Output: Allocation and charging for each coming request.

- 1: Start a new decision phase at beginning.
- 2: A request $\mathbf{e}_i = (b_i, a_i, t_i)$ will be admitted during a decision phase if the following conditions are met:
 - 1) No conflict request is admitted and running,
 - 2) $\tau \leq t_i \leq 2\tau$,
 - 3) Request \mathbf{e}_i arrives during a time interval $[s_i, s_i + \beta t_i]$ for a s_i such that $\alpha t_i \leq s_i \leq t_i$ where $\alpha \leq 1$ is a constant, and
 - 4) The bid value b_i by the user satisfies that $b_i \geq p_{\leq s_i}^{(1)}$.
- 3: Decide if current decision phase will end or not. The clock of each new decision phase is reset as 0.
- 4: For each request \mathbf{e}_i admitted, it will be charged $p_{\leq s_i}^{(1)}$ per unit time. The total charge will be $\mathbf{p}_i = p_{\leq s_i}^{(1)} \cdot t_i$. For each request \mathbf{e}_i which is not admitted, it will be charged 0.

phase will end if (1) either a request is admitted and finished (2) or no request is admitted after $2(1 + \beta)\tau$ time slots for a given constant β . Another new decision phase will start when a previous decision phase ends. For simplicity of presentation, we assume that the clock of each new decision phase is reset as 0. This means that, in [Algorithm 6](#), when we say a request arrived in time t_i , it actually arrived t_i time slots after this new decision phase started. [Algorithm 6](#) summarizes the allocation method.

Theorem 15 Mechanism \mathcal{M}_1 is strategyproof.

Proof We should prove that no request could make more profit by bidding other than its true valuation or/and announcing larger time requirement. In other words, we need to prove *value-SP*, *time-SP*, and *value- and time-SP*. We will prove these properties separately.

Value-SP: According to the pricing scheme of \mathcal{M}_1 , we know that each request \mathbf{e}_i will be charged $p_{\leq s_i}^{(1)} t_i$ and make $\mathbf{v}_i - p_{\leq s_i}^{(1)} t_i$ profit if it is admitted. Request \mathbf{e}_i will be charged 0 and make 0 profit if it is not admitted. Since $p_{\leq s_i}^{(1)}$ does not depend on b_i , for a request \mathbf{e}_i admitted by mechanism \mathcal{M}_1 , it cannot improve its profit by lying on its bid value b_i .

On the other hand, for a request \mathbf{e}_i which is not admitted by mechanism \mathcal{M}_1 , there are two possible reasons causing its rejection. The first reason is that \mathbf{e}_i does not appear in a time interval $[s_i, s_i + \beta t_i]$ that satisfies the conditions in mechanism \mathcal{M}_1 . For this reason, no matter how request \mathbf{e}_i lies on its bid b_i , it will never be admitted. The second reason is that \mathbf{e}_i bids $b_i < p_{\leq s_i}^{(1)}$ while it bids truthfully, i.e., $\mathbf{v}_i = b_i t_i < p_{\leq s_i}^{(1)} t_i$. For this reason, if request \mathbf{e}_i bids lower than its true valuation, i.e., $b_i t_i < \mathbf{v}_i$, it still cannot be admitted and its profit is still 0; if request \mathbf{e}_i bided higher than its true valuation, i.e., $b_i t_i > \mathbf{v}_i$, there are two cases. Case 1: $b_i < p_{\leq s_i}^{(1)}$,

request \mathbf{e}_i is still not admitted and no more profit is made. Case 2: $b_i \geq p_{\leq s_i}^{(1)}$, request \mathbf{e}_i is admitted and make $\mathbf{v}_i - b_i t_i < 0$ profit, which implies request \mathbf{e}_i loses profit.

As stated above, no matter how request lies on its bid value, it cannot make more profit.

Time-SP: Similarly, we know each request \mathbf{e}_i will make $\mathbf{v}_i - p_{\leq s_i}^{(1)} t_i$ profit when it is admitted; otherwise, \mathbf{e}_i will make 0 profit when it is not admitted.

For request \mathbf{e}_i which is admitted by mechanism \mathcal{M}_1 , if it announces a larger required time duration $t'_i > t_i$, \mathbf{e}_i can be still admitted or not admitted. If \mathbf{e}_i is not admitted due to lying on t_i , it loses profit due to lying. If \mathbf{e}_i is still admitted, it needs to pay $p_{\leq s'_i}^{(1)}$ per unit time where $s'_i \geq s_i$ is the parameter described in mechanism \mathcal{M}_1 . According to the definition of $p_{\leq s'_i}^{(1)}$, we know that $p_{\leq s'_i}^{(1)} \geq p_{\leq s_i}^{(1)}$ when $s'_i \geq s_i$. Therefore, request \mathbf{e}_i makes no more profit by lying since $\mathbf{v}_i - p_{\leq s'_i}^{(1)} t'_i < \mathbf{v}_i - p_{\leq s_i}^{(1)} t_i$ when $p_{\leq s'_i}^{(1)} \geq p_{\leq s_i}^{(1)}$ and $t'_i > t_i$.

For request \mathbf{e}_i which is not admitted by mechanism \mathcal{M}_1 , there are two possible reasons causing its rejection. The first reason is that \mathbf{e}_i does not appear in a time interval $[s_i, s_i + \beta t_i]$ that satisfies the conditions in mechanism \mathcal{M}_1 . For this reason, no matter how request \mathbf{e}_i announces a larger t_i , it will never be admitted. The second reason is that \mathbf{e}_i bids $b_i < p_{\leq s_i}^{(1)}$ while it bids truthfully, i.e., $\mathbf{v}_i = b_i t_i < p_{\leq s_i}^{(1)} t_i$. For this reason, if request \mathbf{e}_i announces a larger $t'_i > t_i$, \mathbf{e}_i may be admitted when $b_i \geq p_{\leq s'_i}^{(1)}$ where s'_i is the new parameter when t'_i is announced. Since $t'_i > t_i$, we have $s'_i \geq s_i$ according to the mechanism. Therefore, even if \mathbf{e}_i is admitted due to lying higher on its required time slots, it makes $\mathbf{v}_i - b_i t'_i < \mathbf{v}_i - p_{\leq s'_i}^{(1)} t'_i \leq \mathbf{v}_i - p_{\leq s_i}^{(1)} t_i \leq 0$ since $p_{\leq s'_i}^{(1)} \geq p_{\leq s_i}^{(1)}$ when $s'_i \geq s_i$.

Value- and time-SP: When request lies on its bid value and time requirement, we can consider it as a lie on bid value and another lie on time requirement. As we proved above, neither of these could make more profit, we finish this part. \square

Lemma 9 At any decision phase, mechanism \mathcal{M}_1 could admit the request with highest bid value and charge that request at second highest bid value during that phase with a probability at least $\frac{\alpha\beta}{2(\beta+2)^2}$.

Proof To admit a request \mathbf{e}_i in a decision phase, the required time duration t_i should be within $[\tau, 2\tau]$. We know that $\Pr(\tau \leq t_i \leq 2\tau) \geq \frac{1}{2}$ according to the learning algorithm $\mathcal{M}_1(\mathcal{L})$. To admit a request \mathbf{e}_i with highest bid value with a charge equal to the second highest bid during a decision phase, the request with second highest bid value should arrive during time interval $[0, s_i]$ and the request with highest bid value should arrive during time interval $[s_i, s_i + \beta t_i]$.

Since the arrival of requests is memoryless, the number of arrival during a time interval only depends on the length of that interval. The probability that the request with second highest bid arrives during $[0, s_i]$ is at least $\frac{s_i}{s_i + \beta t_i + t_i} \geq \frac{\alpha}{2 + \beta}$. The probability that the request with highest bid value arrives during $[s_i, s_i + \beta t_i]$ is at least $\frac{\beta t_i}{s_i + \beta t_i + t_i} \geq \frac{\beta}{2 + \beta}$.

Thus, at each decision phase, the mechanism could admit the request with highest bid value and charge it at second highest bid value with constant probability $\frac{1}{2} \frac{\alpha}{2+\beta} \frac{\beta}{2+\beta} = \frac{\alpha\beta}{2(2+\beta)^2}$. \square

Lemma 10 At each decision phase, mechanism \mathcal{M}_1 is $\frac{2(2+\beta)^3}{\alpha\beta}$ -competitive during that phase with respect to offline Vickrey auction for both social and revenue efficiency.

Proof According to Lemma 9, we know that \mathcal{M}_1 has a constant probability $\frac{\alpha\beta}{2(2+\beta)^2}$ to admit the request with highest bid and charge it with second highest bid. We know that decision phase lasts at most $s_i + \beta t_i + t_i \leq (2 + \beta)t_i$ time when e_i is admitted. The maximum total valuation is at most $(2 + \beta)b_i t_i$. The total valuation of winner of \mathcal{M}_1 is at least $b_i t_i$ with probability $\frac{\alpha\beta}{2(2+\beta)^2}$. Therefore, the social efficiency ratio is at least $\frac{\alpha\beta}{2(2+\beta)^3}$ which implies \mathcal{M}_1 is at least $\frac{2(2+\beta)^3}{\alpha\beta}$ -competitive for social efficiency.

Similarly, it is easy to show that \mathcal{M}_1 is also at least $\frac{2(2+\beta)^3}{\alpha\beta}$ -competitive for revenue efficiency. We finish the proof. \square

This lemma shows that, in *single* decision phase, the protocol does manage to get a social efficiency and revenue within a constant factor of optimum. This does not directly imply that the protocol is overall a constant approximation for social and revenue efficiency because many decision phases exist in $[0, T]$.

Definition 7 We call a decision phase *good* decision phase if a request is admitted during this phase. Otherwise, we call it *bad* decision phase.

We proved that for *good* decision phase, \mathcal{M}_1 is $\frac{2(2+\beta)^3}{\alpha\beta}$ -competitive for both social and revenue efficiency. According to the mechanism, the length of a *bad* decision phase is always $2(1 + \beta)\tau$. In following lemma, we prove that the expected length of a *good* decision phase is at least $(1 + \alpha)\tau$.

Lemma 11 The expected length of a good decision phase is at least $(1 + \alpha)\tau$.

Proof When a request e_i is admitted in a decision phase, the length of that decision phase is at least $s_i + t_i \geq (1 + \alpha)t_i$. So the expected length of such decision phase is at least $(1 + \alpha)t_i \geq (1 + \alpha)\tau$ since the decision algorithm guarantees that $t_i \geq \tau$ for all admitted request e_i . \square

Theorem 16 Mechanism \mathcal{M}_1 is $\Theta(1)$ -competitive with respect to offline Vickrey auction for both social and revenue efficiency.

Proof According to Lemma 9, we know that during time interval $[\delta T, T]$, for each decision phase, with probability $P = \frac{\alpha\beta}{2(2+\beta)^2}$, we have a *good* decision phase with expected length at least $(1 + \alpha)\tau$, and with probability $1 - P$, we have a *bad* decision phase with length at most $2(1 + \beta)\tau$. Thus, after each decision phase, the expected total length of all *good* decision phases increases $P(1 + \alpha)\tau$ and the expected total

length of all *bad* decision phases increases $2(1-P)(1+\beta)\tau$. So the expected total length of all *good* decision phases is $\frac{P(1+\alpha)}{P(1+\alpha)+2(1-P)(1+\beta)}(1-\delta)T = \Theta(1)T$.

We know that \mathcal{M}_1 is $\frac{2(2+\beta)^3}{\alpha\beta}$ -competitive for both social and revenue efficiency during each of the *good* decision phases. Then, \mathcal{M}_1 is at least $\frac{2(2+\beta)^3}{\alpha\beta} \frac{P(1+\alpha)+2(1-P)(1+\beta)}{P(1+\alpha)} \frac{1}{1-\delta}$ -competitive for both social and revenue efficiency. \square

4.2 Random-Arrival Case

In this section, we consider the random-arrival case where the bid values and required time durations follow some known/unknown distributions. We will propose an online mechanism \mathcal{M}_2 with performance analysis. Note that in this section, the time is also assumed to be slotted.

If the distributions or arrival rate is unknown, similar to previous protocol \mathcal{M}_1 , in the first δT ($\delta < 1$) time, we learn the distributions and arrival rate based on the information of arriving requests [21]. We already proved that the sample size is large enough to achieve relatively small estimate error even that δ is very small. So in this section, we mainly focus on the case where the central authority knows the distributions and the arrival rate in advance.

Since we know all distributions, at each time t , we can compute the expected social efficiency of the offline Vickrey auction from the current time slot t to T of the spectrum channel by *dynamic programming (DP)*. Let $V(t)$ denote this expected social efficiency from time slot t to T of offline Vickrey auction, and let event X_k denote that k requests arrive at same time, event Y_t denote requested time duration of a request is t , and the event Z_b denote bid value of a request is b . It is not difficult to derive that

$$V(t) = \sum_{k=0}^{+\infty} \mathbf{Pr}(X_k) \left(\sum_{t_i=1}^{T-t} \mathbf{Pr}(Y_{t_i})(b_m(k) \cdot t_i + V(t+t_i)) \right).$$

Here, $b_m(k)$ is the expected highest bid value among k requests' bid values. It is easy to show that $\int_{-\infty}^{b_m(k)} \mathbf{Pr}(Z_x) dx = \frac{1}{k+1}$. And we have following lemma.

Lemma 12 *Function $V(t)$ is monotonic nonincreasing as t grows from 0 to T .*

Proof First, it is trivial to show that $\forall t \in [0, T]$, $V(t) \geq 0$. Let $V^k(t)$ denote the expected social efficiency where k requests arrive at time t . For any k , we have

$$\begin{cases} V^k(t+1) &= \sum_{t_i=1}^{T-t-1} \mathbf{Pr}(Y_{t_i})(b_m(k)t_i + V(t+1+t_i)) \\ V^k(t) &= \sum_{t_j=1}^{T-t} \mathbf{Pr}(Y_{t_j})(b_m(k)t_j + V(t+t_j)). \end{cases}$$

Algorithm 7 Decision algorithm $\mathcal{M}_2(\mathcal{D})$ for mechanism \mathcal{M}_2

Input: Probability distribution of bid values, discrete probability distribution of requested durations, arrival rate λ and requests arriving at time t .

Output: Allocation and charging scheme

- 1: Compute $V(t)$, $\forall t \in [0, T]$.
- 2: **if** the channel is being used **then**
- 3: Reject all coming requests.
- 4: **else**
- 5: Admit request \mathbf{e}_i s.t. $i = \arg \max V'(t)$ and reject others. Here, $V'(t) = b_i t_i + V(t + t_i)$ if \mathbf{e}_i is admitted.
- 6: If a request \mathbf{e}_i is admitted, charge it $b_j t_j + V(t + t_j) - V(t + t_i)$ where \mathbf{e}_j is the request that makes the second highest $V'(t)$; if a request \mathbf{e}_i is not admitted, charge it 0.

Then, $V^k(t+1) - V^k(t) = -\Pr(Y_{(T-t)})((b_m(k)(T-t) + V(T)) \leq 0$. From above, we prove that for any k , $V^k(t)$ is monotonic nonincreasing as t grows from 0 to T , which implies that $V(t)$ is monotonic nonincreasing. \square

Notice that if all secondary users announce requests truthfully, $V(0)$ is actually the expected social efficiency and revenue for Vickrey auction. Next, we are going to give a scheme that guarantees the truthfulness of both bid values and requested time durations.

The admission method of the protocol is as following. We assume a virtual request \mathbf{e}_0 with bid value $b_0 = 0$ and required time duration $t_0 = 1$ arrive at each time. If the protocol admits \mathbf{e}_0 at some time, then it means no request will be admitted at that time. For example, if k requests arrive, together with the virtual request, we have totally $k+1$ requests. Let $V'(t)$ denote the expected social efficiency from time t to T after a decision is made at time t . We always admit a request \mathbf{e}_i which maximizes the expected total social efficiency

$$V'(t) = b_i t_i + V(t + t_i)$$

and reject others.

Assume that \mathbf{e}_j is the request which made the *second highest* expected social efficiency. If request \mathbf{e}_i ($i \neq 0$) is admitted, then the secondary user who proposed \mathbf{e}_i will be charged:

$$\mathbf{p}_i = b_j t_j + V(t + t_j) - V(t + t_i),$$

i.e., it will be charged as the second highest expected social efficiency excluding the expected social efficiency after he finishes. **Algorithm 7** summarizes the method.

Theorem 17 *Mechanism \mathcal{M}_2 is strategyproof.*

Proof We will prove *value-SP*, *time-SP*, and *value- and time-SP*.

Value-SP: If a request \mathbf{e}_i is admitted when the bid value is truthful, since the charging scheme does not rely on the bid value of the request itself, so lying on bid value will not bring more profit.

If a request \mathbf{e}_i is not admitted when the bid value is truthful, there are two cases when it lies on the bid value. If \mathbf{e}_i is still not admitted, it is trivial that the profit will not increase (always be 0). If \mathbf{e}_i is admitted by bidding b'_i , then it will be charged $b_j t_j + V(t + t_j) - V(t + t_i)$. Since \mathbf{e}_i is not admitted if bidding is truthful, we know that $b_i t_i + V(t + t_i) < b_j t_j + V(t + t_j)$ which implies the profit $b_i t_i - \mathbf{p}_i$ by reporting untruthfully is no more than 0. Thus, no matter how a secondary user lies on its bid value, it cannot make more profit.

Time-SP: Recall that we assume each request could only claim a longer required time duration than its actual requirement. If request \mathbf{e}_i is admitted when it claims its true time requirement, it will still be admitted when claiming a longer required time $t'_i > t_i$. Then, it will have to pay: $V(t + t'_i) - V(t + t_i)$ more than before. Since $V(t)$ is monotonic nonincreasing by Lemma 12, it does not make more profit by lying.

If a request \mathbf{e}_i is not admitted when claiming its time requirement truthfully, there are two cases when it lies on the time requirement. If \mathbf{e}_i is still not admitted, it is trivial that the profit will not increase (always be 0). If \mathbf{e}_i is admitted when it lies its time requirement as $t'_i > t_i$, it will be charged $b_j t_j + V(t + t_j) - V(t + t'_i)$. Since \mathbf{e}_i is not admitted if bidding is truthful, we know that $b_i t_i + V(t + t_i) < b_j t_j + V(t + t_j)$. Together with $V(t + t'_i) \geq V(t + t_i)$, we have

$$b_i t_i \leq b_j t_j + V(t + t_j) - V(t + t'_i)$$

which implies the profit is no more than 0.

In brief, no matter how request lies on its time requirement, it cannot make more profit.

Value- and time-SP: When a request lies on its bid value and time requirement, we consider it as a lie on bid value and another lie on time requirement. As we proved above, neither of these could make more profit, we finish this part. \square

Lemma 13 *At each time, mechanism \mathcal{M}_2 will admit a request with constant probability if the channel is not being used.*

Proof When the channel is empty, the probability that request \mathbf{e}_i can be admitted is $\mathbf{Pr}(b_i \cdot t_i + V(t_i) \geq V(t + 1))$. We can rewrite $V(t)$ as

$$V(t) = b \sum_{t_i=1}^{T-t} (Y_{t_i} \cdot t_i) + \sum_{t_i=1}^{T-t} (Y_{t_i} V(t + t_i)),$$

where $b = \sum_{k=0}^{+\infty} \mathbf{Pr}(X_k) \cdot b_m(k)$ is a constant. So the probability whether request \mathbf{e}_i can be admitted or not is only related to the current time t and the required time duration t_i .

When k requests arrive at the same time, the probability that the bid value of one request is greater than the expected maximum bid value $b_m(k)$ is $\frac{1}{k+1}$. Given the distributions of bid values, required time durations, and the arrival rate, when k requests arrive at time t , we can find a $c(t_i)$ such that

$$\Pr(b_i \cdot t_i + V(t + t_i) \geq V(t + 1)) \geq \frac{c(t_i)}{k + 1}.$$

Note that without the specific distributions, we cannot give the exact form of $c(t_i)$; however, after the distributions given, $c(t_i)$ can be calculated.

We use A_1 to denote the event that a request could be admitted (the expected social revenue exceeded the reserved social revenue $V(t + 1)$) and A_0 to denote the event that no request could be admitted. When k requests arrive at time t , the probability that no requests could be admitted is

$$\Pr(A_0|X_k) \leq \prod_{i=1}^k \left(1 - \frac{c(i)}{k+1}\right) \leq \left(1 - \frac{c_m}{k+1}\right)^k,$$

where $c_m = \min_{t=1}^T c(t)$ is a constant. The probability that a request could be admitted is $\Pr(A_1|X_k) \geq 1 - \left(1 - \frac{c_m}{k+1}\right)^k$.

At time t , the expected probability that some request could be admitted is

$$\begin{aligned} \Pr(A_1) &= \sum_{k=1}^{+\infty} \Pr(X_k) \cdot \Pr(A_1|X_k) \geq \sum_{k=1}^{+\infty} \Pr(X_k) \cdot \left(1 - \left(1 - \frac{c_m}{k+1}\right)^k\right) \\ &= 1 - e^{-\frac{c_m + o(1)}{2}} \cdot \sum_{k=1}^{+\infty} \left(\frac{\lambda^k \cdot e^{-\lambda - \frac{(c_m + o(1))(k-1)}{2(k+1)}}}{k!} \right) \geq 1 - e^{-\frac{c_m + o(1)}{2}} \end{aligned}$$

which is at least a constant. \square

Theorem 18 *Mechanism \mathcal{M}_2 is $\Theta(1)$ -competitive with respect to offline Vickrey auction for both social and revenue efficiency.*

Proof According to Lemma 13, we know a request could be admitted with probability greater than a constant P , thus no request could be admitted with probability smaller than $1 - P$ at each time. Then, it is easy to show that in expectation, the channel is busy for $\frac{P_t}{P_t+1-P} T$ time slots where $t \geq 1$ is the expected time requirement of admitted request.

When the channel is busy, the social efficiency and revenue efficiency of \mathcal{M}_2 is no less than that of Vickrey auction. Then, we know in expectation, \mathcal{M}_2 is $\frac{P_t+1-P}{P_t}$ -competitive. \square

4.3 General Conflict Graph Model

In this section, we show that the protocols can be easily extended for networks where the conflict graph is growth-bounded by a polynomial function f , which implies the one-hop independent number of conflict graph H is $f(1)$.

4.3.1 Semi-arbitrary-arrival Case

For the semi-arbitrary-arrival case, we do not need to change the learning algorithm of the protocol. Here is the new decision algorithm for the extended protocol \mathcal{M}'_1 . We define $p_{\leq \tau}^{(s)}(\mathcal{R})$ as s -th highest bid among all requests which is received during time interval $[0, \tau]$ and proposed by secondary users in set \mathcal{R} .

The theoretical analysis of performance is similar to that of previous section. We omit the details due to space limit. The main difference is that when H has a one-hop independent number $f(1)$, with certain probability, the protocol may accept a request e_i with highest bid value during certain time interval and miss at most $f(1)b_i$ bid values. Therefore, compared with what we did in Sect. 4.1, there is an additional factor $f(1)$ in both social and revenue efficiency ratio.

4.3.2 Random-Arrival Case

For the random-arrival case, we have new decision algorithm $\mathcal{M}'_2(\mathcal{D})$ for the extended online mechanism \mathcal{M}'_2 as following. We still use $V(t)$ to denote the expected revenue of offline Vickrey auction from time t to T . When the conflict graph H is not a completed graph, more than one requests could be running at same time. Assume \mathcal{R} is a set of requests; we use $V'_{\mathcal{R}}(t)$ to denote the expected revenue after a request is admitted at time t , and all requests in \mathcal{R} are running before it is admitted. The expected revenue can be achieved by dynamic programming

Algorithm 8 Decision algorithm $\mathcal{M}'_1(\mathcal{D})$ for mechanism \mathcal{M}'_1

Input: Parameter τ learned by learning algorithm and requests that arrive during $[\delta T, T]$.

Output: Allocation and charging scheme.

- 1: All secondary users start a new *decision phase* initially.
 - 2: A request e_i will be admitted during a decision phase if:
 - 1) e_i does not conflict with any running requests in geometry region and the secondary user proposed e_i is in its *decision phase*.
 - 2) $\tau \leq t_i \leq 2\tau$.
 - 3) Request e_i arrives during a time interval $[s_i, s_i + \beta t_i]$ for a s_i such that $\alpha t_i \leq s_i \leq t_i$ where $\alpha < 1$ is a constant.
 - 4) Bid value $b_i \geq p_{\leq s_i}^{(1)}(\mathcal{R})$ where R is the set of secondary users in *decision phase* and whose requests will conflict with e_i in geometry region.
 - 3: When request e_i is admitted, *decision phases* of the secondary user who proposed e_i and those secondary users in \mathcal{R} will end. Start *service phases* for these secondary users. These *service phases* end when e_i is finished.
 - 4: New *decision phase* will start when either *service phase* ends or no request is admitted after $2(1 + \beta)\tau$ time slots. Time of each new *decision phase* is reset as 0.
 - 5: For each request e_i admitted, it will be charged $p_{\leq s_i}^{(1)}(\mathcal{R})$ per time slot; otherwise, it will be charged 0.
-

Algorithm 9 Decision algorithm $\mathcal{M}'_2(\mathcal{D})$ for mechanism \mathcal{M}'_2

Input: Probability distribution of bid values, required time durations and arrival rate λ , a set of requests \mathcal{R} at time t , and a set of running requests \mathcal{C} .

Output: Allocation and charging scheme

- 1: **while** \mathcal{R} is not empty **do**
- 2: Admit request \mathbf{e}_i such that $i = \arg \max V'_{\mathcal{C}}(t)$ where \mathbf{e}_i does not conflict with any request in \mathcal{C} .
- 3: If \mathbf{e}_i is a dummy request, then $\mathcal{R} = \emptyset$. Otherwise, (1) let $\mathcal{R} = \mathcal{R} - \mathcal{R}_i$ where \mathcal{R}_i is a set of requests which conflicts with \mathbf{e}_i in geometry region (including \mathbf{e}_i itself), and (2) $\mathcal{C} = \mathcal{C} \cup \{\mathbf{e}_i\}$.
- 4: For each request \mathbf{e}_i admitted, it will be charged $b_j t_j + V(t + t_j) - V(t + t_i)$ where \mathbf{e}_j is the request that makes the second highest $V'_{\mathcal{C}}(t)$ before \mathbf{e}_i is admitted; otherwise, it will be charged 0.

as described in Sect. 4.2. Details are omitted due to space limit. In the process of dynamic programming, we may need to find maximum weighted independent set. Finding maximum weighted independent set problem is *NP-hard* [12] and hard to approximate within $n^{1-o(1)}$ factor [29]. However, using the growth-bounded property, we could find a $1 + \epsilon$ approximation in polynomial time [24]. Algorithms 9 summarizes the method.

The theoretical analysis of performance is similar to that of previous Section. Again, compared with what we did in Sect. 4.2, there is an additional factor $f(1)$ in both social and revenue efficiency ratios.

4.4 Simulation Results

In this section, we conducted extensive simulations to study the performance of the online mechanisms \mathcal{M}_1 and \mathcal{M}_2 . In the simulations, we set the total time $T = 1,000$ time slots. We generate random requests with random bid values and time requirements. The arrival of these requests follows *Poissonian* distribution with arrival rate λ , which varies in the simulations to simulate lightly loaded or heavily loaded system. We omit the learning phase since we want to study the performance of the online mechanisms and the influence of learning is proven neglectable when the number of total time slots is large enough.

The bid value and time requirement of each request are either *uniformly* distributed or *normally* distributed. Here, we generate four different sets of requests. In set 1, the bid value of each request is uniformly distributed in $[0, 1]$, and time requirement of each request is uniformly drawn from all integers in $[1, 50]$; in set 2, the bid value of each request is uniformly distributed in $[0, 1]$, and time requirement of each request is uniformly drawn from all integers in $[1, 500]$; in set 3, the bid value of each request is normally distributed with mean value $\mu_{bid} = 0.5$ and standard deviation $\sigma_{bid} = 2$, and time requirement of each request is normally distributed with mean value $\mu_{time} = 25$ and standard deviation $\sigma_{time} = 3$; in set 4, the bid value of each request is normally distributed with mean value $\mu_{bid} = 0.5$ and standard deviation $\sigma_{bid} = 2$, and time requirement of each request is normally distributed

with mean value $\mu_{time} = 250$ and standard deviation $\sigma_{time} = 3$. The bid values are randomly matched with the time requirements.

4.4.1 Mechanism \mathcal{M}_1 for Semi-arbitrary-arrival Case

We set $\alpha = 1$ and $\beta = 1$ in the experiments. In Fig. 10a, b, we plot the competitive ratio for social and revenue efficiency when the arrival rate λ varies for different requests sets. As we stated in Theorems 13 and 14, the social efficiency ratio is no more than 37 % and the revenue efficiency ratio is no more than 66 %. Therefore, the performance of the mechanism \mathcal{M}_1 in the simulations, both social efficiency ratio and revenue efficiency ratio are almost 20–30 %, is close to the theoretical upper bound. We also observe that the competitive ratios increase when the system load increases since it is easier for \mathcal{M}_1 to admit a request when the system load is high, i.e., the competition among requests is high.

In Fig. 10c, we plot the spectrum utilization ratio of the method \mathcal{M}_1 . The spectrum utilization ratio is defined as the ratio between the busy time of the spectrum channel and the total time T . In all cases, the utilization ratio is no more than 50 %. According to mechanism \mathcal{M}_1 , a request with time requirement t_i is admitted while at least αt_i time slots are empty. Since we set $\alpha = 1$, then the utilization ratio is no more than 50 % which is corroborated by the simulation result.

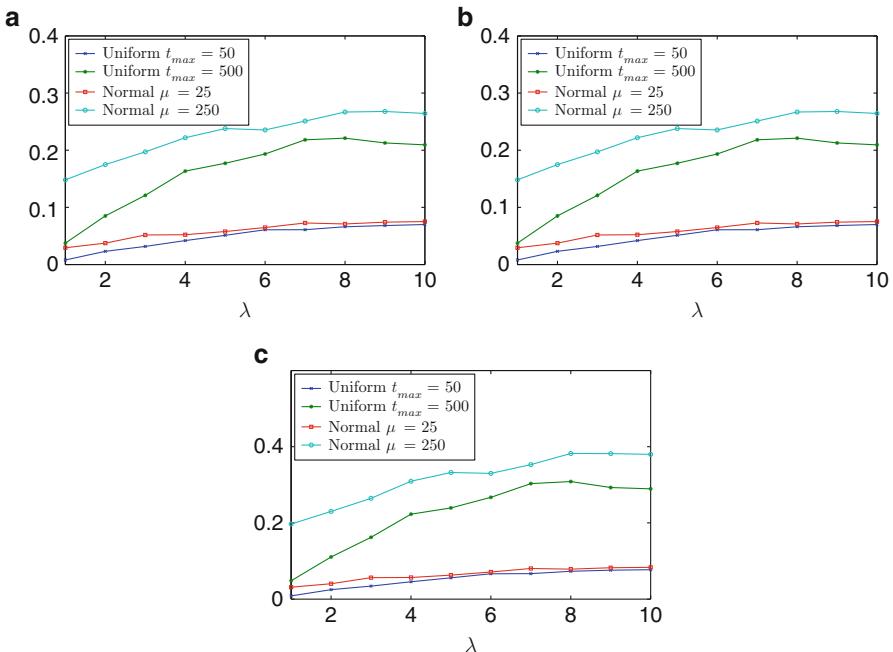

Fig. 10 The performance of online mechanism \mathcal{M}_1 . (a) Social efficiency ratio. (b) Revenue efficiency ratio. (c) Spectrum utilization ratio

4.4.2 Mechanism \mathcal{M}_2 for Random-Arrival Case

In Fig. 11a, b, we plot the competitive ratio for social and revenue efficiency when the arrival rate λ varies. Unsurprisingly, the performance of mechanism \mathcal{M}_2 is much better than that of \mathcal{M}_1 since \mathcal{M}_2 has more known information. We can see that the mechanism \mathcal{M}_2 even outperforms the average performance of Vickrey auction in all cases. The reason is that the protocol will choose the request maximizes the social efficiency and compare it with the average performance of Vickrey auction. In slightly loaded systems, the social efficiency and the revenue efficiency of the protocol are about 2–6 times of the performance by the Vickrey mechanism. The reason is that in slightly loaded system, the average performance of Vickrey auction is poorer, so the ratios are higher. Observe that the competitive ratios decrease when the arrival ratios increase. When the arrival ratio is big, the system load is high and the competition among requests is high. Then, it is more difficult to admit a request which outperforms the expected performance of Vickrey auction.

In Fig. 11c, we plot the spectrum utilization ratio of the method \mathcal{M}_2 . When the system is highly loaded, the spectrum utilization ratio of \mathcal{M}_2 is more than 95 %, while the spectrum utilization ratio is more than 75 % for lightly loaded system. When the system load is low, the competition among requests is low and thus it is harder to admit feasible request than that in a heavily loaded system. In all cases, mechanism \mathcal{M}_2 improves the efficiency ratios without sacrificing the spectrum utilization.

5 Literature Reviews

The allocation of spectrums is essentially the combinatorial allocation problem, which has been well studied in the literature [2, 23]. Yuan et al. [40] introduced the concept of a time-spectrum block to model spectrum reservation in cognitive radio networks. Li et al. [25, 38] designed efficient methods for various dynamic spectrum assignment problems. They also showed how to design truthful mechanism based on those methods. Xu et al. [34] first studied online spectrum allocation when secondary users could bid arbitrarily. They designed efficient mechanisms that could thwart the selfish behavior of secondary users. In [35], Xu and Li designed protocols for spectrum allocation when requests are submitted in advance and the central authority only needs to make decisions within a certain time period. Zhou et al. [42] propose a truthful and efficient dynamic spectrum auction system to serve many small players. In [43], Zhou and Zheng designed truthful double spectrum auctions where multiple parties can trade spectrum based on their individual needs. In [31], Wang et al. designed an online version of truthful double auctions for spectrum allocation where the requests arrive in an online fashion. Ben-Porat et al. [6] gave a scheme scheduling decisions on the Cumulative Distribution Function (CDF). In [33], Wu and Tsang studied the distributed multichannel power allocation problem for the spectrum-sharing cognitive ratio networks. All these results are based on offline models.

In this work, we use the online model which is similar to the online job scheduling problems [15]. Various online scheduling problems focus on optimizing different objective functions. The most common objective function is *makespan*, which is the length of the schedule. The first proof of competitiveness of an online scheduling algorithm was given by Graham in 1966 [15]. This is one of the most basic problems in online scheduling. Suppose that we are given m identical machines, jobs arrive one by one, and no preemption is allowed. Graham [15] proved that greedy algorithm, which assigns a new job to the least loaded machine, is $2 - \frac{1}{m}$ -competitive. A number of results have been proved to improve the upper bounds [3, 10, 20] and lower bounds [19]. In 1992, Bartal et al. [3] gave an algorithm that is 1.986-competitive. Then, the bound was improved to 1.945 [20], to 1.923 [1], and finally to 1.9201 [10] which is the best upper bound known to date. And the best lower bound up to now for any deterministic algorithm is 1.88-competitive which was proposed by Rudin et al. [19]. Closing the gap between the best lower bound (1.88 [19]) and the upper bound (1.9201 [10]) is an open problem. Many authors [14, 27] also investigated the case where preemption is allowed without penalty. Phillips et al. [27] gave an $(8 + \epsilon)$ -approximation algorithm for preemptive single-machine scheduling problem. The approximation ratio was improved to 2 [13], and to 1.47 [14]. However, all these results did not consider the penalty of preemption. Bartal et al. [4] considered a version of online scheduling problem in which we pay penalty for rejecting jobs. This was improved later in [18] by Hoogeveen et al: they gave $(1 + \phi)$ -competitive algorithm, where ϕ is the golden ratio. Hoogeveen et al. [18] improved the ratio to 1.58. They assume that the penalty is job-dependent only and is not affected by the preemption time.

Above results focus on minimizing *makespan*. When jobs have deadlines, however, it is usually impossible to finish all jobs. Thus, another model aims to maximize the profit or number of completed jobs. There are different variants: preemption-restart, preemption-resume, and preemption-discard. In *preemption-restart* model, it is allowed to preempt a running job, and the preempted job has to be restarted again from the beginning. In *preemption-resume* model, it is allowed to preempt a running job, and the preempted job could resume from where it was preempted. And other models assume that a preempted job cannot be restarted or resumed. In 1991, Baruah et al. [5] proved that no online scheduling algorithm can make profit more than $\frac{1}{(1+\sqrt{D})^2}$ times the optimal. Koren et al. [22] gave an algorithm matching the lower bound in [5]. Woeginger [32] studied an online model of maximizing the profit of finished jobs where there is some relationship between the weight and length of job. He provided a four-competitive algorithm for tight deadline case and gave a matching lower bound. Hoogeveen et al. [17] gave a $\frac{1}{2}$ -competitive algorithm which maximizes the number of early jobs. They assume that preemption is allowed while no penalties will be charged. Chrobak et al. [8] gave a $\frac{2}{3}$ -competitive algorithm which maximizes the number of satisfied jobs that have uniform length in the *preemption-restart* model. Fung et al. [11] addressed a general model of nonuniform length and gave a $\Delta + 2\sqrt{\Delta} + 2$ -competitive algorithm. Zheng et al. [41] studied the *preemption-restart* model where a penalty is the weight of the preempted job. They gave a $3\Delta + o(\Delta)$ -competitive for $\Delta > 9$.

The work that is most similar to the work is a recent result by Constantin et al. [9]. They proposed and studied a simple model for auctioning ad slot reservations in advance. A seller will display a set of slots at some point T in the future. Until T , bidders arrive sequentially and place a bid on the slots they are interested in. The seller must decide immediately whether or not to grant a reservation. Their model allows the seller to cancel at any time any reservation made earlier with a penalty proportional to the bid value. The major differences between the model and their model are as follows. Their model considers online requests and *offline* services. The services (ad slots) start from a *fixed* time and last for one unit time. And the preemptions happen before services start. In the model, the services (spectrum usage) can start from *any* time, lasting for an *arbitrary* duration (subject to time bound Δ), and the preemptions happen after the spectrum usages are assigned. We also considered the spatial reuse of spectrum resources.

6 Conclusion

In this chapter, we studied online spectrum allocation for wireless networks where a set of secondary users will bid for leasing a spectrum channel for certain time duration in different locations. After the central authority received the bidding request, it has to make a decision within a certain time γ . For a number of variants, we reviewed efficient online scheduling algorithms and analytical proof of the constant competitive ratios of these methods. Especially, when γ is around

the maximum requested time duration Δ , the algorithm *TOFU* results in a profit that is almost optimum. For *TOFU* protocol, Xu and Li [36] showed that no user will bid lower than its willing payment under their mechanism *TOFU*. Under a simple assumption that the requests by secondary users arrive with the Poisson distribution and the willing payment per unit time slot is independent from the number of time slots required, Wang et al. [39] are able to prove that their *SALSA* protocols simultaneously approximately maximize the expected social efficiency and the expected revenue. They also analytically proved that every secondary user will maximize its expected profit if it proposed requests truthfully.

There are a number of interesting questions left for future research. It remains open to design a truthful mechanism for online spectrum auction when we do not know the distributions of user arrivals. It is also interesting to extend the *TOFU* mechanism to deal with different models, such as OFDM networks. It is also interesting to study the performance of the protocols when first price auction is used. In this case, secondary users may have tendency to lower their bids. Another challenge is to relax the wireless interference model used in both results. They assumed that the conflicts of spectrum usage among secondary users can be characterized by interference graphs. This assumption although is widely adopted in the literature and gives us some leverage in designing efficient protocols, it cannot perfectly reflect the interference in practice. Thus, it is important to extend the design of these protocols to network models with more complicated interference models.

Abstract

This chapter provides a survey on the problem of partitioning points in the d -dimensional space with the goal of maximizing a given objective function; the survey is based on the forthcoming book (Hwang FK, Rothblum UG (2011b) Partitions: optimality and clustering. World Scientific). The first two sections describe the framework, terminology, and some background material that are useful for the analysis of the partition problem. The middle two sections study the case of $d = 1$, and the last two sections study the case of general d . Results

are presented without proofs, but with motivations, comments, and references. Complete proofs can also be found in the forthcoming book.

1 Formulation and Classification of Partition Problems

Consider a finite set \mathcal{N} of distinct positive integers (for most of the development $\mathcal{N} = \{1, \dots, |\mathcal{N}|\}$). A *partition* of \mathcal{N} is a finite collection of sets $\pi = (\pi_1, \dots, \pi_p)$ where π_1, \dots, π_p are pairwise disjoint nonempty sets whose union is \mathcal{N} . In this case, p is called the *size* of π , and the sets π_1, \dots, π_p are called the *parts* of π . Further, if n_1, \dots, n_p are the sizes of π_1, \dots, π_p , respectively, the vector (n_1, \dots, n_p) is called the *shape* of π ; of course, in this case, $\sum_{j=1}^p n_j = |\mathcal{N}|$. The prefix “ p -” or “ (n_1, \dots, n_p) -” is sometimes added to explicitly express the size or shape of a partition, referring to a p -*partition* of \mathcal{N} or to an (n_1, \dots, n_p) -*partition* of \mathcal{N} . Further, for brevity, the reference to the set \mathcal{N} as the partitioned set is frequently omitted, referring simply to *partitions*. In the forthcoming development, it is sometimes required that partitions’ parts are nonempty, while at other times, this requirement is relaxed.

Partition problems are (combinatorial) optimization problems in which a partition π is to be selected out of a given set Π so as to optimize (i.e., minimize or maximize) an objective function F that is defined over Π . Such problems are classified by (i) the *set of partitions* Π over which optimization takes place, (ii) the *number of characteristics* associated with each of the partitioned elements, and (iii) the *objective function* F that is defined over Π . It is next elaborated on each of these classifiers.

