c_T - N_T c'_T + \lambda_T c'_T - (\lambda_T + \lambda_U) D' = 0 \quad (78)$$

$$\frac{\partial \Lambda}{\partial N_U} = D - c_U - N_U c'_U + \lambda_U c'_U - (\lambda_T + \lambda_U) D' = 0 \quad (79)$$

Fig. 3 The untolled two-route problem

$$\frac{\partial \Lambda}{\partial f_T} = \lambda_T = 0 \quad (80)$$

$$\frac{\partial \Lambda}{\partial \lambda_T} = c_T + f_T - D = 0 \quad (81)$$

$$\frac{\partial \Lambda}{\partial \lambda_U} = c_U - D = 0. \quad (82)$$

Solving the second-best framework presented, the author obtains that

$$\lambda_U = \frac{N_U c'_U}{c'_U - D'}, \quad (83)$$

and by substituting the first-order conditions into the last equation, the result given in Eq. (77) is found (Fig. 3).

Another example of Verhoef's framework consistency to earlier research results is the optimal parking policy for congestion management. As was noted by Glazer and Niskanen [44], it is realistic to assume that several network users have access to private parking spots; therefore, they form a subset of users that are not required to pay the parking fees. Once more, Verhoef applies the first-order conditions to obtain

$$\frac{\partial \Lambda}{\partial N_{II}} = D_{II} - c_1 - N_1 c'_1 + (\lambda_{II} + \lambda_{III}) c'_1 - \lambda_{II} D'_{II} = 0 \quad (84)$$

$$\frac{\partial \Lambda}{\partial N_{III}} = D_{III} - c_1 - N_1 c'_1 + (\lambda_{II} + \lambda_{III}) c'_1 - \lambda_{III} D'_{III} = 0 \quad (85)$$

$$\frac{\partial \Lambda}{\partial f_2} = \lambda_{II} = 0 \quad (86)$$

$$\frac{\partial \Lambda}{\partial \lambda_{II}} = c_1 + f_2 - D_{II} = 0 \quad (87)$$

$$\frac{\partial \Lambda}{\partial \lambda_{III}} = c_1 - D_{III} = 0, \quad (88)$$

where, clearly, $N_1 = N_{II} + N_{III}$. Again, solving the framework presented, the author obtains that

$$\lambda_{III} = \frac{N_1 c'_1}{c'_1 - D'_{III}}, \quad (89)$$

which, in turn, substituted in the first-order condition gives us

$$f_2 = N_1 c'_1 \frac{-D'_{III}}{c'_1 - D'_{III}}, \quad (90)$$

which is the same result that Glazer and Niskanen extracted in their work in 1992.

3.5 Hybrid Genetic Algorithms for the Toll Booth and the Toll Pricing Problems

A genetic algorithm is a metaheuristic, based on population members that provide us with high quality solutions in combinatorial optimization. In the context of the problems studied here, every member of the population is a feasible solution. In every generation (iteration) the solutions become of higher quality, since elite members of the population have a higher probability of selection, until a solution that is considered satisfactory is reached.

In literature, genetic algorithms have been successfully applied to a series of large-scale network combinatorial optimization problems. It was applied to the Open Shortest Path First problem Internet routing problem by Ericsson et al. in 2002 [34] with success and that led to Buriol et al. adapting the genetic algorithm presented with a local improvement procedure to further improve the results [15].

The above success stories gave the idea to Buriol et al. [16] to approach the toll booth problem with a hybrid genetic algorithm. The similarities between the Internet routing problem tackled and the toll booth problem predicated the very good results obtained in this research.

The feasible solutions are represented by two arrays, w and b . The first array stores the arc weights, while the latter is a binary array with the toll locations. An arc can have a positive weight if the corresponding entry in the binary array is true. Otherwise it is set to be zero. Another important note that needs to be made is that two paths are considered to be of equal cost if they have the same distance and the same number of nodes visited.

At each iteration, crossover is applied on the members selected in order to produce the next generation of population. At this point, a biased random key scheme [8] is used, and each pair of parents consists exclusively of an elite member of the population and a nonelite one. Each element of the eight array w either inherits the value of one of its parents or a mutation resets it with probability p_m . If a mutation does not take place, then the elite parent's weight value is favored, implying that the probability that this is the value inherited to the offspring is more than 1/2.

After the crossover is performed, the binary array b is adjusted as follows. If both parents i th element is equal to true, then the offspring inherits that value. If only one of the parents has an element set to true, then 50% of these positions are set to true, while all other positions are filled us false.

That way, the algorithm devised proceeds to the solution evaluation. After this step, a local improvement procedure is deployed in order to detect better quality solutions in the neighborhood of the initial solution. Last, the solution is dynamically updated in order to avoid recomputing all the shortest paths, a process that would be computationally expensive.

This work inspired an improved biased random key genetic algorithm by Buriol et al. in 2010 [17]. The problem of the traffic optimization tackled can be written as:

$$\min \Phi = \sum_{\alpha \in A} l_\alpha t_\alpha \left[1 + B_\alpha \left(\frac{l_\alpha}{c_\alpha} \right)^{p_\alpha} \right] \Bigg/ \sum_k \in K d_k \quad (91)$$

$$\text{s.t. } l_\alpha = \sum_{k \in K} x_\alpha^k, \quad \forall \alpha \in A \quad (92)$$

$$\sum_{i:(j,i) \in A} x_{(j,i)}^k - \sum_{i:(i,j) \in A} x_{(i,j)}^k = \begin{cases} -d_k & \text{if } j = d_k \\ d_k & \text{if } j = o(k), \forall j \in N, k \in K \\ 0 & \text{otherwise} \end{cases} \quad (93)$$

$$x_\alpha^k \geq 0, \quad \forall \alpha \in A, \forall k \in K. \quad (94)$$

The approach adopted is to place toll fares on K arcs of the network, such that the user equilibrium and the system optimum are simultaneously accomplished and the objective-fitness function Φ is minimized. An extension to the hybrid genetic algorithm, a random key genetic algorithm was devised in [17]. Therein, the authors depict its success in obtaining better quality results in large-scale, realistic transportation networks.

4 Vehicle Routing and Vehicle Fleet Management

4.1 Introduction

Another important problem in both transportation and logistics engineering is the vehicle routing problem, which was introduced by Dantzig and Ramser [29]. Its statement is simple, however it is a generalization of the infamous Traveling Salesman Problem, which proves the complexity and difficulties encountered when attempting to solve it.

Given a depot and a set of customers, find the least cost path/paths that a vehicle/fleet of vehicles needs to follow in order to serve each customer and return to the depot.

Fig. 4 The optimal parking policy problem

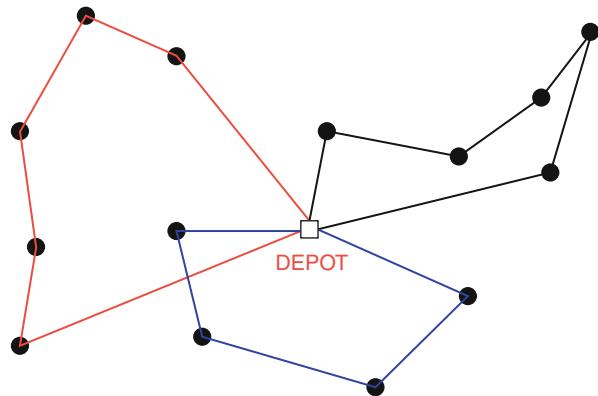

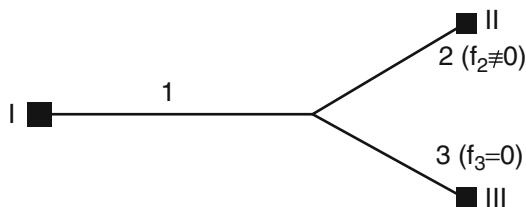

Fig. 5 A vehicle routing problem solution with a fleet of three vehicles

An example for a fleet of three and one vehicles accordingly are given in Figs. 4 and 5. It is clear that Fig. 4 (the vehicle routing problem solution with one vehicle) is essentially the Hamiltonian path that optimally solves the corresponding Traveling Salesman Problem (Fig. 6).

As Toth and Vigo [110] mention, the utilization of advanced operations research techniques in distribution and transportation systems produces very significant savings. Apart from the financial savings that are produced, even a small increase in the fleet's utilization has important environmental and social gains.

In general, the important parts of a vehicle routing or vehicle scheduling problem are the following:

1. Transportation infrastructure—graph
2. Customers—nodes
3. Vehicles

Of course, each of these elements is associated with different specificities and characteristics. The network is represented as a graph and consists of arcs-links, which connect nodes. If two nodes are connected, then the vehicle has a certain cost of traversing that link. The most commonly used objective is to minimize the costs of transportation of each of the vehicles using the infrastructure.

Each customer has different characteristics as to how they need to be serviced. Hence, customers are represented as special nodes on the graph that is studied. It is vital for the vehicle routing problem to have the knowledge of the exact node where the customer has to be serviced. Another very important detail for any customer is

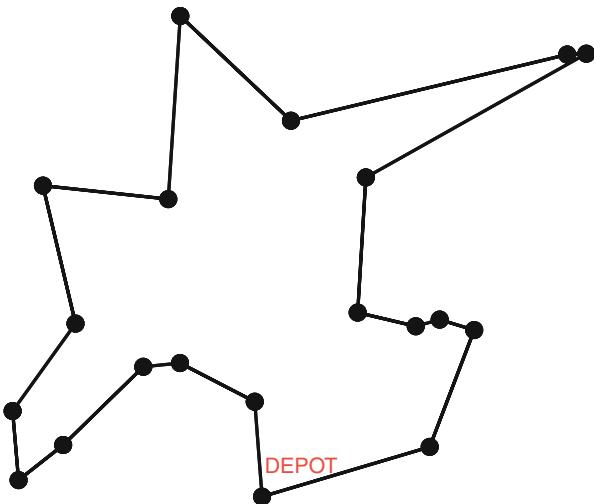

Fig. 6 A vehicle routing problem solution with a fleet of one vehicle

the demand of goods that would need to be transported. According to the model used, there exist other specifications which are necessary such as:

- Customer location
- Demand
- Time window of service
- Collection and/or delivery customer
- Service time required
- Type of vehicle suitable for the customer

Last, the vehicles that are used to satisfy the demands while meeting the objectives set can be characterized by:

- Initial point-depot
- Capacity
- Type
- Links that they can use
- Customers that they can serve

There has been a brief mention of objectives, which is a general notion and, hence, there exist many objective functions associated with different types of vehicle routing problems, often contradicting each other. Usually one of the following is encountered:

1. Minimize the overall costs
2. Minimize the number of vehicles used
3. Balancing of the vehicles' times and loads
4. Maximizing the quality of service

Table 7 Notation used for the vehicle routing problems presented

Notation	Definition
G	Transportation network
V	Set of nodes-vertices of the network
c_{ij}	Cost of traversing the edge that connects nodes i and j
K	Set of vehicles in our disposal, $k = 1, \dots, K$
C	Set of vehicle capacities
S	Set of customers, $S \subseteq V$
d_i	Demand of customer $i \in S$
x_{ijk}	Binary variable $x_{ijk} = \begin{cases} 1, & \text{if vehicle } k \text{ uses the arc that connects } i \text{ and } j \\ 0, & \text{otherwise} \end{cases}$
y_{ik}	Binary variable $y_{ik} = \begin{cases} 1, & \text{if vehicle } k \text{ serves customer } i \\ 0, & \text{otherwise} \end{cases}$

In the following subsection, the most widely known vehicle routing problems will be tackled, beginning with the simple, uncapacitated version and moving towards more realistic approaches.

4.2 Vehicle Routing Problem

The most commonly used versions of the vehicle routing problem are:

- Capacitated vehicle routing
- Vehicle routing with time windows

Each one of them is characterized by different aspects and details. The most commonly used formulations are presented in this subsection ([Table 7](#)).

At this point, it is interesting to study the simple version of the *capacitated* vehicle routing problem. The model most commonly used is the three-index model presented in [110].

$$\min \quad \sum_{i \in V} \sum_{j \in V} c_{ij} \sum_{k=1}^K x_{ijk} \quad (95)$$

$$\text{subject to } \sum_{k=1}^K y_{ik} = 1, \quad \forall i \in V \setminus \{0\} \quad (96)$$

$$\sum_{k=1}^K y_{0k} = K \quad (97)$$

$$\sum_{j \in V} x_{ijk} = \sum_{j \in V} x_{jik} = y_{ik}, \quad \forall i \in V, k = 1, \dots, K \quad (98)$$

$$\sum_{i \in V} d_i y_{ik} \leq C \quad (99)$$

$$\sum_{i \in S} \sum_{j \notin S} x_{ijk} \geq y_{hk}, \quad \forall S \subseteq V \setminus \{0\}, h \in S, \quad k = 1, \dots, K \quad (100)$$

$$x_{ijk} \in \{0, 1\}, \quad \forall i \in V, k = 1, \dots, K \quad (101)$$

$$y_{ik} \in \{0, 1\}, \quad \forall i, j \in V, k = 1, \dots, K. \quad (102)$$

The similarities with the traveling salesman problem are immediately apparent. For instance, Eq. (100) can be studied. The constraint ensures that the optimal route found is complete, that is, it does not include any subtours. In Fisher and Jaikumar [36], it is replaced by

$$\sum_{i \in S} \sum_{j \in S} x_{ijk} \leq |S| - 1, \quad S \subseteq V \setminus \{0\}, |S| \geq 2, k = 1, \dots, K, \quad (103)$$

which is the subtour elimination constraint used in the TSP. The model presented is widely used because it is very easy to incorporate a nonhomogeneous fleet of vehicles with distinct capacities and costs. In addition to that, by adopting large costs in the arcs leaving the depot and changing the constraint

$$\sum_{k=1}^K y_{0k} = K$$

to

$$\sum_{k=1}^K y_{0k} \leq K,$$

then the solution found is forced to use the minimum number of vehicles possible.