1.1 Sets of Partitions

At times, attention is restricted to the set of all partitions or to the set of all partitions whose size or shape satisfies prescribed restrictions; these situations are, respectively, referred to as *open*, *constrained-size*, and *constrained-shape sets of partitions*. Situations where the restrictions on the size or shape are expressed by prescribing a single element are referred to as *single-size* or *single-shape sets of partitions*, and situations where restrictions are expressed through lower and upper bounds on the size or shape are referred to as *bounded-size* or *bounded-shape sets of partitions*, respectively. All of the above classes of sets of partitions can be treated as special cases of a constrained-shape class. Their respective names simply emphasize the kind of constraints on the shapes. For example, the class of p -partitions collects those partitions with p (nonempty) parts, and the class of open partitions collects all partitions without restriction on the number of (nonempty) parts. Thus, constrained-shape class is the most general class. Still, the general framework of constrained-shape sets of partitions does not appear in the forthcoming development, and whenever constrained-shape partition problems are mentioned, all shapes have the same size; consequently, the terminology “constrained shape” is used for sets of

Table 1 Classification of sets of partitions

Open	Constrained-size	Constrained-shape (size given)
Bounded-size		Bounded-shape (size given)
Single-size		Single-shape

partitions with restricted shapes that have the same size (though formally, these are *single-size constrained-shape sets of partitions*). Sometimes, the above adjectives will be used casually to refer to partitions that belong to corresponding sets.

Let the (partitioned) set \mathcal{N} be given and let $n \equiv |\mathcal{N}|$. When a single-size set of partitions is considered, the prescribed single-size is given as a positive integer p . Given a positive integer p and a set Γ of positive integervectors (n_1, \dots, n_p) , each satisfying $\sum_{j=1}^p n_j = n$, Π^Γ will denote the corresponding constrained shape partitions, that is, all partitions with shape in Γ . In particular, if Γ consists of a single vector (n_1, \dots, n_p) , the notation $\Pi^{(n_1, \dots, n_p)}$ refers to (the single-shape set of partitions) Π^Γ . Also, if L and U are nonnegative integer p -vectors satisfying $L \leq U$ and $\sum_{j=1}^p L_j \leq n \leq \sum_{j=1}^p U_j$, $\Gamma^{(L,U)}$ will denote the set of nonnegative integervectors (n_1, \dots, n_p) satisfying $L_j \leq n_j \leq U_j$ for $j = 1, \dots, p$; in this case, the notation $\Pi^{(L,U)}$ is used for (the bounded-shape set of partitions) $\Pi^{\Gamma^{(L,U)}}$. (The restrictions on L and U assure that $\Gamma^{(L,U)}$ and $\Pi^{(L,U)}$ are nonempty.) Of course, single-size and single-shape sets of partitions are instances of bounded-shape sets obtained, respectively, by setting $L_j = 1$ and $U_j = |\mathcal{N}| - p + 1$ for all j or $L_j = n$ for all j . Similarly, open and single-size sets partitions are instances of bounded-size sets. The hierarchy of the classification of partitions is summarized in [Table 1](#).

A *multiset* is a group of elements where each element is allowed to have multiple occurrence. The formal notation of a multiset has double brackets, for example, $\{\{1, 1, 2, 2, 3\}\}$, or is given as a bracketed list of distinct elements with superscripts designating their duplications, for example, $\{1^2, 2^2, 3\}$. However, at times, (the abused notation of) single brackets is used, for example, $\{1, 1, 2, 2, 3\}$.

It is implicitly assumed in the above definitions that the parts of partitions are distinguishable. But, in some applications, the parts are indistinguishable and can be permuted without any restrictions. These situations are referred to as unlabeled partitions. Formally, an *unlabeled partition of \mathcal{N}* is a finite collection of sets $\pi = \{\pi_1, \dots, \pi_p\}$ where the π_j 's are as above. Again, p and the sets π_1, \dots, π_p are referred to as the *size* and the *parts of π* , respectively. Further, if n_1, \dots, n_p are the sizes of π_1, \dots, π_p , respectively, the *shape of π* is the multiset $\{\{n_1, \dots, n_p\}\}$; again, $\sum_{j=1}^p n_j = |\mathcal{N}|$ is required. In the literature, unlabeled partitions are commonly referred to as *allocations*. Herein, the term “partitions” is reserved to labeled ones; but, at times (when potential ambiguity may arise), there is reference to *labeled partitions*.

The classification to sets of labeled partitions applies to unlabeled ones; see [Table 1](#). Single-shape and bounded-shape sets of unlabeled partitions are defined, respectively, by a multiset $\{\{n_1, \dots, n_p\}\}$ or a multiset of pairs $\{\{(L_1, U_1), \dots, (L_p, U_p)\}\}$; the specification or the bounds on the sizes of the parts of partitions then hold for some labeling of the parts. Frequently, as parts of

unlabeled partitions are indistinguishable, sizes and bounds of unlabeled partitions are uniform, namely, all parts have the same size and a multiset of bounds $\{(L_1, U_1), \dots, (L_p, U_p)\}$ consists of p identical pairs.

1.2 The Number of Characteristics Associated with each Partitioned Elements

It is assumed throughout that each element i of the partitioned set \mathcal{N} is *associated* with a vector $A^i \in \mathbb{R}^d$ where d is a fixed positive integer (independent of i); the coordinates of A^i are referred to as *parameters* or *characteristics* associated with i . The n vectors A^i are part of the data for the problem and are given in the form of a real $d \times n$ matrix A . For a subset S of $\mathcal{N} = \{1, \dots, n\}$, A^S is the submatrix of A consisting of the columns of A indexed by S , ordered as in A . Also, “bars” over matrices are used to denote the multiset consisting of their columns, for example, a subset S of $\mathcal{N} = \{1, \dots, n\}$, \bar{A}^S is the set of columns of A^S , accounting for multiplicities.

1.3 The Objective Function

An objective function $F(\cdot)$ associates each (feasible) p -partition π with a value $F(\pi)$, and $F(\pi)$ is to be maximized (or minimized) over the given set of partitions. The value $F(\pi)$ of a partition π is assumed to depend on the parameters of the elements that are assigned to each part. More specifically, for each positive integer v , there is a column-symmetric function $h_v : \mathbb{R}^{d \times v} \rightarrow \mathbb{R}^d$, defined over multisets of v d -vectors; there are functions $g_j : \mathbb{R}^d \rightarrow \mathbb{R}^m$, $j = 1, \dots, p$, and a function $f_p : \mathbb{R}^{m \times p} \rightarrow \mathbb{R}$. Then the value $F(\pi)$ associated with partition π having shape (n_1, \dots, n_p) is given by

$$F(\pi) = f_p(g_1[h_{n_1}(\bar{A}^{\pi_1})], \dots, g_p[h_{n_p}(\bar{A}^{\pi_p})]) . \quad (1)$$

The functions h_{n_j} can, in a more general context, depend on the location within the variables of f_p , that is, on the index j ; also, the functions g_j may depend on n_j . In many common applications, each of the functions h_{n_j} is the summation function; in such cases, the problems are called *sum-partition problems*. When h_v or g_j is independent of the indexing parameter, the corresponding subscripts are dropped. Also, when referring to partitions of common size, the subscript “ p ” of f_p is dropped. Functions f_p are called *additive* when f_p is the sum function. It is also possible to consider partition problems where the domain of the functions h_{n_j} consists of ordered lists (and the functions h_{n_j} are not symmetric).

Some further notation is next introduced for a more concise form of sum-partition problems. For a $d \times n$ real matrix A and a p -partition $\pi = (\pi_1, \dots, \pi_p)$ of \mathcal{N} , the π -summation-matrix of A , denoted A_π , is given by

$$A_\pi \equiv \left[\sum_{i \in \pi_1} A^i, \dots, \sum_{i \in \pi_p} A^i \right] \in \mathbb{R}^{d \times p}, \quad (2)$$

where the empty sum is defined to be 0. When each of the g_j 's is the identity over \mathbb{R}^d , the objective function F associates with partition π the value $F(\pi)$ with the representation

$$F(\pi) = f_p(A_\pi). \quad (3)$$

(As was already mentioned, when the optimization over partitions concerns only partitions of fixed size p , the dependence of the functions f_p on p is suppressed).

Of particular interest is the case where all A^i 's have a common coordinate, say the first one, and it equals 1 for each A^i . In this case, row 1 of A_π is the shape of π . It follows that (3) allows for the objective function F to depend on the shape of partitions. Of course, for single-shape problems, the part-sizes (i.e., the coefficients of the shape) are fixed and can be viewed as parameters of the objective function.

In summary, the major classifiers of partition problems are:

- (1) *The family of partitions Π over which the function F (with representation as in (1) or (3)) is considered and optimized:* Using the classification of families of partitions provided in Table 1, there are *open*, *constrained-size*, *bounded-size*, *single-size*, *constrained-shape*, *bounded-shape*, and *single-shape partition problems*. In addition, *relaxed-size problems* refer to single-size problems which allow for empty parts. The description of the set of feasible partitions has to specify whether or not empty parts are allowed.
- (2) *The number of parameters associated with each of the partitioned elements:* The forthcoming development refers to *single-parameter problems*, *two-parameter problems*, and *multiparameter problems*.
- (3) *The objective (cost) function F as expressed by (1):* Adjectives like “sum-,” “max-,” or “mean-” of partition problems reflect properties of h_v while properties of f , like “linear,” “convex,” “Schur convex,” and “separable,” are explicitly referred to f_p , for example, sum-partition problems with f Schur convex.

A partition that maximizes/minimizes $F(\cdot)$ over a prescribed family of partitions Π is called *optimal over Π* .

For single-, bounded-, and constrained-shape families of partitions, the inclusion or exclusion of empty parts is implicit in the description of the set of feasible shapes – empty parts are prohibited when the set of feasible shapes consists only of positive vectors, whereas the inclusion of nonnegative shapes that are not (strictly) positive indicates that empty parts are allowed. In particular, results that apply to all single-, bounded-, or constrained-shape partition problems with empty parts allowed extend to corresponding problems with empty parts prohibited (by restricting attention to corresponding sets of shapes that consist only of positive vectors). Still, there are results in this chapter that apply to constrained-shape

problems that require the exclusion of empty parts. For sets of partitions that are determined by restrictions on size, for example, the case of single-size, the inclusion or exclusion of empty parts, must be made explicit as neither variant captures the other; see the results of the forthcoming Sect. 3 (summarized Table 4) about the optimality of monopolistic partitions for size problems with empty parts allowed and the optimality of extremal partitions for size problems with empty parts prohibited. Default positions in different parts of this chapter differ – at times they allow for empty parts, at times they exclude them, and at times they allow either way (to be determined through the specification of the set of feasible shapes).

The above classification refers to labeled partitions. Optimization problems over sets of unlabeled partitions can be embedded in the above framework, with Π and F being invariant under part permutation.

A major goal of this chapter is the identification of properties that are present in optimal partitions, thereby allowing one to restrict attention to corresponding subclasses of partitions. These properties are usually defined in terms of geometric/algebraic characteristics of the set of vectors associated with the indices assigned to the parts of the underlying partition. In particular, the focus is on properties that capture “clustering” of these vectors. The number of single-shape partitions is exponential in n (which implies the number of size partitions, open partitions, and other varieties of partitions are all exponential in n), so that it is not feasible to enumerate efficiently the partitions for selecting the optimal one. On the other hand, if a property has only polynomially many members, then it is possible to find an optimal partition by enumerating the subclasses of partitions having this property and comparing the values of the objective function.

Formally, a *property* Q of a partition is a unitary relation over sets of partitions, and it can be identified with the sets of partitions that satisfy it. Properties that are considered when studying multiparameter problems depend on the A^i ’s; as such, it seems natural to consider the partitioning of the A^i ’s rather than the partitioning of the underlying index set. But, possible equality among the A^i ’s often obscures the partition property. This situation is easily handled when the partitions are of the set of distinct indices and not of the A^i ’s.

A *type 1 result* for a partition problem is one that establishes a property for every optimal partition; a *type 2 result* is one that establishes a property for some optimal partition.

The next lemma, observed by Golany et al. [29], records a useful implication for the presence of properties in optimal solutions for single-shape/size and constrained-shape/size partition problems. For simplicity, attention is restricted to partitions whose size p is fixed.

Lemma 1 *Consider an objective function F over partitions, a set Γ of integer p -vectors whose coordinate-sum is n and a property Q of partitions such that each single-shape partition problem corresponding to a shape in Γ and the objective function F , Q is satisfied by some (every) optimal partition. Then, for each constrained-shape partition problem corresponding to a subset of Γ and the*

objective function F , Q is satisfied by some (every) optimal partition. Also, the above holds with “shape” replaced by “size.”

For single-parameter problems, the n elements in the single row of A are usually denoted $\theta^1, \dots, \theta^n$. In particular, for single-shape sum-partition problems, the π -summation matrix associated with a partition π is a p -vector, which is denoted θ_π and referred to as π -summation vector, that is,

$$\theta_\pi \equiv \left(\sum_{i \in \pi_1} \theta^i, \dots, \sum_{i \in \pi_p} \theta^i \right) \in \mathbb{R}^{1 \times p}. \quad (4)$$

Evidently, when $\theta^i = 1$ for each i , θ_π is the shape of π . For single-parameter problems, the partitioned elements can be renumbered so that θ^i is monotone in i , that is,

$$\theta^1 \leq \dots \leq \theta^n. \quad (5)$$

(Still, when analyzing the complexity of algorithm that solve partition problems, one should account for time required to sorting θ^i 's, if needed).

Much of the analysis focuses on partition problems with fixed size (single-shape, bounded-shape, constrained-shape, and single-size problems). When considering problems that allow for varying partition sizes, the objective function is, effectively, parameterized by an integer p representing the partition sizes; see (1). In particular, results about optimal partitions will then depend on some structure that expresses a connection between the objective function of p -partitions for different values of p . The most natural structure is the “*reduction assumption*” that asserts that F is invariant under the permutation/elimination of empty parts. For example, this is the case when f_p in (1) is the sum- (max/min)-function and the value assigned to empty parts is 0 ($-\infty/\infty$). A natural assumption that accompanies the “reduction assumption” is *symmetry* of F under part permutations.

Open problems that do not satisfy the reduction assumption can be difficult to analyze: They may have infinitely many feasible partitions, and there need not be an optimal one; this situation is demonstrated in the next example.

Example 1 Let $\mathcal{N} = \{1, 2\}$ and consider the open problem where empty sets are allowed and objective function is given by $F(\pi) = \sum_{j=1}^p j \left(\sum_{i \in \pi_j} i \right)$ for partitions π of size p . Then every single-size problem will assign both elements of \mathcal{N} to the part with the highest index. But, the open problem does not have an optimal partition as every p -partition is dominated by the best $(p+1)$ -partition. \square

When the “reduction assumption” is satisfied, each partition with p nonempty parts can, effectively, be viewed as (one of several) p' -partitions (with empty sets allowed) for any $p' \geq p$. In particular, upper bounded-size problems with upper bound p and open problem can be embedded in single-size problems with,

respectively, p or n as the prescribed size (and with empty parts allowed). The amount of computation of solving n -size problems may be high, but the reduction may be useful in establishing properties of optimal solutions. Further, in cases where an optimal solution for a single-size problem with empty parts excluded is simple, optimizing over the number of nonempty parts may be computationally tractable. When the reduction assumption is in effect, allowing for empty parts is a technical notion that helps us address bounded-size and open problems.

The following list provides a collection of applications of the optimal partition problem reported in the literature (number 11 has not yet appeared in the literature):

1. Assembly of systems (Derman et al. [17]; El-Newehbi et al. [22, 23]; Du [19]; Du and Hwang [20]; Malon [49]; Hwang et al. [41]; Hwang and Rothblum [36])
2. Group testing (Dorfman [18], Sobel and Groll [68], Gilstein [28], Pfeifer and Enis [59], Hwang et al. [41])
3. Circuit card library (Kodes [47]; Garey et al. [27])
4. Clustering (Fisher [24]; Boros and Hwang [7]; Golany et al. [29])
5. Abstraction of finite state machines (Oikonomou and Kain [58], Oikonomou [56, 57]).
6. Multischeduling (Mehta et al. [51] Rothkopf [62], Tanaev [69], Graham [31], Cody and Coffman [16], Chandra and Wang [13], Easton and Wong [21])
7. Cashe assignment (Gal et al. [26])
8. Blood analyzer problem (Nawijn [53])
9. Joint replenishment of inventory (Chakravarty et al. [11, 12], Goya [30], Silver [67], Nocturne [55], Chakravarty [10], A.K. Chakravarty 1983, Coordinated multi-product purchasing inventory decisions with group discounts, unpublished manuscript; A.K. Chakravarty, 1982b, Consecutiveness rule for inventory grouping with integer multiple constrained group-review periods, unpublished manuscript)
10. Statistical hypothesis testing (Neyman and Pearson [54])
11. Nearest neighbor assignment
12. Division of property (Granot and Rothblum [32])
13. Consolidating farm land (Brieden and Gritzmann [8]; Borgwardt et al. [5])

2 Preliminaries: Optimality of Extreme Points

This section presents sufficient conditions for the optimality of vertices, conditions that unify classical quasi-convexity and of Schur convexity. Throughout, standard definitions and facts about polytopes and convex sets are used; in particular, the *vertices* of a polytope are its *extreme points*.

Let C be a convex subset of \mathbb{R}^p and let $f : C \rightarrow \mathbb{R}$. The function f is (*strictly*) *quasi-convex along* a nonzero vector $d \in \mathbb{R}^p$, or briefly (*strictly*) d -*quasi-convex*, if the maximum of f over every line segment in C with direction d is attained (only) at one of the two endpoints of that line segment, possibly both. The function f is (*strictly*) *quasi-convex along* a set $D \subseteq \mathbb{R}^p$, or briefly (*strictly*) D -*quasi-convex*, if f is (*strictly*) quasi-convex along every nonzero vector $d \in D$. The function f

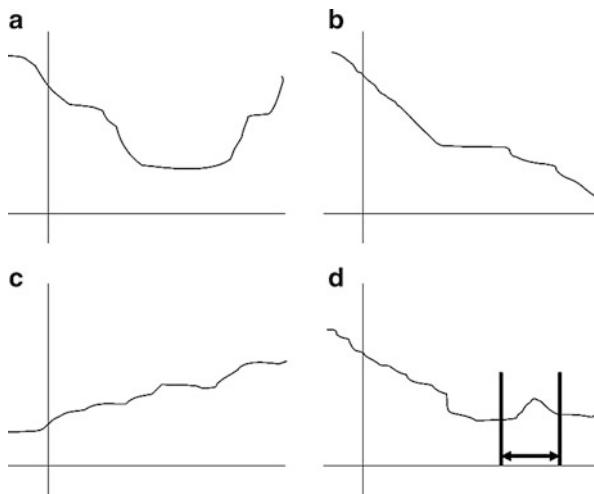

Fig. 1 Quasi-convexity

is (*strictly*) *quasi-convex* if it is (*strictly*) \mathbb{R}^p -quasi-convex. Reference to (*strict*) *directional quasi-convexity* is an abbreviation of (*strictly*) quasi-convexity along sets. Recall that a function f is (*strictly*) *convex* on C if for every distinct $x, y \in C$ and $0 < \alpha < 1$, $f[\alpha x + (1 - \alpha)y] \leq (<) \alpha f(x) + (1 - \alpha)f(y)$; of course, every (*strictly*) convex function is (*strictly*) quasi-convex.

The next lemma states a simple, but useful, characterization of directional quasi-convexity.

Lemma 2 *Let C be a convex subset of \mathbb{R}^p , $f : C \rightarrow \mathbb{R}$ and $d \in \mathbb{R}^p \setminus \{0\}$. Then the following are equivalent:*

- (a) *f is d -quasi-convex.*
- (b) *For each $x \in C$, the restriction of f to $C \cap \{x + \gamma d : \gamma \in \mathbb{R}\}$ (when viewed as a function in the parameter γ) cannot decrease after an increase.*

The behavior of a function, which is d -quasi-convex over line segments with direction d , can follow the patterns demonstrated in Figures (a), (b), or (c) of Fig. 1, but not (d) (where a line segment is identified over which the function does not attain a maximum at an endpoint).

Let C and D be subsets of \mathbb{R}^p where C is compact and convex. The set D is a *through-set* for C if for every point $x \in C$ which is not an extreme point of C , there is a line segment $L \subseteq C$ with direction in D such that x is in the relative interior of L . The following lemma identifies a necessary condition for through-sets. It also shows that this condition is sufficient for polytopes.

Lemma 3 *Let C be a convex set in \mathbb{R}^p . Then a subset D of \mathbb{R}^p is a through-set for C only if D contains a direction for each edge of C . Further, if C is a*

polytope, then every subset of \mathbb{R}^p that contains a direction for each edge of C is a through-set for C .

There are convex sets which have no edges, for example, the ℓ_2 -unit ball in \mathbb{R}^p . As the empty set is obviously not a through-set for any convex set of positive dimension, the sufficiency condition of [Lemma 2](#) does not generalize from polytopes to general convex sets.

Sufficient conditions for optimality of extreme points are next presented. The result was developed independently by Tardella [70] and Hwang and Rothblum [37]. It unifies the classical conditions of quasi-convexity and results about Schur convexity (see the paragraph following [Corollary 2](#)).

Theorem 1 *Let C be a compact convex set in \mathbb{R}^p , let E be the set of extreme points of C , and let D be a through-set for C , and let $f : C \rightarrow \mathbb{R}$ be D -quasi-convex. Then $\sup_C f = \sup_E f$; in particular, if f is continuous or if C is a polytope, f attains a maximum over C at one of C 's extreme points.*

Theorem 2 *Let C be a compact convex set in \mathbb{R}^p , let D be a through-set for C , and let $f : C \rightarrow \mathbb{R}$ be strictly quasi-convex along D . Then every maximizer of f over C is an extreme point of C ; in particular, if f is continuous or if C is a polytope, then such maximizers exist.*

Let C be a convex subset of \mathbb{R}^p and let $f : C \rightarrow \mathbb{R}$. The function f is (*strictly*) *edge-quasi-convex* on C if it is (*strictly*) quasi-convex along every (some) subset D of \mathbb{R}^p that contains a direction for each edge of C . Evidently, f is (*strictly*) edge-quasi-convex on C if and only if the maximum of f over any line segment in C which is parallel to one of C 's edges is attained at one of the two endpoints (and not at a point in the relative interior). Also, a (*strictly*) quasi-convex function is (*strictly*) edge-quasi-convex on every convex set over which it is defined.

Corollary 1 *Let P be a polytope and let $f : P \rightarrow \mathbb{R}$. If f is edge-quasi-convex on P , then f attains a maximum over P on one of P 's vertices. Further, if f is strictly edge-quasi-convex, then every maximizer of f over P is a vertex of P ; in particular, such a maximizer exists.*

The assumption in [Corollary 1](#) depends on the polytope P through its edge-directions, and the conclusion of the corollary specifically refers to P .

For $k \in \{1, \dots, p\}$, let e^k be the k -th *unit vector* in \mathbb{R}^p . Also, let $\Lambda \equiv \{(i, j) : i, j \in \{1, \dots, p\} \text{ and } i \neq j\}$, and for $(i, j) \in \Lambda$, let $e^{ij} \equiv e^i - e^j$. Let C be a convex subset of \mathbb{R}^p and $f : C \rightarrow \mathbb{R}$. The function f is called (*strictly*) *asymmetric Schur convex* if it is (*strictly*) quasi-convex along the set $\{e^{ij} : (i, j) \in \Lambda\}$. The use of the term “asymmetric” is to emphasize that these properties apply to functions which are not necessarily symmetric. Of course, every quasi-convex function, let alone a

convex function, is asymmetric Schur convex. (See the forthcoming definition of Schur convex functions).

The next lemma provides a characterization of asymmetric Schur convexity of continuously differentiable functions.

Lemma 4 *Let $C \subseteq \mathbb{R}^p$ be an open convex set of dimension p and let $f : C \rightarrow \mathbb{R}$ be continuously differentiable. Then f is asymmetric Schur convex on C if and only if*

$$\text{for all } x \in I^p \text{ and } i, j = 1, \dots, p, \left[\frac{\partial f}{\partial x_i} - \frac{\partial f}{\partial x_j} \right] [x + \gamma(e^i - e^j)] \quad (6)$$

cannot change sign from positive to negative as γ increases.

For a vector $x \in \mathbb{R}^n$ and $k = 1, \dots, n$, let $x_{[k]}$ be the k -th largest coordinate of x . A vector $a \in \mathbb{R}^p$ majorizes a vector $b \in \mathbb{R}^p$, written $a \succ b$, if

$$\sum_{i=1}^k a_{[i]} \geq \sum_{i=1}^k b_{[i]} \text{ for all } k = 1, \dots, p \quad (7)$$

and

$$\sum_{i=1}^p a_{[i]} = \sum_{i=1}^p b_{[i]}. \quad (8)$$

Evidently, (7) and (8) are, respectively, equivalent to

$$\max_{|I|=k} \sum_{i \in I} a_i \geq \max_{|I|=k} \sum_{i \in I} b_i \text{ for all } k = 1, \dots, p \quad (7a)$$

and

$$\sum_{i=1}^p a_i = \sum_{i=1}^p b_i. \quad (8a)$$

The vector a strictly majorizes b if a majorizes b , but b does not majorize a .

Let B be a convex subset of \mathbb{R}^p and let $f : B \rightarrow \mathbb{R}$. The function f is called *Schur convex on B* if

$$f(a) \geq f(b) \text{ for all } a, b \in B \text{ satisfying } a \succ b. \quad (9)$$

Condition (9) asserts that f is order-preserving with respect to the partial order majorization. The function f is called *strictly Schur convex* if it is Schur convex and (9) holds strictly whenever a strictly majorizes b .

Asymmetric Schur convexity is next related to classical Schur convexity. A subset B of \mathbb{R}^p is *symmetric* if B contains all vectors obtained by permuting

the coordinates of vectors in B . A real-valued function on a symmetric subset of \mathbb{R}^p is called *symmetric* if it is invariant under coordinate-permutations.

Theorem 3 *Let $I \subseteq \mathbb{R}$ be an open interval and $f : I^p \rightarrow \mathbb{R}$. Then the following are equivalent:*

- (a) *f is (strictly) Schur convex on I^p .*
- (b) *f is symmetric and (strictly) asymmetric Schur convex on I^p .*

As every (strictly) convex function is clearly (strictly) asymmetric Schur convex, **Theorem 3** implies that a symmetric (strictly) convex function is necessarily (strictly) Schur convex.

The next result relates asymmetric Schur convexity to edge quasi-convexity. Let \mathbb{R}_+ be the nonnegative real numbers.

Corollary 2 *Let $f : (\mathbb{R}_+)^p \rightarrow \mathbb{R}$. Then f is asymmetric Schur convex if and only if for every $\beta > 0$ the restriction of f to the polytope $\{x \in \mathbb{R}^p : x \geq 0, \sum_{i=1}^p x_i = \beta\}$ is edge-quasi-convex.*

Evidently, quasi-convex functions and Schur convex functions are asymmetric Schur convex. Thus, asymmetric Schur convexity unifies classical quasi-convexity and Schur convexity. The following example identifies functions that are asymmetric Schur convex but neither convex nor symmetric, let alone Schur convex.

Example 2 Let $f : \mathbb{R}^2 \rightarrow \mathbb{R}$ be given by $f(x_1, x_2) = g(x_1 + x_2) + h(x_1 - x_2)$ with g arbitrary and h convex. To see that f is asymmetric Schur convex consider a line with direction $e^1 - e^2$, say $\{x + \gamma(e^1 - e^2) : \gamma \in \mathbb{R}\}$. It then follows that $f[x + \gamma(e^1 - e^2)] = g(x_1 + x_2) + h(x_1 - x_2 + 2\gamma)$, and this expression is clearly convex in γ . The function f need not be symmetric nor convex, for example, $f(x) = \sin(x_1 + x_2) + (x_1 - x_2)^2$. \square

Theorem 4 *Let P be a polytope all of whose edges have direction in $\{e^{ij} : (i, j) \in \Lambda\}$ and let $f : P \rightarrow \mathbb{R}$. If f is asymmetric Schur convex on P , then f attains a maximum over P at one of P 's vertices. Further, if f is strictly asymmetric Schur convex, then every maximizer of f over P is a vertex of P ; in particular, such a maximizer exists.*

Polytopes of the form $\{x \in \mathbb{R}^p : x \geq 0, \sum_{i=1}^p x_i = \beta\}$ with $\beta \geq 0$ clearly satisfy the assumption of **Theorem 4** about the direction of their edges. **Theorem 4** follows Hwang and Rothblum [37]. It streamlines the classical result about quasi-convexity being a sufficient condition for optimality of extreme points with a corresponding result about Schur convex functions. Interestingly, historically, these two conditions were considered distinct; in fact, Marshall and Olkin [50, p. 13] refer to the use of “convexity” in describing Schur convex functions as “inappropriate” and state that they adhere to the “historically accepted term ‘Schur convexity.’” **Figure 2** below provides a graphical illustration of the relationships between quasi-convexity, directional quasi-convexity, classical Schur convexity (for symmetric functions), and asymmetric Schur convexity.

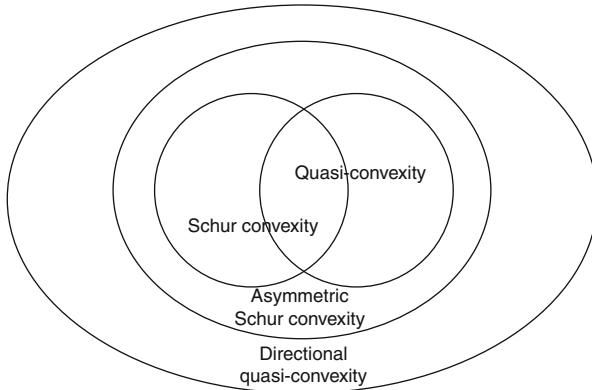

Fig. 2 Relationships among quasi-convexity, directional quasi-convexity, Schur convexity, and asymmetric Schur convexity

3 Single-Parameter: Polyhedral Approach

This section examines single-parameter partition problems. In particular, a class of polytopes, called *partition polytopes*, is introduced, and these polytopes are used to study partition problems.

Throughout this section and the next one, let (the partitioned set) $\mathcal{N} = \{1, \dots, n\}$, (the size of partitions) p and (the real numbers associated with the partitioned elements) $\theta^1, \dots, \theta^n$ be fixed. Without loss of generality, assume that the θ^i 's are ordered and satisfy

$$\theta^1 \leq \theta^2 \leq \dots \leq \theta^n ; \quad (10)$$

also, θ will stand for the vector $(\theta^1, \dots, \theta^n)$.

Recall from Sect. 1 that for a p -partition $\pi = (\pi_1, \dots, \pi_p)$ of \mathcal{N} , θ_π is given by

$$\theta_\pi \equiv (\theta_{\pi_1}, \dots, \theta_{\pi_p}) = \left(\sum_{i \in \pi_1} \theta^i, \dots, \sum_{i \in \pi_p} \theta^i \right) \in \mathbb{R}^p . \quad (11)$$

Given a set Π of ordered p -partitions, the Π -partition polytope is denoted $P^\Pi \equiv \text{conv} \{ \theta_\pi : \pi \in \Pi \} \subseteq \mathbb{R}^p$; when the set Π is either generic or clear from the context, the prefix “ $\Pi-$ ” is omitted. In forthcoming sections, partition problems are examined where the partitioned elements are associated with vectors rather than scalars; in the broader context, the above polytopes are called *single-parameter partition polytopes*.

The abbreviated notation P^Γ will be used for P^{Π^Γ} when Γ is a set of nonnegative integer p -vectors (n_1, \dots, n_p) satisfying $\sum_{j=1}^p n_j = n$, and such a polytope will be referred to as a *constrained-shape partition polytope*. Further, if Γ consists of a

single vector (n_1, \dots, n_p) , $P^{\Pi(n_1, \dots, n_p)}$ will stand for $P^{\Pi^{(n_1, \dots, n_p)}}$ and such a polytope will be referred to as a *single-shape partition polytope*; if L and U are nonnegative integer p -vectors satisfying $L \leq U$ and $\sum_{j=1}^p L_j \leq n \leq \sum_{j=1}^p U_j$, $P^{(L,U)}$ will stand for $P^{\Pi^{(L,U)}}$ and such a polytope will be referred to as a *bounded-shape partition polytope*; finally, if Π consists of all partitions of size p , P^P will stand for P^{Π^P} and such a polytope will be referred to as a *single-size partition polytope*.

The vertices of a Π -partition polytope P^Π have a representation θ_π with $\pi \in \Pi$. Thus, in seeking an optimal partition in Π when the objective function F has the representation $F(\pi) = f(\theta_\pi)$ for each $\pi \in \Pi$, it is useful to examine an extension of the functions f to P^Π (from $\{\theta_\pi : \pi \in \Pi\}$) and use results of Sect. 2 to determine conditions that suffice for this extension to attain a maximum over P^Π at a vertex.

Consider a single-shape problem corresponding to shape. If $n_j = 0$ for some $j = 1, \dots, p$, then for every partition $\pi \in \Pi^{(n_1, \dots, n_p)}$ π_j is empty and $(\theta_\pi)_j = 0$; so, part j is redundant. Consequently, such indices j can be eliminated, and there is no loss of generality by imposing the restriction that all n_j 's are positive. But, such a reduction needs not be possible when considering constrained-shape problems. The analysis of partition polytopes usually allows for empty parts (diverting from the default position that empty parts are prohibited).

The following example identifies an important class of partition polytopes.

Example 3 Consider the single-shape partition polytope defined by $(n_1, \dots, n_p) = (1, \dots, 1)$. In particular, in this case, $n = \sum_{j=1}^p 1 = p$. A partition π with shape $(1, \dots, 1)$ corresponds to a permutation of $(1, \dots, p)$, and for such a partition, θ_π is the p -vector obtained from the corresponding coordinate permutation of $(\theta^1, \dots, \theta^p)$. The partition polytope $P^{(1, \dots, 1)}$ is then the convex hull of these (permuted) vectors, and it is called the *generalized permutohedron* corresponding to $(\theta^1, \dots, \theta^p)$. The *standard permutohedron* is the generalized permutohedron with $\theta^i = i$ for $i = 1, \dots, p$. \square

Generalized permutohedra were first investigated by Schoute [63]; see also Ziegler [71, pp. 17–18 and 23].

A set of partitions Π is next associated with two additional polytopes; it will be shown that the definition of these polytopes provides useful representations for partition polytopes under general conditions. First, let C^Π be the solution set of the following system of linear inequalities:

$$\sum_{j \in I} x_j \geq \min \left\{ \sum_{j \in I} (\theta_\pi)_j : \pi \in \Pi \right\} \text{ for each } \emptyset \subset I \subseteq \{1, \dots, p\} \quad (12)$$

$$\sum_{j=1}^p x_j = \sum_{i=1}^n \theta^i; \quad (13)$$

evidently, C^Π is bounded and it is therefore a polytope.

An important property of partitions is next introduced; it will then be used to define the third polytope associated with a set of partitions. A partition is called *consecutive* if each of its parts consists of consecutive integers. Such a partition is determined by an order on its (nonempty) parts with a part preceding another when the indices of each element in the first part are smaller than each element in the second part. When the parts of a partition are nonempty, the order defining a consecutive partition is unique; further, a consecutive partition is uniquely determined by its order and its shape. In particular, for every nonnegative integer vector (n_1, \dots, n_p) , there exists a consecutive partition π with shape (n_1, \dots, n_p) . The third polytope associated with a set of partitions Π , denoted H^Π , is defined by $H^\Pi \equiv \text{conv}\{\theta_\pi : \pi \text{ is a consecutive partition in } \Pi\}$.

When $\Pi \equiv \Pi^{(n_1, \dots, n_p)}$ or $\Pi = \Pi^{(L, U)}$, superscripts (n_1, \dots, n_p) and (L, U) are used for $\Pi^{(n_1, \dots, n_p)}$ and $\Pi^{(L, U)}$, respectively, to index the polytope C and H , for example, $C^{(n_1, \dots, n_p)}$ and $H^{(L, U)}$. The next result relates the polytopes P^Π , C^Π , and H^Π for sets of partitions Π .

Lemma 5 *For every set Π of p -partitions, $H^\Pi \subseteq P^\Pi \subseteq C^\Pi$.*

In order to explore conditions under which the inclusions in Lemma 5 hold as equalities (yielding useful representations for partition polytopes), two polytopes associated with a real-valued functions on subsets are next introduced.

Let λ be a real-valued function on the subsets of $\{1, \dots, p\}$ with $\lambda(\emptyset) = 0$. A *permutation* (of $\{1, \dots, p\}$) is formally defined as an ordered collection of sets $\sigma = (\sigma_1, \dots, \sigma_p)$ where $\sigma_1, \dots, \sigma_p$ are singletons that partition $\{1, \dots, p\}$; given such a partition σ and $k \in \{1, \dots, p\}$, there is a unique index j with $\sigma_j = \{k\}$ – it is denoted $j_\sigma(k)$. Each permutation σ defines a vector $\lambda_\sigma \in \mathbb{R}^p$ whose k -th coordinate $(\lambda_\sigma)_k$ for $k = 1, \dots, p$ equals $\lambda(\cup_{t=1}^j \sigma_t) - \lambda(\cup_{t=1}^{j-1} \sigma_t)$ with $j = j_\sigma(k)$ (i.e., j as the unique index satisfying $\sigma_j = \{k\}$). The *permutation polytope corresponding to λ* , denoted H^λ , is the convex hull of the vectors λ_σ with σ ranging over all permutations of $\{1, \dots, p\}$. A second polytope associated with λ , denoted C^λ , is the solution set of the system of linear inequalities given by

$$\sum_{j \in I} x_j \geq \lambda(I) \text{ for each nonempty subset } I \text{ of } \{1, \dots, p\}, \quad (14)$$

$$\sum_{j=1}^p x_j = \lambda(\{1, \dots, p\}). \quad (15)$$

In the game theoretic literature, C^λ is referred to as the *core* of the p -person game defined by λ . Under this interpretation, $1, \dots, p$ are considered players, subsets of $\{1, \dots, p\}$ are called *coalitions*, $\lambda(I)$ for a coalition I is the *value* of I , and the vectors in C^λ represent allocations to the players with (14) assuring that the players in coalition I get *together* at least $\lambda(I)$ and (15) assuring that all players together get the value of the *grand coalition* $\{1, \dots, p\}$. These games and their cores were introduced by Morgenstern and Von Neuman [52] and explored in Shapley [66].

A real-valued function λ on the subsets of $\{1, \dots, p\}$ with $\lambda(\emptyset) = 0$ is called *supermodular* if for every pair I and J of subsets of $\{1, \dots, p\}$,

$$\lambda(I \cup J) + \lambda(I \cap J) \geq \lambda(I) + \lambda(J); \quad (16)$$

λ is called *strictly supermodular* if strict inequality holds whenever the two sets I and J are not ordered by set inclusion, that is, $I \not\subseteq J$ and $J \not\subseteq I$. Supermodular/submodular functions have extensive applications in optimization and polyhedral combinatorics.

The p standard unit vectors (in \mathbb{R}^p) will be denoted e^1, \dots, e^p . Parts (a) and (b) of the next theorem are due to Shapley [66], whereas part (c) is due to Hwang, Lee, and Rothblum [46].

Theorem 5 Suppose λ is supermodular on the subsets of $\{1, \dots, p\}$. Then:

- (a) $H^\lambda = C^\lambda$
- (b) For $v \in \mathbb{R}^p$, the following are equivalent:
 - (i) v is a vertex of H^λ
 - (ii) There is a permutation σ of $\{1, \dots, p\}$ with $v = \lambda_\sigma$;
in particular, H^λ has at most $p!$ vertices. Further, if λ is strictly supermodular, then the correspondence between vertices of H^λ and permutations of $\{1, \dots, p\}$ is one to one.
- (c) For distinct vertices v and v' of H^λ , the following are equivalent:
 - (i) $\text{conv}\{v, v'\}$ is an edge of H^λ
 - (ii) There exist permutations σ and σ' of $\{1, \dots, p\}$ such that $\{v, v'\} = \{\lambda_\sigma, \lambda_{\sigma'}\}$ and σ and σ' coincide on all but exactly two parts which are indexed by consecutive integers under both σ and σ' .

Further, if the above equivalent conditions hold and j and k are the elements in the noncoinciding parts of the permutations corresponding to v and v' , then $v - v'$ is a scalar multiple of $(e^j - e^k)$.

Theorem 5 will be used to provide conditions that suffice for having the inclusions in **Lemma 5** hold as equalities. For that purpose, for each set of partition Π , define the function θ_*^Π on the subsets of $\{1, \dots, p\}$ by setting

$$(\theta_*^\Pi)(I) \equiv \min \left\{ \sum_{j \in I} (\theta_\pi)_j : \pi \in \Pi \right\} \quad \text{for each } I \subseteq \{1, \dots, p\}; \quad (17)$$

in particular,

$$(\theta_*^\Pi)(\{1, \dots, p\}) = \sum_{i=1}^n \theta^i. \quad (18)$$

Trivially, $C^\Pi = C^{\theta_*^\Pi}$.

The set of partitions Π is called *complete* if for every permutation σ of $\{1, \dots, p\}$, there exists a partition π in Π with

$$\theta_\pi = (\theta_*^\Pi)_\sigma. \quad (19)$$

Note that for a permutation $\sigma = (\{j_1\}, \dots, \{j_p\})$ of $\{1, \dots, p\}$ and $t = 1, \dots, p$,

$$\sum_{s=1}^t [(\theta_*^\Pi)_\sigma]_{j_s} = (\theta_*^\Pi)(\{j_1, \dots, j_t\}) = \min_{\tau \in \Pi} \sum_{s=1}^t (\theta_\tau)_{j_s};$$

hence, $\theta_\pi = (\theta_*^\Pi)_\sigma$ for a partition π , if and only if

$$\sum_{s=1}^t (\theta_\pi)_{j_s} = \min_{\tau \in \Pi} \sum_{s=1}^t (\theta_\tau)_{j_s} \text{ for each } t = 1, \dots, p.$$

It is emphasized that completeness depends both on Π and on the θ^i 's.

The vector θ is called *one-sided*, if all θ^i 's are nonnegative or if all of them are nonpositive. Also, a constrained shape set of partitions is called *single symmetric shape* if the corresponding set of shapes consist of all coordinate-permutations of a single shape. The next result follows Hwang and Rothblum [39] in identifying several families of complete sets of partitions.