Initially, it is interesting to note that the TSP has provided researchers with numerous relaxations for the vehicle routing problem, starting as early as 1971 and the 1-tree relaxation of Held and Karp [57]. This relaxation gave way to more recent attempts like the proposed branch-and-bound algorithm of Christofides [23], who focused on the k -degree center tree relaxation. This tree is a minimum cost spanning tree with a degree of k at the initial node. Immediately after that, the algorithm proceeds to choose K least cost arcs to be added, where $2K - k$ are incident while the remaining are not. This relaxation worked efficiently solving problems of up to 25 customers.

Another bound can be obtained by the Lagrangian dual function, which in reality can provide researchers with solutions of much better quality. The problem with these dualizations arise with the exponentially large number of constraints that are included (i.e., either the capacity-cuts or the subtour eliminations). Thus, the process

is as follows. Find a solution to the Lagrangian problem and at each iteration, find a violated constraint and add it to the problem. This method is applied in Fisher and Jaikumar [36] and Miller [85] and is exact.

Last, the set partitioning branch-and-bound algorithm that was proposed by Balinsky and Quandt [5] and was advanced by Hadjiconstantinou [49] is also a method that has attracted scientific interest because of its high efficiency. The model used in [5] is presented in Eqs. (104)–(107).

$$\min \sum_{j=1}^M c_j x_j \quad (104)$$

$$\text{s.t. } \sum_{j=1}^M a_{ij} x_j = 1, \quad \forall i \in V \setminus \{0\} \quad (105)$$

$$\sum_{j=1}^M x_j = K \quad (106)$$

$$x_j \in \{0, 1\}, \quad \forall j = 1, \dots, M. \quad (107)$$

This model has been applied successfully in a number of applications as observed by Descrosiers [30].

For large-scale problems which reflect more practical applications and, therefore, are very important, the use of branch-and-bound algorithms is limiting and inefficient. Mainly several heuristic approaches have been implemented with success, increasing the size of the problems solved to optimality in the last decades as was noted by Laporte et al. [68]. In their work, they present the most commonly used heuristics, such as:

- Sweep [43]
- Petal [107]
- Cluster-First, Route-Second [14]

The sweep algorithm is pretty simple and easily implemented given that each customer-vertex can be represented by its polar coordinates (ρ_i, θ_i) . First of all, the vertices need to be sorted in increasing angles from an arbitrary vertex \tilde{i} with $\theta_{\tilde{i}} = 0$. Then, these steps can be followed:

1. Choose an unassigned vehicle k .
2. Detect the unserviced customer i with the smallest θ_i and assign customers to vehicle k until the capacity is not exceeded. If there exist other customers remaining to be serviced, return to Step 1.
3. Solve the corresponding TSP for each of the vehicle routes created above.

A natural extension of the sweep algorithm was given by Ryan et al. [107]. It consists of generating different routes and, then, solve a set partitioning problem in order to select the best routes possible. The form of the set partitioning problem is given in Eqs. (108)–(110).

Table 8 Notation used for the vehicle routing problem with time windows

Notation	Definition
G	Transport network
V	Set of vehicles to be routed
N	Set of all the nodes of the network
A	Set of all the arcs of the network
c_{ij}	Cost associated with each arc $(i, j) \in A$
t_{ij}	Time required to cross arc $(i, j) \in A$ including the service time at customer $i \in N$
q_k	Capacity of vehicle $k \in V$
d_i	Demand of customer at node $i \in N$
$[a_i, b_i]$	Time window of customer $i \in N$
x_{ijk}	Binary decision variable $x_{ijk} = \begin{cases} 1, & \text{if vehicle } k \text{ uses arc } (i, j) \\ 0, & \text{otherwise} \end{cases}$
s_{ik}	Decision variable that represents the time vehicle k services customer i

$$\min \sum_{k \in S} d_k x_k \quad (108)$$

$$\text{s.t. } \sum_{k \in S} a_{ik} x_k, \quad \forall i = 1, \dots, n \quad (109)$$

$$x_k \in \{0, 1\}, \quad \forall k \in S, \quad (110)$$

where S is the set of routes. Also, it can be obtained for the binary variable x_k :

$$x_k = \begin{cases} 1 & \text{if route } k \text{ is in the solution} \\ 0 & \text{otherwise.} \end{cases}$$

Of course it is vital for the efficiency of the algorithm to produce and check only a sufficient subset of all the possible routes set, otherwise the method is computationally expensive. Heuristic rules for detecting such subsets were proposed by Foster and Ryan [106] and Ryan et al. [107]. In 1996, however, an advancement was proposed by Renaud et al. [101] to include configurations of multiple vehicles with embedded or intersecting routes, instead of just one vehicle route.

Now, a more realistic approach to the classical vehicle routing problem can be considered, the one with time windows. It is widely known that every customer needs not only to be serviced but also to be satisfied within certain time slots. The major difference to the original version studied until now is this: every customer vertex of the graph is assigned, in addition to the previous characteristics, a time period in which they require the service to take place. These constraints are considered soft by some researchers, that is, they can be violated with a certain penalty cost, and hard by others (Table 8).

The mathematical formulation of the vehicle routing problem with time windows is presented here:

$$\min \sum_{k \in V} \sum_{i \in N} \sum_{j \in N} c_{ijk} x_{ijk} \quad (111)$$

$$\text{s.t. } \sum_{k \in V} \sum_{j \in N} x_{ijk} = 1, \quad \forall i \in C \quad (112)$$

$$\sum_{i \in C} d_i \sum_{j \in N} x_{ijk} \leq q, \quad \forall k \in V \quad (113)$$

$$\sum_{j \in N} x_{0jk} = 1, \quad \forall k \in V \quad (114)$$

$$\sum_{i \in N} x_{ihk} - \sum_{j \in N} x_{hjk} = 0, \quad \forall h \in C, \quad \forall k \in V \quad (115)$$

$$\sum_{i \in N} x_{i,n+1,k} = 1, \quad \forall k \in V \quad (116)$$

$$x_{ijk} (s_{ik} + t_{ij} - s_{jk}) \leq 0, \quad \forall i, j \in N, \quad \forall k \in V \quad (117)$$

$$a_i \leq s_{ik} \leq b_i \quad \forall i \in N, \quad \forall k \in V \quad (118)$$

$$x_{ijk} \in \{0, 1\} \quad \forall i, j \in N, \quad \forall k \in V. \quad (119)$$

The problem is defined as the attempt to service each customer in the graph exactly once, while starting and ending by a depot vertex. The difference is that now there is a time of service associated with each of the customers that is required to be met by the vehicle planned to satisfy the demand of that customer. The objective function shown above is minimizing the total travel cost, selecting the least expensive arcs in order to satisfy all the demands. The next two constraints are used to visit exactly once each customer in the graph and to ensure that the capacity of each of the vehicles is not exceeded. Equations (114)–(116) ensure that each vehicle is starting from the depot, servicing a customer and moving on to another customer or returning to the depot. The next constraint indicates when arriving at a customer at a specific time, then the next customer will be serviced at some time after that event. Last, the time window constraints are given. Once more, a limit to the number of vehicles that are planned to be used is given like in the case of Descrosiers et al. [30] using Eq. (120).

$$\sum_{k \in V} \sum_{j \in N} x_{0jk} \leq |V| \quad \forall k \in V, \quad \forall j \in N. \quad (120)$$

It becomes immediately clear that the vehicle routing problem is a generalization of the original vehicle routing problem. When the time window constraints are

dropped, the problem is relaxed to the vehicle routing problem studied earlier in this chapter. By looking closer at the mathematical formulation, only Eq. (112) is a constraint that binds a vehicle to a particular customer [62]. Hence, decomposition methods such as Lagrange or Dantzig–Wolfe seem like natural choices for algorithmic designs. One of the first research groups to apply Dantzig–Wolfe decomposition was Desrochers, Descrosiers, and Solomon in 1992 [31], considering the assignment constraints as the coupling ones, while the subproblem consisted of a shortest-path problem with resource constraints.

If the problem formulated in Eqs. (111)–(119) is considered again, then, as stated, the coupling constraint is considered to be Eq. (112). Hence, let us define the master problem consisting of Eqs. (111)–(112) and (119), so basically the problem is restricted to take into consideration the objective function, the coupling constraint of every vehicle to a specific customer, and the binary restriction on the variables. The rest of the constraints are still used in the subproblem which will be described shortly.

Now it can be assumed that P^k is the set of all the paths that vehicle k , $k \in V$ can follow. Also, let it be defined that

$$x_{ijp}^k = \begin{cases} 1, & \text{if vehicle } k \text{ is moving from node } i \text{ to node } j \text{ using path } p \\ 0, & \text{otherwise.} \end{cases}$$

Then, any solution to the master problem can be represented as convex combination of some of the paths, that is,

$$x_{ij}^k = \sum_{p \in P^k} x_{ijp}^k y_p^k \quad \forall k \in V, \quad \forall (i, j) \in A \quad (121)$$

$$\sum_{p \in P^k} y_p^k = 1 \quad \forall k \in V \quad (122)$$

$$y_p^k \geq 0 \quad \forall k \in V, \quad \forall p \in P^k. \quad (123)$$

Using the notation for x_{ijp}^k , c_p^k (the cost of a path p for vehicle k) and α_{ip}^k (number of times customer i is serviced by vehicle k) can be defined as

$$c_p^k = \sum_{(i,j) \in A} c_{ij}^k x_{ijp}^k \quad \forall k \in V, \quad \forall p \in P^k \quad (124)$$

$$\alpha_{ip}^k = \sum_{j \in N \cup \{n+1\}} x_{ijp}^k \quad \forall k \in V, \forall i \in N, \forall p \in P^k. \quad (125)$$

Using the above notations and definitions, the master problem is rewritten as

$$\min \sum_{k \in V} \sum_{p \in P^k} c_p^k u_p^k \quad (126)$$

$$\text{s.t. } \sum_{k \in V} \sum_{p \in P^k} \alpha_{ip}^k y_p^k = 1 \quad \forall i \in C \quad (127)$$

$$\sum_{p \in P^k} y_p^k = 1 \quad \forall k \in V \quad (128)$$

$$y_p^k \geq 0 \quad \forall k \in V, \forall p \in P^k. \quad (129)$$

Usually, the case studied involved one depot and a homogeneous fleet of vehicle [62]; hence, the problem can be transformed into

$$\min \sum_{p \in P} c_p y_p \quad (130)$$

$$\text{s.t. } \sum_{p \in P} \alpha_{ip} y_p = 1 \quad \forall i \in C \quad (131)$$

$$y_p \geq 0 \quad \forall p \in P, \quad (132)$$

which is derived by aggregating the constraints in Eq. (128) and by letting $y_p = \sum_{k \in V} y_p^k$. The model described by Eqs. (130)–(132) is the linear relaxation of the set partitioning formulation. Now, the problem can be restricted to only take into consideration the set of columns that have already been generated, let P' . The resulting formulation uses the decision variables y_p as a counter of the times that path $p \in P'$ has been used and in the relaxed version can take any value in the interval $[0, 1]$.

$$\min \sum_{p \in P'} c_p y_p \quad (133)$$

$$\text{s.t. } \sum_{p \in P'} \alpha_{ip} y_p = 1 \quad \forall i \in C \quad (134)$$

$$y_p \geq 0 \quad \forall p \in P', \quad (135)$$

Solving the above model, a solution $y = (y_1, y_2, \dots, y_{|P'|})$ and the corresponding dual solution $\phi = (\phi_1, \phi_2, \dots, \phi_{|C|})$ are obtained. It is important to note here that the solution obtained might not be an integer however, even in the case that it is, the procedure does not guarantee an optimal solution, but merely a feasible one.

Now, the subproblem that the column generation approach aims to solve can be brought to attention. As stated before, the subproblem decomposes in the case of the vehicle routing problem with time windows into $|V|$ identical problems. They all are a shortest-path problem with resource constraints, which reflect the time windows and the vehicle capacities [62]. The subproblem is then formulated mathematically as

$$\min \sum_{i \in N} \sum_{j \in N} \hat{c}_{ij} x_{ij} \quad (136)$$

$$\text{s.t. } \sum_{i \in C} d_i \sum_{j \in N} x_{ij} \leq q \quad (137)$$

$$\sum_{j \in N} x_{0j} = 1 \quad (138)$$

$$\sum_{i \in N} x_{ih} - \sum_{j \in N} x_{hj} = 0 \quad \forall h \in C \quad (139)$$

$$\sum_{i \in N} x_{i,n+1} = 1 \quad (140)$$

$$s_i + t_{ij} - M_{ij}(1 - x_{ij}) \leq s_j \quad \forall i, j \in N \quad (141)$$

$$\alpha_i \leq s_i \leq b_i \quad \forall i \in N \quad (142)$$

$$x_{ij} \in \{0, 1\} \quad \forall i, j \in N. \quad (143)$$

In the above formulation, \hat{c}_{ij} is the *modified* cost and is equal to $\hat{c}_{ij} = c_{ij} - \pi_i$. The above problem has already been proved to be NP-hard by Dror in 1994 [32]. In order to solve it, this approach needs to be adapted by including another set of decision variables

$$x_{ij}^l = \begin{cases} 1, & \text{if arc } (i, j) \text{ is the } l\text{-th arc of the shortest path} \\ 0, & \text{otherwise} \end{cases}$$

and s_i^l that signal the starting time of service for a customer at node i when l is the rank of the customer, that is, the l th customer of the vehicle service. Also, the customer number $l \in L = \{1, 2, \dots, |L|\}$ and $|L| = \left\lfloor \frac{b_{n+1}}{\min t_{ij}} \right\rfloor$. Then the above problem formulation can be rewritten as

$$\min \sum_{l \in L} \sum_{i \in N} \sum_{j \in N} \hat{c}_{ij} x_{ij}^l \quad (144)$$

$$\text{s.t. } \sum_{i \in N} \sum_{j \in N} x_{ij}^1 = 1 \quad (145)$$

$$\sum_{i \in N} \sum_{j \in N} x_{ij}^l - \sum_{i \in N} \sum_{j \in N} x_{ij}^{l-1} \leq 0 \quad \forall l \in L - \{1\} \quad (146)$$

$$\sum_{i \in C} d_i \sum_{l \in L} \sum_{j \in N} x_{ij}^l \leq q \quad (147)$$

$$\sum_{j \in N} x_{0j}^1 = 1 \quad (148)$$

$$\sum_{i \in N} x_{ih}^{l-1} - \sum_{j \in N} x_{hj}^l = 0 \quad \forall h \in C \quad \forall l \in L - \{1\} \quad (149)$$

$$\sum_{l \in L} \sum_{i \in N} x_{i,n+1}^l = 1 \quad (150)$$

$$s_i^l + t_{ij} - K(1 - x_{ij}^l) \leq s_j^l \quad \forall i, j \in N \quad \forall l \in L - \{1\} \quad (151)$$

$$\alpha_i \leq s_i^l \leq b_i \quad \forall i \in N \quad (152)$$

$$x_{ij}^l \in \{0, 1\} \quad \forall i, j \in N. \quad (153)$$

In that formulation, Eq. (145) ensures that the first arc can only be used once, the constraint in Eq. (146) guarantees that arc l cannot be used unless arc $l - 1$ is also used, while the rest of the constraints remain the same with the alterations required. This formulation has been solved in the past by the algorithm designed by Desrochers, Descrosiers, and Solomon and is described in [31]. However, it has been shown that if the distances in the problem satisfy the triangle inequality (this is actually the case in most practical applications), then the optimal solution contains *only* elementary routes. That implies that there is a possibility that the master problem lower bound obtained decrease and, hence, improvements need to be made in the algorithmic part. Such an improvement was studied by Kolen et al. [67].