Theorem 6 *Every single-shape set of partitions is complete. If θ is one-sided, then every bounded-shape, single-size with empty parts allowed or prohibited, and single symmetric shape are complete.*

The following result is fundamental to the forthcoming development.

Theorem 7 *Let Π be a complete set of partitions. Then:*

- (a) θ_*^Π is supermodular.
- (b) $P^\Pi = C^\Pi = H^\Pi = H^{\theta_*^\Pi}$.
- (c) The direction of each edge of P^Π is the difference of two unit vectors.
- (d) v is a vertex of P^Π if and only if $v = (\theta_*^\Pi)_\sigma$ for some permutation σ of $\{1, \dots, p\}$, and in this case, $v = \theta_\pi$ for some consecutive partition π .
- (e) If no partition in Π has an empty set and the θ^i 's are distinct, then θ_*^Π is strictly supermodular, and for each vertex v , there is a unique permutation σ of $\{1, \dots, p\}$ satisfying $v = (\theta_*^\Pi)_\sigma$; in particular, P^Π has exactly $p!$ vertices.
- (f) If Π is constrained-shape, the θ^i 's are distinct, and either all θ^i 's are positive or they are all negative, then there is a unique partition π with $\theta_\pi = v$.

Theorem 7 shows that when the set of partitions Π is complete, the edge-directions of P^Π are differences of unit vectors, assuring (by [Theorem 4](#)) that asymmetric Schur convex functions over P^Π attain a maximum at a vertex. The next result states these conclusions formally, providing conditions for some (every) optimal partition to have its associated vector a vertex of the corresponding partition polytope.

Theorem 8 Suppose Π is a set of p -partitions and $f : P^\Pi \rightarrow \mathbb{R}$ where either f is quasi-convex, or Π is complete, and f is asymmetric Schur convex. Then:

- (a) A partition π^* is optimal if and only if θ_{π^*} maximizes f over P^Π .
- (b) There exists a partition π^* which is optimal over Π and has θ_{π^*} as a vertex of P^Π .
- (c) If f satisfies the corresponding property strictly on P^Π , then every partition π that is optimal over Π has θ_π as a vertex of P^Π .

Theorem 8 provides a tool for establishing properties of optimal partitions for a wide range of partition problems by identifying properties of partitions whose associated vectors are vertices of corresponding partition polytopes. Constrained shape problems are considered first, establishing the optimality of consecutive partitions.

Theorem 9 Suppose Π is a constrained-shape set of partitions and $f : P^\Pi \rightarrow \mathbb{R}$ is asymmetric Schur convex. Then:

- (a) There exists a partition which is optimal and consecutive; if furthermore either f is quasi-convex or Π is complete, then there exists a partition π which is optimal and consecutive and has θ_π as a vertex of P^Π .
- (b) If the θ^i 's are distinct and f is strictly asymmetric Schur convex, then every optimal partition is consecutive; if furthermore either f is strictly quasi-convex or Π is complete, then every optimal partition π is consecutive and has θ_π as a vertex of P^Π .

Jointly, [Theorems 8](#) and [9](#) present ten(!) results about optimal partitions – five providing conditions under which some optimal partition π is consecutive and/or has θ_π as a vertex of the partition polytope and five providing conditions under which every optimal partition has those properties. The “some” results are useful as they facilitate the restriction of the search for an optimal solution to subclasses of all partitions. When the set of partitions is complete, vertex enumeration is particularly efficient as the partition polytope is a permutation polytope having at most $p!$ vertices. The “some” results of [Theorems 8](#) and [9](#) are summarized in [Table 2](#). In this table (and the forthcoming ones in this section), “ Π^Γ ” under the “ Π ”-column means that Π is constrained-shape, “q-c” stands for quasi-convex, “(a)-S-c” stands for (asymmetric) Schur convex, an empty entry in the θ -column reflects no restrictions on θ , and a “+” in the “ P^Π perm”-column means P^Π is a permutation polytope. Other abbreviations are self-explanatory (e.g., “cons.” stands for “consecutive”).

Table 2 Properties of optimal partitions

Π	f	θ	Property of π^*	$\theta_{\pi^*} \in V(P^\Pi)$	P^Π perm	Ref

	a-S-c			+	+	Theorems 8 and 7
Π^Γ	a-S-c		cons			Theorem 9
Π^Γ	q-c		cons	+		Theorem 9
$\Pi^\Gamma + \text{comp}$	a-S-c		cons	+	+	Theorems 9 and 7

Additional partition problems are next explored – their analysis requires additional definitions. A partition is *size-consecutive* (*reverse size-consecutive*) if it is consecutive and the larger elements are assigned to the bigger (smaller) parts. Also, a set of shapes is called *symmetric* if it contains every coordinate permutation of each of its members.

Theorem 10 Suppose Γ is a symmetric set of shapes, $\Pi = \Pi^\Gamma$, $\theta \geq 0$ ($\theta \leq 0$) and $f : P^\Pi \rightarrow \mathbb{R}$ is asymmetric Schur convex. Then:

- (a) There exists a partition which is optimal and size-consecutive (*reverse size-consecutive*); if furthermore either f is quasi-convex or Π is complete, then there exists a partition π which is optimal and size-consecutive (*reverse size-consecutive*), and has θ_π as a vertex of P^Π .
- (b) If the θ^i 's are distinct and f is strictly asymmetric Schur convex, then every optimal partition is size-consecutive (*reverse size-consecutive*); if furthermore either f is strictly quasi-convex or Π is complete, then every optimal partition π is size-consecutive (*reverse size-consecutive*) and has θ_π as a vertex of P^Π .

Theorem 11 Suppose Π is a constrained-shape set of partitions corresponding to a set of partitions Γ , $\theta \geq 0$ ($\theta \leq 0$) and $f : \mathbb{R}^P \rightarrow \mathbb{R}$ is Schur convex. Then:

- (a) There exists a partition which is optimal and size-consecutive (*reverse size-consecutive*); if furthermore Π is complete, then there exists a partition π which is optimal, size-consecutive (*reverse size-consecutive*), and has θ_π as a vertex of P^Π .
- (b) If the θ^i 's are distinct and f is strictly Schur convex, then every optimal partition is size-consecutive (*reverse size-consecutive*); if furthermore Π is complete, then every optimal partition π is size-consecutive (*reverse size-consecutive*) and has θ_π as a vertex of P^Π .

Theorem 11 does not include a variant that parallels the “quasi-convexity” of Theorem 10 as an alternative to completeness that allows one to augment (*reverse*) size-consecutiveness of optimal partitions with the property that θ_π is a vertex of P^Π . Situations where the last property can be used to accelerate the search for an optimal partition when Π is not complete are not known.

Table 2 is next augmented with the “some” results of Theorems 10 and 11 into Table 3.

Theorem 12 Suppose Π is a bounded-shape set of partitions, $f : P^\Pi \rightarrow \mathbb{R}$ is asymmetric Schur convex. Then (i) there exists a partition π which is optimal, consecutive, and has θ_π as a vertex of P^Π ; (ii) if the θ^i 's are distinct and f is strictly asymmetric Schur convex, then every optimal partition π is consecutive and has θ_π as a vertex of P^Π . Further, if f is Schur convex and $\theta \geq 0$ ($\theta \leq 0$), “consecutive” can be tightened to “size-consecutive (*reverse size-consecutive*).”

Of course, the conclusions of Theorem 12 apply to single-shape problems which are instances of bounded-shape problems.

Complete	S-c	≤ 0	r-s-cons	+	+	Theorems 11 and 7

A bounded-shape set of partitions is called *uniform bounded-shape* if both L and U are multiples of the vector $(1, \dots, 1)$ (i.e., the lower/upper bounds of all parts coincide).

Theorem 13 Suppose Π is a uniform bounded-shape set of partitions, $f : P^\Pi \rightarrow \mathbb{R}$ is asymmetric Schur convex and $\theta \geq 0$ ($\theta \leq 0$). Then (i) there exists a partition π which is optimal, size-consecutive (reverse size-consecutive), and has θ_π as a vertex of P^Π ; (ii) if the θ^i 's are distinct and f is strictly asymmetric Schur convex, then every optimal partition π is size-consecutive (reverse size-consecutive) and has θ_π as a vertex of P^Π .

An important instance of [Theorem 13](#) is the case where Π is single-symmetric shape.

The following additional properties of partitions are relevant only for size problem since the sets of shapes meeting the requirements of the definitions are severely restricted.

A (reverse) size-consecutive partition π with all parts, but one, consisting of a single element is called *(reverse) extremal*; if all parts, but one, are empty, π is called *monopolistic*. A consecutive partition is called *bipolar* if either of the following conditions holds: (i) It has two nonempty parts, one containing all indices i with $\theta^i < 0$ and the other containing all indices i with $\theta^i > 0$, and the two parts arbitrarily split the indices with $\theta^i = 0$, or alternatively (ii) if either $\theta \geq 0$ or $\theta \leq 0$ and the partition is monopolistic. Evidently, if all θ^i 's are positive or all of them are negative, a partition is bipolar if and only if it is monopolistic. Finally, the definition of the next property is lengthy. For $p > 1$, a consecutive partition π is called *polarized-extremal* if it has two distinguished parts, say $\pi_{j\oplus}$ and $\pi_{j\ominus}$, such that:

- (i) (a) If $i \in \pi_{j\oplus}$ and $u > i$, then $u \in \pi_{j\oplus}$.
(b) If $i \in \pi_{j\ominus}$ and $u < i$, then $u \in \pi_{j\ominus}$.
- (ii) (a) If $\pi_{j\oplus}$ is not a singleton, then $\pi_{j\oplus} \subseteq \{i \in \mathcal{N} : \theta^i \geq 0\}$.
(b) If $\pi_{j\ominus}$ is not a singleton, then $\pi_{j\ominus} \subseteq \{i \in \mathcal{N} : \theta^i \leq 0\}$.

- (iii) If $j \notin \{j_{\oplus}, j_{\ominus}\}$, then π_j is a singleton; further, if either $\pi_{j_{\oplus}}$ is not a singleton and $\theta^u = 0$ for some $u \in \pi_{j_{\oplus}}$, or $\pi_{j_{\ominus}}$ is not a singleton and $\theta^u = 0$ for some $u \in \pi_{j_{\ominus}}$, then the single element in π_j , say i , has $\theta^i = 0$.

When $\theta \geq 0$ ($\theta \leq 0$), every extremal (reverse-extremal) partition is polarized-extremal and when $\theta > 0$ ($\theta < 0$), a partition is extremal (reverse-extremal) if and only if it is polarized-extremal.

Example 4 Let $n = 7$ and $\theta = (-3, -2, -1, 0, 0, 1, 2)$. Then $(\{1, 2, 3\}, \{4\}, \{5, 6, 7\})$ and $(\{1, 2\}, \{3\}, \{4\}, \{5\}, \{6, 7\})$ are polarized-extremal partitions, but $(\{1, 2\}, \{3\}, \{4\}, \{5, 6, 7\})$ is not.

Theorem 14 Suppose Π is a single-size set of partitions with empty parts allowed, $f : P^{\Pi} \rightarrow \mathbb{R}$ is asymmetric Schur convex and $\theta \geq 0$ ($\theta \leq 0$). Then (i) there exists a partition π which is optimal, monopolistic, and has θ_{π} as a vertex of P^{Π} ; (ii) if the θ^i 's are distinct and f is strictly asymmetric Schur convex, then every optimal partition π is monopolistic and has θ_{π} as a vertex of P^{Π} .

Attention is next turned to the partition problems considered in [Theorem 14](#) without the restriction that the θ^i 's are one-sided.

Theorem 15 Suppose Π is a single-size set of partitions with empty parts prohibited and $f : P^{\Pi} \rightarrow \mathbb{R}$ is quasi-convex. Then (i) there exists a partition π which is optimal, polarized-extremal, and has θ_{π} as a vertex of P^{Π} ; (ii) if the θ^i 's are distinct and nonzero and f is strictly quasi-convex, then every optimal partition π is polarized extremal and has θ_{π} as a vertex of P^{Π} .

When $\theta \leq 0$ or $\theta \geq 0$, the conclusions of [Theorem 15](#) follow from [Theorem 14](#).

Theorem 16 Suppose Π is a single-size set of partitions with empty parts allowed and $f : P^\Pi \rightarrow \mathbb{R}$ is asymmetric Schur convex. Then (i) there exists a partition π which is optimal, bipolar, and has θ_π as a vertex of P^Π ; (ii) if the θ^i 's are distinct and nonzero and f is strictly asymmetric Schur convex, then every optimal partition π is bipolar and has θ_π as a vertex of P^Π . Further, if $\theta \geq 0$ or $\theta \leq 0$, then “bipolar” in the above conclusions can be replaced by “monopolistic.”

[Sections 2](#) and [3](#) are next augmented with a summary of the “some” results of [Theorems 12–16](#) ([Table 4](#)).

4 Single-Parameter: Combinatorial Approach

The main goal in this section is to develop combinatorial tools for establishing that given a partition property Q and a set of partitions, some (every) partition in the set satisfies Q . Such results are useful for the analysis of partition problems when the set consists of all optimal partitions for a particular partition problem. The tool that is developed, referred to as *local sorting*, is to move from a partition in the given family that does not satisfy Q to a partition (in the family) that does by recursively rearranging (the elements in) a small number of parts at each step. Two conditions must be observed to guarantee that successive (local) sorting will produce a partition satisfying the given property Q have two parts: first, in each step, the sorting must produce a partition in the given set; and second, in order to avoid being trapped in a cycle, some statistic must decrease (or increase) monotonely as the sorting progresses. The first condition concerns the set of partitions, while the other concerns property Q . A useful approach of local sorting is the intuitive one which requires that the (sub)partition consisting of the sorted parts satisfies Q . These techniques will be applied to some specific optimization problems later, demonstrating the existence of optimal partitions with particular properties.

Some properties of partitions were introduced in [Sect. 3](#). These include (with abbreviations added in parenthesis) consecutiveness (C), size-consecutiveness (S), reverse size-consecutiveness (S^{-1}), extremalness (E), reverse extremalness (E^{-1}), monopolisticness (M_p), bipolar (BP), and polarized-extremalness (PE).

Let S and S' be two disjoint subsets of \mathcal{N} . Then S is said to *penetrate* S' , written $S \rightarrow S'$, if there exists a, c in S' and b in S such that $a < b < c$. Note that if $(S \cup S') \rightarrow S''$ then either $S \rightarrow S''$ or $S' \rightarrow S''$, but if $S \rightarrow (S' \cup S'')$, it is possible that neither $S \rightarrow S'$ nor $S \rightarrow S''$. In addition, the convention that each part penetrates itself will be adopted.

For a partition $\pi = \{\pi_1, \dots, \pi_p\}$ of a subset \mathcal{N}' of \mathcal{N} , define the digraph associated with π , denoted $G(\pi)$, as the digraph with p vertices representing the parts of π and edges (i, j) for $i, j \in \{1, \dots, p\}$ if π_i penetrates π_j . A partition π is called *noncrossing* (NC) if $\pi_i \rightarrow \pi_j$ implies $\pi_j \not\rightarrow \pi_i$. Noncrossing partitions were first studied in Kreweras [[48](#)].

Table 5 Properties of partitions

Noncrossing	NC	Consecutive	C
Nested	N	Nearly nested	$N_e N$
Size-consecutive	S	Reverse size-consecutive	S^{-1}
Extremal	E	Reverse extremal	E^{-1}
Polarized-extremal	PE	Order-nonpenetrating	O
Monopolistic	M_p	Bi-polar	BP

There are three special cases of noncrossingness that are of particular interest. The first concerns the consecutive partitions, introduced and studied in Sect. 3. A partition is called consecutive if and only if the penetration relation among its parts is an empty partial order, that is, no part penetrates any other part. The second instance of NC is *nestedness* (N); a p -partition π is called *nested* if the penetration relation among its parts is linear. Finally, a partition π is called *order-nonpenetrating* (O) if its parts can be indexed (ordered) such that for $i = 2, \dots, p$, $\pi_i \not\rightarrow \cup_{j=1}^{i-1} \pi_j$. Note that order-nonpenetrating was called *order-consecutive* by Chakravarty et al. [11]. Examples of partitions that satisfy the properties considered so far are next illustrated.

Example 5 Let $\mathcal{N} = \mathcal{N}' = \{1, \dots, 5\}$, $n = 5$ and $p = 3$. Then:

- (a) $\{\{2\}, \{4\}, \{1, 3, 5\}\}$ is noncrossing but, is not order-nonpenetrating.
- (b) $\{\{2\}, \{1, 3\}, \{4, 5\}\}$ is order-nonpenetrating, but neither nested nor consecutive.
- (c) $\{\{1\}, \{2, 3\}, \{4, 5\}\}$ is consecutive.
- (d) $\{\{3\}, \{2, 4\}, \{1, 5\}\}$ is nested. □

A noncrossing partition is called *nearly nested* ($N_e N$) if it is nested except for some parts of size 1.

Example 6 Let $\mathcal{N} = \{1, 2, 3, 4, 5, 6, 7\}$ and $p = 4$. Then the partition $\{\{1, 4, 7\}, \{2, 3\}, \{5\}, \{6\}\}$ is nearly nested but not order-nonpenetrating. □

Table 5 summarizes partition properties mentioned so far.

The following result records implications among the above properties of partitions. The relationship between C , N , NC , and O was determined in Hwang et al. [42].

Theorem 17 *The implications among the properties C , N , NC , O , $N_e N$, S , E , PE , M_p , and BP of partitions are represented precisely by the partial order illustrated in Fig. 3.*

Given a (single-parameter) partition problem, let n_+ , n_- , and n_0 denote the number of θ 's which are positive, negative, and equal 0, respectively. Following Hwang and Mallows [35] and [39], Table 6 provides the exact numbers of (single-)size partitions for the various properties listed in Table 5. Note that all the numbers are polynomial in n .

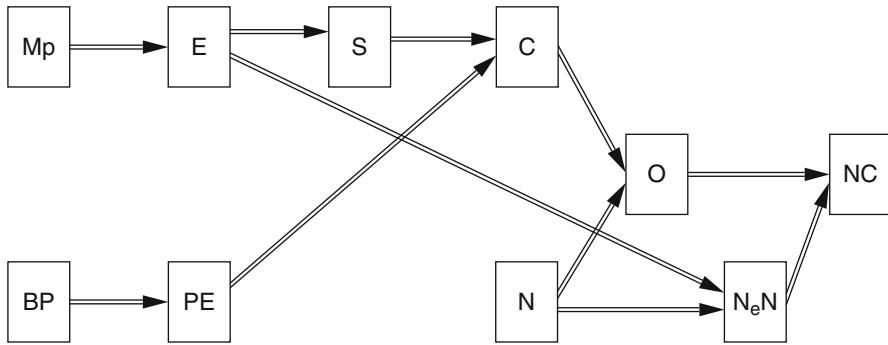

Fig. 3 Implications among $E, S, C, O, N, N_eN, NC, PE, M_p$, and BP

Table 6 The number of size partitions satisfying $NC, C, N, N_eN, S, S^{-1}, E, E^{-1}, PE, O, M_p$, and BP

Q	Number	Q	Number
NC	$\binom{n}{p-1} \binom{n}{p}$	C	$\binom{n-1}{p-1}$
N	$\frac{n}{\binom{n-1}{p-2}}$	N_eN	$\sum_{j=0}^{p-1} n_j \binom{n-j-2}{2p-2j-2}$
S	$\frac{n^{p-1}}{(p-1)p!}$	S^{-1}	$\frac{n^{p-1}}{(p-1)p!}$
E	1	E^{-1}	1
PE	$n_0 - p - 1$ if $n_0 \geq p - 2, n_+ > 0$ and $n_- > 0$ (different numbers in other cases)	O	$\sum_{j=0}^{p-1} \binom{n-1}{j} \binom{n-1-j}{2p-2j-2}$
M_p	1	BP	$n_0 + 1$

The focus will be on *local sorting* which changes only a prescribed number of parts. Local sorting requires that attention be given to subsets of the set of parts of a given partition which are then considered themselves as (sub)partitions. Let $\mathcal{N} = \{1, \dots, n\}$ and $\mathcal{E} = \{1, \dots, p\}$. To facilitate reference to the indices of these (sub)partitions, it will be useful to consider a framework where a *labeled partition* of a set $\mathcal{N}' \subseteq \mathcal{N}$ over an index set $\mathcal{E}' \subseteq \mathcal{E}$ is a set $\pi = \{(j, \pi_j) : j \in \mathcal{E}'\}$ where the π_j 's are disjoint subsets of \mathcal{N}' whose union is \mathcal{N}' . In particular, \mathcal{E}' , $|\mathcal{E}'|$, and $\{(j, |\pi_j|) : j \in \mathcal{E}'\}$ will be referred to as, respectively, the *support*, *size*, and *shape* of π . The notation $\pi = (\pi_1, \dots, \pi_p)$ for “(labeled) partitions,” used so far, captures the case where $\mathcal{N}' = \mathcal{N}$ and $\mathcal{E}' = \mathcal{E}$; its use will be continued in those cases. Given a labeled partition of \mathcal{N}' over \mathcal{E}' , say $\pi = \{(j, \pi_j) : j \in \mathcal{E}'\}$, and a subset J of \mathcal{E}' , $\pi_J \equiv \{(j, \pi_j) : j \in J\}$ will be called the *subpartition* of π corresponding to J ; in particular, π_J is a partition of $\cup_{j \in J} \pi_j$ over J (having support J , size $|J|$ and shape $\{(j, |\pi_j|) : j \in J\}$). The reference to the partitioned set and/or the support will be sometimes suppressed, referring to partition, subpartitions, etc. Also, a *k-partitions/subpartition* is a partition/subpartition of size k . Generically, “local” will refer to subpartitions of limited size.

Some definitions about properties of partitions that connect global satisfiability and local satisfiability are next introduced. Suppose Q is a property of partitions. Property Q is *hereditary* if every subpartition of a partition that satisfies Q must also satisfy Q . Also, for a positive integer k , property Q is k -*consistent* if for each $p \geq k$, a p -partition satisfies Q whenever all of its k -subpartitions satisfy Q . The *minimum consistency index* of a property of partitions is defined as the minimal positive integer k for which the property is k -consistent provided such an integer exists and as ∞ if Q is not k -consistent for any positive integer k .

The next lemma records an order for k -consistency.

Lemma 6 *Let k be a positive integer and let Q be a property of partitions such that a partition π satisfies Q if and only if every k -subpartition of π satisfies Q . Then Q is k' -consistent for all $k' > k$.*

Attention is next turned to transformations of partitions, where the image of a partition π consists of partitions obtained from π by sorting elements of subpartitions of π that do not satisfy Q to subpartitions that satisfy Q , while preserving the remaining parts of the partition.

For a partition π , let $\rho(\pi)$ denote its support and $v(\pi)$ denote its shape. Formally, three partition-transformations are defined for a given property Q of partitions and a given positive integer k . The transformations are $T_J^{Q,k,\text{open}}$, $T_J^{Q,k,\text{support}}$, and $T_J^{Q,k,\text{shape}}$, where for $J \subseteq \mathcal{E}$ and partition π , $T_J^{Q,k,t}(\pi) \equiv [T^{Q,k,t}]_J(\pi)$ is given by

$$T_J^{Q,k,\text{open}}(\pi) = \begin{cases} \{\pi' : \pi_{\rho(\pi) \setminus J} = \pi'_{\rho(\pi) \setminus J}, \\ \quad \cup_{j \in \rho(\pi)} \pi_j = \cup_{j \in \rho(\pi')} \pi'_j, \\ \quad \text{and } \pi'_{\rho(\pi') \setminus [\rho(\pi) \setminus J]} \in Q\} & \text{if } \pi_J \notin Q \text{ and } |J| = k \leq |\pi| \\ \{\pi' : \pi' \in Q\} & \text{if } \pi_J \notin Q \text{ and } |J| = k > |\pi| \\ \emptyset & \text{otherwise,} \end{cases}$$

$$T_J^{Q,k,\text{support}} = \left\{ \pi' \in T_J^{Q,k,\text{open}}(\pi) : \rho(\pi') = \rho(\pi) \right\}$$

and

$$T_J^{Q,k,\text{shape}}(\pi) = \left\{ \pi' \in T_J^{Q,k,\text{open}}(\pi) : v(\pi') = v(\pi) \right\}.$$

For $t \in \{\text{open, support, shape}\}$, partitions in $T^{Q,k,t}(\pi)$ are called (Q, k, t) -*sortings of π* .

Recall that $\mathcal{N} = \{1, \dots, n\}$ and $\mathcal{E} = \{1, \dots, p\}$ are assumed given. The natural universal domains for $T^{Q,k,\text{open}}$, $T^{Q,k,\text{support}}$, and $T^{Q,k,\text{shape}}$ are partitions without restriction, those with a prescribed support and those with prescribed shape, respectively (where no restriction is to be interpreted as $p = n$ and the support of the partitions is restricted to subsets of $\mathcal{E} = \{1, \dots, n\}$). To index these potential domains, define $X^{\text{open}} \equiv \{\text{open}\}$, $X^{\text{support}} \equiv \{\rho : \emptyset \neq \rho \subseteq \mathcal{E}\}$, and $X^{\text{shape}} \equiv \{v = \{(j, n_j) : j \in \rho\} : \rho \subseteq \mathcal{E}; \text{each } n_j \text{ is an integer and } \sum_{j \in \rho} n_j = |\mathcal{N}|\}\}.$

in particular, X^{support} and X^{shape} represent, respectively, all potential supports and shapes of subpartitions over \mathcal{E} . If $\widehat{\Pi}$ is the set of all partitions, then it will be denoted $\widehat{\Pi}^{\text{open}}$ (the support of partitions in $\widehat{\Pi}^{\text{open}}$ is in the power set of $\{1, \dots, n\}$). Further, the set of all partitions with a prescribed support ρ will be denoted $\widehat{\Pi}^\rho$, the set of all partitions with a prescribed shape v will be denoted $\widehat{\Pi}^v$, and finally, for positive integer p , write $\widehat{\Pi}^p$ for $\widehat{\Pi}^{\{1, \dots, p\}}$. If $\widehat{\Pi}$ is, respectively, $\widehat{\Pi}^{\text{open}}$, $\widehat{\Pi}^\rho$ for a particular ρ , or $\widehat{\Pi}^v$ for a particular v , a corresponding transformation on $\widehat{\Pi}$ is called *open*, *support-preserving*, or *shape-preserving*, respectively. The potential domains of the transformations $T^{Q,k,t}$ for given Q and $t \in \{\text{open, support, shape}\}$ are then the sets $\widehat{\Pi}^x$ with $x \in X^t$ (but degenerate instances are sometimes excluded).

For $t \in \{\text{open, support, shape}\}$ and $x \in X^t$, a property Q of partitions is *t-regular* for x , if for every $\mathcal{N}' \subseteq \mathcal{N}$ with $\Pi^x(\mathcal{N}') \neq \emptyset$, there is a partition in $\Pi^x(\mathcal{N}') \cap Q$ (with the intuitive interpretation of $\Pi^x(\mathcal{N}')$); Q is *t-regular* if it is *t-regular* for every $x \in X^t$.

Lemma 7 *Let Q be a t-regular property of partitions. Then for every $x \in X^t$, $\pi \in \widehat{\Pi}^x$ and $J \subseteq \mathcal{E}$ with $|J| = k$,*

$$[\pi_J \in Q] \Leftrightarrow [T_J^{Q,k,t}(\pi) = \emptyset]; \quad (20)$$

further, if Q is also *k-consistent* and *hereditary*, then

$$[\pi \in Q] \Leftrightarrow [T^{Q,k,t}(\pi) = \emptyset]. \quad (21)$$

Let k be a positive integer, let $t \in \{\text{open, support, shape}\}$, let Q be a property of partitions, and let Π^* be a set of partitions. Then:

- (i) Π^* is *Q-(strongly, k, t)-invariant* if for each $\pi \in \Pi^* \setminus Q$: for every subset J of \mathcal{E} having k elements and with $\pi_J \notin Q$, every π' in $(T_J^{Q,k,t})(\pi)$ satisfies $\pi' \in \Pi^*$.
- (ii) Π^* is *Q-(sort-specific, k, t)-invariant* if for each $\pi \in \Pi^* \setminus Q$: for every subset J of \mathcal{E} having k elements and with $\pi_J \notin Q$, some π' in $(T_J^{Q,k,t})(\pi)$ satisfies $\pi' \in \Pi^*$.
- (iii) Π^* is *Q-(part-specific, k, t)-invariant* if for each $\pi \in \Pi^* \setminus Q$: for some subset J of \mathcal{E} having k elements and with $\pi_J \notin Q$, every π' in $(T_J^{Q,k,t})(\pi)$ satisfies $\pi' \in \Pi^*$.
- (iv) Π^* is *Q-(weakly, k, t)-invariant* if for each $\pi \in \Pi^* \setminus Q$: for some subset J of \mathcal{E} having k elements and with $\pi_J \notin Q$, some π' in $(T_J^{Q,k,t})(\pi)$ satisfies $\pi' \in \Pi^*$.

When referring to *Q-(ℓ, k, t)-invariance*, the values of ℓ , k , and t are called *level*, *degree*, and *type* of the corresponding invariance. The level ℓ can take four possible values, forming two pairs – {strongly, weakly} and {part-specific, sort-specific}; if ℓ is a specific value, then and ℓ^{-1} is defined as the other value in the same pair. Also, type can take one of three possible values – “open,” “support,” and “shape” – and the possible values of degree are $k = 1, 2, \dots$. When a variable is not quantified

in forthcoming statements/results about (ℓ, k, t) , it means that the statement is valid for all choices of that variable.

A multivalued function on a set of partitions will be called a *statistic*. To compare values of a statistics, “ $<$ ” will stand for “ \leq and \neq .” Let k be a positive integer, let $t \in \{\text{open, support, shape}\}$, and let Q be a t -regular property of partitions. Then:

- (i) Q is (*strongly, k, t -sortable*) if for every $x \in X^t$, there is a statistic $s(\cdot)$ on $\widehat{\Pi}^x$ such that for every $\pi \in \Pi^x \setminus Q$ for every $J \subseteq \mathcal{E}$ having k elements and $\pi_J \notin Q$: every $\pi' \in (T_J^{Q,k,t})(\pi)$ satisfies $s(\pi') < s(\pi)$.
- (ii) Q is (*sort-specific, k, t -sortable*) if for every $x \in X^t$, there is a statistic $s(\cdot)$ on $\widehat{\Pi}^x$ such that for every $\pi \in \Pi^x \setminus Q$ and for every $J \subseteq \mathcal{E}$ having k elements and $\pi_J \notin Q$: some $\pi' \in (T_J^{Q,k,t})(\pi)$ satisfies $s(\pi') < s(\pi)$.
- (iii) Q is (*part-specific, k, t -sortable*) if for every $x \in X^t$, there is a statistic $s(\cdot)$ on $\widehat{\Pi}^x$ such that for every $\pi \in \Pi^x \setminus Q$, for some $J \subseteq \mathcal{E}$ having k elements and $\pi_J \notin Q$: every $\pi' \in (T_J^{Q,k,t})(\pi)$ satisfies $s(\pi') < s(\pi)$.
- (iv) Q is (*part-specific, k, t -sortable*) if for every $x \in X^t$, there is a statistic $s(\cdot)$ on $\widehat{\Pi}^x$ such that for every $\pi \in \Pi^x \setminus Q$, for some $J \subseteq \mathcal{E}$ having k elements and $\pi_J \notin Q$: some $\pi' \in (T_J^{Q,k,t})(\pi)$ satisfies $s(\pi') < s(\pi)$.

As for invariance, the variables ℓ , k , and t of (ℓ, k, t) -sortability are referred to as *level*, *degree*, and *type*. A comparison of the above definitions of sortability and historic ones is deferred till after [Theorem 19](#).

Theorem 18 *Let Q be a k -consistent and hereditary property of partitions, let $x \in X^t$, and let $\Pi^* \subseteq \widehat{\Pi}^x$. If Π^* is Q - (ℓ, k, t) -invariant and Q is (ℓ^{-1}, k, t) -sortable on $\widehat{\Pi}^x$, then for every partition $\pi \in \Pi^*$, there is a finite sequence $\pi^0 = \pi, \pi^1, \dots, \pi^s$ of partitions in Π^* with π^s satisfying Q ($s = 0$ when $\pi \in Q$). In particular, if Π^* is nonempty, then $\Pi^* \cap Q$ is nonempty.*

Suppose one wishes to prove that a property Q of partitions is not T -sortable. Using the definition of (ℓ, k, t) -sortability, it is then necessary to demonstrate that there is no statistic s having the property that all corresponding (Q, k, t) -sorting of a partition π in $\widehat{\Pi}$ which does not satisfy Q have a lower s -value than π . It is impossible to consider all potential statistics. But, the next corollary of [Theorem 18](#) and the following [Theorem 19](#) provide one with tools to establish non-sortability.

Corollary 3 *Let Q be a k -consistent and hereditary property of partitions and let $x \in X^t$. If some $\Pi^* \subseteq \widehat{\Pi}^x$ is Q - (ℓ, k, t) -invariant and does not satisfy Q , then Q is not (ℓ^{-1}, k, t) -sortable on $\widehat{\Pi}^x$.*

Theorem 19 *Let Q be a t -regular, k -consistent, and hereditary property of partitions. Then the following are equivalent:*

- (a) Q is (*strongly, k, t -sortable*).
- (b) For every $x \in X^t$, every set of partitions $\Pi^* \subseteq \widehat{\Pi}^x$ which is (*weakly, k, t -invariant*) satisfies Q .
- (c) There exist no $x \in X^t$ and finite sequence $\pi^0, \pi^1, \dots, \pi^{q-1}, \pi^q = \pi^0$ of partitions in $\widehat{\Pi}^x$ with $\pi^j \in (T^{Q,k,t})(\pi^{j-1}) \setminus Q$ for $j = 1, \dots, q$.
- (d) For every $x \in X^t$, $\Gamma(Q, t, x)$ is acyclic.

The historic evolution of sortability is next reviewed. The notion of sortability (as well as consistency and invariance, the latter under a different name) was first proposed by Hwang et al. [42]. However, this reference focused on sortability parameterized by (sort-specific, k , support). Chang et al. [15] extended the definition to the full (ℓ, k, t) range and gave sortability results in the full range to most properties listed in [Table 5](#). Both papers defined sortability by the conclusion of [Theorem 18](#), namely, a property Q is called (ℓ, k, t) -sortable if for every Q - (ℓ^{-1}, k, t) -invariant family Π contains a partition satisfying Q . While sortability results for particular properties relied on the construction of a corresponding decreasing statistic, the existence of a statistic was not part of the definition of sortability. [Theorem 18](#) demonstrates that the definition used herein is more demanding than the historic definition. Still, [Theorem 19](#) establishes an equivalence between the two definitions when $\ell = \text{strongly}$ (but, for other values of ℓ , “historic sortability” does not imply the “current sortability” as the implication $(b) \Rightarrow (a)$ of [Theorem 19](#) needs not hold. It is noted that the current definition of sortability explicitly requires consistency, whereas the historic definition does not; consequently, a result asserting that any (ℓ, k, t) -sortability implies k -consistency (e.g., Hwang et al. [42], Chang et al. [15]) does not appear in this chapter.

The next lemma summarizes some implications of (ℓ, k, t) -sortability of partition properties.

Lemma 8 *Let Q be a k -consistent, hereditary property of partitions. The various categories of sortability of Q satisfy the following implications:*

- (a) *(strongly, k, t) implies both (sort-specific, k, t) and (part-specific, k, t), and (sort-specific, k, t) and (part-specific, k, t) imply, each by itself, (weakly, k, t).*
- (b) *With $\ell \in \{\text{strongly, part-specific}\}$, if Q is support-regular, then (ℓ, k, open) implies $(\ell, k, \text{support})$, and if Q is shape-regular, then $(\ell, k, \text{support})$ implies (ℓ, k, shape) .*
- (c) *With $\ell \in \{\text{sort-specific, weakly}\}$, (ℓ, k, shape) implies $(\ell, k, \text{support})$, and $(\ell, k, \text{support})$ implies (ℓ, k, open) .*

The table below summarizes the implications among the various categories of sortability established in [Lemma 8](#) (using obvious abbreviations). The table should be viewed as a 2×6 matrix where each cell specifies a different pair (ℓ, t) , for example, cell $(1, 2)$, corresponds to $\ell = \text{strongly}$ and $t = \text{support}$. Implications represented by “ \Rightarrow^* ” require the corresponding regularity of Q , see part (b) of [Lemma 8 \(Table 7\)](#).

The (ℓ, k, t) -sortability of each property Q discussed in this section has been explicitly solved in the literature (see Hwang et al. [42], Chang et al. [15], and Hwang and Rothblum [39]).

It is next shown how the notions of consistency and sortability can be used to facilitate the search of an optimal partition in a family Π under a given objective function F . Let $\Pi_F^* \subseteq \Pi$ denote the set of partitions that maximize F over Π . Recall that there are two general types of results:

Table 7 Sortability-implications

$(st,k,op) \Rightarrow^* (st,k,supp)$	$\Rightarrow^* (st,k,shape)$	$\Rightarrow (s-s,k,shape)$	$\Rightarrow (s-s,k,supp)$	$\Rightarrow (s-s,k,op)$
\Downarrow	\Downarrow	\Downarrow	\Downarrow	\Downarrow
$(p-s,k,op) \Rightarrow^* (p-s,k,supp)$	$\Rightarrow^* (p-s,k,shape)$	$\Rightarrow (w,k,shape)$	$\Rightarrow (w,k,supp)$	$\Rightarrow (w,k,op)$

Type 1. Every optimal partition in Π satisfies a property Q , that is, $\Pi_F^* \subseteq Q$.

Type 2. There exists an optimal partition in Π satisfying a property Q , that is, $\Pi_F^* \cap Q$ is not empty.

Tools for establishing type 2 results are sortability arguments that show that starting from a partition in Π_F^* , local Q -sortings which preserve optimality will result in an optimal partition satisfying Q . Type 1 results are typically easier to prove, if true, by showing that the objective function of a partition not satisfying Q can be strictly improved. This last idea is next cast formally.

Theorem 20 Suppose Q is k -consistent and Π is a t -family for $t \in \{shape, support\}$. If every $\pi \in \Pi$ not satisfying Q has a k -subpartition which can be (Q, k, t) -sorted with F increasing, then every optimal partition in Π satisfies Q .

Consider objective functions of the form

$$F(\pi) = f(g_1[h(\theta_{\pi_1})], \dots, g_p[h(\theta_{\pi_p})]), \quad (22)$$

where $f : \mathbb{R}^p \rightarrow \mathbb{R}$ is (monotone), convex, or Schur convex, the g_j 's are real-valued functions over the reals, and h is a real-valued function over finite subsets of the reals. Types 1 and 2 results will be established for such objective functions. In stating type 1 results, “strict conditions” will be imposed on f, g , and h that are strict (e.g., “nondecreasing” becomes “increasing” and “nonnegative” becomes “positive”) along with the requirement that the θ^i 's are distinct. Also, **Lemma 1** shows that for verifying the optimality of partitions that satisfy a particular property, it suffices to consider the “single” versions. Instances of (22) with h as the sum-function and g_j 's as the identity, that is, F expressed by $F(\pi) = f(\sum \theta_{\pi_1}, \dots, \sum \theta_{\pi_p})$, were studied in [Sect. 3](#). Results which are in a more general form are next recorded.

Theorem 21 Suppose $F(\cdot)$ is given by (22) where f is convex and one of the following holds:

- (a) f is nondecreasing, and each g_j is convex.
- (b) f is nonincreasing, and each g_j is concave.
- (c) Each g_j is linear (and no monotonicity assumption imposed on f).

Then every shape-problem has a consecutive optimal partition. Further, if $\theta \geq 0$ ($\theta \leq 0$), then every shape problem has a size-consecutive (reverse size-consecutive) optimal partition, every size-problem has an extremal (reverse extremal) optimal partition and every relaxed-size problem has a monopolistic optimal partition. Finally, under strict conditions that exclude f from being strictly convex under (a) and (b), the corresponding type 1 conclusions hold.

The case of single-shape-problems with $g_j(\sum \theta_{\pi_j}) = g(\theta_{\pi_j}, n_j)$ where (n_1, \dots, n_p) is the prescribed shape of π was first studied by Chakravarty et al. [11].

Recall the definition of majorization in Sect. 2 and the terminology used in that section. The notion of majorization is next extended to (two types of) weak majorization by dropping the requirement $\sum_{i=1}^p a_{[i]} = \sum_{i=1}^p b_{[i]}$ (condition (8)). Specifically, a p -vector a is said to *weakly submajorize* a p -vector b , written $a \succ_w b$ if

$$\sum_{i=1}^k a_{[i]} \geq \sum_{i=1}^k b_{[i]} \quad \text{for } k = 1, \dots, p; \quad (23)$$

a is said to *weakly supermajorize* b , written $a \succ^w b$ if

$$\sum_{i=k}^p a_{[i]} \leq \sum_{i=k}^p b_{[i]} \quad \text{for } k = 1, \dots, p. \quad (24)$$

Strict weak sub-/super-majorization will refer to situations where at least one of the corresponding inequalities is strict. The following lemma is standard (e.g., Marshall and Olkin [50]).

Lemma 9 Suppose $f : \mathbb{R}^p \rightarrow \mathbb{R}$ is Schur convex and nondecreasing (nonincreasing) and a and b are vectors in \mathbb{R}^p with a weakly submajorizing (supermajorizing) b . Then $f(a) \geq f(b)$. Further, if the weak submajorization (supermajorizations) is strict and the function f is strictly Schur convex and increasing (decreasing), then $f(a) > f(b)$.

As majorization and weak sub/super-majorization are invariant over permutations of vectors, these relations can be applied to multisets of real numbers (with the interpretation that the relation holds for any representing vectors).

Lemma 10 Let f be Schur convex and nondecreasing (nonincreasing) and Q be (ℓ, k, t) -sortable with $\ell \in \{\text{strongly, sort-specific, part-specific, weak}\}$, $k = 2, 3, \dots$ and $t \in \{\text{shape, size}\}$. Suppose for any partition π not satisfying Q , there always exists an (ℓ^{-1}, k, t) - Q -sorting from π to π' such that, with K as the indices of the sorted parts, $\{\{g_j[h(\theta_{\pi'_j})] : j \in K\}\}_w \succ (^w \succ) \{\{g_j[h(\theta_{\pi_j})] : j \in K\}\}$. Then every t -problem has an optimal partition satisfying Q . Further, under strict conditions, every optimal partition satisfies Q . Finally, the above conclusions hold if f is just Schur convex and the weak majorization requirement is replaced by majorization.

Objective functions that are given by (22) with f Schur convex, g_j independent of j and h as the sum-function, are next addressed. The result modifies Theorem 21 which considered problems with f convex and g_j 's allowed to depend on j .

Theorem 22 Suppose

$$F(\pi) = f[g(\theta_{\pi_1}), \dots, g(\theta_{\pi_p})], \quad (25)$$

where f is Schur convex and either of the following holds:

- (a) f is nondecreasing, and g is convex and nondecreasing (nonincreasing).
- (b) f is nonincreasing, and g is concave and nondecreasing (nonincreasing).
- (c) g is linear and nondecreasing (nonincreasing) (and no monotonicity assumption imposed on f).

Then every shape-problem has a consecutive optimal partition. Further, if in addition $\theta \geq 0$ ($\theta \leq 0$), then every shape-problem has a size-consecutive (reverse size-consecutive) optimal partition, every size-problem has an extremal (reverse extremal) optimal partition, and every relaxed-size problem has a monopolistic optimal partition. Finally, under strict conditions, the corresponding type I conclusions hold.

The objective function of (25) with g as the identity and f Schur convex, but not necessarily monotone, was studied in Sect. 3. In fact, the conclusions of Theorem 22 for those cases were established in Theorem 11 for shape-problems and in Theorem 14 for size-problems (the latter with the Schur convexity of f relaxed to asymmetric Schur convexity).

In a clustering problem, one wishes to partition the points into clusters such that under some distance measure, points in the same cluster are close to each other compared to points in different clusters. It is natural to formulate the clustering problem into a minimization problem. To preserve this spirit, consider through the end of this section partition problems where $F(\pi)$ is to be minimized. The notion of “strict conditions,” will continue to refer to strict properties of functions appearing in the objective function, for parameters (the forthcoming w_j ’s) to be distinct and nonzero and, in addition, for θ^i ’s being distinct.

A general distance function (gdf) is a continuous symmetric function $D : \mathbb{R}^2 \rightarrow \mathbb{R}$ such that for $x' \geq x \geq y \geq y'$, $D(x', y) \geq D(x, y)$ and $D(x, y') \geq D(x, y)$ (the continuity requirement can be relaxed for much of the forthcoming results, but technical details are required). A gdf is strict if nondecreasing and nonincreasing are replaced by increasing and decreasing, respectively. A gdf is normalized if $D(x, x)$ is independent of x .

Boros and Hammer [6] considered the strict and normalized gdf $D(x, y) = |x - y|$ and established the following theorem.

Theorem 23 Suppose

$$F(\pi) = \sum_{j=1}^p \sum_{i,u \in \pi_j} |\theta^i - \theta^u|. \quad (26)$$

Then every size problem has a noncrossing optimal partition. Further, under strict conditions, the corresponding type I conclusions hold.

It is not known whether or not the conclusions of [Theorem 23](#) extend to shape-problems, except that the case of uniform shape was solved by Pfersky et al. [[60](#)].

Theorem 24 Suppose p divides n and consider the single shape-problem corresponding to $(n/p, \dots, n/p)$ with F defined by [\(26\)](#). Then there exists a consecutive optimal solution. Further, under strict conditions, a corresponding type 1 conclusion holds.

Assume the θ^i 's are given. For a given gdf D and a set $S \subseteq \mathcal{N}$, c is called a *centroid* of S with respect to D , or briefly the D -centroid of S , if $c \in \operatorname{argmin}_x \sum_{i \in S} D(\theta_i, x)$; continuity assures that every finite set has a centroid. When $D(x, y) = d(|x - y|)$ where $d(\cdot)$ is a continuous, nondecreasing function on the nonnegative reals with $d(0) = 0$, a d -centroid will refer to the corresponding D -centroid. If d is the identity, then the d -centroid is the *median*. Chang and Hwang [[14](#)] proved the type 1 results of the following theorem.

Theorem 25 Suppose

$$F(\pi) = \sum_{j=1}^p w_j \sum_{i \in \pi_j} d(|\theta^i - c_j|), \quad (27)$$

where $d(\cdot)$ is a nondecreasing function on the nonnegative reals with $\lg d$ concave and $d(0) = 0$, and for each j , $w_j > 0$ and c_j is a d -centroid of θ_{π_j} . Then every size problem has a noncrossing optimal partitions. Further, under strict conditions the corresponding type 1 conclusions hold.

Boros and Hwang [[7](#)] considered shape problems with the objective function given by [\(27\)](#) where d is the identity function (and c_j is a medium). They proved the following result.

Theorem 26 Suppose

$$F(\pi) = \sum_{j=1}^p w_j \sum_{i \in \pi_j} |\theta^i - m_j|, \quad (28)$$

where for each j , $w_j > 0$ and m_j is the median of π_j . Then every shape problem has a noncrossing optimal partition. Further, under strict conditions, the corresponding type 1 conclusions hold.

For uniform weights, the consecutive property can be preserved under more general distance functions.

Theorem 27 Suppose

$$F(\pi) = \sum_{j=1}^p \sum_{i \in \pi_j} D_i(\theta^i, c_j), \quad (29)$$

where for each i , D_i is a gdf and for each j , c_j is a centroid of π_j with respect to $\{D_i : i \in \pi_j\}$ (in the sense that $c_j \in \min \arg_x \sum_{i \in \pi_j} D_i(\theta^i, x)$). Then every size problem has a consecutive optimal partition. Further, under strict conditions, the corresponding type I conclusions hold.

Theorem 27 for $D_i(\theta^i, c_j) = w_i d(\theta^i - c_j)^2$ where w_i is a weight on element was proved by Fisher [24]. Hwang [34] extended the Fisher result to distance functions $D_i(\theta^i, c_j) = w_i D(\theta^i, c_j)$.

To obtain a shape-version of **Theorem 27**, uniform D_i 's that satisfy some further structure have to be assumed. Specifically, a gdf D is *submodular* if for every $x, x', y, y' \in \mathbb{R}$ with $x \leq x'$ and $y \leq y'$, $D(x', y') + D(x, y) \leq D(x', y) + D(x, y')$. The following result was proved by Hwang et al. [41].

Theorem 28 Suppose

$$F(\pi) = f \left(\sum_{i \in \pi_1} D(\theta^i, c_1), \dots, \sum_{i \in \pi_p} D(\theta^i, c_p) \right), \quad (30)$$

where D is a submodular gdf, f is Schur concave nondecreasing, and for each j , c_j is a D -centroid of π_j . Then every shape problem has a consecutive optimal partition. Further, under strict conditions, the corresponding type I conclusions hold.

5 Multiparameter: Polyhedral Approach

Sections [Sect. 3](#) and [Sect. 4](#) examined partition properties that facilitate a reduction of the size of the set of partitions through which one has to search for an optimal partition (for one-dimensional problems). This approach is continued in the current section and the next one but with $d \geq 1$ instead of $d = 1$. The properties that were explored in those sections are mostly geometric in nature, though the geometric characteristics may be in disguise for some of them. For example, the property “consecutive” was defined as “each part consists of consecutive integers,” but it can also be defined as “the convex hulls of the parts are pairwise disjoint.” This section and the next one continue the study of geometric properties of partitions but when the partitioned points are vectors in a high-dimensional space.

A unique feature of \mathbb{R}^1 vs. \mathbb{R}^d for $d > 1$ is that it has a natural order. In particular, when ordering the partitioned elements $\theta^1, \theta^2, \dots, \theta^n$ so that $\theta^1 \leq \theta^2 \leq \dots \leq \theta^n$, it is possible to express all relevant geometric properties of the partitioned elements in terms of the corresponding partition of the index set \mathcal{N} , except hiding the distinction whether two disjoint intervals of θ 's touch at the boundary (see next paragraph on this issue). This conversion allows us to focus on “index-partitions.” However, when the dimension d exceeds one, there is no natural ordering of the points which allows the conversion of geometric properties that depend on the formation of the points to properties of partitioned indices. Consequently, it is more natural to define partitions on the set of vectors and not on the set of indices.

There is still the question why the focus so far was on partitioning index sets in the case of single-parameter partition problems. The reason is that “index-partitions” have an advantage over “vector-partitions” in situations where the columns of A have duplicate vectors. As the indices are always distinct, such situations do not require any attention when partitioning the index set. But, when considering “vector-partitions,” the presence of duplicate points requires one to account for the duplication of each vector in each part, that is, the parts are multisets, rather than sets, and more importantly, the same vector may appear in different parts. Partitioning the index set in the case where $d = 1$ voided the need of dealing with multisets and allowed us to focus on the main development of the theory. In Sect. 5, the focus is to prove that there exists an extreme point of the partition polytope which corresponds to an optimal partition with certain geometric property. When A^i ’s are distinct, then this geometric property does not allow two disjoint parts to touch at boundary; when A^i ’s are not distinct, then the geometric property is weakened to allow such touching. But this distinction does not affect the role the partition polytopes play. Therefore, partition of the index set can be continued so as to take advantage of the convenience it provides. However, in Sect. 6, the emphasis is to study these two and other geometric properties in detail, not only in their natures, but also in their differences. In order to understand these fine points, the framework will then revert to partitioning the set A .

Throughout this section, it is assumed that $d \geq 1$ and $A^1, \dots, A^n \in \mathbb{R}^d$ are given. In the sum-partition problem, an objective function $F(\cdot)$ is maximized over a family of p -partitions Π where the objective value of a p -partition $\pi = (\pi_1, \dots, \pi_p)$ is given by $F(\pi) = f(A_\pi)$, with $A_\pi = \left(\sum_{i \in \pi_1} A^i, \dots, \sum_{i \in \pi_p} A^i \right) \in \mathbb{R}^{d \times p}$ and $f(\cdot)$ a real-valued function on $\mathbb{R}^{d \times p}$ (or a relevant subset thereof). The approach that is followed in the current section is to consider the problem of optimizing (an extension of) f over the partition polytope P_A^Π defined as the convex hull of $\{A_\pi : \pi \in \Pi\}$. When the function f is guaranteed to obtain a maximum over P_A^Π at a vertex, enumerating the vertices of P_A^Π and selecting a partition corresponding to a vertex that maximizes f will produce a solution to the partition problem. This approach is enhanced when the vertices are associated with partitions having properties that are present only in a “small number” of partitions.

The case that is considered has the function $f(\cdot)$ linear. It will be shown how linear programming can be used to solve the corresponding partition problem. Here, the approach is to obtain a representation of the problem as a projection of an optimization problem over a (generalized transportation) polytope which has a simple linear inequality representation. The resulting algorithm is polynomial in the number of partitioned vectors, their dimension, and the number of parts of the partitions. The approach follows Hwang, Onn, and Rothblum [44].

Superscripts will be used to denote columns of matrices, subscripts for rows, and double indices for elements, for example, U_t , U^j , and U_t^j . For matrices U and V of common dimension, say $d \times p$, the *inner product* of U and V is defined as the scalar $\langle U, V \rangle \equiv \sum_{t=1}^d \sum_{j=1}^p U_t^j V_t^j$. For matrices U , V , and W of dimension $d \times p$, $d \times q$, and $q \times p$, respectively,

$$\langle U, VW \rangle = \langle V^T U, W \rangle = \langle UW^T, V \rangle. \quad (31)$$

Let I be the $n \times n$ identity matrix. At times, the columns of I (the n standard unit vectors in \mathbb{R}^n) will be the vectors that are associated with the partitioned elements $1, \dots, n$. In such cases, for each p -partition π , $I_\pi \in \mathbb{R}^{n \times p}$ is the matrix associated with π , namely,

$$(I_\pi)_t^j \equiv \begin{cases} 1 & \text{if } t \in \pi_j \text{ and} \\ 0 & \text{otherwise.} \end{cases} \quad (32)$$

For a set of partitions Π , $P_I^\Pi = \text{conv}\{I_\pi : \pi \in \Pi\}$ will be referred to as a *generalized transportation polytope* (associated with Π) and to the corresponding partition problem as a *generalized transportation problem*. Classical transportation polytopes are obtained when Π consists of a single shape. The special attention given to this class of partition problems is justified by the following properties that will be established:

- (i) The correspondence $\pi \rightarrow I_\pi$ is a bijection; further, none of the matrices I_π are expressible as a convex combination of others.
- (ii) Explicit representing systems of linear inequalities are available for bounded-shape generalized transportation polytopes.
- (iii) Constrained-shape partition problems are reducible to generalized transportation problems.

These properties are next verified and then used to develop efficient computational methods for solving the (linear) partition problem.

Lemma 11 *Let Π be a set of p -partitions. Then the correspondence $\pi \rightarrow I_\pi$ is a bijection of Π onto the vertices of P_I^Π ; in particular, the vertices of P_I^Π are precisely the matrices $\{I_\pi : \pi \in \Pi\}$. Further, the inverse correspondence of vertices of P_I^Π onto the partitions of Π has vertex v corresponding to the partition π with $\pi_j = \{t : v_t^j = 1\}$ for $j = 1, \dots, p$.*

An important feature of the bijection $\pi \rightarrow I_\pi$ of Lemma 11 is the fact that it is constructive in both directions, namely, it is easy to determine I_π from π and, vice versa, π from I_π .

Linear-inequality representation for bounded-shape generalized transportation polytopes is next provided.

Theorem 29 *Let L and U be positive integer p -vectors satisfying $L \leq U$ and $\sum_{j=1}^p L_j \leq n \leq \sum_{j=1}^p U_j$, and let $\Pi \equiv \Pi^{(L,U)}$. Then P_I^Π is the solution set of the linear system:*

$$(a) \quad X_t^j \geq 0 \text{ for } t = 1, \dots, n \text{ and } j = 1, \dots, p. \quad (33)$$

$$(b) \quad \sum_{j=1}^p X_t^j = 1 \text{ for } t = 1, \dots, n.$$

$$(c) \quad L_j \leq \sum_{t=1}^n X_t^j \leq U_j \text{ for } j = 1, \dots, p.$$

When $L = U$, [Theorem 29](#) specializes to the following inequality description of classical transportation polytopes.

Corollary 4 *Let n_1, \dots, n_p be positive integers with $\sum_{j=1}^p n_j = n$ and let $\Pi \equiv \Pi^{(n_1, \dots, n_p)}$. Then P_I^Π is the solution set of the linear system:*

- (a) $X_t^j \geq 0$ for $t = 1, \dots, n$ and $j = 1, \dots, p$. (34)
- (b) $\sum_{j=1}^p X_t^j = 1$ for $t = 1, \dots, n$.
- (c) $\sum_{t=1}^n X_t^j = n_j$ for $j = 1, \dots, p$.

□

Theorem 30 *Let $A \in \mathbb{R}^{d \times n}$ and let Π be a set of p -partitions. Then the partition polytope P_A^Π is the image of the generalized transportation polytope P_I^Π under the linear function mapping $X \in P_I^\Pi \subseteq \mathbb{R}^{n \times p}$ into $AX \in \mathbb{R}^{d \times p}$. In particular, for every p -partition π , $A_\pi = AI_\pi$.*

The representation of partition polytopes as a projection of generalized transportation polytopes derived in [Theorem 30](#) yields the following test for vertices of constrained-shape partition polytopes:

Corollary 5 *Let $A \in \mathbb{R}^{d \times n}$, let Π be a set of p -partitions, and let $V \in P_A^\Pi$. Then V is a vertex of P_A^Π if and only if every representation $V = \frac{1}{2}A(X' + X'')$ with $X', X'' \in P_I^\Pi$ has $AX' = AX''$. □*

[Theorem 30](#) yields the following result that shows that partition problems over Π may be lifted to optimization problems over generalized transportation polytopes.

Corollary 6 *Let $A \in \mathbb{R}^{d \times n}$, Π be a set of p -partitions, $f : \mathbb{R}^{d \times p} \rightarrow \mathbb{R}$, and $F : \Pi \rightarrow \mathbb{R}$ with $F(\pi) = f(A_\pi)$ for each $\pi \in \Pi$. Consider the function $h : P_I^\Pi \rightarrow \mathbb{R}$ with $h(X) = f(AX)$ for each $X \in P_I^\Pi$. If π is a p -partition such that I_π maximizes h over $\{I_{\pi'} : \pi' \in \Pi\}$, then π maximizes $F(\cdot)$ over Π ; further, if f is linear with $f(X) = \langle C, X \rangle$ for every $X \in \mathbb{R}^{k \times p}$, then*

$$h(Z) = \langle C, AZ \rangle = \langle A^T C, Z \rangle \quad \text{for all } Z \in P_I^\Pi, \quad (35)$$

and a partition π with I_π maximizing h over $P_I^\Pi \supseteq \{I_{\pi'} : \pi' \in \Pi\}$ exists.

Let $A \in \mathbb{R}^{d \times n}$, $C \in \mathbb{R}^{d \times p}$ and let L and U be positive integer vectors satisfying $L \leq U$ and $\sum_{j=1}^p L_j \leq n \leq \sum_{j=1}^p U_j$, and $F : \Pi^{(L,U)} \rightarrow \mathbb{R}$ with $F(\pi) = \langle C, A_\pi \rangle$ for each $\pi \in \Pi^{(L,U)}$. The goal is to maximize $F(\cdot)$ over $\Pi \equiv \Pi^{(L,U)}$. Let $h : P_I^\Pi \rightarrow \mathbb{R}$ with $h(X) = \langle C, AX \rangle = \langle A^T C, X \rangle$ for each $X \in P_I^\Pi$. In view of [Corollary 6](#) and [Lemma 11](#), the problem of maximizing F over $\Pi^{(L,U)}$ reduces to finding a vertex of P_I^Π that maximizes the linear objective with coefficients $\{(A^T C)_t^j : t = 1, \dots, n \text{ and } j = 1, \dots, p\}$ over P_I^Π ; with $a \equiv \max\{\lg |A_t^i| : A_t^i \neq 0\}$ and $c \equiv \max\{\lg |C_i^j| : C_i^j \neq 0\}$, these coefficients are bounded by ke^{a+c} and are computable in time $O[npd(a+c)]$ (the availability of sophisticated fast algorithms for multiplying matrices is ignored); using the explicit representation of P_I^Π provided in [Theorem 29](#), the problem reduces to a structured linear program, and standard results show that an optimal vertex for P_I^Π can be identified in strongly polynomial time $O[(n+p)np + (n+p)^2u]$ where $u \equiv \max_i \lg(U_i - L_i) \leq n$ (see Ahuja and Orlin [1] or Ahuja, Orlin, and Tarjan [2]).

The above solution method applies (in fact, in a simplified form) to single-shape partition problems (with linear objective) and, consequently, to constrained-shape problems where the set of shapes is tractable. Thus, for a set of shapes Π whose size is polynomial in the parameters k, n , and p , a polynomial solution method by solving $|\Pi|$ linear programs (each having $L = U$ is available).

It is next shown that, with linear objective and special structure, a solution to single-shape partition problems can be obtained explicitly without addressing the linear programming problem over P_I^Π .

Theorem 31 *Let $A \in \mathbb{R}^{d \times n}$, $C \in \mathbb{R}^{d \times p}$, n_1, \dots, n_p be positive integers with $\sum_{j=1}^p n_j = n$, and $F : \Pi^{(n_1, \dots, n_p)} \rightarrow \mathbb{R}$ with $F(\pi) = \langle C, A_\pi \rangle$ for each $\pi \in \Pi^{(n_1, \dots, n_p)}$. If A and C satisfy*

$$(A^t - A^{t+1})^T (C^j - C^{j+1}) \geq 0 \text{ for } 1 \leq t < n \text{ and } 1 \leq j < p, \quad (36)$$

then the p -partition π with $\pi_j = \left\{ \sum_{u=1}^{j-1} n_u + 1, \dots, \sum_{u=1}^j n_u \right\}$ for $j = 1, \dots, p$ maximizes $F(\cdot)$ over $\Pi^{(n_1, \dots, n_p)}$; further, if the inequalities of (36) hold strictly, then π is a unique maximizer.

Standard arguments show that condition (36) is equivalent to (the seemingly stronger assertion):

$$(A^{t_1} - A^{t_2})^T (C^{j_1} - C^{j_2}) \geq 0 \text{ for } 1 \leq t_1 < t_2 \leq n \text{ and } 1 \leq j_1 < j_2 \leq p. \quad (37)$$

[Theorem 31](#) facilitates the identification of optimal partitions when specified permutations of the columns of A and C satisfy (36). This is always possible when $d = 1$ by sorting the two sets of scalars A^1, \dots, A^n and C^1, \dots, C^p to increasing sequences, thereby yielding an explicit solution to the partition problem.

Two properties of partitions – separability and almost separability – are next introduced. In particular, conditions are determined for these properties to be present

in partitions whose associated vector is a vertex of a constrained-shape partition polytope; results of Sect. 2 can then be used to deduce conditions which assure the existence of optimal partitions which are (almost) separable.

Two subsets Ω^1 and Ω^2 of \mathbb{R}^d are called *separable* if there exists a nonzero d -vector C such that

$$C^T u^1 > C^T u^2 \quad \text{for all } u^1 \in \Omega^1 \text{ and } u^2 \in \Omega^2. \quad (38)$$

Two subsets Ω^1 and Ω^2 of \mathbb{R}^d are called *almost separable* if there exists a nonzero d -vector C such that

$$C^T u^1 > C^T u^2 \quad \text{for all } u^1 \in \Omega^1 \text{ and } u^2 \in \Omega^2 \text{ with } u^1 \neq u^2. \quad (39)$$

In either of these cases, the vector C is referred to as a *separating vector*. Of course, separable sets are necessarily almost separable and disjoint and for disjoint sets almost separability and separability coincide. When two sets are not disjoint, almost separability (as defined by (39)) is the strongest possible form of separation by a linear functional, as the condition asserts strict separation of the values of the functional for all pairs of points at which the sets do not overlap. In particular, (39) implies that $\Omega^1 \cap \Omega^2$ contains at most a single point, for if u and w were distinct points u and w in the intersection, it would follow that $C^T u > C^T w$ and $C^T w > C^T u$.

The next lemma converts separability of finite sets to separability of their convex hulls, yielding as a corollary, a characterization of the former.

Lemma 12 *Let Ω^1 and Ω^2 be two finite sets in \mathbb{R}^d and let C be a nonzero vector in \mathbb{R}^d . Then:*

- (a) *$C^T u^1 > C^T u^2$ for all $u^1 \in \Omega^1$ and $u^2 \in \Omega^2$ if and only if $C^T w^1 > C^T w^2$ for all $w^1 \in \text{conv } \Omega^1$ and $w^2 \in \text{conv } \Omega^2$.*
- (b) *$C^T u^1 > C^T u^2$ for all $u^1 \in \Omega^1$ and $u^2 \in \Omega^2$ with $u^1 \neq u^2$ if and only if $C^T w^1 > C^T w^2$ for all $w^1 \in \text{conv } \Omega^1$ and $w^2 \in \text{conv } \Omega^2$ with $w^1 \neq w^2$.*

Call a partition $\pi = (\pi_1, \dots, \pi_p)$ *separable (almost separable)* if the sets $\{A^i : i \in \pi_j\}$ for $j = 1, \dots, p$ are pairwise separable (almost separable). The next result and its corollary establish (almost) separability of a partition π whose associated matrix A_π is a vertex of a corresponding constrained-shape partition polytope. Under the restriction that the columns of A are distinct, the results are due to Barnes et al. [4]. Some of the results about separable partitions for the general case appear in Hwang et al. [43] and the results about almost separable partitions are from Hwang and Rothblum [38, 40].

Theorem 32 *Let Γ be a nonempty set of positive integer p -vectors with coordinate-sum n , and let π be a partition in Π^Γ where A_π is a vertex of P_A^Γ . Then for some matrix $C \in \mathbb{R}^{d \times p}$ (with columns C^1, \dots, C^p)*

$$(C^r - C^s)^T u > (C^r - C^s)^T w \text{ for all distinct } r, s \in \{1, \dots, p\}, u \in \text{conv} \{A^i : i \in \pi_r\} \text{ and } w \in \text{conv} \{A^i : i \in \pi_s\} \text{ with } u \neq w. \quad (40)$$

Corollary 7 Let Γ be a nonempty set of positive integer p -vectors with coordinate-sum n , and let π be a partition in Π^Γ where A_π is a vertex of P_A^Γ . Then π is almost separable; further, if the columns of A are distinct, then π is separable.

The next result shows that when $d = 1$, the necessary condition for the matrix (in fact, vector for $d = 1$) associated with a partition to be a vertex is also sufficient.

Theorem 33 Let $A \in \mathbb{R}^{1 \times n}$, let n_1, \dots, n_p be positive integers with $\sum_{j=1}^p n_j = n$ and let π be a partition with shape (n_1, \dots, n_p) . Then π is almost separable if and only if A_π is a vertex of $P_A^{(n_1, \dots, n_p)}$ ($= P_A^\Gamma$ for $\Gamma = \{(n_1, \dots, n_p)\}$).

The next result establishes the optimality of (almost) separable partitions.

Theorem 34 Let Γ be a nonempty set of positive integer p -vectors with coordinate-sum n and let $f(\cdot)$ be an (edge-)quasi-convex function on the constrained-shape partition polytope P_A^Γ . Then there exists an optimal partition π which is almost separable and has A_π as a vertex of P_A^Γ . Further, if $f(\cdot)$ is strictly (edge-)quasi-convex, then every optimal partition π is almost separable and has A_π as a vertex of P_A^Γ . If A 's columns are distinct, the quantifier “almost” can be dropped in the above statements.

Theorem 34 shows that when considering constrained-shape partition problems with $f(\cdot)$ (edge-)quasi-convex, it suffices to consider partitions that are (almost) separable (and whose associated matrix is a vertex of the corresponding partition polytope).

Cone-separability, another property of partitions, it next introduced and studied. In particular, it will be shown that single-size partition problems have optimal partitions with this property and an enumeration algorithm for solving such problems will be developed. It is emphasized that the results require the assumption that empty parts are allowed. Of course, single-size problems with empty parts prohibited (allowed) are instances of constrained-shape problems corresponding to the set of all positive (nonnegative) shapes. In particular, problems of either type have optimal solutions that are (almost) separable, and enumerating (almost) separable partitions can be used to solve these problems. The following stronger conclusions do not apply to single-size problem when parts are required to nonempty.

Two subsets Ω^1 and Ω^2 of \mathbb{R}^d are called *cone-separable* if there exists a nonzero d -vector C such that

$$C^T u^1 > 0 > C^T u^2 \text{ for all } u^1 \in \Omega^1 \setminus \{0\} \text{ and } u^2 \in \Omega^2 \setminus \{0\} \quad (41)$$

(if either $\Omega^1 \setminus \{0\}$ or $\Omega^2 \setminus \{0\}$ is empty and the other set is not, then (41) is to be interpreted as a requirement just on the elements of the nonempty set).

A relation between cone-separability and (almost) separability is determined in the next lemma.

Lemma 13 Suppose Ω^1 and Ω^2 are subsets of \mathbb{R}^d that are cone-separable. Then Ω^1 and Ω^2 are almost separable with the vector C satisfying (41) as a separating vector; in this case, 0 is the only possible vector in $\Omega^1 \cap \Omega^2$. Further, if $0 \notin \Omega^1$ or $0 \notin \Omega^2$, then Ω^1 and Ω^2 are separable.

The next example demonstrates that (almost)-separability does not imply cone-separability.

Example 7 For $k = 1, 2$, let $\Omega^k = \{\binom{k}{0}, \binom{k}{2}\} \subseteq \mathbb{R}^2$. Then Ω^1 and Ω^2 are separable (with $C = \binom{1}{0}$ as a separating vector), but they are not cone-separable as a vector $C \in \mathbb{R}^2$ satisfies $C^T \binom{1}{0} > 0$ if and only if $C^T \binom{2}{0} > 0$. \square

Recall that the *conic hull* of a set $\Omega \subseteq \mathbb{R}^d$, denoted $\text{cone } \Omega$, is defined as the set of linear combinations $\sum_{t=1}^q \Gamma_t x^t$ with $\Gamma_t \geq 0$ and $x^t \in \Omega$ for $t = 1, \dots, q$ (with $\text{cone } \emptyset = \{0\}$). A set is a *cone* if it equals its conic hull. A cone is *pointed* if for no nonzero vector x , both x and $-x$ are in the cone. A fundamental result about cones (see Rockafellar [61], Schrijver [64], or Ziegler [71]) shows that a set is the conic hull of a finite set in \mathbb{R}^m if and only if it has a representation $\{x \in \mathbb{R}^m : Ax \leq 0\}$ with A as a real matrix having m columns; such a cone is called a *polyhedral cone*.

Lemma 14 Let Ω^1 and Ω^2 be two finite sets in \mathbb{R}^d and let C be a nonzero vector in \mathbb{R}^d . Then $C^T u^1 > 0 > C^T u^2$ for all $u^1 \in \Omega^1 \setminus \{0\}$ and $u^2 \in \Omega^2 \setminus \{0\}$ if and only if $C^T w^1 > 0 > C^T w^2$ for all $w^1 \in (\text{cone } \Omega^1) \setminus \{0\}$ and $w^2 \in (\text{cone } \Omega^2) \setminus \{0\}$.

The next result provides characterizations of cone-separability for polyhedral cones.

Lemma 15 Let Ω^1 and Ω^2 be two finite sets in \mathbb{R}^d . Then the following are equivalent:

- (a) Ω^1 and Ω^2 are cone-separable.
- (b) $\text{cone } \Omega^1$ and $\text{cone } \Omega^2$ are cone-separable.
- (c) $\text{cone } \Omega^1$ and $\text{cone } \Omega^2$ are almost separable.
- (d) $\text{cone } \Omega^1$ and $\text{cone } \Omega^2$ are pointed cones and $(\text{cone } \Omega^1) \cap (\text{cone } \Omega^2) = \{0\}$.

Attention is next turned to partition problems. Here, fixed-size problems with a relaxation of the assumption that partitions' parts are nonempty are considered. Formally, let $\widehat{\Pi}^p$ denote the set of p -partitions which allow empty parts. For $\pi \in \widehat{\Pi}^p$, A_π has the natural definition with the empty sum taken as zero. The partition polytope corresponding to $\widehat{\Pi}^p$ is defined by $P_A^{\widehat{\Pi}^p} \equiv \text{conv} \{A_\pi : \pi \in \widehat{\Pi}^p\}$. As in all sum-partition problems, it is assumed that the objective function F over $\widehat{\Pi}^p$ is given by $F(\pi) = f(A_\pi)$ with f as a real-valued function on $P_A^{\widehat{\Pi}^p}$.

Call a partition $\pi = (\pi_1, \dots, \pi_p)$ *cone-separable* if the sets $\{A^i : i \in \pi_j\}$ for $j = 1, \dots, p$ are pairwise cone-separable. Lemma 13 shows that cone-separability implies almost separability, with 0 as the only potential overlapping vector for any pair of parts; moreover, a cone-separable partition with at most one part containing indices that correspond to the 0 vector is separable. The next two theorems extend results of Barnes, Hoffman, and Rothblum [1992] (which considered the case where the A^i 's are distinct).

Theorem 35 *If $\pi \in \widehat{\Pi}^p$ and A_π is a vertex of $P_A^{\widehat{\Pi}^p}$, then for some matrix $C \in \mathbb{R}^{d \times p}$*

$$(C^r)^T u > (C^s)^T u \text{ for all distinct } r, s = 1, \dots, p \text{ and } u \in (\text{cone } \pi_r) \setminus \{0\}. \quad (42)$$

Theorem 36 *Let $f(\cdot)$ be an (edge-)quasi-convex on $P_A^{\widehat{\Pi}^p}$. Then there exists an optimal partition π which is both cone-separable and (almost) separable and has A_π as a vertex of $P_A^{\widehat{\Pi}^p}$. Further, if $f(\cdot)$ is strictly (edge-)quasi-convex, then every optimal partition π is cone-separable and has A_π as a vertex of $P_A^{\widehat{\Pi}^p}$.*

The next two results consider cone-separable partitions when $d = 1$ and $d = 2$.

Theorem 37 *Suppose $A \in \mathbb{R}^{1 \times n}$ has no zero column. If $p \geq 2$, then a p -partition π is cone-separable if and only if two of its parts are $\{i \in \mathcal{N} : A^i > 0\}$ and $\{i \in \mathcal{N} : A^i < 0\}$ (where either may be empty) and all other parts are empty. If $p = 1$, then the (only) 1-partition (\mathcal{N}) is cone-separable if and only if A contains either just positive elements or just negative elements.*

To study cone-separable partitions with $d = 2$, associate each $x \in \mathbb{R}^2 \setminus \{0\}$ with the *angular coordinate* of its polar-coordinate representation denoted $\phi(x)$ (measured in degrees). It is observed that for $\emptyset \neq C \subseteq \mathbb{R}^2 \setminus \{0\}$, $C \cup \{0\}$ is a pointed polyhedral cone if and only if for some $0 \leq \underline{\phi} \leq \bar{\phi}$: $\underline{\phi} < 360^\circ$, $\bar{\phi} < \underline{\phi} + 180^\circ$ and

$$C = \begin{cases} \{x \in \mathbb{R}^2 \setminus \{0\} : \underline{\phi} \leq \phi(x) \leq \bar{\phi}\} & \text{if } \bar{\phi} < 360^\circ \\ \{x \in \mathbb{R}^2 \setminus \{0\} : \underline{\phi} \leq \phi(x) < 360^\circ \text{ or } 0 \leq \phi(x) \leq \bar{\phi} - 360^\circ\} & \text{if } \bar{\phi} \geq 360^\circ. \end{cases}$$

Theorem 38 *Suppose $A \in \mathbb{R}^{2 \times n}$ has no zero column. A p -partition π is cone-separable if and only if for some $q \leq p$, there exist $0 \leq \underline{\phi}_1 \leq \bar{\phi}_1 < \underline{\phi}_2 \leq \bar{\phi}_2 < \dots < \underline{\phi}_q \leq \bar{\phi}_q < \underline{\phi}_1 + 360^\circ$ such that $\underline{\phi}_q < 360^\circ$, $\bar{\phi}_t - \underline{\phi}_t < 180^\circ$ for each $t = 1, \dots, q$, and the nonempty parts of π are*

$$\{i \in \mathcal{N} : \underline{\phi}_t \leq \phi(A^i) \leq \bar{\phi}_t\} \text{ for } t = 1, \dots, q-1$$

and

$$\begin{cases} \{i \in \mathcal{N} : \underline{\phi}_q \leq \phi(A^i) \leq \bar{\phi}_q\} & \text{if } \bar{\phi}_q < 360^\circ \\ \{i \in \mathcal{N} : \underline{\phi}_q \leq \phi(A^i) < 360^\circ \text{ or } 0 \leq \phi(A^i) \leq \bar{\phi}_q - 360^\circ\} & \text{if } \bar{\phi}_q \geq 360^\circ; \end{cases}$$

further, the $\underline{\phi}_t$'s and $\bar{\phi}_t$'s can be selected from $\{\phi(A^i) : i \in \mathcal{N}\}$.

6 Multiparameter: Combinatorial Approach

This section explores a combinatorial approach which can apply to partition problems that are more general than the sum-partition problems studied in Sect. 5. Here, vector partitions rather than index partitions are used – see the first three paragraphs of Sect. 5.

A finite subset Ω^1 of \mathbb{R}^d penetrates another finite subset Ω^2 of \mathbb{R}^d , written $\Omega^1 \rightarrow \Omega^2$, if $\Omega^1 \cap (\text{conv } \Omega^2) \neq \emptyset$; Ω^1 strictly penetrates Ω^2 if $\Omega^1 \cap (\text{ri}[\text{conv } \Omega^2]) \neq \emptyset$. Some implications about penetration that are true in \mathbb{R}^1 do not hold in \mathbb{R}^d with $d > 1$. For example, $\Omega^1 \rightarrow \Omega^2$ and $\Omega^2 \not\rightarrow \Omega^1$ no longer imply $\text{conv } \Omega^1 \subset \text{conv } \Omega^2$.

Properties of partitions of vectors in \mathbb{R}^d , with $d > 1$, are next introduced. The fact that some implications of penetration in \mathbb{R}^1 do not hold in \mathbb{R}^d for $d > 1$ implies that some properties of partitions of points in \mathbb{R}^1 that were defined in terms of penetration have more than one counterpart for partitions of points in \mathbb{R}^d .

A *sphere* in \mathbb{R}^d is defined as a set of the form $S = \{x \in \mathbb{R}^d : \|x - a\| \leq R\}$ for some $a \in \mathbb{R}^d$ and $R > 0$, where $\|\cdot\|$ stands for the Euclidean norm. The interior and boundary of such a sphere is given by $\text{int } S = \{x \in \mathbb{R}^d : \|x - a\| < R\}$ and $\text{bd } S = \{x \in \mathbb{R}^d : \|x - a\| = R\}$.

Consider a partition $\pi = (\pi_1, \dots, \pi_p)$ of a finite set of vectors in \mathbb{R}^d . The following properties of such partitions will be considered; the first three were introduced in Sect. 5.

- *Separable (S)* (also referred to as “disjoint” in the literature): For all distinct $r, s = 1, \dots, p$, π_r and π_s are separable, that is, $(\text{conv } \pi_r) \cap (\text{conv } \pi_s) = \emptyset$.
- *Almost separable (AS)*: For all distinct $r, s = 1, \dots, p$, π_r and π_s are almost separable, that is, $(\text{conv } \pi_r) \cap (\text{conv } \pi_s)$ contains at most a single point, and if the intersection contains a point, it is a vertex of both $\text{conv } \pi_r$ and $\text{conv } \pi_s$.
- *Cone-separable ($C_n S$)*: For all distinct $r, s = 1, \dots, p$, π_r and π_s are cone-separable, that is, $(\text{cone } \pi_r) \cap (\text{cone } \pi_s) = \{0\}$.
- *Sphere-separable (SS)*: For all distinct $r, s = 1, \dots, p$, there exists a sphere $S \subset \mathbb{R}^d$ such that either $(U, W) = (\pi_r, \pi_s)$ or $(U, W) = (\pi_s, \pi_r)$, satisfies $S \supseteq U$ and $S \cap W = \emptyset$.
- *Convex-separable ($C_v S$)*: For all distinct $r, s = 1, \dots, p$, there exists a convex set $S \subset \mathbb{R}^d$ such that either $(U, W) = (\pi_r, \pi_s)$ or $(U, W) = (\pi_s, \pi_r)$, satisfies $S \supseteq U$ and $S \cap W = \emptyset$. (Evidently, without loss of generality, it is possible to assume that $\dim S = d$.)
- *Almost sphere-separable (ASS)*: For all distinct $r, s = 1, \dots, p$, there exists a sphere $S \subset \mathbb{R}^d$ such that either $(U, W) = (\pi_r, \pi_s)$ or $(U, W) = (\pi_s, \pi_r)$, satisfies $S \supseteq U$ and $|S \cap W| \leq 1$ and if x is a single point in $S \cap W$, then $U \cap (\text{bd } S) = \{x\}$.
- *Nonpenetrating (NP)*: For all distinct $r, s = 1, \dots, p$, $\pi_r \not\rightarrow \text{conv } \pi_s$.
- *Noncrossing (NC)*: For all distinct $r, s = 1, \dots, p$, either $(\text{conv } \pi_r) \cap (\text{conv } \pi_s) = \emptyset$ or one convex hull is contained in the other with no member of the larger part penetrating the smaller part.

- *Acyclic (AC)*: There do not exist $q \geq 2$ parts of π , say $\pi_{i_1}, \dots, \pi_{i_q}$, such that $\pi_{i_1} \rightarrow \pi_{i_2} \rightarrow \dots \rightarrow \pi_{i_q} \rightarrow \pi_{i_1}$.
- *Monopolistic (M_p)*: One part has all elements. Note that if empty parts are prohibited, there is only one partition satisfying M_p and its size is 1, if empty parts are allowed it means that $p - 1$ parts are empty.
- *Nearly monopolistic ($N_e M_p$)*: At most one part of π has more than a single point.
- *Nearly cone-separable ($N_e C_n S$)*: For all distinct $r, s = 1, \dots, p$, π_r and π_s are either cone-separable or at least one of them is a singleton.

A property defined by penetration is called “weak” if the penetration allows touching at boundary. Also note that two subsets Ω^1 and Ω^2 of \mathbb{R}^d are separable if and only if there exists a (closed) half-space S such that $S \supseteq \Omega^1$ and $S \cap \Omega^2 = \emptyset$, and Ω^1 and Ω^2 are cone-separable if and only if there exists a (closed) cone S of dimension d such that $S \supseteq \Omega^1$ and $S \cap \Omega^2 = \{0\}$.

S and $C_n S$ were first considered in Barnes et al. [4]; $C_v S$ (called “noncrossing”) in Boros and Hwang [7]; AS in Hwang and Rothblum [38]; SS , NP (called “nested”), and AC (called “connected”) in Boros and Hammer [6]; NC (for $d = 1$) in Kreweras [48], and $N_e M_p$ in Pfersky et al. [60].

When $d = 1$, both S and NP reduce to consecutiveness, while $N_e C_n S$, NC , SS , AC , and $C_v S$ all reduce to noncrossingness. Further, when $d = 1$, partitions in $C_n S$ can have at most one part containing positive elements, at most one part containing negative elements, and some parts each consisting of only the 0-element (but may have multiple copies). For a set of points with k 0-elements, this set is not size(p)-regular for $p > k + 2$ and not shape-regular for almost all shapes. Hence, $C_n S$ is not studied for $d = 1$. For $d = 1$, when there are enough 0-elements, $C_n S$ reduces to bi-extremal, but $N_e M_p$ does not reduce to extremal since the singletons can be anywhere, not necessarily the smallest elements.