4.3 Special Cases and Recent Advancements

Recently, the vehicle routing problem has escaped the fields of logistics and transportation and has advanced in other fields where machinery operation and route planning is costly. The mostly noted example is the one of robotic autonomous routing and is investigated in numerous publication during the last 5 years. The issues investigated include:

- Communication coverage planning [96]
- Robot docking [13]
- Multi-robot motion in an environment with obstacles [112] or in an environment with other moving robots [118]

This is the framework that Baskar et al. [7] adopted in their research on optimal routing that uses an Intelligent Vehicle Highway System. The assumption they make for the infrastructure is that it is an automated highway system where autonomous vehicles are fully controlled in order to reach their respective destinations.

The framework, described in Baskar et al. [6], consists of the following elements:

1. The vehicle controllers, which control the speed and steering of the vehicles by receiving orders from the platoon controllers

Table 9 Notation used in the autonomous vehicle routing by Baskar et al. [7]

O	Origin nodes
D	Destination nodes
I	Internal nodes
V	The set of all nodes, $V = O \cup I \cup D$
L	The set of links in the network
(o, d)	One origin–destination pair, $(o, d) \in O \times D$
$L_{o,d}$	The set of links that belong to a route connecting o to d
$D_{o,d}$	The demand of the pair (o, d)
C_l	The capacity of the link $l \in L$
v_l	The speed on link $l \in L$
τ_l	The travel time on link $l \in L$
L_v^{in}	The set of all links incoming to node v
L_v^{out}	The set of all links leaving node v
$x_{l,o,d}$	Decision variables denoting the flows for every pair $(o, d) \in O \times D$
T	The simulation period

2. The platoon controllers, which take care of the merges and splits of platoons and the vehicle to vehicle distances by receiving control commands from the roadside controllers
3. The roadside controllers, which are in charge of a segment of the whole network in the infrastructure
4. The higher-level controllers, which coordinate the whole network and supervise all other controllers

Using this infrastructure, the authors focus on optimal routing to each platoon that is currently in the network (Table 9). The notation that is used is given in the following network.

The authors focus on the following cases:

1. The static case with sufficient capacities
2. The static case with queues forming at the boundaries only
3. The dynamic case with queues forming at the boundaries only

In the static case, the assumption has to do with the constant nature of the demand of each (o, d) pair in the network. Hence, the model for the static case with sufficient capacities is described in Eqs. (154)–(157).

$$\min J_{\text{links}} = \sum_{(o,d) \in O \times D} \sum_{l \in L_{o,d}} x_{l,o,d} \tau_l T \quad (154)$$

$$\text{s.t. } \sum_{l \in L_o^{\text{out}} \cap L_{o,d}} x_{l,o,d} = D_{o,d}, \quad \forall o \in O, \forall d \in D \quad (155)$$

$$\sum_{l \in L_v^{\text{in}} \cap L_{o,d}} x_{l,o,d} = \sum_{l \in L_v^{\text{out}} \cap L_{o,d}} x_{l,o,d}, \quad \forall v \in V, \forall (o, d) \in O \times D \quad (156)$$

$$\sum_{(o,d) \in I_{od,l}} x_{l,o,d} \leq C_l, \quad \forall l \in L. \quad (157)$$

The above model is simple to grasp since it involves only the preservation of the flows in the network and the capacity constraints for each of the links. The objective function described in Eq. (154) is a measure of the time that the vehicles have to stay on the network using its infrastructure while traveling.

In order to make the model a little more realistic, the authors then proceed to tackle the problem of queues being formed at the “entrance” points of the infrastructure. So now the model can be written as

$$\min J_{\text{links}} + J_{\text{queue}} = \sum_{(o,d) \in O \times D} \sum_{l \in L_{o,d}} x_{l,o,d} \tau_l T + \quad (158)$$

$$\sum_{(o,d) \in O \times D} \frac{1}{2} (D_{o,d} - F_{o,d}^{\text{out}}) T^2 \quad (159)$$

$$\text{s.t. } \sum_{l \in L_v^{\text{in}} \cap L_{o,d}} x_{l,o,d} = \sum_{l \in L_v^{\text{out}} \cap L_{o,d}} x_{l,o,d}, \quad \forall v \in V, \forall (o,d) \in O \times D \quad (160)$$

$$\sum_{(o,d) \in I_{od,l}} x_{l,o,d} \leq C_l, \quad \forall l \in L \quad (161)$$

$$\sum_{l \in L_o^{\text{out}} \cap L_{o,d}} x_{l,o,d} \leq D_{o,d}, \quad \forall o \in O, \forall d \in D \quad (162)$$

$$F_{o,d}^{\text{out}} = \sum_{l \in L_o^{\text{out}} \cap L_{o,d}} x_{l,o,d}. \quad (163)$$

In order to estimate J_{queue} which is a measure of the time spent by the vehicles in the queues formed in the origin nodes, the authors note that the queue size increases with time with a rate of $D_{o,d} - F_{o,d}^{\text{out}}$. Hence, at the end of the simulation time, the total length is $(D_{o,d} - F_{o,d}^{\text{out}})T$ and the average is calculated as $\frac{1}{2}(D_{o,d} - F_{o,d}^{\text{out}})T$. That is how the term of J_{queue} is computed in the objective function above. Once more, the mathematical program is linear.

It is easy to observe that the model is yet unrealistic. In most practical applications, it is not wise to assume that the demands are constant and, thus, a dynamic modeling approach has to be adopted. In order to do so, the authors introduce a discretization of the time spent on each link, with the elementary measurement of T_s . This can be written more clearly as

$$\tau_l = \kappa_l T_s, \text{ where } \kappa_l \in \mathbb{Z}^+. \quad (164)$$

Letting $q_{o,d}(k)$ be the partial queue length of vehicles traveling from o to d at time k , that is, $t = kT_s$, and by assuming that the network is initially empty, that is,

$q_{o,d}(k) = 0$ and $x_{l,o,d}(k) = 0$ for $k \leq 0$ for each of the origin nodes o , it can be obtained that

$$\sum_{l \in L_o^{\text{out}} \cap L_{o,d}} x_{l,o,d}(k) \leq D_{o,d}(k) + \frac{q_{o,d}(k)}{T_s} \quad \forall d \in D, \quad (165)$$

and by definition $D_{o,d}(k) = 0$ for $k \geq K$. Now, by considering the fact that every vehicle on link l will reach the end of the link after κ_l time segments, it is obtained that

$$\begin{aligned} \sum_{l \in L_v^{\text{in}} \cap L_{o,d}} x_{l,o,d}(k - \tau_l) &= \sum_{l \in L_v^{\text{out}} \cap L_{o,d}} x_{l,o,d}(k), \\ \forall v \in I \quad \forall (o, d) \in O \times D. \end{aligned} \quad (166)$$

Also for every link, the capacity constraints need to be enforced, however taking into consideration the time period. So Eq. (161) is now transformed in the dynamic case into

$$\sum_{(o,d) \in I_{od,l}} x_{l,o,d}(k) \leq C_l, \quad \forall l \in L. \quad (167)$$

The important part of this model is the way the queues formed are described. The flow is given by a similar constraint to the one presented in Eq. (163), which however is transformed in order to accommodate the time factor into

$$F_{o,d}^{\text{out}}(k) = \sum_{l \in L_o^{\text{out}} \cap L_{o,d}} x_{l,o,d}(k). \quad (168)$$

Therefore, the queue length is increasing linearly with the rate of $D_{o,d}(k) - F_{o,d}^{\text{out}}(k)$ for the time interval $[k T_s, (k+1) T_s]$ and the following equation for the queue length can be written:

$$q_{o,d}(k+1) = \max(0, q_{o,d}(k) + (D_{o,d}(k) - F_{o,d}^{\text{out}}(k)) T_s). \quad (169)$$

Two cases exist for the determination of the time $J_{\text{queue},o,d}(k)$ that a vehicle has to spend in the queue formed at an origin o :

- The queue length becomes zero while the interval $[k T_s, (k+1) T_s]$.
- The queue length remains positive in the same interval.

Now, the latter case can be considered. Defining the time after $k T_s$ at which the queue length becomes zero as

$$T_{o,d}(k) = \frac{q_{o,d}(k)}{F_{o,d}^{\text{out}}(k) - D_{o,d}(k)}, \quad (170)$$

J_{queue} can now be estimated as

$$J_{\text{queue},o,d}(k) = \begin{cases} \frac{1}{2}(q_{o,d}(k) + Q_{o,d}(k+1))T_s & \text{for the first case} \\ \frac{1}{2}q_{o,d}(k)T_{o,d}(k) & \text{for the second case.} \end{cases} \quad (171)$$

In general now, for the queue

$$J_{\text{queue}} = \sum_{k=0}^{K_{\text{end}}-1} \sum_{(o,d) \in O \times D} \sum_{l \in L_{o,d}} J_{\text{queue},o,d}(k) \quad (172)$$

and

$$J_{\text{links}} = \sum_{k=0}^{K_{\text{end}}-1} \sum_{(o,d) \in O \times D} \sum_{l \in L_{o,d}} x_{l,o,d}(k) \kappa_l T_s^2. \quad (173)$$

So finally the mathematical formulation becomes

$$\min (J_{\text{links}} + J_{\text{queue}}) \quad (174)$$

$$\text{s.t. } (165) - (169). \quad (175)$$

This model is for the second case a nonlinear, nonconvex, and nonsmooth problem. As such, this problem is hard to solve, and hence, the authors present an approximate solution algorithm. Either way, by transforming the above problem into a mixed integer linear program, there exist several solvers that can solve it efficiently [98]. For this transformation to take place, the authors use some binary variables with no practical meaning and a series of properties proved by Bemporad and Morari in 1999 [10] that state:

Property 1 $[f \leq 0] \iff [\delta = 1]$ is true iff

$$\begin{cases} f \leq M(1-\delta) \\ f \geq \varepsilon + (m-\varepsilon)\delta, \end{cases}$$

where ε is a small positive number.

Property 2 $y = \delta f$ is equivalent to

$$\begin{cases} y \leq M\delta \\ y \geq m\delta \\ y \leq f - m(1-\delta) \\ y \geq f - M\delta. \end{cases}$$

Then, by eliminating the term of $F_{o,d}^{\text{out}}(k)$ from Eq. (169), they obtain

$$q_{o,d}(k+1) = \max(0, q_{o,d}(k) + (D_{o,d}(k) - \sum_{l \in L_o^{\text{out}} \cap L_{o,d}} x_{l,o,d}(k))T_s), \quad (176)$$

which still is nonlinear. However, by letting $D_{\max,o,d}$ be the maximum demand for $(o, d) \in O \times D$, $F_{\max,o,d}$ be the maximum feasible flow (i.e., $F_{\max,o,d} = \sum_{l \in L_o^{\text{out}} \cap L_{o,d}} C_l$) and $q_{\max,o,d}$ be the maximum queue length formed from origin o to destination d and equal to $D_{\max,o,d} T_s K_{\text{end}}$, then two new parameters can be defined as

$$m_{o,d}^{\text{low}} = -F_{\max,o,d} T_s \quad (177)$$

$$m_{o,d}^{\text{upp}} = q_{\max,o,d} + D_{\max,o,d} T_s, \quad (178)$$

hence the following always stands:

$$m_{o,d}^{\text{low}} \leq q_{o,d}(k) + (D_{o,d}(k) - \sum_{l \in L_o^{\text{out}} \cap L_{o,d}} x_{l,o,d}(k))T_s \leq m_{o,d}^{\text{upp}}. \quad (179)$$

Now, by introducing the binary variables $\delta_{o,d}(k)$ as

$$\delta_{o,d}(k) = \begin{cases} 1 & \text{iff } q_{o,d}(k) + (D_{o,d}(k) - \sum_{l \in L_o^{\text{out}} \cap L_{o,d}} x_{l,o,d}(k))T_s \geq 0 \\ 0 & \text{otherwise.} \end{cases} \quad (180)$$

So, applying Property 1, constraint (Eq. 176) takes the form of

$$q_{o,d}(k+1) = \delta_{o,d}(k) \left(q_{o,d}(k) + D_{o,d}(k) - \sum_{l \in L_o^{\text{out}} \cap L_{o,d}} x_{l,o,d}(k) T_s \right). \quad (181)$$

Note that this constraint remains *nonlinear*; however, it can be turned into one by using Property 2 mentioned above. Finally, a series of *linear* inequalities is obtained and the problem can now be solved approximately by one of the well known mixed integer linear programming solvers. The authors tested their formulation using several solvers from the overviews presented by Atamtürk and Savelsbergh [3] and Linderoth and Ralphs [77] and obtained high quality solutions, even better at some instances than local search algorithms.