Theorem 39 *The relations among the properties of partitions that were introduced are represented in Fig. 4.*

Golany et al. [29] proved an unexpected relation between S and SS . Here, an “almost” version of the result is added. To state these results, the partitioned vectors are embedded in \mathbb{R}^{d+1} by defining

$$\widehat{A}^i \equiv \begin{pmatrix} A^i \\ \|A^i\|^2 \end{pmatrix} \in \mathbb{R}^{d+1} \text{ for } i = 1, \dots, n. \quad (43)$$

Next, for each p -partition $\pi = (\pi_1, \dots, \pi_p)$, let $\widehat{\pi}$ be the p -partition for the problem with partitioned vectors $\widehat{A}^1, \dots, \widehat{A}^n$ with $\widehat{\pi}_j = \{\widehat{A}^i : A^i \in \pi_j\}$ for $j = 1, \dots, p$; in particular,

$$\widehat{A}_{\pi} = \left[\sum_{A^i \in \pi_1} \widehat{A}^i, \dots, \sum_{A^i \in \pi_p} \widehat{A}^i \right] \in \mathbb{R}^{(d+1) \times p}. \quad (44)$$

Theorem 40 *A partition π is (almost) sphere-separable if and only if $\widehat{\pi}$ is (almost) separable when the partitioned vectors are $\widehat{A}^1, \dots, \widehat{A}^n$.*

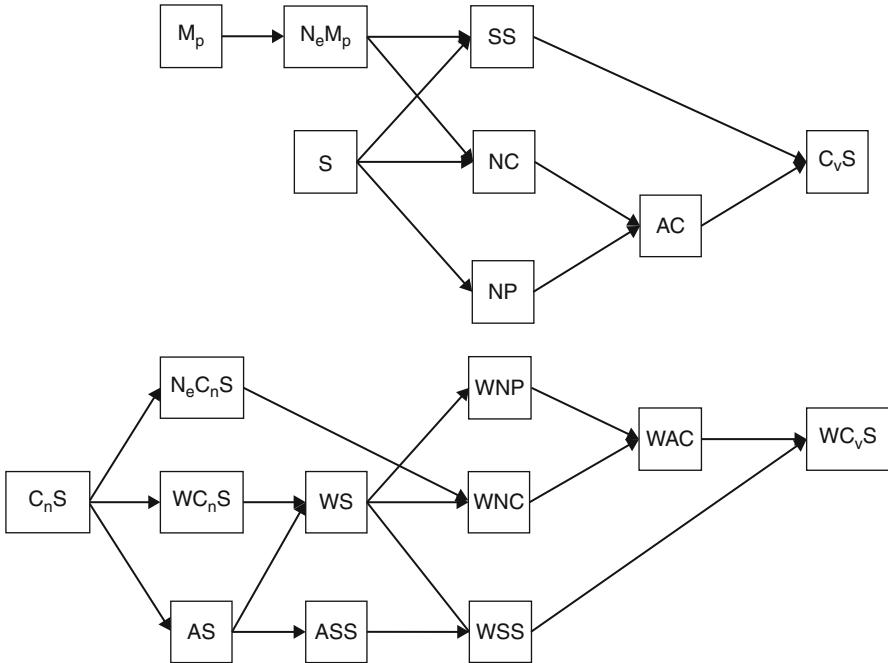

Fig. 4 Implications among properties of multiparameter partitions

The proofs of (Golany et al. [29]) of the equivalences of [Theorem 40](#) are constructive and show how to convert separating vectors that verify (almost) separability into spheres that verify (almost) sphere separability and vice versa.

The next result provides conditions that suffice for $(A)SS \Rightarrow (A)S$.

Lemma 16 *Assume that all the A^i 's lie on the boundary of a sphere. Then a partition is (almost) sphere-separable if and only if it is (almost) separable.*

Next, the number of Q -partitions for each property Q introduced earlier is bounded. Since vector-partitions are considered, the counts may depend on the partitioned vectors. For each $A \in \mathbb{R}^{d \times n}$, let $\#_Q^A(p)$ be the number of p -partitions of the columns of A that satisfy Q , allowing empty parts. The emphasis is to examine whether $\#_Q(n, p, d) \equiv \max_{A \in \mathbb{R}^{d \times n}} \#_Q^A(p)$ grows exponentially or polynomially in n , with $p \geq 2$ and d fixed (in the latter case, enumeration algorithms exist for all relevant properties Q , see [39]). Counting of a polynomial class is usually done by providing an upper bound of the form $O(n^m)$ for some positive m .

Every unlabeled p -partition corresponds to at most $p!$ labeled partitions (the option for identical parts implies that the bound needs not always be tight). Thus, the number of labeled p -partitions is bounded by $p!$ times the number of unlabeled p -partitions (for index-partitions, there are no identical parts, so the bound is

realized), a multiplier that is independent of n . Consequently, the $O(\cdot)$ order of the classes of labeled and unlabeled partitions with a given property coincide. Here, it is convenient to count the labeled classes. Also, empty parts will be allowed.

When columns of A are not distinct, a vector $x \in \mathbb{R}^d$ is referred to as a *multiple point* (of A) if it appears more than once among the columns of A ; the *multiplicity* of a multiple point x is the number of times x appears among the columns of A . As vector partitions are considered, two partitions are identified if their parts are assigned, respectively, the same number of copies of each multiple point. The next lemma records a standard combinatorial fact.

Lemma 17 *Suppose a point in \mathbb{R}^d has n copies. Then there are $\binom{n-1}{p-1}$ ways of splitting the point into p nonempty (labeled) parts and $\binom{n+p-1}{p-1}$ ways of splitting it into p parts when empty parts are allowed; in either case, the number is bounded by $O(n^{p-1})$.*

A set of points in \mathbb{R}^d is called *generic*, or in *general position*, if for $k = 1, \dots, d$ no $k + 1$ points of them lie in a $k - 1$ -dimensional hyperplane. A matrix is called *generic*, if the set of its columns is generic. Harding [33, Theorem 1] gave an exact count of the number of A -separable 2-partitions when A is generic. Harding's result is next presented in a more general context which corrects [33, Theorem 2]; see Hwang and Rothblum [38]. For $n, d \geq 1$, define the (n, d) -Harding number, denoted $H(n, d)$, by

$$H(n, d) \equiv \sum_{j=0}^d \binom{n-1}{j}, \quad (45)$$

(where the standard convention that $\binom{n}{0} = 1$ for each $n \geq 0$ and $\binom{n}{k} = 0$ if $k > n$ is used).

For $A \in \mathbb{R}^{d \times n}$ and $E \in \mathbb{R}^{d \times u}$, a p -partition π is (A, E) -separable if every pair of parts of π are separable by a hyperplane that contains the columns of E .

Theorem 41 *Suppose $A \in \mathbb{R}^{d \times n}$ and $E \in \mathbb{R}^{d \times u}$, where $0 \leq u \leq d$ and $[A, E]$ is generic. With empty parts allowed, the number of $(A|E)$ -separable 2-partitions is $2H(n, d-u) \leq 2^{d-u+1} \binom{n}{d-u}$. With empty parts prohibited, the number of $(A|E)$ -separable 2-partitions is $2H(n, d-u) - 2$ if either $u < d$ or if $u = d$ and neither side of the unique hyperplane spanned by the columns of E contains all of A 's columns. Finally, if empty parts are prohibited, $u = d$ and all columns of A are on one side of the unique hyperplane spanned by the columns of E , then the number of $(A|E)$ -separable is 0.*

Corollary 8 *Suppose $A \in \mathbb{R}^{d \times n}$ is generic. Then $\#_S^A(2) \leq 2H(n, d) = O(n^d)$.*

Hwang et al. [43] proved the equality $\#_S^A(2) = O(n^d)$ of Corollary 8 without using the Harding function. They also extended their result to arbitrary A in $\mathbb{R}^{d \times n}$ by perturbing A into A' which is generic and proved that the set of A -separable

2-partitions is contained in the set of A' -separable 2-partitions, thus bounding $\#_S^A(2)$ by $\#_{S'}^A(2)$ which equals $O(n^d)$ by Corollary 8. Finally, they gave a construction of each A -separable partition by merging a given set of $\binom{p}{2}$ 2-partitions π_{ij} of A , for all “ $1 \leq i < j \leq p$,” and showed that all A -separable p -partitions can be obtained from such constructions (by varying the given set of 2-partitions).

Theorem 42 For $A \in \mathbb{R}^{d \times n}$, $\#_S^A(p) \leq [\#_S^A(2)]^{\binom{p}{2}} = O(n^{d\binom{p}{2}})$. Also, $\#_S(n, p, d) = O(n^{d\binom{p}{2}})$.

Alon and Onn [3] proved that the $O(n^{d\binom{p}{2}})$ bound of Theorem 42 cannot be improved for either $p \geq 3$ or $d \geq 3$.

Using Theorem 40, the above results can be used to derive bounds for sphere-separability.

Theorem 43 Suppose $A \in \mathbb{R}^{d \times n}$, $p \geq 2$ and \bar{n} is the number of distinct columns of A . Then $\#_{SS}^A(p) \leq [\#_{SS}^A(2)]^{\binom{p}{2}} \leq [2H(\bar{n}, d + 1)]^{\binom{p}{2}} \leq [2^{d+1} \binom{\bar{n}}{d+1}]^{\binom{p}{2}}$. Also, $\#_{SS}(n, p, d) = O(n^{(d+1)\binom{p}{2}})$.

Given $A \in \mathbb{R}^{d \times n}$, Theorem 40 also shows that any enumeration method for separable partitions immediately yields a method for enumerating the A -sphere-separable partitions (with a complexity bound obtained by substituting $d + 1$ for d).

Hwang and Rothblum [39] obtained the following result.

Theorem 44 For $A \in \mathbb{R}^{d \times n}$ having no zero-column, $\#_{C_n S}^A(p) \leq [\#_{C_n S}^A(2)]^{\binom{p}{2}} \leq [2H(n, d - 1)]^{\binom{p}{2}} = O[n^{(d-1)\binom{p}{2}}]$. Also, $\#_{C_n S}(n, p, d) \leq [2H(n, d - 1)]^{\binom{p}{2}} = O(n^{(d-1)\binom{p}{2}})$.

Almost separable partitions are next considered, starting with 2-partitions. The result follows Hwang and Rothblum [40].

Lemma 18 For $A \in \mathbb{R}^{d \times n}$ having \widetilde{n} distinct columns, $\#_{AS}^A(2) \leq 2H(n, d) + (n - \widetilde{n})[2H(\widetilde{n} - 1, d - 1)] \leq 2H(n, d)$. Also, $\#_{AS}(n, 2, d) = \#_S(n, 2, d) = 2H(n, d)$.

Two difficulties prevent one from mimicking the perturbation argument and the merging argument used for separable partitions to obtain an extension of Lemma 18 to general p . First, using the same perturbation A to A' , the set of A -almost separable 2-partitions is no longer contained in the set of A' -separable partitions (though for generic A' , almost separable and separable coincide). Thus, one cannot transform a bound of the latter into a bound of the former. Second, the straightforward merging construction for separable partitions is not delicate enough to cover the almost separable case. Hwang and Rothblum [40] showed how to overcome these two problems. The first problem is solved by using the second conclusion of Lemma 18, that is, $\#_{AS}(n, 2, d) = 2H(n, d)$ for the need to bound $\#_{AS}^A(2)$. They also gave a much more elaborated construction to deliver the merging successfully. The resulting bound of $\#_{AS}(n, p, d)$ is given in the next theorem.

Table 8 Bounds of $\#_Q(n, p, d)$

Q	$\#_Q(n, p, d)$	Ref.
S	$O\left(n^d \binom{p}{2}\right)$	Theorem 42
SS	$O\left(n^{(d+1)\binom{p}{2}}\right)$	Theorem 43
$C_n S$	$O\left(n^{(d-1)\binom{p}{2}}\right)$	Theorem 44
AS	$O\left(n^d \binom{p}{2}\right)$	Theorem 45
ASS	$O\left(n^{(d+1)\binom{p}{2}}\right)$	Theorem 46

Theorem 45 $\#_{AS}(n, p, d) \leq [\#_{AS}(n, 2, d)]^{\binom{p}{2}} = O(n^{d\binom{p}{2}})$.

The following result is an immediate consequence of Theorems 40 and 45.

Theorem 46 $\#_{ASS}(n, p, d) = O(n^{(d+1)\binom{p}{2}})$.

The following Table 8 summarizes the bounds of $\#_Q(n, p, d)$ for those properties Q discussed above.

Several simple bounds on the number of partitions that satisfy other properties are next recorded. First, it is trivial that $\#_{MP}(n, p, d) = \binom{n}{p-1} = O(n^{p-1})$, consequently, $\#_{NeMP}(n, p, d) = p! \binom{n}{p-1}$. Also, a careful combinatorial argument yields $\#_{NeCnS}(n, p, d) = \sum_{q=0}^{p-1} \binom{n}{q} q! \#_{CnS}(n-q, p-q, d) = O(n^{(d-1)\binom{p}{2}+p-1})$. Finally, for $Q \in \{NP, AC, NC\}$, Hwang, Lee, Liu, and Rothblum [45] gave examples to show that even for $d = p = 2$, the number of Q -partitions is exponential. From the implication relation shown in Fig. 4, the number of CvS partitions must also be exponential. Finally, it is easily verified that all weak properties are exponential.

Consistency and sortability, as introduced in Sect. 4, refer to properties of index-partitions, without reference to the representation of the partitioned elements. However, p -partition or k -subpartition is said to satisfy Q , and then satisfaction of a part or parts of indices always implies the same satisfaction of the part or parts of the corresponding points. Further, the extension of the notion of satisfaction from a 1-dimensional point to a multi-dimensional point is straightforward. Hence, consistency and sortability can still be discussed for vector-partitions, and the approach of using Q -sortability to prove the existence of a Q -optimal partition is valid as it was for the single-parameter case.

The remainder of this section discusses geometric properties that are present in optimal partitions. Let $\{A^1, \dots, A^n\}$ be a set of n vectors in \mathbb{R}^d and let $F(\cdot)$ denote an objective function over partitions of these vectors. Throughout the remainder of this section, unless explicitly stated otherwise, $F(\cdot)$ is to be minimized in the partition problems that are considered (as is usually the case in “clustering problems”). Also, the results for size problems hold regardless of whether empty parts are allowed or not (for constrained-shape problems, prohibiting empty parts is captured by having the set of feasible shapes contain only positive integer vectors). However, if a result depends on allowing empty parts or on prohibiting such parts, then the condition will be stated explicitly.

Golany et al. [29] extended results of Barnes et al. [4] to the following (which extends [Theorem 34](#)):

Theorem 47 *Suppose*

$$F(\pi) = f(|\pi_1|, \dots, |\pi_p|, A_\pi), \quad (46)$$

where for each fixed set of values $(|\pi_1|, \dots, |\pi_p|)$, f is (edge-)quasi-concave on the corresponding single-shape partition polytope (in the $d \times p$ variables of A_π). Then every constrained-shape problem has an almost separable optimal partition. If furthermore, f is strictly (edge-)quasi-concave, then every optimal partition for a constrained-shape problem is almost separable.

Recall the use of “ $\widehat{\cdot}$ ” introduced in (43) and (44). The following result is reported in Golany et al. [29].

Corollary 9 *Suppose*

$$F(\pi) = f(|\pi_1|, \dots, |\pi_p|, \widehat{A}_\pi), \quad (47)$$

where for each fixed set of values $(|\pi_1|, \dots, |\pi_p|)$, f is (edge-)quasi-concave on the corresponding single-shape partition polytope (in the $(d+1) \times p$ variables of \widehat{A}_π). Then every constrained-shape problem has an almost sphere separable optimal partition. Further, if f is strictly (edge-)quasi-concave, then every optimal partition for a constrained-shape problem is almost sphere separable.

If the function f in [Corollary 9](#) is linear in the variables corresponding to \widehat{A}_π and in the shape-variable, the results of [Sect. 5](#) can be used; that is, bounded-shape partition problems with such objective functions can be solved by LP methods, applied in the enlarged $(d+2)$ -dimensional space where the partitioned vectors are $\binom{\widehat{A}^i}{1}$.

Following Golany et al. [29], [Corollary 9](#) is next used to address some clustering problems.

Theorem 48 *Let w_1, \dots, w_p be positive numbers. Suppose $F(\cdot)$ has either one of the following three expressions:*

- (i) $F(\pi) = \sum_{j=1}^p w_j \sum_{A^i, A^k \in \pi_j} \|A^i - A^k\|^2.$
- (ii) $F(\pi) = \sum_{j=1, \pi_j \neq \emptyset}^p w_j \sum_{A^i \in \pi_j} \|A^i - \bar{A}_j\|^2,$ where for $j = 1, \dots, p$,

$$\bar{A}_j = \frac{\sum_{A^k \in \pi_j} A^k}{|\pi_j|}.$$
- (iii) $F(\pi) = \sum_{j=1}^p w_j \sum_{A^i \in \pi_j} \|A^i - t_j\|^2,$ where t_1, \dots, t_p are prescribed d -vectors.

Then every constrained-shape problem has an almost sphere separable optimal partition.

The third objective function can be expressed as a linear function of \widehat{A}_π and of the parts' sizes. Consequently, the comment following [Corollary 9](#) applies and corresponding bounded-shape partition problems can be solved by LP methods.

Uniform versions of the objective functions that are listed in [Theorem 48](#) are next considered, where uniform means that the w_j 's are constant.

Theorem 49 Consider uniform versions of the objective functions that are listed in [Theorem 48](#). Then:

- (i) For a constrained-shape problem with constant part-sizes and with the first function, every optimal partition is almost separable.
- (ii) For a constrained-shape problem with the second function, every optimal partition is almost separable.
- (iii) For a constrained-shape problem with the third function, there exists an almost separable optimal partition.

Boros and Hammer [6] considered case (i) of [Theorem 49](#) and proved that every single size problem has a weakly separable optimal partition. [Theorem 49](#) strengthens their result in several ways: A stronger property is satisfied for every optimal partition, and the conclusion holds for a wider class of partition problems.

Attention is next turned to single-size problems. For a p -partition π and $i \in \mathcal{N}$, let $j_\pi(i)$ denote the index of the part of π that contains A^i (here, distinction must be made between multiple copies of the same vector).

Lemma 19 Let t_1, \dots, t_p be prescribed distinct vectors in \mathbb{R}^d . Then, allowing for empty parts, there is a separable partition π such that

$$\|A^i - t_{j_\pi(i)}\| \leq \|A^i - t_{j_{\pi'}(i)}\| \quad \text{for every partition } \pi' \text{ and } i \in \mathcal{N}. \quad (48)$$

Further, a partition π satisfies (48) if and only if each vector A^i is assigned to a part π_j for which $\|A^i - t_j\| = \min_{u=1,\dots,p} \|A^i - t_u\|$; each such partition is weakly separable.

Theorem 50 Let t_1, \dots, t_p be prescribed distinct vectors in \mathbb{R}^d and consider the single-size problem, allowing empty parts, which has

$$F(\pi) = f(\|A^1 - t_{j_\pi(1)}\|, \dots, \|A^n - t_{j_\pi(n)}\|), \quad (49)$$

where $f : \mathbb{R}^n \rightarrow \mathbb{R}$ is nondecreasing. Then the partition π which assigns each vector A^i to the part π_j with the lowest index j among those for which $\|A^i - t_j\|$ is minimized is both optimal and separable. Further, if f is increasing, then a partition π is optimal if and only each vector A^i is assigned to a part π_j for which $\|A^i - t_j\| = \min_{u=1,\dots,p} \|A^i - t_u\|$, and every optimal partition is weakly separable.

Corollary 10 *The conclusions of Theorem 50 hold for the single-size problem, allowing empty parts, which has*

$$F(\pi) = \sum_{j=1, \pi_j \neq \emptyset}^p \sum_{A^i \in \pi_j} h(\|A^i - t_j\|), \quad (50)$$

where t_1, \dots, t_p be prescribed distinct vectors in \mathbb{R}^d where $h : \mathbb{R} \rightarrow \mathbb{R}$ is nondecreasing/increasing.

Theorem 50 and Corollary 10 specify a single separable partition that is uniformly optimal for all underlying partition problems, independently of the functions f and h that occur in (49) and (50).

The characterization of optimal partition of Theorem 50 (and Corollary 10) allows one to construct all optimal solutions by assigning each vector A^i to any part π_j for which t_j is the closest to A^i . More specifically, associate each vector $A^i \in \mathbb{R}^d$ with the vector $D^i \equiv (\|A^i - t_1\|, \dots, \|A^i - t_p\|)^T \in \mathbb{R}^p$. A partition is then optimal if and only if it assigns A^i to π_j with D_j^i being any minimal coordinate of D^i . The amount of effort needed to compute each vector D^i is $O(dp)$, so the total amount of effort to compute all of the D^i 's (and thereby solve the partition problem) is $O(dpn)$.

Since the boundary of the convex hull of two parts can contain points of both parts, the optimal partitions identified in Theorem 50 and Corollary 10 need not be almost separable, let alone separable. Still, it is noted that breaking ties by using any part-ranking will produce separable partitions.

The geometric figure of the partition of \mathbb{R}^d into p convex subsets S_1, \dots, S_p with S_j consisting of all points in \mathbb{R}^d closest to t_j (a point on a boundary is closest to all t_j whose S_j shares that boundary) is known in the literature as the Voronoi diagram. Efficient constructions of Voronoi diagrams are well studied in theoretical computer science (see Fortune [25] for a survey). In particular, hyperplanes representing a Voronoi diagram for p given points t_1, \dots, t_p in \mathbb{R}^d can be constructed in $O(d^{\frac{p+1}{2}})$ -time. For $d = 2$, Shamos and Hoey [65] showed that the Voronoi diagram can be constructed in $O(p \log p)$ -time.

A tool is next developed for using results about properties of optimal partitions of problems with objective functions that depend on prescribed vectors to results where the prescribed vectors are replaced by some minimizing vectors. Two new definitions are needed to present a formal result. A function $g : \mathbb{R}^d \rightarrow \mathbb{R}$ is *inverse-bounded* if for every $K \in \mathbb{R}$ $\{x \in \mathbb{R}^d : |g(x)| \leq K\}$ is a bounded set of \mathbb{R}^d . Evidently, an inverse-bounded function that is continuous is guaranteed to attain a minimum over \mathbb{R}^d . Also, let $P^*(\mathbb{R}^d)$ be the set of finite subsets of \mathbb{R}^d , that is, $P^*(\mathbb{R}^d) = \{\Omega \subset \mathbb{R}^d : |\Omega| \text{ is finite}\}$.

Theorem 51 *Let Q be a partition property, $f : \mathbb{R}^p \rightarrow \mathbb{R}$ be nondecreasing and $g : P^*(\mathbb{R}^d) \times \mathbb{R}^d \rightarrow \mathbb{R}$ with the property that for every $\Omega \in P^*(\mathbb{R}^d)$, $g(\Omega, \cdot)$ is inverse-bounded and continuous. Let Γ be a set of p -integer vectors with coordinate-sum n .*

Assume that for any $t_1, \dots, t_p \in \mathbb{R}^d$, some optimal partition of the constrained-shape problem corresponding to Γ and having objective function $F^{t_1, \dots, t_p}(\cdot)$, empty parts not allowed, given by

$$F^{t_1, \dots, t_p}(\pi) = f[g(\pi_1, t_1), \dots, g(\pi_p, t_p)] \text{ for each partition } \pi \quad (51)$$

satisfies Q . Then some optimal partition for the corresponding constrained-shape problem with objective function $F(\cdot)$ given by

$$F(\pi) = f \left[\min_{x_1 \in \mathbb{R}^d} g(\pi_1, x_1), \dots, \min_{x_p \in \mathbb{R}^d} g(\pi_p, x_p) \right] \text{ for each partition } \pi \quad (52)$$

satisfies Q . Further, the above holds with “every” replacing “some.”

Theorem 51 can be used to obtain **Theorem 49** (ii) from **Theorem 49** (iii) by noting that $\sum_{j=1}^p w_j \sum_{A^i \in \pi_j} \|A^i - t_j\|^2$ is minimized over (t_1, \dots, t_p) at $(\bar{A}_1, \dots, \bar{A}_p)$ (with $\bar{A}_j = \frac{\sum_{A^k \in \pi_j} A^k}{|\pi_j|}$ for $j = 1, \dots, p$).

The proof of **Theorem 51** in [39] can, in fact, be applied to a partition that is not optimal. Specifically, if π is any partition and t_1, \dots, t_p are minimizers of $g(\pi_1, \cdot), \dots, g(\pi_p, \cdot)$, respectively, then any partition $\pi^\#$ that satisfies $F^{t_1, \dots, t_p}(\pi^\#) \leq F^{t_1, \dots, t_p}(\pi)$ satisfies $F(\pi^\#) \leq F(\pi)$. In particular, any sorting method that is applicable to partition problems with objective function $F^{t_1, \dots, t_p}(\cdot)$ for fixed t_j 's which does not rely on a statistics depending on the t_j 's, applies to the partition problem with objective function $F(\cdot)$. This is the case for p -sortings for which no statistics is needed.

For $h : \mathbb{R} \rightarrow \mathbb{R}$, an h -centroid of a finite set $\Omega \subseteq \mathbb{R}^d$ is a minimizer of $\sum_{A^i \in \Omega} h(\|A^i - x\|)$ over $x \in \mathbb{R}^d$. When h is continuous, bounded from below and inverse-bounded, each finite set Ω has an h -centroid. (This definition extends the definition given in the paragraph preceding **Theorem 25** from $d = 1$ to $d > 1$.)

Theorem 52 Consider the single-size problem which has

$$F(\pi) = \sum_{j=1}^p \sum_{A^i \in \pi_j} h(\|A^i - c_j\|), \quad (53)$$

where $h : \mathbb{R} \rightarrow \mathbb{R}$ is nondecreasing, continuous, and inverse-bounded, and for $j = 1, \dots, p$, c_j is the h -centroid of π_j and where the sum over an empty set of $h(\cdot)$ -values in (53) is defined to be 0. Then there exists a separable optimal partition. Further, if h is increasing, then every optimal partition is weakly separable.

Corollary 11 Consider the partition problem of **Theorem 52**. Then there exists a separable optimal partition without empty parts. Further, if h is increasing, then every optimal partition has no empty parts.

[Theorem 52](#) asserts the existence of a separable optimal partition that is specific to the function h which occurs in (53). This type of result is weaker than the uniform optimality of a specific separable partition asserted in [Theorem 50](#).

The second paragraph following [Theorem 51](#) shows that the assignment of each vector to its closest t_j can be used to replace a partition π that is not separable with one that is and has improved F -value where $F(\cdot)$ is given by (53).

Partition problems that are next considered have objective functions that depend on the least radii of spheres that, respectively, include the parts. It is first shown that given a partition whose parts are included in prescribed spheres, there is a separable partition with the same property. The proof of this result follows an approach of Capoyleas, Rote, and Woeginger [9] who proved the case $d = 2$ (and claimed its extension to general d).

Lemma 20 *Let t_1, \dots, t_p be prescribed distinct vectors in \mathbb{R}^d . Allowing partitions to have empty parts, for each partition π , there exists a separable partition π' such that*

$$\max_{A^i \in \pi'_j} \|A^i - t_j\| \leq \max_{A^i \in \pi_j} \|A^i - t_j\| \quad \text{for } j = 1, \dots, p. \quad (54)$$

Further, if $r_j \equiv \max_{A^i \in \pi_j} \|A^i - t_j\|$ for $j = 1, \dots, p$ (i.e., r_j is the smallest radius of a sphere that is centered at t_j and contains π_j), then π' can be selected by the following rule: $A^i \in \pi'_j$ if j is the lowest index of those for which $\|A^i - t_j\|^2 - r_j^2 = \min_u [\|A^i - t_u\|^2 - r_u^2]$ (of course, one may use any a priori permutation of the part-indices).

Capoyleas, Rote, and Woeginger [9] did not mention a tie-breaking rule; as such, the “power diagram” they used to repartition the vectors leads to weak separability rather than strict separability (earlier results in this section show that the number of weakly separable partitions is not necessarily polynomial in the number of partitioned vectors).

The separating hyperplane between parts π'_j and π'_w of the partition π' constructed in [Lemma 20](#) is given by

$$\begin{aligned} H &\equiv \{x \in \mathbb{R}^d : \|x - t_j\|^2 - r_j^2 = \|x - t_w\|^2 - r_w^2\} \\ &= \{x \in \mathbb{R}^d : 2(t_w - t_j)^T x = \|t_w\|^2 - \|t_j\|^2 + r_j^2 - r_w^2\}. \end{aligned} \quad (55)$$

This hyperplane is called the *power-hyperplane* of the underlying spheres $\{x \in \mathbb{R}^d : \|x - t_s\| \leq r_s\}$ and $\{x \in \mathbb{R}^d : \|x - t_w\| \leq r_w\}$. Further, the construction of π' from π in the proof of [Lemma 20](#) is a sorting operation of all p -parts called *power-hyperplane sorting*. The use of p -sorting has the advantage that it achieves the goal in one step and therefore does not require a monotone statistics that shows iterative sortings will not cycle.

A natural variant of the use of power-hyperplane p -sorting to prove the conclusions of [Lemma 20](#) is to iteratively apply power-hyperplane 2-sorting (of pairs of parts). For this approach to work, that is to avoid the possibility of cycling, it

is necessary to identify a statistics over partitions that is reduced at each iteration. Unfortunately, it is not known that such a statistics exists. Still, power-hyperplane 2-sortings can be used to prove a weaker result. Specifically, consider $t_1, \dots, t_p \in \mathbb{R}^d$ and $r_1, \dots, r_p \in \mathbb{R}$. [Lemma 20](#) implies that power-hyperplane p -sorting will convert a partition π whose parts are included, respectively, in the spheres $\{x \in \mathbb{R}^d : \|x - t_j\| \leq r_j\}, j = 1, \dots, p$, into a separable partition having the same property. Here, one can use iterative power-hyperplane 2-sorting and assure that the process does not cycle because of strict lexicographic reduction of the statistics

$$s(\pi) \equiv \left(\sum_{j=1}^p \sum_{A^i \in \pi_j} [\|A^i - t_j\|^2 - r_j^2], -|\pi_1|, \dots, -|\pi_p| \right)$$

in each step. In particular, this proves that S is (sort-specific, 2, support)-sortable with “sort-specific” referring to the power-hyperplane method with fixed center and fixed radii.

Theorem 53 *Let t_1, \dots, t_p be prescribed distinct vectors in \mathbb{R}^d and consider the single-size problem, allowing empty parts, which has*

$$F(\pi) = f[\max_{A^i \in \pi_1} \|A^i - t_1\|, \dots, \max_{A^i \in \pi_p} \|A^i - t_p\|], \quad (56)$$

where $f : \mathbb{R}^p \rightarrow \mathbb{R}$ is nondecreasing. Let π be a given partition. Then the partition π' which satisfies the conclusions of [Lemma 20](#) is separable and satisfies $F(\pi') \leq F(\pi)$. In particular, the underlying single-size problem has a separable optimal partition.

[Theorem 53](#) provides a construction (appearing explicitly in the statement of [Lemma 20](#)) of a separable partition that improves on the objective function of a given partition π . This result can be cast as p -sortability result, as were the results of [Theorem 50](#) and [Corollary 10](#). The construction of [Theorem 53](#) is independent of the f appearing in (56), but unlike the construction of [Theorem 50](#) (and [Corollary 10](#)), it is specific to the underlying partition π .

For a bounded set $\Omega \subset \mathbb{R}^d$, let $r(\Omega)$ denote the minimum radius of a sphere that includes Ω ; in particular, when Ω is finite, $r(\Omega) = \inf_{x \in \mathbb{R}^d} [\sup_{y \in \Omega} \|x - y\|]$, and the “inf” and “sup” are attained (and can therefore be replaced by “min” and “max”). For a p -partition π , let $r(\pi) = (r(\pi_1), \dots, r(\pi_p))$. The next result considers partition problems with objective function that is determined by these partition characteristics; Capoyleas, Rote, and Woeginger [9] considered the case $d = 2$.

Theorem 54 *Consider the single-size problem which has $F(\pi) = f[r(\pi)]$ where $f : \mathbb{R}^p \rightarrow \mathbb{R}$ nondecreasing. Then some optimal partition is separable.*

A result of Pfersky et al. [60] is next generalized; their result is then deduced as a corollary.

Theorem 55 Consider the single-size problem, not allowing empty parts, which has

$$F(\pi) = \sum_{\substack{u,v=1 \\ u \neq v}}^p \sum_{A^i \in \pi_u} \sum_{A^k \in \pi_v} h(A^i, A^k), \quad (57)$$

where $h(\cdot, \cdot)$ is a metric. Then there exists a nearly monopolistic optimal partition. If h is strict, then every optimal partition is nearly monopolistic. Finally, when allowing empty parts, “nearly monopolistic” can be replaced by “monopolistic.”

The reason that there is no strict version for [Theorem 55](#) is that even if h is strict, when the A^i ’s are all the same point, then all p -partitions are optimal.

The Pfersky, Rudolf, and Woeginger result is next derived. It is stated in the original framework of a maximization problem (of course, multiplying the objective function by -1 converts a maximization problem into an equivalent minimization problem).

Corollary 12 Consider the single-size problem in which

$$F(\pi) = \sum_{j=1}^p \sum_{A^i, A^k \in \pi_j} \|A^i - A^k\|^2. \quad (58)$$

is to be maximized. Then there exists a nearly monopolistic optimal partition.

Abstract

Although most of research efforts are made on single-channel wireless networks, multichannel environment already exists in real world systems. In this chapter, we survey current research works in multi-channel wireless networks, especially in multihop wireless networks, such as wireless ad hoc, sensor, and mesh networks. We will focus on those optimization issues, to explore the hardness of extensions from single-channel to multichannel and valuable research topics. The chapter is divided into four parts: (1) introduction, (2) multi-interface assignment, (3) channel assignment, and (4) network routing. For each part, we give a detail explanation of the latest research in multichannel wireless networks.

1 Introduction

Although most of research efforts are made on single-channel wireless networks, multichannel environment already exists in real world systems such as 2.4 GHz and 5 GHz spectrum. To utilize those resource and to take advantage of this environment, many research works have made contributions to extend techniques from single-channel to multichannel environment and explore valuable new research problems. In this chapter, we survey those research works, especially on optimization issues.

2 Multi-interface Assignment

An interface is a network interface card equipped with a half-duplex radio transceiver, for example, a commodity IEEE 802.11 wireless card. Also, the definition of wireless network interface is a network card (NIC) connected to a radio-based computer network.

There are several advantages in using multi-interface instead of a single interface.

First, with multi-interface, a node can receive and transmit data in parallel so that the throughput on a multihop route can be increased, possibly doubled. Secondly, with multi-interface, the end-to-end latency can be reduced if different hops traversed are on different channels. Indeed, for each node with a single interface, if the interfaces of two nodes are on different channels, then they cannot communicate. Thus, when packets are traversing multihop paths, delaying may occur at each hop and hence the end-to-end latency can be increased.

A multichannel wireless mesh network (WMN) consists of a number of stationary wireless routers, forming a wireless backbone. Each router is equipped with multiple network interface cards (NICs) [45, 48, 55]. Each interface operates on a distinct frequency channel in the IEEE 802.11a/b/g bands. A logical topology is comprised of the sets of routers and logical links.

A problem for using a WMN as a backbone for large wireless access is the high bandwidth requirements, which cause capacity reduction. One solution to address this problem is to use multiple nonoverlapping channels on the interfering links to maximize the parallel transmission and throughput. Although the one-NIC

architecture is able to support simultaneous transmissions as long as the interfering links operate in different channels, its limit on the parallel use of multiple channels cannot be ignored. Since different NICs can operate on different channels without interference, multi-NICs for mesh network have made it possible for one node to access multiple channels at the same time.

Many researchers study on channel allocation issues. There are some exiting centralized and distributed algorithms to solve this problem. Marina et al. [41] and Tang et al. [51] proposed the joint channel allocation and topology control problem. Marina et al. [41] proposed a permanent channel allocation algorithm to solve the problem; this algorithm aims to minimize the interface among the links while maintaining the network connectivity. Tang et al. [51] proposed a permanently allocating frequency channels method to solve the problem; the method is to minimize the maximum number of interfering logical links within each neighborhood. The constraint is that the logical topology graph should be K-connected. In [45], the authors consider channel allocation and topology control as two separate but related problems and formulate the logical topology formation and interface assignment as a joint optimization problem. In [46] and [48], the authors assume that there is no system or hardware support to allow a radio interface to switch channels on a per-packet basis. They proposed a centralized joint channel assignment and multipath routing algorithm. This algorithm considers high load edges first. The routing algorithm uses both shortest path routing and randomized multipath routing algorithm. In [25, 27], they both assume that a radio interface is capable of switching channels rapidly and is supported by system software. In [25], the authors give a channel assignment and routing algorithm to characterize the capacity regions. In [27], the authors focus on how the capacity of multichannel wireless networks scale related to the number of radio interfaces and the number of channel as the number of nodes grow.

The backbone of the WMN is modeled as a directed graph $G = (V, E)$, where V represents the set of nodes in the network and E represents the set of directed links. Each node u ($u \in E$) may be equipped with a number of NICs, where the number is denoted as $I(u)$ ($I(u) \geq 1$). The total number of nonoverlapping channels is k , and the channel set is denoted as $C(|C| = k)$. Each NIC can be fixed on one channel during the entire transmission lifetime or can switch channels after several packets have been sent out. Two nodes can communicate with each other via wireless links when one pair of their NICs is tuned to be on the same channel.

2.1 Bandwidth Allocation and NIC Assignment

In this section, the bandwidth allocation and NIC assignment problem are addressed for the WMNs, which is shown in [55]. There are the following assumptions: (1) the topology of the WMN has been established; (2) each node u , due to physical constraints, can be equipped with at most $\delta(u)$ numbers of NICs and all NICs are fixed; and (3) each node u has a bandwidth requirement of $req(u)$. The objective of the problem is to max–min bandwidth allocation α_{\max} , that is, maximize guaranteed bandwidth for each node. This problem is practically interesting because it answers

the following question: If certain bandwidth allocation should be satisfied, what is the requirement to the NIC assignment?

Before the problem formulation given by Wang et al. [55] is formally introduced, some terms and constraints which will be used in the formulation are introduced. Suppose every node $u \in V$ has a bandwidth request as $req(u)$ and it is allocated with bandwidth of $g(u)$, since the allocated bandwidth should not be greater than the required bandwidth, there is the bandwidth constraint as

$$g(u) \leq req(u), \quad \forall u \in V \quad (1)$$

As in [55], for each node, the traffic gathered from local clients has to be relayed to at least one of its neighbors. The traffic flows can be transmitted over different channels. Let $f_{\text{out}}(u, i)$ denote node u 's traffic-out on channel i , and $f_{\text{in}}(u, i)$ the traffic-in on channel i . For a node u , every channel is assumed to have the same capacity, denoted as $c(u)$. In each channel, the traffic-in and traffic-out should not exceed the channel capacity, so there are the following channel capacity constraints:

$$f_{\text{in}}(u, i) + f_{\text{out}}(u, i) \leq c(u), \quad \forall u \in V, i \in C. \quad (2)$$

Since total traffic-in and traffic-out of node u over all channels should keep a balance, the flow balance constraints were also concluded in [55] as follows:

$$\sum_{i \in C} f_{\text{in}}(u, i) + g(u) = \sum_{i \in C} f_{\text{out}}(u, i), \quad \forall u \in V. \quad (3)$$

Another constraint (NIC constraint) was raised in this work [55], that is, to enable the network connectivity, each node must be equipped with at least one NIC. Since the system has total k available channels, different NICs in one node must operate on different channels; hence, there are at most k NICs on a single node. That is the NIC constraint by channels

$$1 \leq I(u) \leq k, \quad I(u) \in \text{Integer}, \quad \forall u \in V. \quad (4)$$

In the case of Fix-NIC [55], $R(u, i)$ is used to indicate whether there is a NIC operating on channel i , and $R(u, i) = 1$ indicates there is a NIC fixed on channel i ; otherwise, $R(u, i) = 0$. The relationship between $I(u)$ and $R(u, i)$ is

$$\sum_{i \in C} R(u, i) \leq I(u), \quad R(u, i) \in \{0, 1\}, \quad \forall u \in V. \quad (5)$$

For every node, a NIC can only transmit or receive from one neighbor at the same time [55]. It is

$$\frac{f_{\text{out}}(u, i)}{c(u)} + \frac{f_{\text{in}}(u, i)}{c(u)} \leq R(u, i), \quad \forall u \in V, i \in C. \quad (6)$$

The problem formally is stated as a linear programming problem. Given $G(V, E)$ and all parameters,

maximize α
subject to:

$$\begin{aligned}
 g(u) &\leq \text{req}(u), \quad \forall u \in V \\
 f_{\text{in}}(u, i) + f_{\text{out}}(u, i) &\leq c(u), \quad \forall u \in V, i \in C \\
 \sum_{i \in C} f_{\text{in}}(u, i) + g(u) &= \sum_{i \in C} f_{\text{out}}(u, i), \quad \forall u \in V \\
 1 \leq I(u) &\leq k, \quad I(u) \in \text{Integer}, \quad \forall u \in V \\
 \sum_{i \in C} R(u, i) &\leq I(u), \quad R(u, i) \in 0, 1, \quad \forall u \in V \\
 \frac{f_{\text{out}}(u, i)}{c(u)} + \frac{f_{\text{in}}(u, i)}{c(u)} &\leq R(u, i), \quad \forall u \in V, i \in C \\
 g(u) &\geq \alpha, \quad u \in V. \tag{7}
 \end{aligned}$$

2.2 Efficient Solution

As the number of nodes in the mesh network increases, the cost to compute the optimal solutions by LP will increase dramatically due to the problem complexity. Hence, the LP solution is only suitable for off-line decisions for building or analyzing the static WMN architecture. If the system would have to recalculate the allocation and assignment strategy online, according to the topology change or new traffic requirement in a large WMN, finding the optimal solution is not practical. In [55], the authors discussed the feasible solutions case by case.

2.2.1 Assign NICs to Satisfy a Bandwidth Allocation

Given a feasible bandwidth allocation $g(u)$ for each node u , the first question is how to calculate the number of NICs ($I(u)$) in order to satisfy the bandwidth requirement. First, the case of Switch-NIC is considered, in which one NIC can switch among different channels. If the channels are not fully utilized around, it can always switch to a less used channel to alleviate the impact of interference, and all NICs in the WMN can work cooperatively. So the NIC is able to fully consume the capacity of $c(u)$. The only constraint is the capacity and the number of NICs. Hence, the number of NICs for node u can be approximated as

$$I_{\text{switch}}(u) = \left\lceil \frac{f(u)}{c(u)} \right\rceil. \tag{8}$$

Here, $f(u)$ represents the total traffic of node u . When taking Fix-NICs into consideration, the proper number of NICs depends much more on the interference

around. For instance, if nearby nodes have heavy traffic and every channel is equally utilized, then the transmission load by using just the same number of Fix-NICs cannot be accomplished in the case of Switch-NICs. Here, a compensation factor $\beta(u)$ to reflect the interference impact is introduced. Let $f_{\text{int}}(u)$ represent all the traffic flows that may conflict with the in and out traffic of node u ; then $\beta(u)$ is defined as

$$\beta(u) = \frac{f_{\text{int}}(u)}{k \cdot c(u)}, \quad k = |C|. \quad (9)$$

So the number of NICs required can be approximated as

$$I_{\text{fix}}(u) = \left\lceil (1 + \beta(u)) \cdot \frac{f(u)}{c(u)} \right\rceil. \quad (10)$$

These equations in [55] can be used to calculate $I(u)$ for each node.

2.2.2 Optimize Bandwidth Allocation with a Given NIC Assignment

For this subproblem, [55] showed the solutions for two cases:

(1) Case 1: Switch-NIC

If each node is assigned a number of Switch-NICs, the algorithm to find a feasible bandwidth allocation for all nodes is presented in [55]. Here, consider two allocation strategies: equally allocating the bandwidth to each node or allocating the bandwidth proportionally to the request. In both scenarios, the algorithm calculates the maximum value. First, an algorithm is proposed to estimate the max-min bandwidth allocation α_{\max} under the assumption that the bandwidth is equally allocated to each node and the bandwidth is α . For a node u , the total available capacity is $I(u) \cdot c(u)$, and the total traffic in and out should not exceed this capacity. So there must have

$$f(u) \leq I(u) \cdot c(u), \quad u \in V. \quad (11)$$

According to the aggregate traffic model, the total traffic-in can be deduced and traffic-out of a node u is $f_{\text{in}}(u) = \alpha \cdot |E|$ and $f_{\text{out}}(u) = \alpha \cdot |E|$. So the total traffic of u is

$$f(u) = \alpha \cdot 2 \cdot |V|. \quad (12)$$

According to Eqs. (11) and (12), there are as follows:

$$\alpha \cdot 2 \cdot |V| \leq I(u) \cdot c(u), \quad u \in V \quad (13)$$

or

$$\alpha \leq \frac{I(u) \cdot c(u)}{2 \cdot |V|}, \quad u \in V. \quad (14)$$

Equation (14) [55] gives an upper bound to the bandwidth allocation for each node. Now another scenario is considered: allocating bandwidth proportionally according to the request $req(u)$. So every node u will have different bandwidth

allocation as $\lambda \cdot req(u)$. Similar to the deduction above, there are

$$f(u) = \lambda \cdot 2 \cdot \sum_{u \in V} req(u) \quad (15)$$

or

$$\lambda \leq \frac{I(u) \cdot c(u)}{2 \cdot \sum_{u \in V} req(u)}, \quad u \in V. \quad (16)$$

The optimal α and λ can be achieved by minimizing Eqs. (14) and (16) [55].

(2) Case 2: Fix-NIC

When the NIC cannot switch channel freely, the total available capacity for each node u is less than $I(u) \cdot c(u)$. As [55] mentioned before, $\beta(u)$ is introduced to represent the impact of interference. Here, the total available capacity is $\frac{I(u) \cdot c(u)}{1 + \beta(u)}$. So the bandwidth allocation $g(u)$ for Fix-NIC is $1/(1 + \beta(u))$ of the bandwidth allocated for Switch-NIC. According to Eqs. (14) and (16), the maximum bandwidth allocation for each node with equal allocation strategy and the maximum proportion value are presented in [55] as the following:

$$\alpha \leq \frac{I(u) \cdot c(u)/(1 + \beta(u))}{2 \cdot |V|}, \quad u \in V \quad (17)$$

$$\lambda \leq \frac{I(u) \cdot c(u)/(1 + \beta(u))}{2 \cdot \sum_{u \in V} req(u)}, \quad u \in V. \quad (18)$$

3 Channel Assignment

Wireless interference significantly impacts the performance in multihop networks. This is because most of the current multihop networks use just a single channel to communicate so that neighboring nodes interfere with each other. The IEEE 802.11 standards provide several orthogonal channels that can be used for wireless networks. Usually, in the networks working in infrastructure mode, neighboring access points operate on orthogonal channels to eliminate interference. However, this kind of design does not apply to most of the multihop networks for some reasons. The most important reason is that most of the commodity mobile devices have only one network interface card, and they cannot operate simultaneously using multichannel.

Recently, wireless mesh architecture is more and more used to provide high-bandwidth wireless network services. But since this architecture is breaking long distances into a series of shorter hops, the interference problem still exists. Recently, many studies begin to focus on using multichannels in WMNs, and some studies have presented channel assignment algorithms to improve the network performance.

Some of the channel assignment algorithms [1, 40, 46, 48, 52] change the channels whenever there are significant changes to traffic loads or network topology.

These channel assignment algorithms are relatively static. But if the network topology or the traffic load changes frequently, the performance of the network would significantly drop because of the delay of the channel switching.

Some other algorithms [5, 49, 59] are designed to change the channel on the interface very frequently. These algorithms use the current state of the medium to determine the channel for each packet. However, an important condition for these algorithms is that the channel switch delay of the devices in the network should be small enough (switching in a packet or a few packets). And this condition eliminates most of the off-the-shelf hardware.

3.1 Minimum Interference

3.1.1 Optimization Problem Description

Recent studies of minimum interference in multichannel wireless networks provide channel assignment algorithms optimizing this problem. In these studies, the main issue is how to design the channel assignment algorithms. The main goal of the algorithms is to use the limited channels and the network interface in each node to minimize the interference.

In [50], the authors present the problem of static assignment of channels to link in the networks with multi-radio nodes. The objective of the channel assignment is to minimize the overall network interference. This channel assignment algorithm is derived from a graph coloring problem. The authors assume a binary interference model, in which there are two links that either interfere or not. Though the interference level between two links depends on the traffic on the links, the paper assumes uniform traffic on all links first and then generalizes the algorithms to nonuniform traffic.

3.1.2 Mathematical Formulation

The communication graph of the network is modeled as an undirected graph over the set of nodes N . Each node $i \in N$ denotes a router that has R_i radio interfaces. There is a total of K channels available in the network. Let $\mathcal{K} = \{1, 2, \dots, K\}$ denote the set of K available channels.

Let the conflict graph G_c [22] represent the interference between nodes. A conflict graph $G_c(V_c, E_c)$ is an undirected graph in which

$$V_c = \{l_{ij} \mid (i, j) \text{ is a communication link}\}.$$

And a conflict edge (l_{ij}, l_{ab}) is used to represent that two communication links (i, j) and (a, b) interfere with each other if they are on the same channel.

Then the channel assignment problem converts to a coloring problem, which is to color the vertices V_c of the conflict graph G_c using K colors without violating the interface constraint and minimizing the number of monochromatic edges in G_c . To solve this problem, a function $f : V_c \rightarrow \mathcal{K}$ needs to be computed to minimize the overall network interference $I(f)$. The following constraint satisfies the interface constraint:

$$\forall i \in N, |\{k | f(e) = k \text{ for some } e \in E(i)\}| \leq R_i$$

where $E(i) = \{l_{ij} \in V_c\}$, that is $E(i)$ is a set of vertices in V_c that denote the communication links incident on node i and the network interference $I(f)$ is

$$I(f) = |\{(u, v) \in E_c | f(u) = f(v)\}|.$$

The network interference is the number of monochromatic edges in the colored conflict graph.

3.1.3 An Existing Solution

In this section, a channel assignment algorithm presented in [50] is introduced. This algorithm, which is based on tabu search [19] technique, consists of two phases. In the first phase, a tabu search-based technique is used to find a solution f without considering the interface constraint. Then the violations of interface constraint are removed to get a feasible channel assignment function f in the second phase.

First Phase: First, each vertex in V_c is given a random color in K . And this assignment is taken as the initial solution f_0 , then a sequence of solutions $f_0, f_1, f_2, \dots, f_j, \dots$ is created to get a solution with minimum network interference. The next solution f_{j+1} in the j th iteration is created.

The j th Iteration: Start by making a certain number (say, r) of random neighboring solutions of f_j . A random neighboring solution of f_j can be made by picking a random vertex u and assigning a different random color in $(K - \{f_j(u)\})$ to it. Therefore, a neighboring solution of f_j is different from f_j in the color assignment of only one vertex. Such randomly generated neighboring solutions of f_j is made a solution set. Then pick the neighboring solution which has the lowest network interference as the next solution f_{j+1} from the set. In order to avoid local minima, $I(f_{j+1})$ cannot be required to be less than $I(f_j)$.

Tabu List: A tabu list [19] τ is maintained in order to avoid reassigning the same color to a vertex more than once. For example, if f_{j+1} is created by assigning a new color to a vertex u , then $(u, f_j(u))$ is put into the tabu list τ . According to the tabu list, the solutions, which assign the color k to vertex u if (u, k) is already in τ , are discarded.

Termination: When the iterations pass the allowed maximum number (say, i_{\max} without any improvement in $I(f_{\text{best}})$, the first phase terminates. In this algorithm, let i_{\max} be $|V_c|$. The network interference $I(f)$ is an integer, and it is lower than $(|V_c|)^2$. Let r denote the number of random neighboring solutions, and d denote the maximum degree of a vertex in G_c . At each iteration, the value of $I(f_{\text{best}})$ decreases by 1 or the first phase terminates. Therefore, the time complexity of the first phase is $O(r d |V_c|^3)$.

Second Phase: After the first phase, a solution of channel assignment is got. However, the number of channels on a node may be larger than the number of

interface cards on a node. The goal of the second phase is to remove the violations by using the following “merge” procedure. Assume a solution f has been got in the first phase. Based on this solution on the conflict graph G_c , the communication graph G is used in the second phase. After the first phase, each edge in the communication graph is colored.

To begin with, a node which the violation is maximum for the merge operation is chosen. Let i be the node picked, two colors k_1 and k_2 incident on i are chosen. Then the color of all k_1 -colored links is changed to k_2 . To avoid creating more interface constraint violations at other nodes, all the k_1 -colored links which are neighboring (two or more links are incident on a common node) are iteratively changed to the link just changed. This procedure ensures that for any node j , either all or none of the k_1 -colored links incident on j are changed to color k_2 .

The steps above can reduce the number of distinct colors incident on i by one and does not increase the number of violations on other nodes. Therefore, this procedure can be repeated to eliminate all the interface constraint violations on the communication graph. However, this procedure will increase the interference in the network. Therefore, those two colors k_1 and k_2 are picked for the merge operation that cause the least increase of network interference.

Simulations in [50] show that this algorithm effectively reduces the interference of the network and therefore significantly improves the performance.

3.2 Maximum Throughput

3.2.1 Optimization Problem Description

Recent studies present multichannel multihop network models to optimize the throughput. In these studies, how to design the channel assignment algorithms is the core problem because the number of channels available and the number of the interfaces in each node are limited. So it is needed to design channel assignment algorithms to get the maximum throughput in the proposed networks. In [3], the authors present a fixed channel assignment algorithm for multi-radio multichannel mesh networks. In [4], the authors formulate the joint channel assignment and routing problem mathematically into a Linear Programming (LP) problem. The LP takes into account the interference constraints, the number of channels in the network, and the number of radios available at each router. Then the authors use this formulation to develop a solution for our problem that optimizes the overall network throughput. The optimization algorithm in [4] will be introduced in the following sections.

3.2.2 Problem Description and System Modeling

In [4], a multichannel multihop infrastructure WMN is used as a network model. The WMN consists of some static wireless mesh routers and some mobile terminal clients. These wireless routers form a multihop wireless backbone. The backbone network relays the traffic from and to the clients. Some routers are the gateway to the wired Internet.

To simplify the problem, it is assumed that there is only outgoing traffic to the wired Internet and $l(u)$ represents the outgoing traffic. Then the mathematical formulation is given in [4].

3.2.3 Mathematical Formulation

The given backbone of the wireless network is modeled as a graph (V, E) . V is the set of all routers. Each edge $e \in E$ denotes a link between two routers in V . For that at least $\lambda l(u)$ of throughput can be routed to the Internet, it requires to find the maximized λ . Let t denote the destination node which connects directly to the Internet.

Some definitions are given as follows:

1. There are K channels available.
2. $I(e) \subset E$ denotes the set of edges that e interferes with.
3. Each node $u \in V$ has $I(u)$ network interface cards.
4. Each node has a total demand $l(u)$ from all the connected users.

To get $\lambda l(u)$ throughput for each node u , to compute the following is necessary:

1. A network flow that consists of edges $e = (u, v)$ and values $f(e(i))$, ($1 \leq i \leq K$) where $f(e(i))$ denotes the rate of the traffic which is transmitted from node u to node v using channel i .
2. A feasible channel assignment $F(u)$, which is an ordered set where the i th interface of u operates on the i th channel in $F(u)$, such that, whenever $f(e(i)) > 0$, $i \in F(u) \cap F(v)$. This case is called that edge e is using channel i to communicate.
3. A feasible schedule S which decides the set of edge channel pair (e, i) (i.e., edge e is using channel i) scheduled at time slot τ , for $\tau = 1, 2, \dots, T$ where T is the period of the schedule.

If the edges of no two edge pairs $(e_1, i), (e_2, i)$ scheduled in the a time slot for the same channel i interfere with each other ($(e_1 \notin I(e_2) \text{ and } e_2 \notin I(e_1))$), the schedule is called as the feasible schedule. Let $c(e)$ denote the maximum rate at which router u can communicate with router v in one hop on a same channel. And let (R_T) denote the interference range, which is assumed to be q times a transmission range R_T for some small fixed constant q .

Then the following constraints are got:

The Link Congestion Constraint: Any valid edge flows without interference must satisfy for channel 1(or other equivalent channels):

$$\frac{f(e(1))}{c(e)} + \sum_{e' \in I(e)} \frac{f(e'(1))}{c(e')} \leq c(q). \quad (19)$$

Link Schedulability Constraint: If the edge flows satisfy for channel 1 (or other equivalent channels) the following link schedulability constraint, then an interference-free edge communication schedule can be found:

$$\frac{f(e(1))}{c(e)} + \sum_{e' \in I(e)} \frac{f(e'(1))}{c(e')} \leq 1. \quad (20)$$

$f(e)$ is defined as the rate at which traffic is transmitted by node u for node v on the only available channel. These values of $f(e)$ form the edge flows for a max-flow on a flow graph H . And H is constructed by the following steps. First, a source node s and sink node t are introduced into the graph G . And every gateway node $v \in V$ has an unlimited capacity directed edge to the sink node t . Node s has a directed edge to every node $v \in V$ with a capacity of $l(v)$. Let the set E_s denote these edges and H be the required flow graph with s and t . The flow on every edge $e \in E$ in H is $f(e)$, and every $e \in E_s$ in H has a flow equal to its capacity. According to the definition, the flow is a valid network flow, and it is a max-flow on H for the given source and sink nodes.

Flow Constraints: Let $V^H(E^H)$ be the set of nodes (edges) in H and $f(e)(c(e))$ denote the flow (capacity) on an edge e of H . At any node $v \in V^H$ other than s or t , the total incoming flow is equal to the total outgoing flow:

$$\sum_{(u,v) \in E^H} f((u,v)) = \sum_{(v,u) \in E^H} f((v,u)), \forall v \in V^H - \{s, t\}. \quad (21)$$

A flow is required on each outgoing edge for the largest possible λ . This result in the constraint

$$f((s, s_v)) = \lambda l(v), \forall v \in V. \quad (22)$$

Also, it is ensured that no capacities are violated:

$$f(e) \leq c(e), \forall e \in E^H. \quad (23)$$

Node Radio Constraints: Let $\alpha(e, i) = \frac{f(e(i))}{c(e)}$ for any $e \in E$ and channel i . It comes to the following linear constraints for each node $v \in V$.

$$\sum_{1 \leq i \leq K} \sum_{e=(u,v) \in E} \frac{f(e(i))}{c(e)} + \sum_{1 \leq i \leq K} \sum_{e=(v,u) \in E} \frac{f(e(i))}{c(e)} \leq I(v). \quad (24)$$

Link Congestion Constraints: The link congestion constraint using link flows is changed:

$$\frac{f(e(i))}{c(e)} + \sum_{e' \in I(e)} \frac{f(e'(i))}{c(e')} \leq c(q), \forall e \in E, 1 \leq i \leq k. \quad (25)$$

Objective Function:

$$\max \lambda \quad (26)$$

The LP above involves channel assignment, routing, and link scheduling constraints. However, all the constraints we listed are necessary conditions. This means if a solution satisfies these constraints, it may still not be a feasible solution. This LP also yields a lower bound on the λ value, which can be used to establish the guaranteed worst performance case.

In [4], the authors present a channel assignment algorithm used to adjust the flow on the flow graph (routing changes) to ensure a feasible channel assignment. This flow adjustment also keeps minimum interference for each channel. The authors also provide algorithms for routing and link scheduling to form a complete solution of the optimization issue.

3.3 Optimal Fairness

In above sections, channel assignments in multichannel multi-radio WMNs have been studied, with the objective of minimum interference and maximum throughput. Now the fairness channel assignment scheme to optimally achieve Nash equilibrium (NE) solution with focus on fairness consideration to equalize the throughput of flows will be discussed.

3.3.1 Optimization Problem Description

Multichannel WMNs often consist of mesh clients, mesh routers, and gateways [2]. A mesh topology is made up of the sets of routers and logical links. To increase the capability of WMNs, each node should be equipped with multiple radios interfaces. Achieving fairness channel assignment of communications in WMNs is important. In some instances, fairness is even more crucial than system-wide throughout optimization [8]. A Nash equilibrium with perfect fairness among all players is provided. And it is proved by using this fair channel assignment; when system converges to a constant status by Nash equilibrium, all game players obtain the equal throughput.

The fairness problem was pointed out by Bharghavan et al., which was caused mainly because of hidden terminal problem as well as the backoff scheme used in the DFWMAC protocol [6, 21]. In this subsection, a system model is firstly formulated and presented, with some concepts of game theory and a game model in channel assignment. Then a Nash equilibrium solution is provided with perfect fairness and abundant proofs is given.

3.3.2 System Model and Concepts

In this section, the model which is going to be studied will formally be defined. Let K be the number of radio transmitters which is manufactured by each user in a single collision domain. Suppose that each user participates and only participates in one such communication. Let N be the set of communicating pairs and C be the channel set. We suppose that the same channels have the same conditions. And let T_c denote the total throughput of channel c and σ_c denote the throughput of each

radio on channel c . So σ_c can be assumed as a decreasing function of the number of radios on channel c [8].

The following definitions are given in [60] about game theory:

1. n is the number of all players.
2. S_i be a strategy set for player i .
3. S is the set of strategy profiles and $S = S_1 \times S_2 \dots \times S_n$.
4. f is the payoff function and $f = (f_1(x), \dots, f_n(x))$.
5. x_{-i}^* is a strategy profile of all players except for player i .

Then for each player $i \in 1, \dots, n$, if strategy x_i resulting in strategy profile $x = (x_1, \dots, x_n)$, then player i obtains payoff $f_i(x)$. Note that the payoff is decided by the strategy profile chosen.

Definition 1 Nash equilibrium: A strategy profile $x^* \in S$ is a Nash equilibrium (NE) if no unilateral deviation in strategy by any single player is profitable for that player; then

$$\forall i, x_i \in S_i, x_i \neq x_i^* : f_i(x_i^*, x_{-i}^*) \geq f_i(x_i, x_{-i}^*). \quad (27)$$

Definition 2 Perfect fairness [8]: In the channel assignment game, the strategy profile s is perfectly fair, if $\forall i, j \in N$,

$$f_i(x) \geq f_j(x), \quad \text{and} \quad \sum_{c \in C} r_{i,c} = \sum_{c \in C} r_{j,c}. \quad (28)$$

3.3.3 Mathematical Formulation

People who use network nowadays need to pay for their connection and communication with other people in the network. Therefore, it is fairly to assume that charging to players for the usage of the channels to transmit packets is necessary. More significantly, a Nash equilibrium with perfect fairness can be completed by evaluating and designing carefully the amount of payment what players should give on the basis of the usage method of the channels. Here there is an assumption that a certain kind of virtual currency exists in the system and it demonstrates the payment for using channels. Every player pays to the system administrator some virtual currency on the basis of the channels which has chosen to use. Therefore, let $p_{i,c}$ represent the payment of player i for using channel c ; a definition for $p_{i,c}$ is given as

$$p_{i,c} = r_{i,c} \left| k_{i,c} - a - \left\lceil \frac{1}{c+1} - \frac{1}{b+1} \right\rceil \right| \quad (29)$$

in which $a = \left\lfloor \frac{K}{|C|} \right\rfloor$, $b = K \bmod |C|$.

Therefore, the total utility of player i is defined as

$$u_i = \sum_{c \in C} r_{i,c} - \sum_{c \in C} p_{i,c}. \quad (30)$$

A strategy profile x^* is defined as for every player $i \in N$,

$$x_i^* = \{x_{i,1}^*, x_{i,2}^*, \dots, x_{i,|C|}^*\} = \{\underbrace{a+1, \dots, a+1}_b, \underbrace{a, \dots, a}_{|C|-b}\}. \quad (31)$$

Note that $(a+1)b + a(|C|-b) = K$, which is the total number of radios that each player has.

Theorem 1 *In the channel assignment game described before, x^* achieves a Nash equilibrium.*

In order to clearly describe the theorem, the following definition for any player i [8] is given:

$$k_{i,c}^* = \begin{cases} a+1 & \text{if } 1 \leq c \leq b \\ a & \text{if } b+1 \leq c \leq |C| \end{cases} \quad (32)$$

Note that for each channel $c \in C$, the identification number of that channel c is also used by us. Given that $b > 0, c > 0$,

$$\left\lceil \frac{1}{c+1} - \frac{1}{b+1} \right\rceil = \begin{cases} 1 & \text{if } 1 \leq c \leq b \\ 0 & \text{if } b+1 \leq c \leq |C| \end{cases}. \quad (33)$$

From previous two equations, for $\forall c \in C$, there is

$$\left| k_{i,c}^* - a - \left\lceil \frac{1}{c+1} - \frac{1}{b+1} \right\rceil \right| = 0. \quad (34)$$

so for $x_i^*, \sum_{c \in C} p_{i,c} = 0$. Therefore,

$$f_i(x_i^*, x_{-i}^*) = \sum_{c \in C} r_{i,c}. \quad (35)$$

Now the strategies other than x_i^* will be taken into consideration. $\forall x_i \neq x_i^*$, let C'_i denote the channel set on which the radio assignment of player i deviates from x_i^* . Since $x_i \neq x_i^*, \exists c \in C, k_{i,c} \neq k_{i,c}^*$. So $|C'_i| > 0$.

Next, it will be proved that for player i , $\forall c \in C'_i, p_{i,c} \geq r_{i,c}$. Since $k_{i,c}$ is not a negative integer and $k_{i,c} \neq k_{i,c}^*, \forall c \in C'_i$,

$$\left| k_{i,c} - a - \left\lceil \frac{1}{c+1} - \frac{1}{b+1} \right\rceil \right| \geq 1. \quad (36)$$

From the previous (1) and (8) equations, it can be obtained that $\forall c \in C'_i, p_{i,c} \geq r_{i,c}$.

Eventually, there is

$$\begin{aligned}
& f_i(x_i^*, x_{-i}^*) - f_i(x_i, x_{-i}^*) \\
&= \sum_{c \in C} r_{i,c}^* - \left(\sum_{c \notin C'_i} r_{i,c} - \sum_{c \notin C'_i} p_{i,c} + \sum_{c \in C'_i} r_{i,c} - \sum_{c \in C'_i} p_{i,c} \right) \\
&\geq \sum_{c \in C} r_{i,c}^* - \left(\sum_{c \notin C'_i} r_{i,c} - 0 + \sum_{c \in C'_i} r_{i,c} - \sum_{c \in C'_i} r_{i,c} \right) \\
&= \sum_{c \in C} r_{i,c}^* - \sum_{c \notin C'_i} r_{i,c} \\
&= \sum_{c \in C} r_{i,c}^* - \sum_{c \notin C'_i} r_{i,c}^* \\
&= \sum_{c \in C'_i} r_{i,c}^* \geq 0.
\end{aligned}$$

Hence, x^* is a Nash equilibrium.

Next, it will be demonstrated that S^* is perfectly fair as well.

Theorem 2 S^* reaches perfect fairness.

From $r_{i,c} = k_{i,c} \Sigma(k_c)$, it can be observed that throughput of player i on channel c depends on $k_{i,c}$ and the sum of the radios number on the channel c , k . It is easy to see that in x_i^* , the total number of radios on channel $c(k_c^*)$ is

$$k_c^* = \sum_{i \in N} k_{i,c}^* = \begin{cases} (a+1)|N| & \text{if } 1 \leq c \leq b \\ a|N| & \text{if } b+1 \leq c \leq |C| \end{cases} \quad (37)$$

where $|N|$ is the number of players. Given (7) and (9), $\forall i \in N$, there is

$$\begin{aligned}
f_i^* &= \sum_{c \in C} r_{i,c} = \sum_{c \in C} k_{i,c}^* \sigma(k_c^*) \\
&= \sum_{1 \leq c \leq b} (a+1) \sigma((a+1)|N|) + \sum_{b+1 \leq c \leq |C|} a \sigma(a|N|) \\
&= b(a+1) \sigma((a+1)|N|) + (|C| - b)a \sigma(a|N|)
\end{aligned}$$

Therefore, the value of f_i^* is independent for i . Therefore, $\forall i, j \in C$, $f_i^* = f_j^*$, and $\sum_{c \in C} r_{i,c} = \sum_{c \in C} r_{j,c}$.

Theorem 2 describes the strategy profile s^* , which achieves a Nash equilibrium. Moreover, the theorem also guarantees the perfect fairness in the system. That means each player can obtain the same total throughput such as perfect fairness when the system converges to a stable state. For all positive values of K and $|C|$, **Theorems 1** and **2** hold true.

3.3.4 Conclusion

In this section, a Nash equilibrium (NE) approach with perfect fair channel assignment in the selfish WMNs was formulated. The fairness is measured by the equal total throughput of all players no matter how many players are in the network.

Using this approach we validated the proposed result, compared it against Max–min fairness channel assignment.

4 Network Routing

4.1 Multicasting

4.1.1 Optimization Problem Description

Limitations on single radio and single channel have explored the attention to apply multichannel technologies in wireless networks. Channel assignment in multi-radio wireless networks apparently mitigates the interference and increases the network capacity. Since channel assignment has an impact on the link bandwidth which affects to the choosing of transmission links without interference, consequently, it also has relation with network routing to satisfy the traffic demand. The routing mechanisms in multichannel wireless networks should be well suited for the use with the proposed channel assignment strategy.

Previous works [16, 47] show the advantage of employing multiple nonoverlapping channels to overcome the interference problems. Several research efforts have been made on channel assignment methods [16, 49] and routing algorithms [14, 47] for multi-radio and multichannel (MR-MC) WMNs. The *minimum cost multicast tree* (MCMT) problem in (MR-MC) wireless networks [32] is discussed. Considering the dynamic traffic model, multicast routing (session) requests arrive one by one without any prior knowledge.

Ruiz and Gomez-Skarmeta [58] have proved that the MCMT problem in WMN is NP-hard. In [29], a heuristic algorithm has been proposed to build up a multicast structure with channels which are assigned to the nodes in the networks to avoid interferences. But this work could only support for one single multicast session with predetermined traffic pattern. In this section, the MCMT problem in MR-MC WMNs with dynamic traffic model is discussed. Assumed that the channel assignment is given and static, an Integer Linear Programming (ILP) model is presented to optimally solve the MCMT problem.

4.1.2 System Model and Concepts

A static MR-MC WMN is considered where each node in the network behaves like a TAP [28, 30]. Some nodes in the networks serve as gateway nodes which could directly access to the Internet. Each node is equipped with one or multiple radios and nonoverlapping channels. The set of available channels is set to Q , and the channel assignment is assumed as given and static. The network is represented as a directed multi-graph $G = (V, E)$ where V is the set of nodes and E is the set of edges. Each edge in E is denoted by $(i, j)_k$, representing a directed edge from node i to j operating on channel k . Assuming that each radio has a common transmission and interference range, a pair of directed edges $(i, j)_k$ and $(j, i)_k$ exists in E if the nodes i and j are in each other's transmission range and have a radio tuned to channel k .

4.1.3 Mathematical Formulation

Given instances, $V(T, k)$ denotes the set of transmitting nodes on channel k in multicast tree T . The multicast tree total cost is

$$\text{cost}(T) = \sum_{k \in Q} |V(T, k)|$$

where Q is the set of available channels.

The MCMT problem is formulated as follows: Given an (G, s, M) , where $G = (V, E)$ is a network graph, $s \in V$ is a source node, and $M \subseteq V$ is a set of destinations. The problem is how to find a minimum cost multicast tree in G that is rooted at s and spans all destinations in M .

An Integer Linear Programming (ILP) model to solve the MCMT problem optimally is proposed. Given an instance (G, s, M) of the MCMT problem, the network topology and channel assignment are described as

$$\{X_{i-j,k} : \forall i, j \in V, i \neq j, k \in Q\}$$

where $C_{i-j,k}$ equals to one if a directed edge $(i, j)_k$ exists in G , and zero otherwise.

A multicast tree solution can be represented by a set of binary variable, $\{X_{i-j,k} : \forall i, j, i \neq j, k \in Q\}$ where $X_{i-j,k}$ equals to one if the multicast tree includes a directed edge $(i, j)_k$, and zero otherwise. If the directed edge $(i, j)_k$ includes in the multicast tree, then it must be in the network G . Thus, the following constraints are obtained:

$$X_{i-j,k} \leq C_{i-j,k}, \forall i, j \in V, i \neq j, \forall k \in Q.$$

The network flow model [31] is used to guarantee that the resulting multicast tree indeed spans all the destinations in M . Let F_{i-j} denote the aggregate amount of energy consume from node i to j on any channel. From the network flow model, the following constraints can be obtained:

1. Source node s sends $|M|$ units of energy to the network:

$$\sum_{j \in V, j \neq s} F_{s-j} = |M|.$$

2. No input flows to the source node:

$$\sum_{j \in V, j \neq s} F_{j-s} = 0.$$

3. Each destination takes out one unit of energy flow from the passing energy flow, while non-destination nodes do not cost energy from the flow:

$$\sum_{j \in V, j \neq i} F_{j-i} - \sum_{j \in V, j \neq i} F_{i-j} = 1, \forall i \in M$$

$$\sum_{j \in V, j \neq i} F_{j-i} - \sum_{j \in V, j \neq i} F_{i-j} = 0, \forall i \in V, i \notin M, i \neq s.$$

4. Only when an edge between nodes i and j is included in the multicast tree it is possible that $F_{i,j} > 0$:

$$|M| \cdot \sum_{k \in Q} X_{i-j,k} \geq F_{i-j}, \forall i, j \in V, i \neq j.$$

The equation in list 4 relates the $X_{i-j,k}$ variables to the flow variables F_{i-j} . Note that the optimization procedure excludes the case that two edges (operating on different channels) between the same two nodes are both included in the multicast tree. To achieve the minimize cost of multicast tree, a set of variables is introduced:

$$\{Y_{i,k} : \forall i \in V, k \in Q\}.$$

$Y_{i,k}$ equals to one if node i is a transmitting node on channel k in the resulting multicast tree, and zero otherwise. Thus, a set of constraints relate to $Y_{i,k}$ to the $X_{i-j,k}$ can be obtained:

$$Y_{i,k} \geq X_{i-j,k}, \forall i, j \in V, i \neq j, \forall k \in Q$$

Therefore, the objective function is

$$\text{minimize } \sum_{k \in Q} \sum_{i \in V} Y_{i,k}$$

where the multicast tree cost is the total number of transmitting nodes in the tree over all channels. The ILP formulation for the MCMT problem is summarized below.

$$\text{minimize } \sum_{k \in Q} \sum_{i \in V} Y_{i,k}$$

subject to

$$X_{i-j,k} \leq C_{i-j,k}; \forall i, j \in V, i \neq j, \forall k \in Q$$

$$\sum_{j \in V, j \neq s} F_{s-j} = |M|;$$

$$\sum_{j \in V, j \neq s} F_{j-s} = 0;$$

$$\sum_{j \in V, j \neq i} F_{j-i} - \sum_{j \in V, j \neq i} F_{i-j} = 1, \forall i \in M;$$

$$\sum_{j \in V, j \neq i} F_{j-i} - \sum_{j \in V, j \neq i} F_{i-j} = 0, \forall i \in V, i \notin M, i \neq s;$$

$$\begin{aligned}
|M| \cdot \sum_{k \in Q} X_{i-j,k} &\geq F_{i-j}, \forall i, j \in V, i \neq j; \\
Y_{i,k} &\geq X_{i-j,k}, \forall i, j \in V, i \neq j, \forall k \in Q; \\
X_{i-j,k} &\in \{0, 1\}; \forall i, j \in V, i \neq j, \forall k \in Q \\
F_{i-j} &\geq 0; \forall i, j \in V \\
Y_{i,k} &\in \{0, 1\}; \forall i \in V, \forall k \in Q.
\end{aligned}$$

4.1.4 Solution

Next, a polynomial-time approximation algorithm, called Wireless Closest Terminal Branching (WCTB), is proposed for the MCMT problem. The main idea of the WCTB is that:

1. For each step, one new branch is added to the current multicast tree to reach a new destination that is closest to the source node.
2. The cost of each link in the networks initials as one. The crux is that when a new branch is included into the multicast tree, the cost of links may become zero due to the broadcast advantage.
3. It is easy to implement based on the Dijkstra's algorithm.

Theorem 3 *The WCTB approximation ratio is no more than $(2 \cdot D_{max})$, that is,*

$$\frac{\text{cost}(T_{\text{WCTB}})}{\text{cost}(T_{\text{opt}})} \leq 2 \cdot D_{max}$$

where T_{opt} denote the optimal multicast tree and T_{WCTB} denote the multicast tree generated by WCTB. And $\text{cost}(T_{\text{WCTB}})$ and $\text{cost}(T_{\text{opt}})$ denote the tree costs produced by the WCTB and the optimal tree, respectively.

Given $G = (V, E; s, M)$, let t_1 denote the source node and t_{i+1} denote the i th destination in M . Let $\text{dist}(u, v)$ denote the shortest distance in terms of hop count from node u to v in G . The proof of **Theorem 3** needs two lemmas.

Lemma 1 *Suppose p_1, p_2, \dots, p_k is a permutation of $1, 2, \dots, k$, then for every $i, 2 \leq i \leq k$, there exists a unique critical pair (p_{j-1}, p_j) such that $\min(p_{j-1}, p_j) < i \leq \max(p_{j-1}, p_j), 2 \leq j \leq k$.*

Lemma 2 *For any instance $(G = (V, E), s, M)$ of the MCMT problem,*

$$\text{cost}(T_{\text{opt}}) \geq \frac{\sum_{i=1}^{|M|} \text{dist}(t_{p_i}, t_{p_{i+1}})}{2 \cdot D_{max}}$$

where $\{t_{p_1}, t_{p_2}, \dots, t_{p_{|M|+1}}\}$ is a permutation of $\{t_1, t_2, \dots, t_{|M|+1}\}$ obtained by a preorder traversal of T_{opt} starting from the source node s .

Both lemmas proof can be found in [32]. From the above lemmas, for $2 \leq i \leq |M| + 1$, there is

$$\sum_{i=2}^{|M|+1} dist(n_i, n'_i) = \sum_{j=2}^{|M|+1} dist(m_{p_{j-1}, m_{p_j}}).$$

In the algorithm WCTB, to reach a new destination, say m_i , a minimum cost path from s is integrated. The cost of the minimum cost path is $cost(s, m_i) = cost(m_1, m_i)$; therefore,

$$cost(T_{WCTB}) = \sum_{i=2}^{|M|+1} cost(m_1, m_i).$$

Furthermore, since the link cost of edges in the current multicast tree T in WCTB is zero, $cost(m_1, m_i)$ is no more than the distance between m_i and any destination that is included in the current multicast tree, and thus no more than the distance between n_i^{earlier} and $n_i^{\text{no-earlier}}$, that is, for $2 \leq i \leq |M| + 1$,

$$cost(m_1, m_i) \leq dist(n_i^{\text{earlier}}, n_i^{\text{no-earlier}}).$$

Combining the above proof equations,

$$cost(T_{WCTB}) \leq \sum_{j=2}^{|M|+1} dist(m_{p_{j-1}}, m_{p_j})$$

is obtained. Accordingly, from Lemma 2 and above equation, there is

$$cost(T_{\text{opt}}) \geq \frac{\sum_{i=1}^{|M|} dist(t_{p_i}, t_{p_{i+1}})}{2 \cdot D_{\max}} \geq \frac{cost(T_{WCTB})}{2 \cdot D_{\max}}.$$

Thus,

$$\frac{cost(T_{WCTB})}{cost(T_{\text{opt}})} \leq 2 \cdot D_{\max}.$$

4.1.5 Conclusion

In this section, MCMT problem is considered in MR-MC WMNs. The problem is in concern of dynamic traffic model. An ILP model for solving this problem optimally has been provided. The polynomial-time near-optimal algorithm, WCTB, is proposed to solve the problem efficiently.

4.2 Data Collection

Multichannel wireless sensor networks for supporting a wide range of applications such as environmental monitoring, military surveillance, and traffic control have been drawn attention to researchers in the current wireless research area. Such kind of networks can be used to collect sensory information from the real world. In order to collect data, there are two types of data gathering in multichannel wireless sensor networks. One is data collection [11, 38, 63] which gathering data from the source nodes and send them to the base station. Different from data collection, data aggregation [15, 24, 33, 57] rather than sending individual data from sensor nodes to base station is that multiple data are aggregated as a data to be forwarded by the sensor network. In data collection [23], the problem of collecting all the sensing information from the sensors at a particular time is defined as snapshot data collection. Continuous data collection is represented as the collection of multiple continuous snapshot.

The network capacity [18] is one of the network measurement for the network performance evaluation, while wireless sensor networks suffer from the interference problem during data transmission. In [23], the data receiving rate at the sink node is used to measure the data collection capacity. Extensive works have been studied in distinct communication tasks such as broadcast capacity [36], multicast capacity [34, 35], unicast capacity [44], and snapshot data collection capacity [11, 38, 63]. Most of the previous works are based on single radio and single channel in wireless sensor networks which the sensor node is only working on the half-duplex mode. In such sensor network environment, data transmission suffers from the radio conflict [12, 27] and channel interference [7, 13] issues. In this section, a dual radio multichannel is applied which dramatically will reduce the interference. The problem considering in this section is based on the protocol interference model [54]. Two algorithms are presented which investigate the snapshot and continuous data collection problem in dual radio multichannel wireless sensor networks.

4.2.1 Network Model and Concepts

The network is represented as a graph $G = (V, E)$, where V is the set of sensor nodes and E is the set of links in V . The network is composed of n sensor nodes and one sink node. Each sensor is equipped with two radios and each radio's transmission radius is fixed to 1 and the interference range is defined as ρ , $\rho > 1$. In protocol interference model, a receiving node v successfully receives the data from the transmitting node u only if $\|u - v\| \leq 1$ and furthermore any other node s which satisfies $\|s - v\| \leq \rho$ will not simultaneously transmit data packet over the same channel with u . Each radio has K nonoverlapping channels as $\omega_1, \omega_2, \omega_3, \dots, \omega_K$. Each sensor can transmit at a rate of W bits/second over a channel [11]. It is assumed that all the transmissions are synchronized and the size of a time slot is $t = b/W$ seconds, where b bits is the size of all the packet transmission in the network. The capacity γ of data collection is the ratio between the size of the data successfully received by the sink and the time τ used to collect these data. The capacity to collect

N snapshots of data is $\gamma = \frac{Nnb}{\tau}$, which is truly the data rate at the sink. A connected dominating set based on the mechanism used in [57] is built for constructing a routing tree. Vertex coloring terminologies have been derived in [43, 57].

4.2.2 Scheduling Algorithm for Snapshot Data Collection

In this section, a novel scheduling algorithm is proposed with a tighter lower capacity bound and order-optimal. Since at any time slot, the sink can receive data from at most one sensor, the upper bound of the snapshot data collection capacity is W [11].

A new multipath scheduling algorithm based on the previous built routing tree in [57] is proposed [23]. First how to schedule a single path and extend it to the schedule of multipath in the routing tree is discussed. For simplicity, the concept of round, which indicates a period of time consisting of multiple continuous time slots, is introduced. The path is denoted by P , and P_0 (resp., P_e) denotes the set of links on P whose heads (resp., tails) are dominators and whose tails have at least one packet to be transmitted. Scheduling P has the following two steps.

Step 1. In an odd round, schedule every link in P_0 once, that is assign a dedicated channel and one dedicated time slot to each link in P_0 .

Step 2. In an even round, schedule every link in P_e once, that is assign a dedicated channel and one dedicated time slot to each link in P_e .

Then the multipath scheduling on the routing tree is discussed. The basic idea of the multipath scheduling algorithm is as follows:

Step 1. For the nonintersecting paths without wireless interference, schedule them by the single path scheduling algorithm concurrently.

Step 2. For the nonintersecting paths with wireless interference, schedule them according to a certain order. The path with the smallest subscript has the highest priority.

Step 3. For the intersecting paths, schedule them according to a certain order, for example, if P_i is the one of these intersecting paths with the smallest subscript, schedule P_i until there is no packet having to be transmitted on the sub-path and then continue to schedule the next path.

Theorem 4 *The capacity γ at the sink of T of the multipath scheduling algorithm is at least*

$$\frac{W}{\frac{3.63}{K} \rho^2 + o(\rho)},$$

which is order-optimal.