4.4 Fixed Charge Network Flows

Last, but definitely not least, the fixed charge network flow problem has attracted scientific interest recently, due to the major practical applications that it has. For

instance, the fixed charge network problem can be encountered in network design, logistics and transportation engineering, and computer networks [42].

The problem is known to be NP-hard, and is a concave minimization problem. Hence, the optimal solution can be found on one of the vertices of the feasible region. With that in mind, Murty [87] suggested a vertex ranking procedure. Unfortunately, the method was still unusable for large-scale, realistic instances. Other heuristics were proposed over time, most notable of which was the effort by Kim and Pardalos [63, 64], called Dynamic Slope Scaling Procedure. The heuristic solves a series of linear problems, where the slope of the cost function is updated using the information obtained by previous iterations. An advancement to that work can be found by Nahapetyan and Pardalos [89] and Sorokin et al. [108].

5 Conclusion

Combinatorial optimization techniques have become more refined leading to numerous success stories in operations research. Especially in transportation and logistics, the vehicle routing problem stands out as an example of the immense capabilities that these new techniques offer. As was noted by Magnanti in 1981 [80], the size of the problems that could be solved was very small, especially compared to the large-scale problems that it is possible to solve to optimality nowadays.

The modern issues that arise have to do with solving real life applications with large-scale instances. The problem is that the more realistic an approach is the more unstable its parameters are. That implies that solutions can be obtained, which by the time they are adopted and put into practice have moved from being optimal to “bad” or, even worse, infeasible. This is a major discrepancy in most approaches that needs to be dealt with and a trade-off between a better solution and a more robust one is to be decided.

Robust optimization [11] is an important aspect of combinatorial problems that needs to be addressed. This branch of optimization deals with uncertainty in the parameters of a given problem and attempts to optimize a problem with the intention of choosing a solution that remains feasible even when the worst case scenarios occur. This is the route that most researchers seem to be choosing for future work, since it is a well known fact that our world is highly stochastic and, as such, it is important to adopt solutions that will remain plausible instead of theoretical approaches that prove to be inflexible towards change and unpredictable events.

Abstract

This chapter surveys various complexity issues of *polynomial time approximation schemes* (PTAS). Also under consideration are the refined subclasses of PTAS, including *fully polynomial time approximation schemes* (FPTAS) and *efficient polynomial time approximation schemes* (EPTAS). The key questions under consideration are as follows: what optimization problems have PTASs, FPTASs, and EPTASs, and how efficient are these algorithms?

On the positive side, there are syntactic classes for characterizing PTAS, FPTAS, and EPTAS. Expressing a problem as a member in these classes automatically gives an approximation scheme for the problem. For many graph problems on planar graphs, there are powerful graph-theory techniques for designing PTAS and EPTAS algorithms, which can be extended to some generalizations of planar graphs. On the negative side, there are convincing evidences that, for a large set of NP-hard optimization problems, efficient approximation schemes do not exist. Even for many problems that have PTASs or EPTASs, their running time has a strong lower bound.

1 Introduction

According to the NP-completeness theory [31], many optimization problems of theoretical interest and practical importance are NP-hard, thus cannot be solved optimally in polynomial time unless $P = NP$. Many approaches have been proposed to cope with the NP-hardness of such problems. The most well studied among these approaches is polynomial time approximation, which involves computing a “good” approximation of an optimal solution in polynomial time.

A notable class of NP-hard optimization problems admits *polynomial time approximation schemes* (PTAS). A PTAS is an algorithm that, for any given instance of an optimization problem and a fixed relative error bound $\epsilon > 0$, produces a solution in polynomial time that is within a ratio $1 + \epsilon$ from being optimal. A large number of NP-hard optimization problems have PTASs, including, based on the recent research, the following well-known problems: Euclidean traveling salesman problem [1, 2], general multiprocessor job scheduling [14, 37], planar Steiner tree [8], planar Steiner forest [5], geometric k-clustering [44], multiple knapsack [11], distinguishing (sub)string selection [24], maximum subforest [55], and k-consensus clustering [18]. In particular, many important graph problems have PTASs on planar graphs and some generalizations of planar graphs, such as vertex cover, independent set, feedback vertex set, longest path, cycle packing, connected vertex cover, graph metric TSP, dominating set, and connected dominating set [20].

The complexity issues of PTAS have received a lot of attention recently. The running time of a general PTAS algorithm of approximation ratio $1 + \epsilon$ can be of the form $O(n^{t(\epsilon)})$, where n is the input size and $t(\epsilon)$ is a function of ϵ . The value of $t(\epsilon)$ can be very large even for moderate values of ϵ . For example, Downey [26] calculated the time complexity of a few well-known PTAS algorithms and showed

that for a moderate error bound of $\epsilon = 20\%$, the running time of these PTASs exceed $n^{10,000}$. Downey [26] gave the following list to illustrate the point:

- Arora [1] gave a PTAS for Euclidean traveling salesman problem with running time $O(n^{3,000/\epsilon})$, which is $O(n^{15,000})$ for $\epsilon = 20\%$.
- Chekuri and Khanna [11] gave a PTAS for multiple knapsack with running time $O(n^{12(\log(1/\epsilon)/\epsilon^8)})$, which is $O(n^{9,375,000})$ for $\epsilon = 20\%$.
- Shamir and Tsur [55] gave a PTAS for maximum subforest with running time $O(n^{2^{2^{1/\epsilon}}-1})$, which is $O(n^{958,267,391})$ for $\epsilon = 20\%$.
- Chen and Miranda [14] gave a PTAS for general multiprocessor job scheduling with running time $O(n^{(3mm!)^{m/\epsilon}+1})$, where m is the number of processors, which is $> O(n^{10^{60}})$ for $\epsilon = 20\%$ and $m = 4$.
- Erlebach et al. [29] gave a PTAS for maximum independent set on geometric graphs with running time $O(n^{4/\pi(1/\epsilon^2+1)^2(1/\epsilon^2+2)^2})$, which is $O(n^{523,804})$ for $\epsilon = 20\%$.

The astronomical growth in the running time of these PTAS algorithms even for a moderate error bound makes them quite infeasible for practical applications. Observing this fact, the class PTAS is further refined in terms of their running time.

A PTAS is referred to as a *fully polynomial time approximation scheme* (FPTAS) if its running time is bounded by a polynomial in both input size and $1/\epsilon$. A notable class of NP-hard optimization problems has FPTASs, including the well-known knapsack, subset-sum, and makespan problem on a fixed number of processors [34]. However, FPTAS does not exist for strongly NP-hard optimization problems unless $P = NP$ [31].

A PTAS is referred to as an *efficient polynomial time approximation scheme* (EPTAS) if the running time of the algorithm is bounded by a polynomial of the input size whose degree is independent of ϵ , that is, in the form $f(\epsilon)n^{O(1)}$, for any function f . EPTAS algorithms are obviously superior to PTAS algorithms of running time of the form $O(n^{t(\epsilon)})$ in the efficiency of the algorithms. In fact, many PTAS algorithms developed for NP-hard optimization problems are actually EPTAS algorithms. Moreover, there are a number of well-known NP-hard optimization problems for which early developed PTAS algorithms had running time of form $O(n^{t(\epsilon)})$, but later were improved to EPTAS algorithms. For example, Arora [2] improved his earlier PTAS algorithm for Euclidean traveling salesman problem [1] to an efficient and practical EPTAS algorithm. The PTAS algorithm for general multiprocessor job scheduling by Chen and Miranda [14] was recently improved by Klaus [37] to an EPTAS algorithm. On the other hand, Cai et al. [10] showed that there are problems that have PTASs but are unlikely to have EPTASs.

This chapter surveys various complexity issues of PTAS. The key questions under consideration are as follows:

What optimization problems have PTASs, FPTASs, and EPTASs, and how efficient are these algorithms?

On the positive side, there are syntactic classes for characterizing PTAS, FPTAS, and EPTAS. Expressing a problem as a member in these classes automatically gives an approximation scheme for the problem. For many graph problems on

planar graphs, there are powerful graph-theory techniques for designing PTASs and EPTASs, which can be extended to some generalizations of planar graphs. On the negative side, there are convincing evidences that, for a large set of NP-hard optimization problems, EPTASs do not exist. For many problems that have PTAS or EPTASs, their running time has a strong lower bound.

The rest of this chapter is organized as follows. [Section 2](#) gives the necessary terms and definitions. [Section 3](#) gives syntactic characterizations of PTAS, FPTAS, and EPTAS. [Section 4](#) discusses the techniques for designing PTAS and EPTAS algorithms. [Section 5](#) presents some recent results on the computational lower bounds of PTAS and EPTAS. The chapter concludes with a summary of the key results in [Sect. 6](#).

2 Preliminary

The problems under consideration in this chapter are NP optimization problem, defined as follows:

Definition 1 An *NP optimization problem* Q is a 4-tuple (I_Q, S_Q, f_Q, opt_Q) , where

- I_Q is the set of input instances. It is recognizable in polynomial time;
- For each instance $x \in I_Q$, $S_Q(x)$ is the set of feasible solutions for x . Given x , $S_Q(x)$ is recognizable in polynomial time.
- $f_Q(x, y)$ is the objective function mapping a pair $x \in I_Q$ and $y \in S_Q(x)$ to a nonnegative integer. The function f_Q is computable in polynomial time.
- $opt_Q \in \{\max, \min\}$. Q is called a *maximization problem* if $opt_Q = \max$ and a *minimization problem* if $opt_Q = \min$.

An *optimal solution* y for an instance $x \in I_Q$ of an optimization problem Q is a feasible solution in $S_Q(x)$ such that $f_Q(x, y)$ is optimized (maximized or minimized depending on opt_Q) among all solutions in $S_Q(x)$. Denote by $opt_Q(x)$ the value of $f_Q(x, y)$ for any optimal solution y to the instance x of the problem Q .

An algorithm A is an *approximation algorithm* for an optimization problem Q if, for any input instance x in I_Q , the algorithm A returns a feasible solution y in $S_Q(x)$. The approximation algorithm A has an *approximation ratio* r if for any instance x in I_Q , the solution y constructed by the algorithm A approximates $opt_Q(x)$ by a factor of r , that is

- $opt_Q(x)/f_Q(x, y) \leq r$ if Q is a maximization problem.
- $f_Q(x, y)/opt_Q(x) \leq r$ if Q is a minimization problem.

An optimization problem Q has a *polynomial time approximation scheme* (PTAS) if there is an algorithm A_Q that takes a pair (x, ϵ) as input, where $x \in I_Q$ is an instance of Q and $\epsilon > 0$ is a real number, and returns a feasible solution $y \in S_Q(x)$ for x such that the approximation ratio of the solution y is bounded by $1 + \epsilon$, and for any fixed $\epsilon > 0$, the running time of the algorithm A_Q is bounded by a polynomial in $|x|$ (but not necessarily a polynomial in $1/\epsilon$). A PTAS algorithm A_Q is called an FPTAS algorithm if the running time of A_Q is bounded by a polynomial

in both $|x|$ and $1/\epsilon$. A PTAS algorithm A_Q is called an EPTAS algorithm if the running time of A_Q is bounded by a polynomial in $|x|$ whose degree is independent of ϵ .

Throughout this chapter, a well-known NP optimization problem planar maximum independent set (planar MIS) is used to illustrate the complexity issues of PTAS. In planar MIS, one is given a planar graph and is asked to find a maximum set of vertices in the graph that do not induce any edge. The formal definition is given as follows:

Planar MIS

- I_Q : the set of planar graphs $G = (V, E)$.
- S_Q : $S_Q(G)$ is the collection of all independent sets in G , where an *independent set* of a graph G is a subset of vertices of G in which no two vertices are adjacent.
- f_Q : $f_Q(G, D)$ is equals to the number of vertices in the independent set D in G .
- opt_Q : \max .

Planar MIS is an NP optimization problem because one can easily verify that the size of any independent set of a graph $G = (V, E)$ is bounded by $|V|$, the set of planar graphs and the independent sets of planar graphs are recognizable in polynomial time, and the number of vertices in an independent set is computable in polynomial time. It is straightforward to prove that planar MIS is NP-hard since the decision version of planar MIS is NP-complete [31].

For an instance $G \in I_Q$ of planar MIS, an optimal solution is a maximum independent set in G . An approximation algorithm A for Planar MIS will return an independent set D of G . Since planar MIS is a maximization problem, the approximation ratio of A is $opt_Q(G)/f_Q(G, D)$, where $opt_Q(G)$ is the size of a maximum independent set of G and $f_Q(G, D)$ is the size of D . A PTAS for planar MIS is an algorithm which takes an instance $G \in I_Q$ and an error bound $\epsilon > 0$ and in polynomial time returns an independent set D of G whose size is $\geq opt_Q(G)/(1 + \epsilon)$.

Many complexity issues of PTAS are closely related to the *parameterized complexity theory*. Parameterized complexity theory [27] is a approach of dealing with NP optimization problems. In contrast to the traditional computational complexity theory that measures the complexity in terms of input size, parameterized complexity theory studies the computational complexity of optimization problems in terms of *both* instance size *and* a properly selected parameter. Parameterized complexity theory has drawn considerable attention because of its applications in developing practical algorithms. More recently, parameterized complexity theory has been used to obtain both positive and negative results on the approximability of NP-hard optimization problems.

A brief review of the terminologies in parameterized complexity is given in the following. For more details, see [27].

A *parameterized problem* Q , formally interpreted as a language, is a subset of $\Omega^* \times N$, where Ω is a finite alphabet set and N is the set of nonnegative integers. Each instance of Q is a pair (x, k) , where the nonnegative integer k is called the *parameter*. The parameterized problem Q is *fixed-parameter tractable* [27] if there

is an algorithm that decides whether an input (x, k) is a yes instance of Q in time $f(k)|x|^{O(1)}$, where f is an arbitrary function. FPT is the class of all fixed-parameter tractable problems.

The inherent difficulty for efficiently solving certain problems even in the presence of small parameters has led to the common belief that certain parameterized problems are not fixed-parameter tractable. A parameterized intractability hierarchy, the W -hierarchy $\bigcup_{t \geq 0} W[t]$, has been introduced and studied, where $W[t] \subseteq W[t+1]$ for all $t \geq 0$. The class FPT of fixed-parameter tractable problems lies at the bottom of the W -hierarchy (the 0th level). The classes $W[t]$, for $t \geq 1$, capture the levels of parameterized intractability of parameterized problems. The notion of W -hardness is defined under FPT reductions for those classes. A parameterized problem Q is $W[h]$ -hard if every parameterized problem in $W[h]$ is FPT -reducible to Q .

A large number of $W[1]$ -hard parameterized problems have been identified [27] including many important NP-hard problems such as INDEPENDENT SET, CLIQUE, DOMINATING SET, and SET COVER. Now it is commonly accepted that no $W[1]$ -hard problem is fixed-parameter tractable [27], and $W[1] \neq FPT$ has become a standard hypothesis in parameterized complexity. Some of the recent results on the lower bounds of the running time of approximation schemes were obtained based on this hypothesis [10, 15].

There is an essential difference between approximation problems and parameterized problems: an approximation problem requires a solution for a given instance of the problem, while a parameterized problem only seeks a “yes/no” decision on an input. To make a meaningful comparison between approximability and parameterized complexity, a formal procedure is introduced to *parameterize* an optimization problem.

Definition 2 Let $Q = (I_Q, S_Q, f_Q, opt_Q)$ be an NP optimization problem.

- If $opt_Q = \max$, then the *parameterized version* of Q is $Q_{para} = \{(x, k) \mid x \in I_Q, opt_Q(x) \geq k\}$.
- If $opt_Q = \min$, then the *parameterized version* of Q is $Q_{para} = \{(x, k) \mid x \in I_Q, opt_Q(x) \leq k\}$.

For example, the parameterized version of planar MIS is characterized by a set Q_{para} of tuples (G, k) , where G is a planar graph and k is an integer, satisfying the condition that the size of an maximum independent set of G is $opt_Q(G) \geq k$.

The above definition offers the possibility to study the relationship between the approximability and the parameterized complexity of NP optimization problems.

3 Syntactic Characterizations of PTAS

Approximability of optimization problems has been studied in terms of their syntactic descriptions. Earlier, Papadimitriou, and Yannakakis [45] introduced the syntactic classes MAXNP and MAXSNP of optimization problems.

Khanna et al. [39] showed that, under proper approximation-ratio-preserving reductions, MAXSNP captures APX, the class of NP optimization problems that can be approximated in polynomial time with constant approximation ratios. Following this important discovery, syntactic characterizations of PTAS, FPTAS, and EPTAS have been studied. This section surveys the main results along this line of research.

3.1 Characterization of PTAS

Khanna and Motwani [38] attempted to characterize PTAS by syntactic classes restricted to instances with a “planar structure.” They introduced three syntactic classes – Planar TMAX, Planar TMIN, and Planar MPSAT – to characterize PTAS. These classes are defined on disjunctive normal form (DNF) formulas, where each DNF formula is a disjunction of conjunctions (sum of products) over n Boolean variables. Both the formulas and the variables are weighted.

Definition 3 (TMAX) The class TMAX consists of NP optimization problems expressible as: given a collection C of DNF formulas whose input literals are all negative, find a maximum weight truth assignment T that satisfies each formula in C .

Definition 4 (TMIN) The class TMIN consists of NP optimization problems expressible as: given a collection C of DNF formulas whose input literals are all positive, find a minimum weight truth assignment T that satisfies each formula in C .

Definition 5 (MPSAT) The class MPSAT consists of NP optimization problems expressible as: given a collection C of DNF formulas, find a truth assignment T of weight at most W that maximizes the total weight of the satisfied formulas in C .

For any instance I in TMAX, TMIN, or MPSAT, the incidence graph of I is a bipartite graph that has a vertex for each variable and a vertex for each formula and an edge between them if the variable occurs in the formula. The class Planar TMAX, Planar TMIN, and Planar MPSAT are TMAX, TMIN, and MPSAT, respectively, restricted to instances with planar incidence graphs.

Khanna and Motwani [38] proved that:

Theorem 1 *Problems in Planar MPSAT, Planar TMAX, and Planar TMIN have PTASs.*

To illustrate the application of these syntactic classes, consider our recurring example of planar MIS. Planar MIS can be expressed by Planar TMAX as follows. Let G be a planar graph. Encode each vertex as a variable. Insert a vertex in the middle of each edge $e = (x, y)$ in G and label it by the formula $(\bar{x} \vee \bar{y})$. The resulting graph is the planar incidence graph of an instance in Planar TMAX. By Theorem 1, it follows that planar MIS has a PTAS.

3.2 Characterization of FPTAS

Since the early results on FPTAS for NP optimization problems [36, 54], researchers have been trying to characterize problems in FPTAS [3, 46, 56]. Earlier results in this research [3, 46] characterized the class FPTAS by certain polynomial time computable functions, but these results did not provide information on how to decide whether such functions exist for a given problem and how to develop an FPTAS for the problem (e.g., see [46]). A more recent approach by Woeginger [56] focused on problems that have a dynamic programming formulation. He showed that as long as such a problem satisfies certain structural conditions, the problem has FPTAS. However, Woeginger's characterization [56] only provides a necessary condition for problems with FPTASs.

Chen et al. [17] provided a stronger characterization. They showed that for NP optimization problems that are “scalable,” the notion of FPTAS is equivalent to a subclass of FPT.

Recall that a fixed-parameter tractable problem has an algorithm of running time of the form $f(k)|x|^{O(1)}$, where f is an arbitrary recursive function. The following is a subclass of FPT that requires the function $f(k)$ to be a polynomial.

Definition 6 An NP optimization problem Q is *polynomial fixed-parameter tractable* (PFPT) if its parameterized version is solvable in time $O(k^{O(1)}|x|^{O(1)})$.

Note that polynomial fixed-parameter tractability does not necessarily imply polynomial time computability because an NP optimization problem Q may have its optimal value $opt_Q(x)$ much larger than the instance size $|x|$. Cai and Chen [9] proved that every FPTAS problem is fixed-parameterized tractable. Their proof in fact shows that every FPTAS problem is in the class PFPT.

Chen et al. [17] showed that the condition PFPT actually coincides with the condition FPTAS when an NP optimization problem is “scalable” in the following sense.

Definition 7 An optimization problem $Q = (I_Q, S_Q, f_Q, opt_Q)$ is *scalable* if there are polynomial time computable functions g_1 and g_2 and a fixed polynomial q such that:

- For any instance $x \in I_Q$, and any integer $d \geq 1$, $x_d = g_1(x, d)$ is an instance of Q such that $|x_d| \leq q(|x|)$ and $|opt_Q(x_d) - opt_Q(x)/d| \leq q(|x|)$.
- For any solution y_d to the instance x_d , $y = g_2(x_d, y_d)$ is a solution to the instance x such that $|f_Q(x_d, y_d) - f_Q(x, y)/d| \leq q(|x|)$.

The property of scalability comes naturally for many NP optimization problems. Take $Q = \text{MAKESPAN}$ as an example. An instance x of MAKESPAN consists of n jobs with integral processing times t_1, t_2, \dots, t_n , respectively, and an integer m , the number of identical processors, and the problem is to schedule the jobs on the m processors so as to minimize the completion time (i.e., the *makespan*). For a given

instance $x = (t_1, t_2, \dots, t_n; m)$ of MAKESPAN and a given integer $d \geq 0$, the scaled instance is

$$x_d = (t'_1, t'_2, \dots, t'_n; m),$$

where $t'_i = \lceil t_i/d \rceil$ for $i = 1, 2, \dots, n$. So x_d is also an instance for MAKESPAN. A solution y_d for x_d is a partitioning of the jobs in x_d among the m processors: $y_d = (T'_1, \dots, T'_m)$, where T'_i is the set of jobs in x_d that are assigned to the i -th processor. The corresponding solution $y = (T_1, \dots, T_m)$ for x is the same partitioning (in terms of index) of the jobs in x among the m processors. Note that the makespan of y is equal to $\max_i \{\sum_{t_j \in T_i} t_j\}$, and the makespan of y_d is equal to $\max_i \{\sum_{t'_j \in T'_i} t'_j\}$. Thus

$$\begin{aligned} f_Q(x_d, y_d) &= \max_i \left\{ \sum_{t'_j \in T'_i} t'_j \right\} = \max_i \left\{ \sum_{t_j \in T_i} \lceil t_j/d \rceil \right\} \\ &\geq \max_i \left\{ \sum_{t_j \in T_i} t_j/d \right\} = \max_i \left\{ \sum_{t_j \in T_i} t_j \right\} / d \\ &= f_Q(x, y)/d, \end{aligned} \tag{1}$$

and

$$\begin{aligned} f_Q(x_d, y_d) &= \max_i \left\{ \sum_{t'_j \in T'_i} t'_j \right\} = \max_i \left\{ \sum_{t_j \in T_i} \lceil t_j/d \rceil \right\} \\ &\leq \max_i \left\{ \sum_{t_j \in T_i} (t_j/d + 1) \right\} \leq \max_i \left\{ \sum_{t_j \in T_i} t_j \right\} / d + n \\ &= f_Q(x, y)/d + n. \end{aligned} \tag{2}$$

It follows from Eqs. (1) and (2) that $|f_Q(x_d, y_d) - f_Q(x, y)/d| \leq n$. Similarly, it can be verified that the instances x and x_d satisfy $|opt_Q(x_d) - opt_Q(x)/d| \leq n$. The mappings from x to x_d and from y_d to y are computable in polynomial time. This verifies that MAKESPAN is scalable.

Chen et al. [17] proved that a “scalable” NP optimization problem is in PFPT if and only if it has FPTAS.

Theorem 2 ([17]) *Let Q be a scalable NP optimization problem. Then Q has an FPTAS if and only if Q is in PFPT.*

In general, the scalability property of an NP optimization problem can be checked in a straightforward manner, as shown above for MAKESPAN. To design

an FPTAS for a scalabe NP optimization problem, one can start by developing an PFPT algorithm for the parameterized version of the problem and then convert the PFPT algorithm into an FPTAS algorithm, following a simple procedure given in [17].

3.3 Characterization of EPTAS

As mentioned in Sect. 3.1, Khanna and Motwani [38] tried to capture the class PTAS by imposing a planar structure on syntactic classes TMAX, TMIN, and MPSAT. In a parallel approach to that of Khanna and Motwani [38], Chen et al. [17] tried to characterize EPTAS by imposing a planar structure on the W -hierarchy in parameterized complexity.

The W -hierarchy has been defined based on satisfiability problems on bounded-depth circuits of a special leveled form: all inputs are in level 0, all AND and OR gates are organized into alternating levels, and edges only going from a level to the next level [13]. The *depth* of a node v is d if v is at the d -th level. The *depth* of a circuit is d if its output node has depth d . A circuit is a Π_h -circuit if it has depth h and its output node is an AND gate. The *weight* of a truth assignment T is the number of variables that are TRUE. A Π_h -circuit is a Π_h^+ -circuit if all of its inputs are labeled by positive literals and is a Π_h^- -circuit if all of its inputs are labeled by negative literals. A Π_h -circuit α is *planar* if α becomes a planar graph after removing the output gate in α .

Chen et al. [17] defined the following syntactic optimization classes:

Definition 8 (Planar MIN- $W[h]$) The class Planar MIN- $W[h]$ consists of optimization problems Q such that each instance of Q can be expressed as a planar Π_h^+ -circuit α , and the problem is to look for a truth assignment of minimum weight that satisfies α .

Definition 9 (Planar MAX- $W[h]$) The class Planar MAX- $W[h]$ consists of optimization problems Q such that each instance of Q can be expressed as a planar Π_h^- -circuit α , and the problem is to look for a truth assignment of maximum weight that satisfies α .

Definition 10 (Planar $W[h]$ -SAT) The class Planar $W[h]$ -SAT consists of optimization problems Q such that each instance of Q can be expressed as a planar Π_h -circuit α , and the problem is to look for a truth assignment that satisfies the largest number of depth- $(h - 1)$ gates in the circuit α .

Note that the classes Planar MIN- $W[h]$, Planar MAX- $W[h]$, and Planar $W[h]$ -SAT are the planar versions of the problem $wcs(h)$, which is the representative problem for the h -th level $W[h]$ of the W -hierarchy in parameterized complexity theory [27].

The class Planar $W[h]$ -SAT captures the optimization problems where the objective is to construct a solution that satisfies the maximum number of constraints. The classes Planar MIN- $W[h]$ and Planar MAX- $W[h]$ capture the optimization problems where the objective is to construct an optimal (minimum or maximum) solution that satisfies all the constraints. Together, Planar MIN- $W[h]$, Planar MAX- $W[h]$, and Planar $W[h]$ -SAT capture many optimization problems on planar graphs.