The proof can be found in [23]. Compared with the recent result in [11], the proposed algorithm has a lower bound of $\frac{W}{8\rho^2}$.

4.2.3 Scheduling Algorithm for Continuous Data Collection

In this section, a novel pipeline scheduling algorithm base on the compressive data gathering (CDG) [38] in dual radio multichannel wireless sensor networks

is presented. From the benefit brought by CDG, the continuous data collection problem with the pipeline technique [11] can be addressed, different from the multipath scheduling algorithm, in which a sensor sends one packet over a link in one time slot. A sensor sends M packets for a snapshot employing CDG. A concept of a super time slot (STS) is introduced which consists of M time slots. In a STS, a sensor can send M packets over a channel for a snapshot. For the links working simultaneously, channels and STSs are assigned using the similar way of the multipath scheduling algorithm.

Theorem 5 *For a long-run continuous data collection, the lower bound of the achievable asymptotic network capacity of the pipeline scheduling algorithm is*

$$\frac{nW}{12M\left(\frac{3.63}{K}\rho^2 + o(\rho)\right)}$$

when $\Delta_e \leq 12$ or

$$\frac{nW}{M\Delta_e\left(\frac{3.63}{K}\rho^2 + o(\rho)\right)}$$

when $\Delta_e > 12$.

Proof detail is explained in [23].

4.2.4 Conclusion

Motivated from the no research work studying the continuous data collection before [23], the problem in the dual radio multichannel wireless sensor networks is investigated. Two algorithms in snapshot and continuous data collection are proposed. The snapshot data collection algorithm can achieve the network capacity of at least $\frac{W}{\frac{3.63}{K}\rho^2 + o(\rho)}$, and the continuous data collection achieves asymptotic network capacity of $\frac{nW}{12M\left(\frac{3.63}{K}\rho^2 + o(\rho)\right)}$ when $\Delta_e \leq 12$ or $\frac{nW}{M\Delta_e\left(\frac{3.63}{K}\rho^2 + o(\rho)\right)}$ when $\Delta_e > 12$. The simulation results show that the proposed algorithms' network capacity outperforms the existing works.

4.3 Data Aggregation

Recent advancement of radio technology has enabled the sensor devices which are capable of sensing, computation, and communication setting in a multichannel environment. A multichannel wireless sensor network (MWSN) communication does not rely on any infrastructure but hop-by-hop sensor communication. To collect the sensory information such as temperature, medical, and surveillance data in this type of network, an efficient and robust data collection mechanism is in need. Data aggregation is one of the data gathering paradigm to perform in-network fusion of data packets with small number and size of data transmission. The goal of data aggregation is to achieve the minimum interference and latency in the network.

Lots of works focus on distinct communication tasks with the objective of minimum latency. Many existing works have been studied in the minimum latency interference-aware broadcast scheduling extensively [9, 39, 56]. In [9], Chen et al. studied the minimum latency interference-aware broadcast scheduling considering the transmission range and interference range. Mahjourian et al. [39] extended a much more consideration of carrier sensing range in the minimum latency conflict-aware broadcast scheduling. Wan et al. [56] investigated the minimum latency scheduling for group communications (broadcast, aggregation, gathering, and gossiping) in multichannel multihop wireless networks. Data aggregation shows out to be more effective in data gathering in MWSN. Previous research considers the conflict-free data aggregation issues [10, 20, 26, 57, 61] in single-channel wireless sensor networks. The works proposed in [10, 20, 61] are only considered the nodes' transmission range, and all nodes in the existing networks have data packet sent to the base station. Wan et al. [57] studied the minimum data aggregation latency problem in a more general situation. An algorithm with latency bound $\beta_{\rho+1}(15R + \Delta - 4)$ was proposed in [57], when the interference range is ρ times of the transmission range. Krishnamachari et al. [26] viewed data aggregation from another aspect. They considered the case where there was a subset of nodes whose data need to be sent to the base station and regarded aggregating these data as a way to save energy. The work [62] is the only one existing for data aggregation considering the interference range and carrier sensing range of the wireless nodes.

From the above existing works, this section addresses the more generic minimum latency conflict-free data aggregation scheduling problem in multi-channel multihop wireless sensor networks [37]. Given an instance in which the network consists of a set of sensor nodes and a base station, the discussed problem is formally defined as to find a schedule such that data from a set of sensors can be successfully transmitted to the base station without any wireless conflict and the latency of accomplishing data transmission is minimized.

4.3.1 Conflicts and Conflict-Free Communication

In this section, the conflict-free communication model is formulated. Two parallel data transmissions can be successfully transmitted only if all the following types of conflicts are avoided. Those transmissions which avoid all the types of conflicts are called conflict-free transmissions:

1. Collision at receiver: If there are two or more nodes in node u 's transmission range to transmit using the same channel k , node u cannot correctly receive messages transmitted by its neighbors using channel k .
2. Interference at receiver: If there is a node in node u 's interference range to transmit using channel k , node u cannot correctly receive the messages from its neighbors transmitting using channel k .
3. Contention at sender: If there is a node in node u 's carrier sensing range transmitting using channel k , node u cannot correctly transmit messages to its neighbors using channel k .

4.3.2 System Model and Problem Definition

The instance network consists of n sensors and a base station. Each sensor is equipped with a RF transceiver with omnidirectional antennae to send or receive data. There are $\lambda \geq 1$ available nonoverlapping channels for node transmitting and receiving data. The transmission range, interference range, and carrier sensing range which roughly represented as disks are considered during the data transmission.

The mathematical formulation of the communication network is illustrated as a unit disk graph (UDG) $G = (V, E)$. Each node has the network factor of $r, \alpha r, \alpha \geq 1, \beta r, \beta \geq 1$ which indicate the transmission range, interference range, and carrier sensing range, respectively. An edge exists between node u and node v if and only if $d(u, v) \leq r$, where $d(u, v)$ is the Euclidean distance between u and v . There exists an edge between node u and the base station b if and only if $d(u, b) \leq r$.

The problem is then formulated as follows: Given instances of a UDG $G = (V, E)$ along with a base station $b \in V$, a subset $S \subseteq V - \{b\}$, and parameters $\lambda, r, \alpha, \beta$, the considering problem is how to find a conflict-free many-to-one data aggregation schedule with latency minimized.

4.3.3 Data Aggregation Scheduling Algorithms

In this section, the data aggregation scheduling algorithm will be proposed and analyzed. The algorithm will mainly contain two phases. The first phase is to construct an initial many-to-one data aggregation tree. The second phase is to derive an aggregation schedule from the initial data aggregation tree.

4.3.4 Many-to-One Data Aggregation Tree Construction

The main idea of the initial data aggregation tree is to firstly take a breath-first search of some nodes which are not taken action in the many-to-one schedule with minimum latency. After that, a many-to-one tree is constructed based on the subgraph induced by these nodes. The breadth-first search (BFS) tree is rooted at the base station denoted by T_{BFS} for the network $G = (V, E)$ and eliminates the nodes from G and T_{BFS} which are not on the paths from any node $u \in S$ to the base station in T_{BFS} . Note that the nodes eliminated will not join in the schedule.

The node elimination could be done as follows. (1) Let $A = V - \{b\}$ and $P(u)$ be the set of all the nodes on the path from node u to the base station in T_{BFS} . Then the nodes in $A - \bigcup_{u \in S} P(u)$ need to be eliminated. (2) After eliminating the nodes, the obtained network and breadth-first search tree are denoted by G_p and $T_{\text{BFS}, p}$, respectively.

The fact is that the subgraph G_p of G and the subgraph $T_{\text{BFS}, p}$ of T_{BFS} are induced by $\bigcup_{u \in S} P(u) \cup \{b\}$.

Based on the subgraphs G_p and $T_{\text{BFS}, p}$, we construct a many-to-one data aggregation tree. After pruning the network, we construct a maximal independent set (MIS) on the pruned network according to the breadth-first search ordering. Then

we transform the MIS to minimum cover problem and compute the minimum cover to obtain the initial data aggregation tree. The data aggregation tree does not prevent any conflicts. More detailed explanation is in [37].

4.3.5 Many-to-One Data Aggregation Scheduling

The assignment of many-to-one data aggregation scheduling is designed by node coloring. The fact in node coloring is that any graph G is able to produce a proper node coloring in G using at most $1 + \delta^*(G)$ colors. Smallest-degree-last ordering of nodes is applied to assign proper color to each node in particular order [42].

The following useful lemmas are given to construct a conflict-free schedule.

Lemma 3 *Two parallel transmissions “ $t_1 \xrightarrow{k_1} r_1$ ” and “ $t_2 \xrightarrow{k_2} r_2$ ” are conflict-free ($t_1 \neq t_2$ and $r_1 \neq r_2$), if and only if at least one of the following two conditions are satisfied:*

1. $d(t_1, r_2) > \alpha r$; $d(t_2, r_1) > \alpha r$; $d(t_1, t_2) > \beta r$
2. $k_1 \neq k_2$

The following lemma shows the sufficient conditions for avoiding the three types of conflict.

Lemma 4 ([39]) *In order for two parallel transmissions “ $t_1 \xrightarrow{k} r_1$ ” and “ $t_2 \xrightarrow{k} r_2$ ” using the same channel k to be conflict-free according to the network model, it is sufficient to have $d(t_1, t_2) > \max(\alpha + 1, \beta)r \vee d(r_1, r_2) > (\max(\alpha, \beta) + 2)r$.*

Two conflict graphs which are denoted by GC_t and GC_r according to Lemma 4 are constructed. The λ channels are denoted by integers $0, 1, \dots, \lambda - 1$. There are two cases. (1) When $\lambda = 1$, there is only one available channel. The only needed thing is to schedule the transmitting time slot of each node. After coloring the conflict graph, if two nodes have the same color, that is, their distance is bigger than $\max(\alpha + 1, \beta)r$ (or $(\max(\alpha, \beta) + 2)r$), then the two nodes can be scheduled to transmit (receive) at the same time slot. The nodes which have distinct colors will not be scheduled to transmit (receive) at the same slot. (2) When $\lambda > 1$, the nodes with distinct colors can schedule at the same time slot when assigning different channels to them. Thus, it is needed to schedule the transmitting time slot and the channel of each node. Fortunately, a uniform method is found to deal with the two situations.

Two sub-schedules are derived to obtain conflict-free scheduling [37]. Basing on the two sub-schedules, the conflict-free data aggregation schedule is constructed; the details can be found in [37].

4.3.6 Performance Analysis

In this section, the approximation ratio of the proposed algorithm, which is for the minimum latency conflict-free many-to-one data aggregation scheduling problem,

is analyzed. The performance of proposed algorithm is compared against the trivial lower bound R , where R is the depth of the T_{BFS_p} . A known theorem [17] is used to prove Lemma 5.

Theorem 6 ([17]) Suppose that C is a compact convex set and U is a set of points with mutual distances at least one, then

$$|U \cap C| \leq \frac{2\text{area}(C)}{\sqrt{3}} + \frac{\text{peri}(C)}{2} + 1,$$

where $\text{area}(C)$ and $\text{peri}(C)$ are the area and perimeter of C , respectively.

Lemma 5 Let $G_p = (V_p, E_p)$, $S \subseteq V_p$ be independent set in G_p , the inductivities of $GC_l[S]$ and $GC_r[S]$ have an upper bound of $\lfloor \frac{\pi}{\sqrt{3}}h^2 + (\frac{\pi}{2} + 1)h \rfloor$ and $\lfloor \frac{\pi}{\sqrt{3}}k^2 + (\frac{\pi}{2} + 1)k \rfloor$, respectively, where $h = \max(\alpha + 1, \beta)$ and $k = \max(\alpha, \beta) + 2$.

Lemma 6 ([57]) The following statements are true:

1. $|C_0| \leq 12$.
2. For each $1 \leq i \leq R_U - 1$, each dominator in U_i is adjacent to at most 11 connectors in C_i .
3. For each $0 \leq i \leq R_U - 1$, each connector in C_i is adjacent to at most 4 dominators in U_{i+1} .

Theorem 7 The algorithm has a latency upper bound $(\lceil \frac{a}{\lambda} \rceil + 11\lceil \frac{b}{\lambda} \rceil)R + (\Delta - 23)\lceil \frac{b}{\lambda} \rceil - \lceil \frac{a}{\lambda} \rceil + 12$, where $a = \lfloor \frac{\pi}{\sqrt{3}}h^2 + (\frac{\pi}{2} + 1)h \rfloor + 1$, $b = \lfloor \frac{\pi}{\sqrt{3}}k^2 + (\frac{\pi}{2} + 1)k \rfloor + 1$, Δ and R are the maximum degree of pruned network G_p and the depth of the pruned BFS tree T_{BFS_p} , respectively.

Corollary 1 For $\lambda = 1$, the algorithm has a latency upper bound $(a + 11b)R + (\Delta - 23)b - a + 12$ and thus it has a nearly constant $(a + 11b)$ ratio.

4.3.7 Conclusion

In this section, the minimum latency conflict-free many-to-one data aggregation scheduling problem in multichannel multihop wireless networks is addressed. Nearly a constant $(\lceil \frac{a}{\lambda} \rceil + 11\lceil \frac{b}{\lambda} \rceil)$ -ratio algorithm for the problem is introduced.

Abstract

Broadcasting is an efficient way to disseminate information to a large number of users. With the fast development of wireless communication techniques, wireless data broadcasting has become a popular data dissemination method. The major performance concerns for any wireless data broadcast systems are response time and energy consumption. Various optimization methods for different aspects of data broadcasting systems have been developed in order to improve the broadcast system performance. This chapter gives a complete overview of different optimization issues in data broadcasting. In this chapter, optimization problems and corresponding algorithms and solutions for data scheduling, indexing, retrieval, and coverage are discussed in various types of data broadcast systems, including single-channel, multichannel, push-based, and on-demand data broadcasting.

1 Introduction

Data broadcasting is not a new concept. The term has been used for more than 30 years. Traditionally, data broadcasting refers to the ability to send data other than video/audio through broadcast television/radio transport [14, 54]. A best-known example is captioning. Takenaga categorized this type of data broadcasting into independent data broadcasting and linked/supplementary data broadcasting. Independent data broadcasting includes only data, such as weather reports or stock information, while linked/supplementary data broadcasting is for the purpose of better facilitating regular television programs and can sometimes be interactive.

Traditional data broadcasting reached its peak during the middle and late 1990s due to the digitalization of broadcasting and the massive use of home networks. A lot of data broadcasting services became available, for example, on-screen TV guide, SkyLife service in South Korea, and Teletext service in United Kingdom. Most of these services, however, still use traditional broadcast media (cable or television satellites) for data transportation.

In recent years, the boosting of wireless technology and mobile communications (GPRS, 3G, 4G, etc.) has given data broadcasting a completely new meaning. In a wireless communication environment, data broadcasting means disseminating data to a large group of candidate clients in a broadcast manner. The beauty of wireless data broadcast is its scalability, flexibility, and bandwidth efficiency.

In wireless data broadcast systems, data are broadcasted from a base station on some channels of particular frequencies within a transmission range. Clients in this

range can access the channels and download the data. Several regulatively located base stations may work together to cover a certain area, each taking charge for its local cell named *microcell* (usually known as hexagon, quadrangle, or triangle, depending on the geometric layout of base stations). Clients can move freely among cells. In contrast to point-to-point data delivery, data broadcast allows a mass number of clients to simultaneously access the data and thus is more scalable. Broadcast technique also fits the asymmetric structures of most wireless systems because clients simply “listen” to the broadcast channels, filter, and pick the data they need, which alleviates the uplink channel load. Therefore, the system can make use of most bandwidth as downlink for data dissemination. Moreover, within the coverage range of a base station, no matter how many clients need to download the data, the network behavior remains the same.

In general, there are three types of data broadcast: push-based, pull-based, and hybrid. Push-based [1] data broadcast uses all bandwidth for broadcast. It is usually used to disseminate public information such as stock price, news reports, or traffic information. One benefit of pure push-based broadcast is that it makes full use of the network bandwidth for data dissemination. It also has very little computational requirement for the server because the broadcast program can be organized off-line. On the other hand, since there is no uplink in a push-based broadcast system, it is very hard to dynamically adjust the broadcast program to changes of clients’ requirement. Hence, push-based data broadcast is suitable for environments where the data and client access patterns are almost static.

Pull-based data broadcast is also known as “on-demand” data broadcast. Compared to push-based data broadcast, it has an additional uplink through which clients can send their requests to the server. Requests are queued in the server. Instead of organizing a broadcast program off-line and then broadcast it periodically, the server will use some online algorithm to decide the broadcast content based on the service queue in real time. In such a way, the broadcast content will usually reflect the clients’ real requirements and can also be adjusted dynamically according to changes of requests. Therefore, on-demand data broadcast can be used in environments where the data and client access patterns change frequently. However, handling client requests and making broadcast decision in real time means a heavy work load for the server and often requires high computational capacity.

Hybrid data broadcast takes advantage of both sides. It combines push- and-pull based mechanisms. Different hybrid systems have different integration methods. Some systems use push-based scheme to broadcast data with static access patterns and on-demand scheme for data with dynamic access patterns, while some other systems broadcast most popular data in a pure push way and handle not-so-popular data individually.

Response time is a major concern for all kinds of data broadcast systems. The definition of response time is not exactly the same for different systems. In general, *response time* for a request is the time interval between the moment a request is generated (or the client first tunes in a channel) to the moment the requested information is completely downloaded. In push-based systems, it is also called *access time*. There are many factors that can affect response time. From the network point of view, an intuitive way is to increase the throughput of the broadcast. Using more

channels for data broadcast can naturally increase the overall throughput. From the server side, different ways of scheduling the broadcast data may result in different response time, even with the same sets of requests. There have been intensive research efforts on scheduling algorithm design in order to optimize response time. [Sections 2 and 3](#) will introduce different scheduling algorithms for different push-based and on-demand data broadcast systems. From the client side, when requesting multiple items, the downloading sequence can also make a difference. [Section 4](#) will discuss several algorithms trying to optimize the retrieval scheduling.

In wireless data broadcast systems, since most clients are mobile devices operating on battery power, energy conservation becomes another important performance concern. A mobile device usually operates on two modes: the active mode and the doze mode. The energy consumed in the active mode can be 100 times of that in the doze mode [42]. Based on this observation, *tuning time*, which is the total time when a client is in the active mode, is defined as a performance criterium to evaluate energy efficiency of a system. In order to optimize energy consumption of a broadcast system, index is introduced. With the help of index information, clients do not need to stay active all the time to wait for requested data. Instead, they can change to the doze mode while waiting and be active again and tune in the broadcast channel right before the requested data arrive. This can significantly reduce the tuning time of clients. [Section 5](#) will talk in detail about dominating index methods for data broadcast in existing literature.

Another optimization issue related to data broadcast is the coverage problem. As discussed before, data are broadcasted from a base station. The range that a base station can cover is determined by the physical feature of both the base station and the terrain. Given a relative wide area, how to locate base stations in order to cover the whole area is an important optimization problem. Based on different objectives such as minimizing financial cost or enhancing reliability, the coverage problem can be formulated differently. In general, most of them are NP-hard and can be converted into combinatorial optimization problems. [Section 6](#) will give the formal model of the coverage problem and introduce different variations of coverage optimization for data broadcast.

2 Scheduling Optimization for Pure-Pushed Data Broadcasting

In a pure-pushed broadcast network, there are two distinct sets of entities: servers and clients. The servers at the base station repeatedly disseminate a fixed set of data items via wireless channels, while the clients listen to the channel, wait for their desired data items, and download them when they are coming. An example is shown in [Fig. 1](#). In general, the data items are scheduled over time, and the clients do not have to send requests to the server, but wait for the requested items to be broadcasted. Informally, the scheduling optimization problem for data broadcast is that given a set of data items, find a schedule for deciding the broadcast time for each data item of the set such that the expected average access time of the requests is minimized.

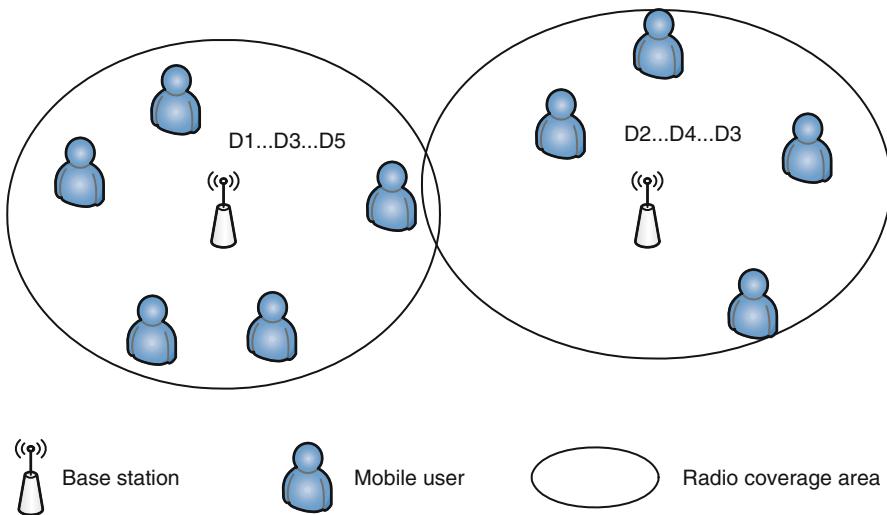

Fig. 1 Broadcast wireless network

In the past two decades, several variants for the scheduling problem of purepushed data broadcast have been discussed, and lots of works have been done. They can be roughly classified into three kinds: scheduling optimization for single-channel data broadcasting, scheduling optimization for multi-channel data broadcasting, and scheduling optimization for dependent data broadcasting. In Sect. 2.1 the works that focus on single channel are presented. Besides developing the single-channel data broadcast, the multichannel data broadcast is also an important area and recently more works focus on this issue. In Sect. 2.2 the research for scheduling multichannel data broadcast is introduced. In addition it is much more likely that a client query a set of data instead of only one data item. Therefore, some works recently discuss about broadcasting dependent data, whose access sequence is pre-ordered. How to schedule dependent data broadcast is discussed in Sect. 2.3.

2.1 Scheduling Optimization for Single-Channel Data Broadcasting

In the early stage of wireless data broadcast research, researchers first study on scheduling data on single broadcast channel. In 1995 Acharya et al. first proposed the scheduling problem for data broadcast [2]. A new technique called broadcast disks for data broadcast is introduced in that paper. In order to make an initial study of the scheduling problem for data broadcast, they defined many assumptions for the broadcasting environments. The assumptions include the following: (1) the data items of the broadcast program remains static; (2) each data item is read only;

(3) clients download the data items of interest from the broadcast server on demand; and (4) there is no upstream communications channels, which means that the clients don't have to send request to servers to get data. Based on these four assumptions, they presented two problems which need to be solved when designing data broadcast programs: the first one is that given a set of data items and the access probabilities for those data items by all the users, how to generate a broadcast program to satisfy as much as possible the needs of the users; the second one is that given the server with a fixed data broadcast schedule, how to manage the data items in cache for the individual users to maximize their own performances.

Furthermore, three types of broadcast programs are demonstrated in that paper. They are flat data broadcast, skewed data broadcast, and regular data broadcast. Examples for the three types of data broadcast programs are shown in Fig. 2. The first program is a flat data broadcast. It is easy to see that the average expected access time for all the data items on a flat broadcast program, regardless of their access frequencies to the clients, is the same for all the items and it equals to half a broadcast period. If considering the access frequencies, the server can also overbalance some data items in a broadcast cycle. Such a program can enhance broadcasting of the popular items. For the second and third programs, both of them broadcast $data_1$ twice as often as $data_2$ and $data_3$. The second program is called a skewed data broadcast, in which the data item $data_1$ is clustered together to be broadcasted, while, the third program is called regular data broadcast, where the same data items are separated by different data items with same intervals. Because the structure design of the third one is similar to the disk and memory design, they refer to regular data broadcast as multi-disk broadcasting.

Based on the idea of broadcast disk, they developed an efficient algorithm for scheduling data broadcast given a set of uniform-length data items and their access pattern. The algorithm has the following steps:

1. Sort the data items in descending order of their popularity.
2. Classify all data items into small subsets, and each subset contains data items with same or similar access frequencies. They call each subset a broadcast disk.
3. Choose an appropriate integer as the broadcast frequency for each of the disks.
4. Calculate the least common multiple (LCM) of all the frequencies; then, split each $disk_i$ into $\frac{LCM}{freq_i}$ small sub-disks.
5. These sub-disks are called chunks and denoted by C_{ij} . i, j refers to the j th chunk in $disk_i$.
6. Let N_i denote the number of chunks in $disk_i$.
7. Let M denote the number of disks.
8. Finally the broadcasting program is generated by [Algorithm 1](#).

The basic idea of the algorithm is to partition the data items into different kinds of disks, and the data items stored in smaller disks are broadcasted more frequently than the data items stored in larger disks. Thus, the data broadcast corresponds to the traditional notion of a memory hierarchy. They also pointed out that automatic determination of the parameters in the algorithm is an interesting optimization problem. Another topic they mentioned is the local cache management for clients.

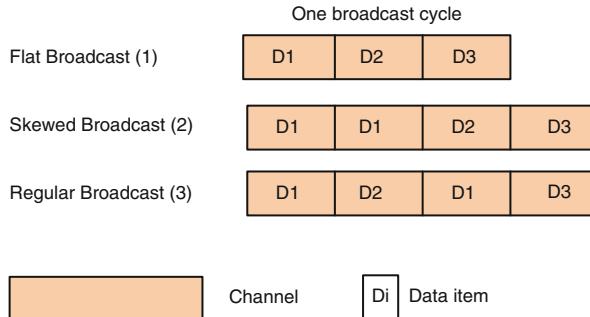

Fig. 2 Three broadcast programs

Algorithm 1 [2]

```

1:  $h \leftarrow \max N_i$ ;
2: for  $i = 0$  to  $h - 1$  do
3:   for  $j = 1$  to  $M$  do
4:      $k \leftarrow i \pmod{N_j}$ ;
5:     Broadcast  $C_{j,k}$ .
6:   end for
7: end for

```

Unlike traditional operating system, in the broadcast systems, a client should cache those data items for which the local probability of access (P) is greater than the frequency of broadcast (X). Based on this idea, they proposed two coast-based data replacement strategies. One is PIX (P Inverse X) which uses the ratio between the access frequency of a data item and its frequency of broadcast as the cost. It is an optimal policy but not easy to implement. The second one LIX (LRU-style) is an approximation for PIX.

In terms of single-channel data broadcast, some researchers concentrate on uniform-length data broadcast; others focus on nonuniform-length data broadcast. Ammar and Wong studied periodic data broadcast with uniform length and proposed a greedy algorithm for it in [7]. Moreover they defined the average response time for nonperiodic schedules; they also analyzed the properties of the optimal schedules and proved that the optimal schedule for periodic data broadcasting is also optimal for arbitrary data broadcasting in [8]. In that paper they presented two algorithms for solving the arbitrary data broadcast scheduling problem by using the works in [36]. The first one is a finite-time algorithm which gives an optimal schedule, and the second one is a heuristic algorithm which gives a nonoptimal schedule. However, they did not provide any performance ratio analysis for the heuristic algorithm in that paper. The similar problem is also pursued by Anily et al. in [9], in which they obtained a 2.5-approximation algorithm for the problem. Later Barnoy et al. developed a 2-approximation algorithm and proved that the heuristic algorithm proposed in [8] has approximation ratio 9/8 in [11].

In terms of nonuniform-length data broadcast, in [57, 58] Vaidya et al. investigated heuristic algorithms for it and showed some experimental results. Kenyon and Schabanel studied approximation algorithms for similar problems and gave theoretical analysis for the problem in both single-channel and multichannel environments, respectively, in [41]. The main results in [41] with respect to the case of single-channel and nonuniform-length data are that they proved the data scheduling problem with nonuniform length is NP-hard, and developed a randomized approximation algorithm for this problem. They first proved that there exists an optimal schedule for the problem which is periodic if broadcast costs are not considered; they also showed even in that case, the problem is NP-hard too. Then, they presented a randomized polynomial approximation algorithm for the problem. Its approximation performance ratio is 3. This is the first paper finding a constant-factor approximation algorithm for nonuniform-length data broadcasting scheduling.

2.2 Scheduling Optimization for Multichannel Data Broadcasting

Besides developing the scheduling mechanisms for single-channel data broadcast, multichannel data broadcast is also an important research area. Recently lots of works have been done for this problem. The multichannel broadcast can be achieved by applying techniques such as frequency-division multiplexing or time-division multiplexing. Consequently multichannel broadcast becomes feasible and can significantly reduce the request response time.

Ardizzone et al. discussed the scheduling problem of data broadcast over multiple channels in [10]. Like other works, they also defined many constraints for the problem such as the data items are allowed to be skewed allocated to different channels but are flat scheduled per channel. The objective is to minimize the average access time for all the requests. The assumptions they defined in that paper for the multichannel data broadcasting environment are as follows: a database $D = \{d_1, d_2, \dots, d_N\}$, which has N data items, is broadcasted by a set of K channels. The bandwidth for each channel is the same. Each data item d_i has a probability p_i and a length z_i . The access frequency of item d_i being requested by clients is denoted by p_i , and the time needed to download the data item d_i is represented by z_i . They also assume that the access frequencies for the items never change and the length z_i for data item d_i is subject to an integer number. It is obvious that $\sum_{i=1}^N p_i = 1$. When the lengths of all the data lengths are the same, it is called uniform-length multichannel data broadcasting, and the z_i for $1 \leq i \leq N$ is one time slot for the uniform-length data scheduling problem. Informally the target of this problem is to partition the N data items into K groups G_1, \dots, G_K such that the average access latency is minimized. The group G_j denotes the set of data items assigned to the j th channel. So there is a integer N_j to represent the size of G_j ,

while the sum of its item lengths is denoted by Z_j . It is clear that $Z_j = \sum_{d_i \in G_j} z_i$. Note that, since the data items in G_j are cyclically broadcasted according to a flat schedule, Z_j is the schedule period on the j th channel. $z_i = 1$ for $1 \leq i \leq N$ for the problem with uniform-length data items, $Z_j = N_j$ for $1 \leq j \leq K$. Assume an item is assigned to the j th channel and clients start to listen at any time slot with the same probability, the client average waiting time for receiving the item equals to half of the period, which is $Z_j/2$. Suppose with the help of indexes the clients know in advance the locations of data items on all the channels; then, the average expected delay (AED) for all the data items over all the channels can be computed by (1):

$$AED = \frac{1}{2} \sum_{j=1}^K \left(Z_j \sum_{d_i \in G_j} p_i \right). \quad (1)$$

To study the uniform-length data scheduling problem for multichannel data broadcasting, [Theorem 1](#) and some notations were proposed in [69].

Theorem 1 ([69]) *Let d_1, d_2, \dots, d_N be N items with access probabilities $p_i \leq p_N$. Then, there exists an optimal solution for partitioning the data items into K groups G_1, \dots, G_K , where $K \leq N$ and each group consists of consecutive elements.*

Let d_1, d_2, \dots, d_N be N data items which are sorted in the descending order of the access probabilities. Partition them in K subsets. Then, an optimal partition $\text{OPT}_{N,K} = (B_1, B_2, \dots, B_{K-1})$ is called leftmost optimal if for any other optimal solution $(B'_1, B'_2, \dots, B'_{K-1})$, B_{K-1} in $\text{OPT}_{N,K}$ is not bigger than B'_{K-1} in that solution, where B_i is the index of the last data item that belongs to group G_i and it is similar for B'_i .

In addition, an optimal solution $(B_1, B_2, \dots, B_{K-1})$ is called strict left-most optimal solution if (B_1, B_2, \dots, B_i) for every $i < K$ is a leftmost optimal solution. In the rest of this section, the leftmost optimal solution is denoted as $L_{N,K}$, and the strict leftmost optimal solution is denoted as $SL_{N,K}$.

In the paper they proposed a dynamic programming (DP) algorithm for the multichannel data scheduling problem. The algorithm computes only the leftmost optimal solution for subproblems and then finds a strict leftmost optimal solution. The most important property of using the DP algorithm is that given the items which are sorted by nonincreasing probabilities, if an optimal solution for the first $N - 1$ data items has been found, then to find an optimal solution for N data items, it only has to check the area larger than B'_{K-1} to find the final border B_{K-1} for $SL_{N,K}$, where B'_{K-1} is the border in the optimal solution for $N - 1$ data items. Such a property can be applied to solve the problems of increasing sizes to reduce the time complexity. If $L_{l,k}$ and $L_{r,k}$ are obtained for some $1 \leq l \leq r \leq N$, then it is clear that B_{k-1}^c is between B_{k-1}^l and B_{k-1}^r , for any $l \leq c \leq r$. If $C_{i,h}$ denotes the

cost of assigning consecutive items d_i, d_{i+1}, \dots, d_h to one of the channels, then $C_{i,h} = \frac{h-i+1}{2} \sum_{q=i}^h p_q$. The recurrences of the DP algorithm can be represent as Eqs. (2) and (3). Equation (3) is derived by choosing $c = \lceil \frac{l+r}{2} \rceil$ in Eq. (2):

$$\text{opt}_{c,k} = \min_{l \in \{B_k^l - 1, \dots, B_k^r\}} \text{opt}_{l,k-1} + C_{l+1,c}. \quad (2)$$

$$\text{opt}_{\lceil \frac{l+r}{2} \rceil, k} = \min_{l \in \{B_k^l - 1, \dots, B_k^r\}} \text{opt}_{l,k-1} + C_{l+1, \lceil \frac{l+r}{2} \rceil}. \quad (3)$$

Based on these two recurrences, it is easy to prove that the uniform-length multichannel data scheduling problem can be solved in $O(KN \log N)$ time by the DP algorithm, where K is the number of channels and N is the number of data items.

Besides the DP algorithm, they also proposed a faster $O(N \log N)$ time algorithm for the uniform-length multi-channel data scheduling problem with the number of channels less than 4. If the data items are already sorted, it requires only $O(N)$ time. The algorithm is based on the special case which has only two channels. When $K = 2$, adding a new item with lowest probability to an optimal solution for the subproblem can be done in constant time. This property can also be applied to find the optimal solution for the case $K = 3$. Actually, the solution for $K = 3$ can be obtained by combining the solutions for $K = 2$ and $K = 1$ in Eqs. (4) and (5):

$$\text{opt}_{N,2} = \min_{l \in \{B_1^{N-l}, B_1^{N-1} + 1\}} C_{1,l} + C_{l+1,N}. \quad (4)$$

$$\text{opt}_{N,3} = \min_{l \in \{1, \dots, N\}} \text{opt}_{1,l} + C_{l+1,N}. \quad (5)$$

For the case that data items have nonuniform lengths, they proved the problem is NP-hard even when $K = 2$. A pseudo-polynomial algorithm is presented with time complexity $O(NZ)$ where Z is the sum of the data lengths and N is the number of data items. They proved the problem is strong NP-hard for arbitrary K . An algorithm is proposed with time exponential to the maximum length of data items. Therefore, the time complexity of this algorithm is only acceptable for small data items. For larger data items, they proposed a heuristic algorithm which is a modified local search algorithm. Its time complexity is $O(N(K + \log N))$, and if the items are already sorted, the time complexity becomes $O(KN)$.

In the aspect of independent data scheduling, the queries issued by clients are assumed to only request one single item at one time. There are a lot of research that investigate how to minimize the average expected response time for multichannel data broadcasting. A brief summary is provided as follows. Yee et al. presented two algorithms to minimize the average expected access delay by partitioning data among multiple channels [69]. They continued their work in this filed to take into consideration the hopping cost in [70]. A near-optimal greedy algorithm for data scheduling of multichannel was proposed by Zheng et al. [73]. In addition, Prabhakara et al. suggested a new system model for multilevel and multichannel data broadcast with air-cache design to improve the server performance [48].

The flat algorithm proposed in [56] adopts a simple allocation algorithm, equally allocating the items to each channel. However, the expected response time for the most popular item is the same as that for a data item not frequently asked by clients. Hsu et al. proposed the VF^k algorithm, which skews the amount of data allocated to each channel [24]. The greedy algorithm in [69], which will be explained in detail later, can achieve a good performance when compared to the DP algorithm, and its time complexity is much better. Although all the algorithms have the same or similar objective function, they assign different weights to complexity and performance.

The greedy algorithm is an efficient algorithm which is often applied to achieve an optimal or near-optimal performance in scheduling problems. In [69], the authors assumed that each data item has a unit length and each channel has the same bandwidth. They also assumed that N_i items were cyclically broadcasted via channel C_i , so the expected delay w_j of receiving d_j on C_i is $\frac{N_i}{2}$. Given these assumptions, the multichannel average expected delay (MCAED) can be derived by Eq. (6), where the access probability of data item d_i is denoted as p_i , and K is the number of channels:

$$\text{MCAED} = \sum_{i=1}^K \sum_{d_j \in C_i} w_j p_j. \quad (6)$$

The greedy algorithm is to allocate data items to K channels in a way that minimizes the MCAED. A simple allocation technique which is easy to implement, called *flat design*, allocates the same number of items to each channel. In the flat design, $N_i = \frac{N}{K}$, $1 \leq i \leq K$, and it is obvious that $\text{MCAED} = \frac{N}{2K}$. In [48], the authors discussed *skewed design*, where items are placed on varying sized channels, depending on their access probabilities. Skewed design has been shown to be better than flat design at reducing the MCAED [2].

The principle of the greedy algorithm proposed in [69] is to find the split points among all the partitions that reduces the total cost of MCAED most significantly. This process is terminated when there are K partitions. In detail, the algorithm is shown in [Algorithm 3](#), where SCAED denotes the single-channel average expected delay for a channel containing data items from d_i to d_j , and it is computed by Eq. (7):

$$\text{SCAED} = C_{i,j} = \frac{j-i+1}{2} \sum_{q=i}^j p_q, (j \geq i, 1 \leq i, j \leq N). \quad (7)$$

The greedy algorithm runs very quickly, in which k denotes the number of partitions. It has the time complexity of $O((N + K) \log K)$, which makes it fast and suitable for practical use. In [69], the authors also discussed the case that the broadcast environment is changed during broadcasting by changing the number of channels as well as adding new data items. They described how a broadcast server generated by the greedy algorithm can easily adjust to changes of the number of channels. They also investigated how to adjust the broadcast with new data items added. Actually adding a channel requires only one more iteration in the greedy algorithm, and removing a channel just requires combines the last two partitions

Algorithm 2 Greedy [69]

Input: a set of N items sorted by probabilities;
Output: K partitions;
 $k \leftarrow 1$;
while $k < K$ **do**
 Let $point_k$ be the split point that most reduces SCAED for each partition P_k ;
 Find the point $point_j$ be the one in $point_1, \dots, point_k$ that most reduces MCAED;
 Split the partition P_j at $point_j$;
 $k \leftarrow k + 1$;
end while

together. It is also possible that items may change their access frequencies since some new data items may be inserted into the broadcast. The new data item is added to the correct position in the broadcast, and the access probabilities are recalculated so that it still holds $\sum p_i = 1$. The good thing is that the scheduler only needs to update split points where necessary. In other words many old split results may still be reused. Although this technique has to recompute the entire solution in the worst case, its efficiency is much better on average.

2.3 Scheduling Optimization for Dependent Data Broadcasting

It is much more likely that a client query requests a set of data items at one time instead of only asking for one data item from the broadcast server. Therefore, besides the independent data broadcast, dependent data scheduling is more useful for developing broadcasting programs in practice. Some works focus on this area, and they usually have the following common assumptions:

1. Data is broadcasted over single or multiple channels.
2. A query requests more than one data item at a time.
3. The queries with multiple data items have different access frequencies.
4. Data items are not necessarily of same sizes.

In [19], Chung et al. discussed the problem of scheduling dependent data to minimize the total access time of queries in wireless data broadcast systems. A query requests a subset of all data items with a query probability. They defined a measure called *query distance* (QD), which represents the coherence degree of the data set requested by a query, and then proposed the problem of *wireless data placement*. The authors also proved that the problem is NP-hard by transforming it from a *optimal linear arrangement* problem. A greedy scheduling algorithm was designed for this problem, in which the QD of queries with higher frequencies is guaranteed not to be changed when minimizing the QD for the queries with lower access probabilities.

In this chapter, the data placement problem for wireless broadcasting is to find a broadcast schedule such that the total access time (TAT) is minimized. The TAT can be computed by Eq. (8), where Q is the set of all the queries q_1, q_2, \dots, q_N , S is

a schedule of solution, and $\text{AT}^{\text{avg}}(q_i, S)$ is the average access time of the query q_i based on S :

$$\text{TAT}(S) = \sum_{q_i \in Q} \text{AT}^{\text{avg}}(q_i, S) \times freq(q_i). \quad (8)$$

The access time of a query for dependent data broadcast not only depends on the starting time of the query but also depends on the data items in the query set. It may spend the whole broadcast cycle for a single query. Thus, in [19], for a given query q_i , if $P(x)$ and $F(x)$ are the probability and the access time of the query q_i issued at time x , respectively, then the estimated average access time of q_i can be computed by the following equation, where k is the factor converting the sizes of data items into time lengths:

$$\begin{aligned} \int_0^B p(x) \cdot F(x) dx &= \frac{1}{B} \int_0^B F(x) dx \\ &= \frac{1}{B} \sum_{j=1}^n \int_0^{t_j} F(y) dy \\ &= \frac{1}{B} \sum_{j=1}^n \left[\int_0^{\text{size}(d_j)} F(y) dy + \int_{\text{size}(d_j)}^{t_j} F(y) dy \right] \\ &= \frac{1}{B} \sum_{j=1}^n \left[\int_0^{\text{size}(d_j)} kB dy + \int_{\text{size}(d_j)}^{t_j} k(B - y + \text{size}(d_j)) dy \right] \\ &= k \left(B - \frac{1}{2B} \sum_{j=1}^n k(t_j - \text{size}(d_j))^2 \right). \end{aligned}$$

The measurement of average access time defined above is too difficult to apply when developing data scheduling methods for wireless broadcasting. Therefore, Chung et al. defined a new metric, called query distance (QD), which indicates the largest distance between any two consecutive data items in a query. Let the total query distance denoted by $\text{TQD}(S)$, which is defined as $\sum_{q_i \in Q} QD(q_i, S) \times freq(q_i)$. They showed that given a set of data items D and a set of queries Q , the problem of finding a broadcast schedule S such that $\text{TQD}(S)$ is minimized is NP-complete. Thus, they proposed a data placement method based on a greedy algorithm for the dependent data scheduling problem.