Based on dynamic programming techniques similar to those in the Baker's approach [4] (discussed in Sect. 4.3), Chen et al. [17] showed that:

Theorem 3 *All optimization problems in the syntactic classes Planar MIN- $W[h]$, Planar MAX- $W[h]$, and Planar $W[h]$ -SAT have EPTAS.*

Take planar MIS as an example. An instance G of planar MIS can be converted into a planar Π_2^- -circuit α_G as follows: make each vertex v in G an input \bar{v} of α_G , replace each edge (v, w) in G by an OR gate with the two inputs \bar{v} and \bar{w} , and connect the OR gate to the unique output AND gate of the circuit α_G . It is easy to see that the circuit α_G is planar and the maximum independent sets of the graph G correspond to the maximum weight assignments that satisfy the circuit α_G . This means that planar MIS is in planar max- $W[2]$, and by Theorem 3, planar MIS has an EPTAS.

4 Techniques for Designing PTAS Algorithms

The main techniques for designing FPTAS include pseudo-polynomial time algorithms and approximation by scaling. These techniques will be demonstrated by the knapsack problem.

Many NP-hard graph problems become more tractable when the underlying graphs are planar, that is, can be drawn in the plane without edge crossing. For example, although maximum independent set on general graphs is unlikely to be approximable within $|V|^{1-\epsilon}$ for any $\epsilon > 0$ [33], the planar version of the problem, Planar MIS, has EPTAS. There are powerful graph-theory techniques for developing PTASs for a broad range of problems on planar graphs and some generalizations of planar graphs.

The two main techniques of designing PTAS algorithms for problems on planar graphs are Lipton-Tarjan's graph separators [41] and Baker's layerwise decomposition [4]. These techniques have been enhanced and generalized by bidimensionality theory [20] to obtain EPTASs for many problems on a broad family of graphs.

4.1 Techniques for Designing FPTAS Algorithms

In this subsection, major techniques for designing FPTAS algorithms are presented, which include pseudo-polynomial time algorithms and approximation by scaling.

The techniques are demonstrated with the knapsack problem, which is defined as follows:

Knapsack

I_Q : tuples $x = \langle s_1, \dots, s_n; v_1, \dots, v_n; B \rangle$, where s_i, v_j, B are integers.

S_Q : $S_Q(x)$ is all sets $S \subseteq \{1, \dots, n\}$ such that $\sum_{i \in S} s_i \leq B$.

f_Q : $f_Q(x, S) = \sum_{i \in S} v_i$.

opt_Q : \max .

In other words, the goal of the knapsack problem is to take the maximized value with a knapsack of size B , given n items of size s_i and value v_i , $1 \leq i \leq n$. For a subset $S \subseteq \{1, \dots, n\}$, $\sum_{i \in S} s_i$ is referred to as the *size* of S and $\sum_{i \in S} v_i$ the *value* of S .

There is a classic dynamic programming algorithm *Knapsack-Dyn* for solving the knapsack problem, which works as follows. Let $V = \sum_{i=1}^n v_i$. For each index i , $1 \leq i \leq n$ and for each value $v \leq V$, consider the following question:

Question $K(i, v)$

Is there a subset S of $\{1, \dots, i\}$ such that the size of S is at most B and the value of S is equal to v ?

The answer to question $K(i, v)$ is “yes” if and only if at least one of the following two cases is true:

1. There is a subset S' of $\{1, \dots, i-1\}$ such that the size of S' is at most B and the value of S' is equal to v (in this case $S = S'$).
2. There is a subset S'' of $\{1, \dots, i-1\}$ such that the size of S'' is at most $B - s_i$ and the value of S'' is equal to $v - v_i$ (in this case $S = S'' \cup i$).

Therefore, the answer to the question $K(i, v)$ can be obtained if the answers to the questions $K(i-1, v')$ for all values v' are known. Using dynamic programming, the algorithm *Knapsack-Dyn* starts with answers to $K(0, v)$ which are always “no” for $v > 0$ and “yes” for $K(0, 0)$. The answers to $K(i, v)$ for $i > 0$ then are inductively computed based on the answers to $K(i-1, v')$ for all $0 \leq v' \leq V$. The solution to the knapsack problem corresponds to the largest value v such that $K(n, v)$ is “yes.”

The *Knapsack-Dyn* algorithm runs in time $O(nV)$ where $V = \sum_{i=1}^n v_i$. Unfortunately, since the value V can be larger than any polynomial of n , *Knapsack-Dyn* is not a polynomial time algorithm in terms of the input length n .

In fact, *Knapsack-Dyn* represents a typical method for solving a class of optimization problems.

Definition 11 Let $Q = (I_Q, S_Q, f_Q, opt_Q)$ be an optimization problem. An algorithm A solving Q runs in *pseudo-polynomial time* if the running time of the algorithm A is bounded by a polynomial in $\text{length}(x)$ and $\max(x)$, where $\text{length}(x)$ is the length of the binary representation of x and $\max(x)$ is the largest number that appears in the input x . In this case, we say that the problem Q is solvable in pseudo-polynomial time.

For the knapsack problem, $V = \sum_{i=1}^n v_i \leq n \cdot \max(x)$. So *Knapsack-Dyn* is a pseudo-polynomial time algorithm for knapsack. In other words, knapsack is solvable in pseudo-polynomial time.

The *Knapsack-Dyn* algorithm can be turned into an approximation algorithm for knapsack that runs in polynomial time. This involves *scaling*: dividing each value v_i by a sufficiently large number K so that $v'_i = \lfloor v_i/K \rfloor$. In doing so, V is scaled down to $V' = V/K$. By selecting a sufficiently large $K > V/(cn^d)$ for some constant c and d , *Knapsack-Dyn* runs in time $O(cn^{d+1})$, a polynomial in n . However, one has to pay a price for “scaling”: because of the floor operation $\lfloor \cdot \rfloor$, one loses precision; an optimal solution for the scaled instance may not be an optimal solution for the original instance. Furthermore, the larger the value K , the better the running time of the *Knapsack-Dyn* algorithm, but also the more precision would be lost. By carefully selecting the value of K (e.g., $K = V/[(1 + 1/\epsilon)n^2]$), it can be shown that while still keeping the running time of the algorithm *Knapsack-Dyn* polynomial of n , one can also bound the approximation ratio to $1 + \epsilon$. This procedure is summarized in the following theorem.

Theorem 4 *For any input instance α of the knapsack problem and for any real number $\epsilon > 0$, there is an approximation algorithm that runs in time $O(n^3/\epsilon)$ and produces a solution to α with approximation ratio bounded by $1 + \epsilon$.*

4.2 Lipton and Tarjan’s Approach of Planar Separators

Lipton and Tarjan [40] in a celebrated paper proved that a planar graph G has a separator of $O(\sqrt{n})$ vertices that separates the graph into two subgraphs of roughly the same size. More precisely, they proved the following theorem.

Theorem 5 *The vertices of a planar graph $G = (V, E)$ can be partitioned into three sets A , B , and S such that*

1. *S contains no more than $\sqrt{8n}$ vertices.*
2. *Neither A nor B contains more than $2n/3$ vertices.*
3. *Vertices in A are not adjacent to vertices in B .*

Moreover, there is an $O(n)$ -time algorithm that, given a planar graph G , constructs the triple (A, B, C) as above.

Taking advantage of such a separator, Lipton and Tarjan [41] developed an approach for designing PTAS for certain problems on planar graphs. In this approach, one partitions a planar graph into three sets A , B , and S as mentioned above, then recursively approximates the solutions on the smaller subgraphs induced by A and B , and finally combine the approximated solutions to the subgraphs into an approximated solution to the original graph.

For this approach to work, the optimal solution of the problem has to be large enough (in the order of $\Theta(n)$) such that the combining process does not increase the approximation ratio. Furthermore, the trade-off between the time complexity and the approximation ratio offered by the Lipton and Tarjan’s separator approach is often unfavorable. A small or moderate approximation ratio could entail a very high time complexity, making the approach infeasible for practical applications.

Let us briefly describe how to apply Lipton and Tarjan's approach to planar MIS (for more details, see [12, 41]). Given a planar graph G of n vertices, one finds a separator S that splits G into two subgraphs A and B each containing no more than $2n/3$ vertices. Recursively split A and B until the number of vertices in each connected component is bounded by a function of ϵ (e.g., $O(1/\epsilon^2)$). Find a maximum independent set in each connected component by brute force. The union of the independent sets of the components yields an independent set of G . The details of the algorithm is given in the following.

Algorithm PlanarIndSet

Input: a planar graph $G = (V, E)$ and a constant ϵ

Output: an independent set D of G

1. If $(|V| \leq K)$ where $K = O(1/\epsilon^2)$ to be determined later, **then**
find a maximum independent set D in G by exhaustive search;
return D .
 2. Partition V into (A, B, S) as in [Theorem 5](#)
 3. Recursively call **PlanarIndSet** on the subgraph G_A induced by A to find an independent set D_A and recursively call **PlanarIndSet** on the subgraph G_B induced by B to find an independent set D_B .
 4. Return $D_A \cup D_B$.
-

The running time of the **PlanarIndSet** algorithm is dominated by the time spent on solving all connected components by brute force, which is polynomial in n for any fixed constant ϵ .

Let F be the set of vertices in the separators constructed by **PlanarIndSet**. Let $opt(G)$ be the size of the maximum independent set of G . One verifies the following:

Fact 1. $n/4 \leq opt(G) \leq |D| + |F|$.

Fact 2. $|F| \leq cn/\sqrt{K}$ for some constant c .

Thus, the approximation ratio of **PlanarIndSet** is

$$\begin{aligned}
\frac{opt(G)}{|D|} &\leq \frac{|D| + |F|}{|D|} \\
&= 1 + \frac{|F|}{|D|} \\
&\leq 1 + \frac{|F|}{opt(G) - |F|} \\
&\leq 1 + \frac{|F|}{n/4 - |F|} \\
&\leq 1 + \frac{cn/\sqrt{K}}{n/4 - cn/\sqrt{K}} \\
&= 1 + \frac{1}{\frac{\sqrt{K}}{4c} - 1}.
\end{aligned} \tag{3}$$

Set $K = (4c)^2(1+1/\epsilon)^2$ and from Eq. (3), $\frac{opt(G)}{|D|} \leq 1+\epsilon$, that is, the approximation ratio of **PlanarIndSet** is $(1 + \epsilon)$. This yields a PTAS for planar MIS (it is in fact an EPTAS). However, this algorithm is hardly practical even for moderate values of ϵ . For example, an analysis by [12] shows that the running time is $O(n \log n + 2^{5184(1+1/\epsilon)^2} n)$.

4.3 Baker's Approach of Layerwise Decomposition

A later approach by Baker [4] is based on layerwise decomposition of plane graphs (i.e., a planar graph embedded in the plane) into k -outerplanar subgraphs and dynamic programming techniques. Baker observed that the vertices of an embedded plane graph G can be arranged in a layered structure as follows:

The vertices on the outer face of G give the first layer. By peeling the first layer, i.e., removing the vertices in the first layer, one obtains a plane subgraph G' of G (which may have more than one connected components). Now the first layer of G' forms the second layer for G . By peeling the second layer of G , one obtains the third layer, and so on.

For any given $0 \leq i < k$, after the vertices in layers $i, i+k, i+2k, \dots$ are removed, the plane graph is divided into a set of subgraphs each of which has at most k layers and becomes a k -outerplanar graph. A k -outerplanar graph has a bounded treewidth, and hence many NP-hard graph problems can be solved in polynomial time on a k -outerplanar graph by dynamic programming. The final solution is constructed from the solutions to the subgraphs. After trying at most k different values of i , one can find a solution which is at least $(1 + 1/k)$ -optimal. By adjusting the value of k , the algorithm can approximate the optimal solution to within ratio $1 + \epsilon$ for any $\epsilon > 0$ in time $2^{O(1/\epsilon)} n^{O(1)}$, which yields an EPTAS. Eppstein [28] has generalized Baker's approach to work on graphs of bounded local treewidth.

Baker [4] demonstrated her approach by applying it to planar MIS. The result was an $O(8^{1/\epsilon} n/\epsilon)$ -time EPTAS for planar MIS, which is much more efficient than the PTAS obtained from Lipton and Tarjan's approach.

4.4 Bidimensionality Theory

Recently, a meta-algorithmic framework called *bidimensionality theory* has received a lot of attention. Bidimensionality theory was introduced by Demaine et al. [19] to develop subexponential-time parameterized algorithms for problems on H -minor-free graphs (graphs exclude any fixed minor). Bidimensionality theory has subsequently been used by Demaine and Hajiaghayi [20] to obtain EPTASs for bidimensional problems. Recently, Fomin et al. [30] have used it to derive linear kernels for bidimensional problems [30]. Bidimensionality seems to capture the core of those problems that become more tractable on planar graphs.

Bidimensionality theory provides powerful algorithmic techniques for a broad range of bidimensional problems on planar graphs and some generalizations of

planar graphs, including bounded genus graphs and H -minor-free graphs. A brief definition of bidimensionality is given below. For the exact definition, see [22].

Definition 12 A parameterized graph problem is *bidimensional* if (1) the parameter is $\Omega(r^2)$ on an $r \times r$ “grid-like” graph, and (2) the parameter does not increase when an edge of the graph is contracted (or deleted in some cases).

Examples of bidimensional problems include natural problems such as vertex cover, independent set, feedback vertex set, longest path, cycle packing, connected vertex cover, graph metric TSP, dominating set, and connected dominating set.

The algorithmic applications of bidimensional theory build on the deep theory of graph minor by Robertson and Seymour [47–53]. In particular, there are two key structural results that link bidimensionality with its algorithmic applications.

Theorem 6 ([21, 23]) Every H -minor-free graph of treewidth w has an $\Omega(w) \times \Omega(w)$ grid as a minor.

Theorem 7 ([21]) If the parameterized version of a graph optimization problem Q is bidimensional, then for every graph G in the associated graph family, the treewidth of G is bounded by $O\left(\sqrt{\text{opt}_Q(G)}\right)$.

Based on the above structural results and by enhancing and generalizing techniques from Lipton-Tarjan’s planar separator [41] and Baker’s layerwise decomposition [4], Demaine and Hajiaghayi proved that:

Theorem 8 ([20]) There is an $(1 + \epsilon)$ -approximation scheme with running time $h(1/\epsilon)n^{O(1)}$ for any bidimensional optimization problem that (1) is computable in $h(w)n^{O(1)}$ on a graph of treewidth w , (2) has a constant ratio approximation, and (3) satisfies the following separation properties:

- The optimal solution on disconnected components equals to the union of the optimal solution of each connected component.
- Let C be a separator, and let X be the union of some connected components in $G - C$. The optimal solution to $G - X$ and the optimal solution to $G - X - C$ differ by $O(|C|)$ in size.
- The optimal solution to G induced on X and the optimal solution to X differ by $O(|C|)$ in size.

As a corollary, it follows that:

Corollary 1 ([20]) Bidimensional problems that satisfy the properties (1)–(3) listed above have EPTASS on planar graphs and some generalizations of planar graphs.

Usually, it is easy to verify bidimensionality of a given problem. Take planar MIS as an example. In the parameterized version of the problem, one is given a planar

graph G and a parameter k and is asked if there is an independent set S of at least k vertices. Planar MIS is bidimensional:

- For an $r \times r$ “grid-like” planar graph, the size of the maximum independent set is at least $\Omega(r^2)$ because of the four-color theorem.
- Contracting an edge of G does not increase the size of the maximum independent set of G .

It is easy to verify that planar MIS satisfies the separation properties. Furthermore, planar MIS can be solved on a graph of treewidth k in time $O(2^k n)$ [7], and planar MIS has a simple constant ratio approximation from five-coloring the planar graph. It follows from Corollary 1 that planar MIS has an EPTAS. The same techniques prove that maximum independent set has an EPTAS on apex-minor-free graphs, which are generalizations of planar graphs.

5 Computational Lower Bounds for PTAS

In this section, negative aspects of the complexity of PTAS are discussed. The emphasis is placed on deriving computational lower bounds on approximation schemes for NP-hard optimization problems.

5.1 Problems That Do Not Have FPTAS

First, many NP-hard optimization problems do not have FPTAS unless $P = NP$.

Definition 13 An NP-hard optimization problem Q is said to be NP-hard in the strong sense (strongly NP-hard) if the problem remains NP-hard when all of its parameters are polynomially bounded in the input size.

Theorem 9 ([31]) *If an optimization problem Q is strongly NP-hard, then Q does not have a fully polynomial time approximation scheme unless $P = NP$.*

It is easy to see that planar MIS is strongly NP-hard because all parameters are polynomially bounded. Thus, by Theorem 9, planar MIS does not have an FPTAS unless $P = NP$.

5.2 Problems That Do Not Have EPTAS

As mentioned in the Introduction, the running time of a PTAS can be quite infeasible for practical applications. On the other hand, the complexity of EPTAS is much more manageable. So the question is

Does every problem that admits a PTAS also has an EPTAS?

To this question, the answer is “very unlikely.”

Theorem 10 ([6, 9]) *If an optimization problem Q has an EPTAS, then the parameterized version of the problem is fixed-parameter tractable.*

Proof Let $Q = (I_Q, S_Q, f_Q, \text{opt}_Q)$ be a minimization problem. Let A be an EPTAS algorithm for Q that runs in time $f(\epsilon)n^{O(1)}$ for some function f . Let $Q_{\text{para}} = \{(x, k) \mid x \in I_Q, \text{opt}_Q(x) \leq k\}$ be the parameterized version of Q . Consider the following algorithm A_{para} for Q_{para} :

Algorithm A_{para} :

On an instance (x, k) of Q_{para} , call the EPTAS algorithm A on x and $\epsilon = 1/(k+1)$. Suppose that A returns a solution y in $S_Q(x)$. If its value is $f_Q(x, y) \leq k$, then return “yes”; otherwise, return “no.”

The approximation ratio of A_{para} is $\epsilon = 1/(k+1)$. So

$$1 \leq f_Q(x, y)/\text{opt}_Q \leq 1 + \frac{1}{k+1}. \quad (4)$$

If $f_Q(x, y) \leq k$, then

$$\text{opt}_Q \leq f_Q(x, y) \leq k,$$

and hence (x, k) is a “yes” instance of Q_{para} . If $f_Q(x, y) \geq k+1$, then by Eq. (4),

$$\text{opt}_Q \geq \frac{k+1}{k+2} \cdot f_Q(x, y) \geq \frac{k+1}{k+2} \cdot (k+1) > k$$

and hence (x, k) is a “no” instance of Q_{para} . Therefore, A_{para} is an algorithm for Q_{para} with running time $f(1/(k+1))n^{O(1)}$. This means that Q_{para} is fixed-parameter tractable. A similar argument applies when Q is a maximization problem. \square

Under the widely believed hypothesis that $W[1] \neq FPT$, this suggests that if the parameterized version of an optimization problem Q is $W[1]$ -hard, then Q does not have an EPTAS.

Take Planar TMIN as an example. Planar TMIN is one of the syntactic classes introduced by Khanna and Motwani [38] to characterize PTAS. So, Planar TMIN has a PTAS. Cai et al. [10] proved that the problem is $W[1]$ -hard and hence does not have EPTAS unless $W[1]=FPT$. Similarly, Cai et al. [10] showed that Planar TMAX and Planar MPSAT are $W[1]$ -hard and hence have no EPTAS unless $W[1]=FPT$.

As another example, Hunt et al. [35] gave an $n^{O(1/\epsilon)}$ -time PTAS for maximum independent set on unit disk graphs. Marx [42] showed that the parameterized version of maximum independent set is $W[1]$ -complete for the intersection graphs of unit disks and axis-parallel unit squares in the plane, and hence maximum independent set on unit disk graphs does not have an EPTAS.

5.3 Lower Bounds on the Running Time of PTAS

Suppose that a problem Q has PTAS but does not have EPTAS from [Theorem 10](#). But this does not answer the following question:

Is there a PTAS for Q whose running time is moderately exponential in $1/\epsilon$, for example, in the form of $f(1/\epsilon)n^{o(1/\epsilon)}$?

Answering this question, Chen et al. [15] gave strong lower bounds on the running time of PTAS. Their lower bounds are based on the widely believed *Exponential Time Hypothesis* (ETH) which states that n -variable 3SAT cannot be solved in subexponential time $2^{o(n)}$. Chen et al. [15] defined a subclass of W[1]-hard, called $W_l[1]$ -hard, consisting of problems that are W[1]-hard under *linear FPT reductions*: FPT reductions where the parameters before and after the reduction are linearly related. They proved the following lower bounds for $W_l[1]$ -hard parameterized problems.

Theorem 11 ([16]) *No $W_l[1]$ -hard parameterized problem can be solved in time $f(k)n^{o(k)}$ for any function f , unless ETH fails.*

From [Theorem 11](#), they prove the following theorem about the nonexistence of PTAS for optimization problems whose parameterized versions are $W_l[1]$ -hard.

Theorem 12 ([16]) *Let Q be an optimization problem. If the parameterized version of Q is $W_l[1]$ -hard, then Q has no PTAS of running time $f(1/\epsilon)n^{o(1/\epsilon)}$ for any function f , unless ETH fails.*

Proof Let $Q = (I_Q, S_Q, f_Q, \text{opt}_Q)$ be a maximization problem such that the parameterized version Q_{para} of Q is $W_l[1]$ -hard.

Suppose to the contrary that Q has a PTAS algorithm A_Q of running time $f(1/\epsilon)n^{o(1/\epsilon)}$ for a function f . The algorithm A_Q can be used to derive the following algorithm A_{para} for the parameterized problem Q_{para} :

Algorithm A_{para} :

On an instance (x, k) of Q_{para} , call the PTAS algorithm A_Q on x and $\epsilon = 1/(2k)$. Suppose that A_Q returns a solution y in $S_Q(x)$. If $f_Q(x, y) \geq k$, then return “yes”; otherwise, return “no.”

We verify that the algorithm A_{para} solves the parameterized problem Q_{para} . Since Q is a maximization problem, if $f_Q(x, y) \geq k$, then obviously $\text{opt}_Q(x) \geq k$. Thus, the algorithm A_{para} returns a correct decision in this case. On the other hand, suppose $f_Q(x, y) < k$. Since $f_Q(x, y)$ is an integer, $f_Q(x, y) \leq k - 1$. Since A_Q is a PTAS for Q and $\epsilon = 1/(2k)$,

$$\text{opt}_Q(x)/f_Q(x, y) \leq 1 + 1/(2k).$$

It follows that (note that $f_Q(x, y) < k$)

$$\text{opt}_Q(x) \leq f_Q(x, y) + f_Q(x, y)/(2k) \leq k - 1 + 1/2 = k - 1/2 < k.$$

Thus, in this case the algorithm A_{para} also returns a correct decision. This proves that the algorithm A_{para} solves the parameterized version Q_{para} of the problem Q . The running time of the algorithm A_{para} is dominated by that of the algorithm A_Q , which by our hypothesis is bounded by $f(1/\epsilon)n^{o(1/\epsilon)} = f(2k)n^{o(k)}$. Thus, the $W_1[1]$ -hard problem Q_{para} is solvable in time $f(2k)n^{o(k)}$, which implies ETH fails by [Theorem 11](#).

The proof is similar for the case when Q is a minimization problem. \square

To demonstrate an application for [Theorem 12](#), consider the problem distinguishing substring selection (DSSP), which is NP-complete [32] and has applications in computational biology [25]. Recently, Deng et al. [24] (see also [25]) developed a PTAS algorithm for DSSP. The running time of the algorithm is bounded by $n^{O(1/\epsilon^6)}$. Obviously, such an algorithm is not practical even for moderate values of the error bound ϵ . Chen et al. [15] showed that the problem is $W_1[1]$ -hard. It follows from [Theorem 12](#) that the optimization problem DSSP has no PTAS of running time $f(1/\epsilon)n^{o(1/\epsilon)}$ for any function f unless ETH fails. Thus essentially, no PTAS for DSSP can be practically efficient even for moderate values of the error bound ϵ .

Recall the syntactic classes Planar TMAX, Planar TMIN, and Planar MPSAT introduced by Khanna and Motwani [38] to characterize PTAS. Khanna and Motwani [38] gave $n^{O(1/\epsilon)}$ -time PTASs for these problems. As discussed in the previous subsection, Planar TMAX, Planar TMIN, and Planar MPSAT are $W[1]$ -hard and hence have no EPTAS unless $W[1]=\text{FPT}$ [10]. Marx [43] gave a stronger lower bound. He proved that if there is a $\delta > 0$ such that any of these problems admits a $2^{(1/\epsilon)^{O(1)}}n^{O((1/\epsilon)^{1-\delta})}$ -time PTAS, then ETH fails.

In the previous subsection, it is shown that maximum independent set on unit disk graphs has a PTAS [35], but not an EPTAS [42]. Marx [43] further improved the inapproximability result by proving that maximum independent set on unit disk graphs does not have a PTAS of running time $2^{(1/\epsilon)^{O(1)}}n^{O((1/\epsilon)^{1-\delta})}$ for any $\delta > 0$ unless ETH fails.

5.4 Lower Bounds on the Running Time of EPTAS

For a problem Q that has EPTAS, the typical running time of the EPTAS is in the form of $2^{O(1/\epsilon)}n^{O(1)}$. One would still be interested in the following question:

Is there an EPTAS for Q whose running time is subexponential in $1/\epsilon$, for example, in the form of $2^{O((1/\epsilon)^{1-\delta})}n^{O(1)}$ for some $\delta > 0$?

Marx [43] proved that the answer to this question is “no” for some important problems. He showed that for several planar and geometric problems, including planar MIS and planar graph metric TSP, if there is a $\delta > 0$ such that any of these problems admits a $2^{O((1/\epsilon)^{1-\delta})}n^{O(1)}$ time PTAS, then ETH fails. This implies that the current $2^{O(1/\epsilon)}n^{O(1)}$ -time EPTASs for planar MIS and for planar graph metric TSP are essentially optimal.

6 Conclusion

In this chapter, various complexity issues concerning PTAS and its refined subclasses FPTAS and EPTAS are surveyed. On the positive side, there are syntactic characterizations and graph-theory techniques that can be used to obtain approximation schemes for optimization problems. On the negative side, parameterized intractability provides strong evidences that certain optimization problems do not have efficient approximation schemes. Many of these results point to a strong connection between approximability and parameterized complexity. The main results are summarized as follows:

- The syntactic classes Planar TMAX, Planar TMIN, and Planar MPSAT characterize PTAS [38].
- The syntactic class PFPT restricted to “scalable” problems characterizes FPTAS [17].
- The syntactic classes Planar MIN-W[h], Planar MAX-W[h], and Planar W[h]-SAT characterize EPTAS [17].
- Graph-theory techniques including Lipton and Tarjan’s planar separator [41] and Baker’s layerwise decomposition [4] lead to PTASs for problems on planar graphs.
- Bidimensionality theory provides general techniques for designing EPTAS for bidimensional problems on planar graphs and some generalizations of planar graphs [20].
- Strongly NP-hard problems do not have FPTASs unless P=NP [31].
- W[1]-hard problems do not have EPTASs unless W[1]=FPT [10].
- W₁[1]-hard problems do not have PTASs of running time $f(1/\epsilon)m^{o(1/\epsilon)}$ unless ETH fails [15].
- Certain optimization problems do not have EPTASs whose running time is $2^{O((1/\epsilon)^{1-\delta})}n^{O(1)}$ for any $\delta > 0$ unless ETH fails [43].

Many of these results can be illustrated by the example of planar MIS. Khanna and Motwani [38] showed that planar MIS is in the syntactic class Planar TMAX and hence has a PTAS. Chen et al. [17] showed that planar MIS is in the syntactic class Planar MAX-W[2] and hence has an EPTAS. Lipton and Tarjan’s separator approach [41] yields an EPTAS for planar MIS of running time $O(n \log n + 2^{5184(1+1/\epsilon)^2}n)$, which is quite inefficient. A better trade-off between the running time and the approximation ratio can be achieved by Baker’s layerwise decomposition approach [4], which gives an EPTAS for planar MIS of running time $O(8^{1/\epsilon}n/\epsilon)$. The various EPTAS algorithms for planar MIS obtained under these different approaches all point to the observation that many graph problems became more tractable on planar graphs, which was captured by the bidimensionality theory [20].

On the negative side, planar MIS is strongly NP-hard and hence has no FPTAS unless P = NP. Marx [43] showed that planar MIS has no EPTAS of running time $2^{O((1/\epsilon)^{1-\delta})}n^{O(1)}$ for any $\delta > 0$ unless ETH fails. This means that the $O(8^{1/\epsilon}n/\epsilon)$ -time EPTAS for planar MIS from Baker’s layerwise decomposition approach [4] is essentially optimal.

Abstract

In this chapter, we survey some results on some transformation-based distances for evolutionary trees. The authors will focus on the nearest-neighbor distance and a closely related distance called the subtree-transfer distance used in dealing with evolutionary histories involving events like recombinations or gene conversions; some variants of these distances will also be discussed.

1 Introduction

Comparing objects to find their *similarities* or, equivalently, *dissimilarities* is a fundamental issue in many fields including pattern recognition, image analysis, drug design, the study of thermodynamic costs of computing, and cognitive science. Various models have been introduced to measure the degree of similarity or dissimilarity in the literature. In the latter case the degree of dissimilarity is also often referred to as the *distance*. While some distances are straightforward to compute, e.g., the Hamming distance for binary strings and the Euclidean distance for geometric objects, some others are formulated as combinatorial optimization problems and thus pose nontrivial challenging algorithmic problems, sometimes even uncomputable, such as the universal information distance between two objects [3].

Distances based on the notion of *economic transformation* usually fall in the latter category. In a nutshell, a transform-based distance model assumes a set of transformation *operations* or *moves*, each associated with a fixed *cost*, which can be applied on the objects in the domain studied. The set of transformation operations should be *complete* in the sense that any object can be transformed into any other object by performing a sequence of such operations. The distance between two objects is then defined as the minimum cost of any sequence of operations transforming one object into the other.¹ The best known transform-based

¹Usually the operations are reversible, so the authors do not have to specify the direction of a transformation.

distances are perhaps the *edit* distances for strings [39], labeled trees [43, 47], and graphs [48] using operations insertion, deletion, and replacement. The edit distances have applications in many fields including computational molecular biology and text processing and have been studied extensively in both the literature and practical settings. For example, the UNIX command *diff* is essentially based on string edit distance. String edit distance is also a particularly suitable model for biological molecular sequence comparison because the edit operations often represent the most common form of evolutionary events.

In this chapter, the authors survey some results on some transformation-based distances for *evolutionary trees* (also called *phylogenies*). Such a tree is an *unordered* tree; it has uniquely labeled leaves and unlabeled interior nodes, can be *unrooted* or *rooted* if the evolutionary origin is known, can be *unweighted* or *weighted* if the evolutionary length on each edge is known, and usually has internal nodes of degree 3. Reconstructing the correct evolutionary tree for a set of species is one of the fundamental yet difficult problems in evolutionary genetics. Over the past few decades, many approaches for reconstructing evolutionary trees have been developed, including (not exhaustively) parsimony [11, 13, 38], compatibility [31], distance [14, 37], and maximum likelihood [2, 11, 12]. The outcomes of these methods usually depend on the data and the amount of computational resources applied. As a result, in practice they often lead to different trees on the same set of species [26]. It is thus of interest to compare evolutionary trees produced by different methods or by the same method on different data. Several distance models for evolutionary trees have been proposed in the literature. Among them, the best known is perhaps the *nearest-neighbor interchange* (nni) distance introduced independently in [34, 36]. The authors will focus on nni and a closely related distance called the *subtree-transfer* distance introduced in [17, 18] for dealing with evolutionary histories involving events like *recombinations* or *gene conversions*. Some variants of these distances will also be discussed. Since computing each such distance is NP-hard, our main interest is in the design of efficient approximation algorithms with guaranteed performance ratios.

The rest of the chapter is organized as follows. The authors first formally define the nni and subtree-transfer distances as well as a variant of subtree-transfer distance, called the *linear-cost subtree-transfer distance*, in Sect. 2. It is also demonstrated that the nni distance coincides with the linear-cost subtree-transfer distance on unweighted evolutionary trees. Section 3 presents results concerning the nni distance on both weighted and unweighted evolutionary trees. In particular, the authors give some tight upper and lower bounds on the nni distance; prove that computing the nni distance is NP-hard, which was a long-standing open problem; and give some logarithmic ratio approximation algorithms. Section 4 is concerned with the subtree-transfer distance on unweighted evolutionary trees. The main results include the NP-hardness of computing the subtree-transfer distance and an approximation algorithm with ratio 3. In Sect. 5, the authors consider the linear-cost subtree-transfer distance on weighted evolutionary trees and present a ratio 2 approximation algorithm. In Sect. 6, the authors discuss a variant of the nni distance for rooted, ordered trees, called the *rotation distance*, and present a nontrivial approximation algorithm. Some open problems are listed in Sect. 7.

The authors assume the reader has the basic knowledge of algorithms and computational complexity (such as NP and P). Consult, e.g., [15] otherwise. Unless otherwise mentioned, all the trees in this chapter are *degree-3* trees with *unique labels on leaves*. An edge of a tree is *external* if it is incident on a leaf; otherwise it is *internal*.

2 The nni and Subtree-Transfer Distances

In this section, the authors first define the nni, subtree-transfer, and linear-cost subtree-transfer distances for unweighted trees. Then the authors extend the nni and linear-cost subtree-transfer distances to weighted trees.

2.1 The Case of Unweighted Trees

An *nni* operation swaps two subtrees that are separated by an internal edge (u, v) , as shown in [Fig. 1](#).

The nni operation is said to *operate* on this internal edge. The nni distance, $D_{\text{nni}}(T_1, T_2)$, between two trees T_1 and T_2 is defined as the minimum number of nni operations required to transform one tree into the other. Although the distance has been studied extensively in the literature [4, 6, 9, 23, 24, 27–29, 32, 34, 36, 41, 46], the computational complexity of computing it has puzzled the research community for nearly 25 years until about a decade ago [7].

An nni operation can also be viewed as moving a subtree past a neighboring internal node. A more general operation is to transfer a subtree from one place to another arbitrary place. [Figure 2](#) shows such a *subtree-transfer* operation.

The subtree-transfer distance, $D_{\text{st}}(T_1, T_2)$, between two trees T_1 and T_2 is the minimum number of subtrees needed to be moved to transform T_1 into T_2 [7, 8, 17–19].

It is sometimes appropriate in practice to discriminate among subtree-transfer operations as they occur with different frequencies. In this case, each subtree-transfer operation can be charged a cost equal to the distance (the number of nodes passed) that the subtree has moved in the current tree. The *linear-cost* subtree-transfer distance, $D_{\text{lcost}}(T_1, T_2)$, between two trees T_1 and T_2 is then the minimum total cost required to transform T_1 into T_2 by subtree-transfer operations [7, 8]. Clearly, both subtree-transfer and linear-cost subtree-transfer models can also be used as alternative measures for comparing evolutionary trees generated by different tree reconstruction methods.

It is easy to demonstrate that the linear-cost subtree-transfer and nni distances in fact coincide. As mentioned before, an nni move is just a restricted subtree transfer where a subtree is only moved across a single node. (In [Fig. 1](#), the first exchange can alternatively be seen as moving node v together with subtree C past node u towards subtree A , or vice versa.) On the other hand, a subtree transfer over a distance d can always be simulated by a series of d nni moves. Hence, the linear-cost

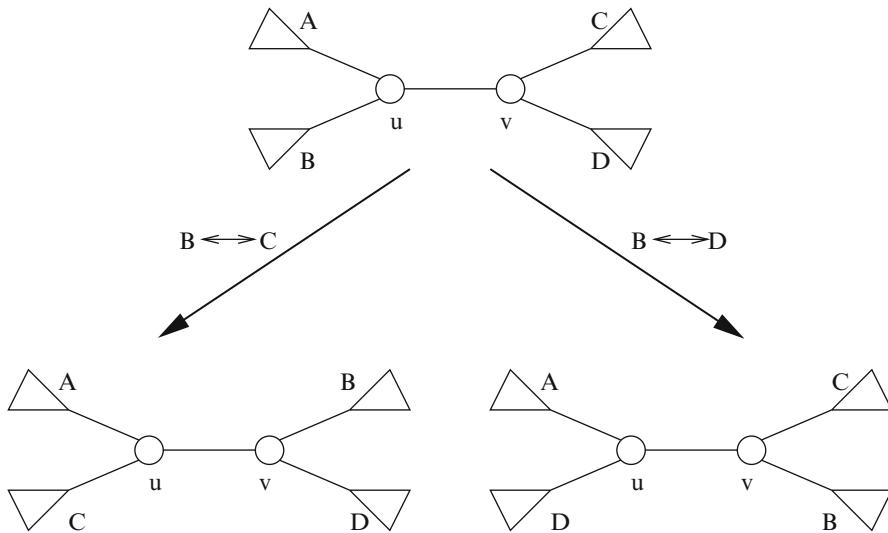

Fig. 1 The two possible nni operations on an internal edge (u, v): exchange $B \leftrightarrow C$ or $B \leftrightarrow D$

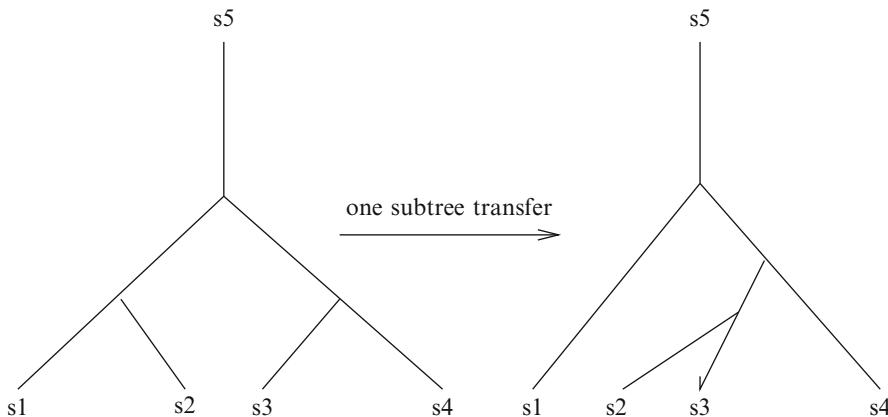

Fig. 2 An example of subtree transfer

subtree-transfer distance is in fact *identical* to the nni distance. However, it will soon become clear that the two models are different on weighted trees.

2.2 The Case of Weighted Trees

An evolutionary may also have weights on its edges, where an edge weight (more popularly known as *branch length* in genetics) could represent the evolutionary

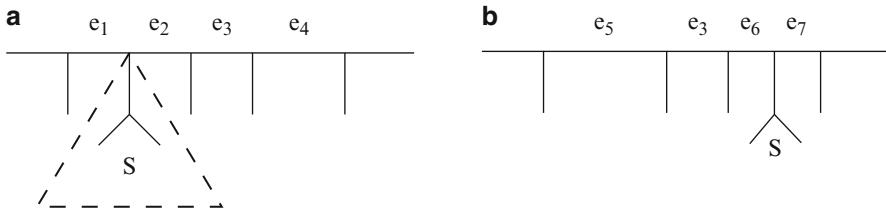

Fig. 3 Subtree transfer on weighted phylogenies. Tree (b) is obtained from tree (a) with one subtree transfer

distance along the edge. Many evolutionary tree reconstruction methods, including the distance and maximum likelihood methods, actually produce weighted evolutionary trees. Comparison of weighted evolutionary trees was studied in [26]. The distance measure adopted is based on the difference in the partitions of the leaves induced by the edges in both trees and has the drawback of being somewhat insensitive to the tree topologies (J. Felsenstein, 1996, personal communication). Both the linear-cost subtree-transfer and nni models can be naturally extended to weighted trees. The extension for nni is straightforward: An nni is simply charged a cost equal to the weight of the edge it operates on. In the case of linear-cost subtree transfer, although the idea is immediate, i.e., a moving subtree should be charged for the weighted distance it travels, the formal definition needs some care and is given below.

Consider (unrooted) trees in which each edge e has a weight $w(e) \geq 0$. To ensure feasibility of transforming a tree into another, it is required that the total weight of all edges to equal one. A subtree transfer is defined as follows. Select a subtree S of T at a given node u and select an edge $e \notin S$. Split the edge e into two edges e_1 and e_2 with weights $w(e_1)$ and $w(e_2)$ ($w(e_1), w(e_2) \geq 0$, $w(e_1) + w(e_2) = w(e)$), and move S to the common endpoint of e_1 and e_2 . Finally, merge the two remaining edges e' and e'' adjacent to u into one edge with weight $w(e') + w(e'')$. The cost of this subtree transfer is the total weight of all the edges over which S is moved. Figure 3 gives an example. The edge weights of the given tree are normalized so that their total sum is 1. The subtree S is transferred to split the edge e_4 to e_6 and e_7 such that $w(e_6), w(e_7) \geq 0$ and $w(e_6) + w(e_7) = w(e_4)$; finally, the two edges e_1 and e_2 are merged to e_5 such that $w(e_5) = w(e_1) + w(e_2)$. The cost of transferring S is $w(e_2) + w(e_3) + w(e_6)$.