Definition 1 Suppose a query q_i with data items d_1, d_2, \dots, d_n in a schedule S , and δ_j is the interval between d_j and d_{j+1} in the schedule S . Then, the QD of q_i in S is defined as $\max(\delta_k)$, $k = 1, 2, \dots, n$.

The algorithm schedules the broadcast program by inserting the set of data items requested by each query based on a greedy strategy. That is, the query data set with higher access frequencies is guaranteed not to be changed when minimizing QD of the queries with lower access probabilities. For this purpose five basic operations are defined in [19] as follows:

1. “Move data to the Right of a Fragment (MRF).”
2. “Move data to the Left of a Fragment (MLF).”
3. “Move data to the Right in a Segment (MRS).”
4. “Move data to the Left in a Segment (MLS).”
5. “Move Data Closest (MDC).”

Each of the five operations may be used for add new data items of a query into a given schedule. The operations MRF, MRS, MLF, and MLS move a set of data item to the most right end of the given schedule or most left end of the given schedule. They are used for minimizing the QD of the newly added data items of a query. The operation MDC is used for minimizing the QD when all data items for a given query are already included in the current schedule. The operation MDC moves the data items for a query as close as possible.

The proposed algorithm constructs a broadcast schedule by adding data items of each query in a greedy manner after sorting the queries based on their frequencies. Thereafter, many approaches have been proposed for minimizing the average expected delay for dependent data broadcast, and some of them further investigated the dependent data scheduling problem over multiple broadcasting channels. To generate a dependent data broadcast schedule in a multichannel environment, the server should partition the data items on multiple groups based on the collection of the data items for each query and their access frequencies. In order to retrieve a set of data items, a client may switch from one channel to another to download the data items until all the items requested in the query list are downloaded. The requested data items in a query can be retrieved in an arbitrary order. Moreover, if more than one queried item appear in different channels simultaneously, only one of them can be downloaded at one time. The other items should be retrieved when they are coming again. In a dependent data broadcasting program, one data item may also be requested by multiple queries. A brief summary of relative works is provided as follows.

Hurson et al., tried to minimize the overall access time, and proposed an allocation algorithm of dependent data based on some heuristics for multichannel broadcast systems in [32]. Lee et al. introduced an algorithm for queries with multiple data items in mobile environments in [44]. After that, Huang and Chen proposed a scheme based on a generic algorithm to handle the similar problem in [28]; and they explored the problem of broadcasting dependent data for ordered query over multiple broadcast channels in [27]. An ordered query means that the access sequence for the given query data set is preordered. Hung et al. studied the same problem and proposed a greedy algorithm called PBA, standing for *placement-based allocation*, in [31]. This algorithm will be explained in detail next.

Huang et al. first proposed a genetic algorithms called GA in [28] for the multichannel dependent data scheduling problem. The GA algorithm has been proved by experimental results to be a good approach; however, there are still

some weaknesses of the GA algorithm which may result in poor performance. For example, genetic algorithms will be affected by the initial setting. The initial setting is generated randomly, so it is not guaranteed to result in a good result constantly. To overcome such drawback, Hung et al. proposed a deterministic algorithm called PBA to schedule the dependent data items onto multiple channels. In PBA, the broadcast cycle length is assumed to be the same for all channels. Since each query contains multiple items in a dependent data broadcasting environment, the main policy of the algorithm PBA is to avoid the occurrence of the conflicting items in a broadcast cycle, which are the situations that multiple data items in a query are located in the same time slot on different channels. In order to explain the algorithm formally, two definitions in [31] need to be introduced.

Definition 2 Given a query q_i , t_{cycle_i} is the number of complete broadcast cycles needed for a mobile user to download the items in q_i . The refined query q'_i denotes the set of remaining items after the $cycle_i$ cycles.

Definition 3 Given a refined query q'_i , let $T_{Startup}(q'_i)$ be the time duration since the query q'_i starts until its first data item appears. Its retrieval time, denoted by $T_{Retr}(q'_i)$, is the time duration since the first data item appears until all the data items in q'_i are downloaded. The access time of a refined query q'_i , $T_{Access}(q'_i)$ is the sum of the start-up time and the retrieval time.

Assume all data items are of the same size. Let s and B represent the size of data item and the bandwidth of each channel, respectively. The access time of a query q_i , denoted by $T_{Access}(q_i)$, equals to $T_{Access}(q'_i) + cycle_i \cdot length_c$, where $length_c$ is the time length of a broadcast cycle. The average access time of the query set Q is denoted as $T_{Access}(Q)$.

It is obvious that a query will wait for multiple broadcast cycles to download all the data items required if there are many conflicting data items. The conflicting data items are in the same time placement on different broadcasting channels, so clients cannot download them in one cycle. Hence, the problem of generating a broadcast program equals to the problem of allocating the items of each query into L groups such that the number of conflicting items is minimized and each group contains items no more than K data items, where K is the number of available channels. The algorithm PBA in detail is outlined in [Algorithm 3](#).

To allocate the data items, the algorithm PBA first sorts the queries in descending order Q according to their access probabilities. A query with higher access probability has higher priority to be scheduled. After that, a broadcast program P , which contains L sets of data items, is constructed. Each data item set D_i contains the data items allocated in the i th time slot, but not the i th channel. Obviously if a query q_j is processed, the data items requested by q_j cannot be processed again. To prevent one data item be allocated more than once, they partition the data items in q_i into two disjoint subsets, q_i^+ and q_i^- , which store the already allocated and remaining items, respectively. The algorithm PBA terminates when all the items in D are allocated in P . A query with high access probability is processed earlier than the lower one. Therefore, it is a greedy approximation algorithm.

Algorithm 3 PBA [31]

Input: the query profile Q , the broadcast database D , and the number of channels K ;

Output: the broadcast program P ;

```

1: Sort elements in  $Q$  according to the access probability in descending order;
2: Let  $L \leftarrow \lceil \frac{\text{size}(D)}{L} \rceil$ ;
3: for each  $q_i \in Q$  do
4:   Unmark all item sets;
5:   Find  $q_i^+$  and  $q_i^-$  which store the scheduled and unscheduled items in  $q_i$ , respectively;
6:   Mark the item sets which contain  $K$  items and the item sets which contain the items in  $q_i^+$ ;
7:   if all item sets are marked then
8:      $curr \leftarrow \arg_i \min \text{size}(D_i)$  for all  $D_i$ ,  $\text{size}(D_i) < K$ ;
9:   else
10:     $curr \leftarrow \arg_i \min \text{size}(D_i)$  for all unmarked  $D_i$ ;
11:   end if
12:   for each item  $d_j \in q_i^-$  do
13:     Insert  $d_j$  into  $D_{curr}$ ;
14:     mark  $D_{curr}$ ;
15:   if all item sets are marked then
16:     Select next from  $D_i$ ,  $\text{size}(D_i) < K$  such that  $DIST(curr, next)$  is minimized;
17:   else
18:     Select  $next$  from the unmarked item sets such that  $DIST(curr, next)$  is minimized
19:   end if
20:   Set  $curr = next$ ;
21: end for
22: end for

```

3 Optimizations for On-Demand Data Broadcasting

In pure push-based data broadcast systems, data access patterns are usually assumed to be static in a certain period. Data are organized into broadcast programs according to their access patterns. The programs will then be broadcasted in cycles and updated periodically. In such systems, individual clients are passive listeners, which means they have no direct influence over the content of a broadcast program. This network structure brings up several issues. Since there is no feedback of clients in the form of requests, it is very difficult for pure push-based systems to get accurate data access patterns. Moreover, in circumstances where the client request pattern changes frequently, the static access pattern assumption will not be true anymore. This may result in longer system response time. In the worst case, the program may not be able to satisfy client requests anymore.

“Pull-based” data broadcast is a different data broadcast method which does not have the aforementioned drawbacks of push-based data broadcast method. It is also referred to as “on-demand” data broadcast [13, 63]. A typical on-demand data broadcast system structure is shown in Fig. 3.

As in Fig. 3, the network connection in an on-demand data broadcast system consists of two types of links: uplink and downlink. Clients send requests through uplink to the server. These requests are queued up at the server upon arrival.

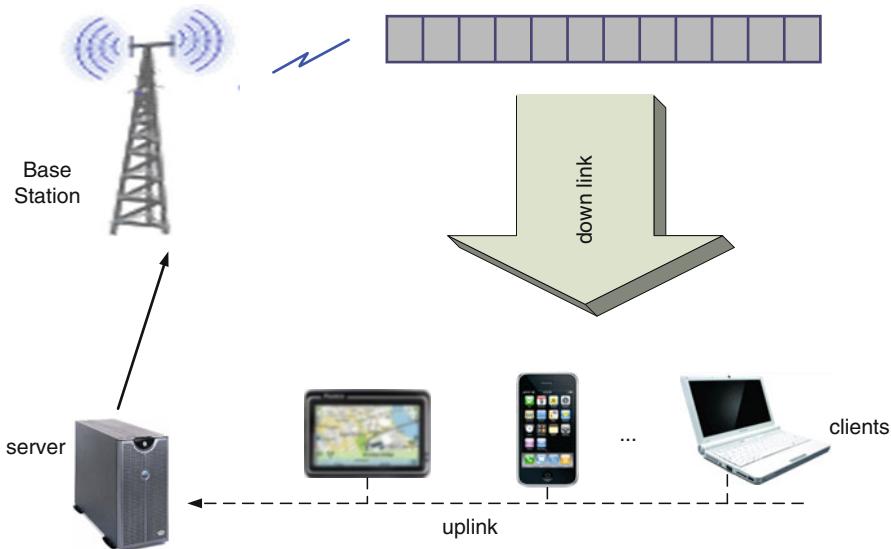

Fig. 3 A typical on-demand data broadcast system structure

The broadcast channel(s) serves as the downlink to broadcast data to clients. The server continuously puts data items onto the broadcast channel(s) according to the queued requests and removes corresponding requests from the queue. Clients will listen to the channel(s) and download their requested data when they arrive. This data dissemination process shows the influence of clients' requests over the choice of broadcasted data. On-demand data broadcast can dynamically adjust broadcast programs according to the client requests and thus is suitable for situations when data access patterns change frequently.

A good online scheduling algorithm to choose data items for broadcast is critical for the good performance of an on-demand data broadcast system. Similar as push-based broadcasting, the main objective of scheduling on-demand data broadcast is also to reduce the response time. Different from push-based broadcasting, the *response time* for a request in an on-demand broadcast system is the time interval between the time the client sends the request through uplink and the time the client downloads the data from broadcast channels.

There have been a lot of literature on scheduling on-demand data broadcast. This section will focus on different on-demand data scheduling algorithms for different communication environments. Section 3.1 introduces several basic scheduling algorithms. Section 3.2 presents the $R \times W$ algorithm which can handle large-scale databases. Section 3.3 gives a scheduling algorithm for time-critical requests with deadlines. Section 3.4 discusses how to schedule heterogeneous data with preempting technique. All on-demand scheduling algorithms discussed in Sect. 3 are based on single broadcast channel.

3.1 Basic Online Scheduling Algorithms for On-Demand Data Broadcast

Earliest studies on online scheduling for on-demand broadcast can be traced back to the late 1980s. In [21, 62], the following algorithms were proposed:

- *First come, first served (FCFS)*: always broadcast the data item of the request that arrives at the earliest time. Ignore a new request if the same request already exists in the queue.
- *Most requests first (MRF)*: always broadcast the data item of the maximum number of requests in the queue.
- *Longest wait first (LWF)*: always broadcast the data item that the sum of waiting times of all its requests in the queue is the longest.

Intuitively, FCFS emphasizes fairness and gives preference to “cold” items, while MRF considers data popularity and prefers “hot” items. LWF tries to balance the waiting time of all requests and also prevents possible “starving” requests. Simulation results in the original papers show that FCFS results in poor average response time when the data access distribution is nonuniform, and LWF performs better than FCFS and MRF in general. A more theoretical analysis of these algorithms were presented in [47], which gives performance ratios of FCFS and MRF.

Assume there are m data items in the database for broadcasting and n requests. Each request contains only one data item. All items are of same length. An *instance* is a data item on the broadcast channel. For any instance, let $\sum_{i=1}^n w_i(\bullet)$ represent the total response time of the solution given by \bullet scheduling algorithm. OPT represents the optimal solution. [47] proved the following theorems:

Theorem 2 $\sum_{i=1}^n w_i(\text{FCFS}) \leq m \sum_{i=1}^n w_i(\text{OPT})$.

Theorem 3 *There exists at least one instance that satisfies $\sum_{i=1}^n w_i(\text{FCFS}) = m \sum_{i=1}^n w_i(\text{OPT})$.*

Theorem 4 $\sum_{i=1}^n w_i(\text{MRF}) \leq m \sum_{i=1}^n w_i(\text{OPT})$.

Theorem 5 *There exists at least one instance that satisfies $\sum_{i=1}^n w_i(\text{MRF}) = m \sum_{i=1}^n w_i(\text{OPT})$.*

3.2 $R \times W$ Scheduling for Large-Scale On-Demand Data Broadcast

When the database size is getting large, simply considering average or total response time as the performance criteria for an on-demand data broadcast system is obviously not enough. In [4, 5], Aksoy and Franklin categorized the performance criteria for on-demand scheduling algorithms as follows:

1. Responsiveness
 - (a) *Average waiting time*: the average amount of time from the moment that a client request arrives at the server to the moment the requested item is broadcast.
 - (b) *Worst case waiting time*: the maximum amount of time that any client request will have to wait in the service queue to be satisfied.
2. Scheduling overhead
 - (a) *Request processing*: the overhead of the server deciding whether to add an entry to the service queue for the requested item and/or updating the queue
 - (b) *Scheduling decisions*: the overhead to choose an item to broadcast at the beginning of each broadcast time slot.
3. Robustness: whether the scheduling algorithm can adjust to the changes of the workload or environment.

Based on the observations of FCFS, MRF, and LWF's performances with respect to the above criteria, Aksoy and Franklin developed a scheduling algorithm named $R \times W$ in [4, 5]. The intuition is to combine the benefits of FCFS and MRF in a way that ensures scalability while preserving low overhead. They first proposed an exhaustive algorithm and then improved it with a pruning technique to reduce the search space. To further reduce the scheduling overhead for large-scale databases, they developed an approximate, parameterized version of $R \times W$ algorithm at the expense of possible suboptimal broadcast decisions.

3.2.1 The Exhaustive $R \times W$ Algorithm

The idea of $R \times W$ algorithm is to broadcast an item either because it is popular or because it has at least one request that has been waiting for a long time. Instead of a straightforward service queue, it maintains a service table that has an entry for each data item with outstanding requests. The structure of the service table is shown in Fig. 4.

- Each entry in the service table consists of the following elements:
- PID : identifier of the data item in the database
 - $IstArrv$: the arrival time of the earliest outstanding request for this item
 - $Prev\ in\ W\text{-List}$: a pointer to the previous entry in the W-List
 - $Next\ in\ W\text{-List}$: a pointer to the next entry in the W-List
 - R : the total number of outstanding requests for this item
 - $Prev\ in\ R\text{-List}$: a pointer to the previous entry in the R-List
 - $Next\ in\ R\text{-List}$: a pointer to the next entry in the R-List

The service table is hashed on PID . W represents the longest waiting time of all requests for a particular data item. W can be computed as $W = \text{clock} - IstArrv$, where clock is the current time. All time used in the rest of Sect. 3 is represented in broadcast ticks, that is, the number of items broadcasted so far. The algorithm uses two sorted lists threaded through the service table: W-List in descending order of W and R-List in descending order of R . An R-Index is introduced to reduce the maintenance overhead of the R-List. For each distinct R value, there is a pointer to the first entry in the R-List of the same R value.

The algorithm can be divided into two steps: request process and broadcast decision. The procedures of these two steps are described in Algorithms 4 and 5.

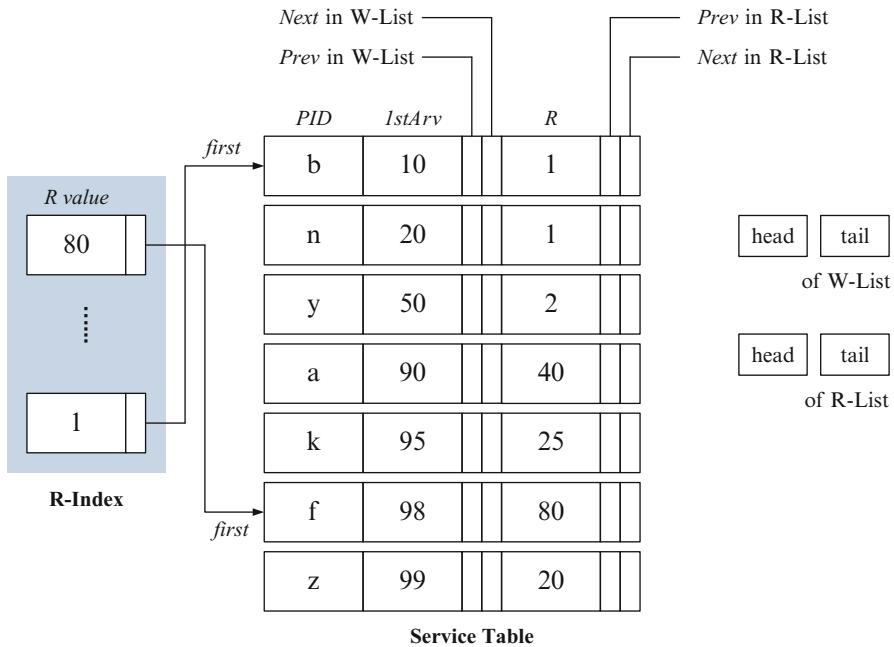

Fig. 4 The service table structure of $R \times W$ algorithm

Algorithm 4 Request process of exhaustive $R \times W$

Input: a request of item with identifier *PID*;

Output: updated service table;

- 1: perform a hash lookup on *PID* in the service table.
 - 2: **if** an entry exists **then**
 - 3: increment the *R* value of the entry.
 - 4: **else**
 - 5: create a new entry with *R* = 1 and *IstArrv* = current time.
 - 6: **end if**
-

Algorithm 5 Broadcast decision of exhaustive $R \times W$

Input: service table;

Output: updated service table;

- 1: find the entry with the maximum $R \times W$ value in the service table. e
 - 2: broadcast the corresponding data item.
 - 3: remove this entry from the service table.
-

A theoretical analysis of the $R \times W$ algorithm in [5] concluded that for an arbitrary data item b , the expected waiting time is

$$W_b = \frac{W_0 + \sum_{i=b+1}^{N-1} \rho_i \sqrt{\frac{p_i}{p_b}} + \sum_{i=0}^{b-1} \rho_i W_i}{1 - \sum_{i=0}^{b-1} \rho_i \left[1 - \sqrt{\frac{p_b}{p_i}} \right]}. \quad (9)$$

In Eq. (9), W_0 is the mandatory wait for the completion of an already initiated page broadcast; ρ_i is the utilization of the bandwidth to broadcast item i ; and p_i is the access probability of item i .

3.2.2 $R \times W$ Algorithm with Pruning

The scheduling overhead of the exhaustive $R \times W$ algorithm is $O(N)$, where N is the total number of data items to broadcast. As N increases, the search space of [Algorithm 5](#) is getting larger, which consequently increases the overhead. Aksoy and Franklin proposed a pruning technique for the $R \times W$ algorithm in [5].

The pruning technique uses the “sorted” feature of the R-List and W-List to reduce the search space when looking for the maximum $R \times W$ value. Suppose the examination starts at the top entry of the R-List. MAX is used to record the current maximum $R \times W$ value. Since the R-List is in descending order, the next entry in the list R' is smaller than R . Naturally, for any unexamined entries with $R \times W$ value greater than MAX, their W value must satisfy

$$W > \frac{\text{MAX}}{R'}.$$

Therefore, the search range of the W-List can be truncated by

$$\text{limit(1stArv)} = \text{clock} - \frac{\text{MAX}}{R'}.$$

That is, no entry with 1stArv greater than limit(1stArv) in the W-List will have $R \times W$ larger than MAX. Similarly, if the examination starts at the top entry of the W-List, the search range of the R-List can also be restricted by

$$\text{limit}(R) = \frac{\text{MAX}}{W'},$$

where W' is the next entry in the W-List.

Based on this observation, the scheduling algorithm starts examining the top entry of the R-List and keeps on alternating between the two lists. It can be described in [Algorithm 6](#).

This pruning technique is effective in reducing the search space. Experiment results in [5] showed that there is a 73 % reduction in entries examined to find the maximum $R \times W$ for their Zipf-based workload.

Algorithm 6 Broadcast decision of $R \times W$ with pruning

Input: service table, R-List and W-List;

Output: updated service table;

- 1: examine the top entry of the R-List; set MAX and $limit(1stArv)$.
 - 2: **while** neither $limit(1stArv)$ nor $limit(R)$ is reached **do**
 - 3: examine the next entry of the previously examined entry in the other list.
 - 4: Set MAX = $R \times W$ if $R \times W > MAX$.
 - 5: update $limit(1stArv)$ and $limit(R)$.
 - 6: **end while**
 - 7: broadcast the corresponding data item.
 - 8: remove this entry from the service table.
-

3.2.3 The Approximate $R \times W$ Algorithm

Although the pruning technique discussed in Sect. 3.2.2 can help reducing the search space, the reduction may not be enough to confine the scheduling overhead within a reasonable range when the database scale is really large. Therefore, an approximating, parameterized variation of the $R \times W$ algorithm was proposed in [5] to further reduce the search space at the expense of possible suboptimal scheduling decisions.

In the approximating algorithm, instead of finding the maximum $R \times W$ value, it chooses the first item encountered with $R \times W \geq \alpha \times threshold$. α is the parameter of the algorithm, which is greater than 0. $threshold$ is the self-adaptive average, whose value can be computed as

$$threshold(t+1) = \frac{threshold(t) + last\ R \times W(t)}{2}$$

$threshold(0)$ is set to 1. $last\ R \times W(t)$ is the $R \times W$ value of the item broadcasted at time t .

α is parameter of the algorithm that can be adjusted. It determines the trade-off between responsiveness and scheduling overhead. The smaller α is the less entries need to be examined, but the more likely the scheduling decision is not optimal. In such cases, the scheduling overhead is reduced but the responsiveness may be jeopardized.

3.3 Scheduling Time-Critical On-Demand Data Broadcast

The work [4,5] by Aksoy and Franklin and many other literature on on-demand data broadcasting use the responsiveness performance criteria as discussed in Sect. 3.2, which aim at minimizing the average or worst waiting time. This implies an assumption that once a client generates and sends a request, it will wait until the request is satisfied. However, this assumption is not always true. In some circumstances, clients may lose patience and drop the request if they have waited

for too long. In order to take the time constraint into consideration for time-critical requests, the concept of deadline is introduced [39, 40, 66].

In a time-critical on-demand data broadcast system, each request has an additional parameter *deadline*. An outstanding request will be dropped after its deadline is reached. Motivated by the EDF (earliest deadline first) scheduling algorithm in unicast and the MRF algorithm in broadcast, Xu et al. proposed a scheduling algorithm for time-critical on-demand data broadcast in [66]. The objective is to satisfy as many requests as possible. A new performance criterion is defined to measure this objective:

$$\text{request drop rate} = \frac{\text{number of requests missing their deadlines}}{\text{total number of requests}}.$$

The idea of the algorithm can be summarized into two rules:

1. If two data items have the same number of outstanding requests, broadcast the one with a closer deadline.
2. If two data items have the same deadline, broadcast the one with more outstanding requests.

The first rule gives priority to *urgent* requests, while the second rule gives preference to requests that are more *productive*. Both rules are for the sake of reducing the request drop rates.

The algorithm proposed by Xu et al. is named as SIN- α (slack time inverse number of outstanding requests). For each data item with at least one outstanding request, there is a $\sin.\alpha$ value attached to it:

$$\sin.\alpha = \frac{\text{slack}}{\text{num}^\alpha} = \frac{\text{1stDeadline} - \text{clock}}{\text{num}^\alpha},$$

where slack represents the remaining time before the earliest deadline of all requests for this item, and num is the total number of requests for this item. $\alpha \geq 0$ is a parameter determining the relative importance of productivity over urgency in the broadcast decision. The larger α is the more influential the number of outstanding requests in computing $\sin.\alpha$.

An exhaustive version of SIN- α is to compute the $\sin.\alpha$ value of all items in the service queue at each broadcast tick and broadcast the item with minimum $\sin.\alpha$ value. The complexity of this implementation is $O(N)$, where N is the total number of data items with outstanding requests.

Inspired by the pruning technique discussed in Sect. 3.2.2, Xu et al. applied a similar pruning method during the searching for the minimum $\sin.\alpha$. Two double-linked sorted lists are maintained: S-List and N-List. Each data item has one entry in both lists. S-List maintains each item's associated earliest request deadline in ascending order, while N-List contains the number of outstanding requests for each item in descending order. Similar as Algorithm 6, the scheduling algorithm starts examining the top entry of the N-List and keeps on alternating between the two lists.

Two limits are also maintained to reduce the search space for minimum $\sin.\alpha$: $limit(N)$ for the N-List and $limit(1stDeadline)$ for the S-List.

During the searching, let MIN denote the current minimum $\sin.\alpha$ value. If an entry in the S-List has just been checked, then any unexamined item with $\sin.\alpha < \text{MIN}$ should have its num value exceeding

$$limit(N) = \left(\frac{NextS}{\text{MIN}} \right)^{\frac{1}{\alpha}},$$

where $NextS$ is the slack of the next entry in the S-List. On the other hand, if an entry in the N-List has just been examined, then the 1stDeadline of any unexamined item should be less than

$$limit(1stDeadline) = (NextN)^\alpha \cdot \text{MIN} + \text{clock},$$

where $NextN$ is the num of the next entry in the N-List.

In [66], Xu et al. also gave a thorough analysis of the theoretical bound of request drop rate when the request arrival rate is approaching infinity. The request drop rate for item i arriving in interval $[0, \tau]$ is

$$\eta(\tau) = \frac{1}{\tau} \int_0^\tau F(\tau - t)dt, \quad (10)$$

where $F(t)$ is the probability that a relative deadline is shorter than t . Relative deadline refers to the time interval between current time and the deadline.

Xu et al. proved that the request drop rate of an item is minimized when instances of the item are broadcasted with equal intervals. Therefore, assume the spacing of any item i is uniform, denoted as s_i . The total request drop rate can be computed as

$$\eta(s_1, \dots, s_N) = \sum_{i=1}^N \frac{\lambda_i}{\lambda} \eta(s_i) = \sum_{i=1}^N \frac{p_i}{s_i} \frac{1}{\tau} \int_0^\tau F(\tau - t)dt, \quad (11)$$

where λ_i is the request rate of item i and λ is the total request rate. Their ratio p_i is exactly the access probability of item i .

If a broadcast tick is l , it means $\frac{l}{s_i}$ of the bandwidth is used to broadcast item i , which means

$$\sum_{i=1}^N \frac{l}{s_i} = 1. \quad (12)$$

Xu et al. proposed the following theorems about the lower bound of request drop rate as computed in Eq. (11) under three different relative deadline distributions.

Theorem 6 *Under exponential distribution of relative deadlines with a mean value of M , the total request drop rate is minimized when (s_1, \dots, s_N) satisfies*

$$p_i \left(1 - \frac{s_i}{M} e^{-\frac{s_i}{M}} - e^{-\frac{s_i}{M}} \right) = K, (i = 1, \dots, N).$$

Theorem 7 Under uniform distribution of relative deadlines between 0 and L , the minimum total request drop rate is given by

$$\begin{aligned} & \min_{\{I, f | 0 \leq I \leq N, f \geq \frac{IL}{L}, f > 1 - \frac{L}{L}\}} \left\{ \frac{1}{2L\{\frac{f}{l} - \frac{I-m}{L}\}} \left(\sum_{i=1}^m \sqrt{p_i} \right)^2 + \sum_{i=m+1}^I \frac{p_i}{2} \right. \\ & \quad \left. + p_{I+1} \left(1 - \frac{L}{2} \cdot \frac{1-f}{l} \right) + \sum_{i=I+2}^N p_i \right\}, \end{aligned}$$

where

$$m = \max \left\{ x \mid \frac{\sum_{j=1}^x \sqrt{p_j}}{(\frac{f}{l} - \frac{I-x}{L}) \sqrt{p_x}} \leq L \right\}.$$

Theorem 8 Under fixed relative deadlines of C , the total request drop rate is minimized when (s_1, \dots, s_N) satisfies

$$s = \begin{cases} C & i \leq \lfloor y \rfloor, \\ \frac{C}{y - \lfloor y \rfloor} & i = \lfloor y \rfloor + 1, \\ \infty & i > \lfloor y \rfloor + 1, \end{cases}$$

where $y = \frac{C}{l}$. The minimum request drop rate is

$$\eta(s_1^*, \dots, s_N^*) = p_{\lfloor y \rfloor + 1}(1 - y + \lfloor y \rfloor) + \sum_{i=\lfloor y \rfloor + 2}^N p_i.$$

3.4 Scheduling Preempting On-Demand Broadcast for Heterogeneous Data

All scheduling algorithms discussed in Sect. 3 so far have one common assumption: the size of all data items are equal. In many real applications of on-demand broadcast, data of requests are heterogeneous, which means that data items can be of different sizes. In [3], Acharya and Muthukrishnan first brought up the problem of scheduling on-demand broadcast for heterogeneous data and proposed the usage of preemption during scheduling.

Preemption is usually used on heterogeneous workload in order to prevent backlog of pending requests when servicing a long job. In a broadcast environment, preemption means the server can abort the current broadcasting item and broadcast items for more valuable requests. Two models allowing preemption have been

proposed: the *restart* model in [40] and the *resume* model in [39]. However, the treatments of the aborted broadcast in these two models are different:

- Restart: the server can restart a preempted broadcast from the beginning
- Resume: the server can resume a preempted broadcast from the point of preemption

Ting [55] designed a scheduling algorithm named *balance* for on-demand broadcast utilizing preemption, under the heterogeneous data assumption. The design is based on the restart model. Given a set of data items, assume the length of the shortest item is 1 and the length of the longest item is Δ . For any item P , $l(P)$ is the time needed to completely broadcast P . A *broadcast*, *schedule*, and *request* are defined respectively as following:

Definition 4 A *broadcast* $B = (P, t)$ is to broadcast item P at time t .

Definition 5 A *schedule* is a sequence of broadcasts $S = \langle (P_1, t_1), \dots, (P_m, t_m) \rangle$, where $t_1 < \dots < t_m$.

For any broadcast (P_i, t_i) , it is a *complete* broadcast if $t_i + l(P_i) < t_{i+1}$; otherwise, it is preempted by (P_{i+1}, t_{i+1}) , and (P_{i+1}, t_{i+1}) is a *preempting* broadcast.

Definition 6 A *request* r is a four-tuple (P, a, d, v) , where P is the requested item, a is its arrival time, d is its deadline, and v is its value.

Given a sequence of requests σ , the scheduling problem for time-critic on-demand data broadcast is to find a schedule S with maximum profit. Let $R_{S,\sigma}(P, t)$ denote the set of outstanding requests of P at time t . The profit $\rho(S, \sigma)$ of a schedule S can be computed as

$$\rho(S, \sigma) = \sum_{(P,t) \in S, (P,t) \text{ is complete}} v_{S,\sigma}(P, t), \quad (13)$$

where $v_{S,\sigma}(P, t)$ is the value of P at time t with respect to (S, σ) , which equals to $\sum_{r \in R_{S,\sigma}(P,t)} r.v$.

The motivation of *balance* algorithm is to reach a good balance between good-profit broadcasts and short-length broadcasts. Good-profit broadcasts are those whose completion will increase the profit of the schedule, while short-length broadcasts are those whose completion will reduce the total time needed for the schedule. All complete broadcasts are considered to be good-profit broadcasts.

Except for the preemption, *balance* has a “greedy”-like strategy. The scheduling process can be illustrated in [Algorithm 7](#).

The preemption in *balance* follows a relatively complicated set of rules in order to achieve better performance ratio. The procedure is described in [Algorithm 8](#).

In his paper [55], Ting also derived an upper bound and lower bound on the performance ratio of *balance*. Suppose S is the schedule generated by *balance*:

Algorithm 7 Balance

```

1: while there are still unsatisfied requests do
2:   find the item of highest total value and broadcast it;
3:   check for possible preempting;
4:   remove the requests of the completely broadcasted item from the service queue.
5: end while

```

Algorithm 8 Preemption

Input: $S = \langle B_1, \dots, B_{gp}, \dots, B_{last} \rangle$, $t \in (t_{gp}, t_{gp} + l(P_{gp}))$, $\lambda = \frac{3\Delta}{\log \Delta}$.

```

1: if  $\exists P$ , s.t.  $v_{S,\sigma}(P, t) > \sqrt{\Delta} v_{S,\sigma}(P_{gp}, t_{gp})$  then
2:   preempt  $B_{last}$  and broadcast  $P$ .
3: else
4:    $\Gamma = \{Q | t + l(Q) < t_{last} + l(P_{last}) \wedge v_{S,\sigma}(Q, t) > \left( \frac{2^{\lfloor \frac{t_c - t_{gp}}{\lambda} \rfloor}}{\Delta^{1/3}} \right) v_{S,\sigma}(P_{gp}, t_{gp}) \}$ .
5:   if  $\Gamma \neq \emptyset$  then
6:      $Q' = \operatorname{argmin}_{Q \in \Gamma} \{l(Q)\}$ .
7:     preempt  $B_{last}$  and broadcast  $Q'$ .
8:   end if
9: end if

```

Theorem 9 $\rho(\text{OPT}, \sigma) \leq \left(\frac{6\Delta}{\log \Delta} + O(\Delta^{5/6}) \right) \rho(S, \sigma)$.

Theorem 10 $\rho(\text{OPT}, \sigma) \geq \left(\frac{\Delta}{2 \ln \Delta} - 1 \right) \rho(S, \sigma)$.

[Theorem 9](#) shows that *balance* breaks the Δ -barrier for all previous schedulers without preemption. This demonstrates the effectiveness of introducing preemption into scheduling heterogeneous data. The combination of [Theorems 9](#) and [10](#) also proves that *balance* is optimal within a constant factor.

4 Data Retrieval Optimization in Data Broadcast Systems

Scheduling data onto broadcast channels is a key optimization research issue on the server side in data broadcast. Similarly, scheduling the data retrieval from broadcast channels for a mobile client is also an important optimization problem. When there is only one broadcast channel, or the client request contains single data item, the data retrieval scheduling problem is usually trivial. With the fast development of mobile communication technology, multichannel data broadcast is gaining more popularity because the utilization of multiple channels can dramatically enlarge the bandwidth for the broadcast downlink. In a multichannel broadcast environment, how to schedule the downloading of multiple data items is the focus of this section.

In an indexed multichannel data broadcast system, the data retrieval for a client is usually composed of three steps:

1. Initial probing: the client tunes in a broadcast channel
2. Searching: the client follows the guide of embedded index information on broadcast channels and gets the locations of requested data.
3. Downloading: the client tunes in the channel and downloads all requested data.

All literature on data retrieval scheduling so far consider only the downloading phase, that is, assume locations and arrival time of all requested data are known. Same as data broadcast scheduling, response time is also a primary concern when scheduling the data retrieval process for a client. Energy conservation is another performance criterion for data retrieval scheduling because of the limit battery lives of mobile clients. Therefore, the data retrieval scheduling problem can be summarized as follows:

Definition 7 (Data retrieval scheduling sroblem) suppose there is a request for multiple data items. Given the channel locations and arrival time of all requested data items, how to scheduling the downloading process so that

- The overall response time and/or
 - The energy consumption
- of the client can be minimized.

The reason why a good retrieval schedule can reduce the response time is straightforward, while why it can reduce energy consumption is not so obvious. Hurson et al. [33] pointed out that switching among broadcast channels during retrieving data also consumes energy: in general, on switching costs about 10 % of one unit time active mode power consumption of a mobile client. Therefore, the energy conservation objective can be converted to minimizing the total number of switchings during the data downloading.

One important issue that needs to be considered during data retrieval scheduling is *conflicts*. When a client just finished downloading one item at time t on channel A , it is impossible to start downloading another item at time t on channel $B \neq A$. This is because switching from one channel to another also takes time. Although it is usually faster than one broadcast tick, it is not neglectable. Hence, when a client just downloaded one item at time t on channel A , it can only start downloading at time $t + 1$ from any channel other than A . An illustration of conflicts can be found in Fig. 5.

Hurson et al. [33] first proposed the problem of downloading multiple data items from multiple broadcast channels with single retrieving process. They also explained the concepts of conflict during retrieval. In their work, they treated the two objectives, minimizing access time and minimizing number of switchings, separately, and proposed a heuristic algorithm for each of them.

With the development of antenna technique, adding MIMO antenna in mobile devices is already feasible. As a consequence, it is possible for clients to use multiple processes to retrieve data in parallel. Shi et al. discussed the retrieval scheduling problem for such a communication environment in [50], which will be introduced in the rest of this section.

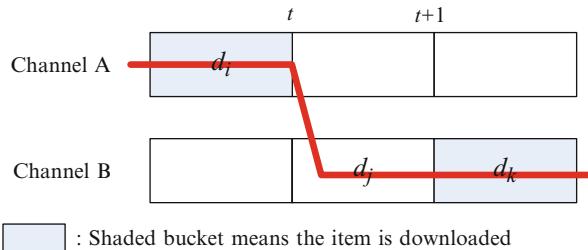

Fig. 5 An illustration of conflicts

Instead of treating the two objectives separately, Shi et al. defined a new cost function that combines the two objectives together:

Definition 8 The *cost* of a parallel data retrieving schedule is evaluated as $c = \alpha \cdot AT + \beta \cdot S$, where AT is the access time of the data retrieving process from the starting time (initial probing and searching processes are not included); S is the number of switches among channels during the retrieving process.

α and β are adjustable parameters which can reflect the user's preference. If the priority for the user is to get the requested data faster, α should be increased; if energy conservation is more important, β should be increased.

The retrieval scheduling only considers the downloading phase, so only channels with requested data on them are of interest, defined as *requested channels*. Suppose the number of requested channels are K , and the number of available retrieving processes for a client is M . When $K \leq M$, it is easy to prove that the optimal schedule is to assign one process to download all requested data on each requested channel. When $K > M$, the problem becomes nontrivial.

Shi et al. designed two greedy heuristic scheduling algorithm in the case of $K > M$. The first algorithm is *least switch*. The idea is to guarantee minimum number of switching during downloading. [Algorithm 9](#) describes the scheduling process. Note that in *least switch*, every time a process finishes downloading one channel, the scheduler will assign a most costly channel to it to continue downloading. This is because the overall access time is determined by the process which takes longest time to finish its task, so balancing the workload among processes is important in order to reduce the overall access time.

The other algorithm is called *best first*. It is a greedy algorithm in that the scheduler always assigns to a process the item which costs least for a process to download. [Algorithm 10](#) demonstrates the scheduling process.

Best first can be divided into three phases: initial assignment, best-first assignment, and channel assignment. As the request list is shrinking during the downloading process, the number of requested channels is also getting smaller. When $K = M$, it is optimal to assign one channel to one process, so the best-first assignment will stop.

Algorithm 9 Least switch

```

1: Assign  $M$  requested channels to  $M$  retrieving processes;  $K = K - M$ ;
2: while  $K > 0$  do
3:   whenever a process finishes downloading, assign to it the most costly channel to download;
4:    $K --$ ;
5: end while

```

Algorithm 10 Best-first

```

1: assign  $M$  requested items with least cost to download to the  $M$  retrieving processes;
2: remove these item from the request list and update  $K$ ;
3: while  $K > M$  do
4:   whenever a process finishes downloading, assign to it an item which costs least to download;
5:   remove this item from the request list and update  $K$ ;
6: end while
7: assign remaining  $M$  requested channels to the  $M$  processes.

```

5 Indexing Techniques for Data Broadcast Optimization

Utilizing indices into the broadcasting program is another way of optimizing data broadcast problem by means of reducing the tuning time so as to improve the energy efficiency of a wireless data [16] broadcast system. An index is a specific data structure with pointers storing the location information that directs to the data items. Due to the nature of data broadcasting, such location information of an index usually indicates the time offset of the target data. Once a client gets this time offset, it could be aware of the total waiting time before the target data item is broadcasted on the broadcasting channel. Then, the client could turn into doze mode (or sleep) to save some energy and then tune back to the broadcasting channel before the data item appears.

Indexing techniques could dramatically reduce the average tuning time for clients within a wireless data broadcasting system. However, if indices are inserted between data items, then the total length of a broadcasting program will increase, which may cause a longer access time. Therefore, when discussing about an indexing scheme, researchers will always consider the balance or trade-off between tuning time and access latency [37]. Since different indexing schemes have different searching efficiencies, how to optimize the tuning time while maintaining acceptable access latency is a critical issue in wireless data broadcasting systems.

5.1 Indexing in Single-Channel Broadcasting Environment

There are a number of works trying to apply traditional disk-based indexing approaches onto air indexing by converting location information or physical address into time offset. A lot of existing air indexing schemes, such as distributed index,

hash-based scheme, and exponential index, were designed for flat broadcast on single-channel broadcasting environment, in which all data items are broadcasted under the same frequency [34, 35, 65, 67]. Imielinski et al. [34] were the first to discuss air indexing schemes, and they proposed flexible index. Furthermore, they customized B⁺-tree index in [35] and proposed (1, m) index as well as distributed index. Distributed index was extended by many other researchers to fit different system requirements. For example, Hsu et al. [24] modified distributed index to deal with data under nonuniform access frequencies. Moreover, Lee et al. [45] discussed a signature-based approach for information filtering in wireless data broadcasting. Later, Hu et al. [25] designed a hybrid indexing scheme combining both distributed index and signature-based index. Xu et al. [67] gave an idea of exponential index that shares links in different search trees and allows clients to start searching at any index node, which is error resilient due to its distributed structure.

More indexing schemes are further developed to deal with skewed access patterns on single-channel broadcasting environment. For instance, Huffman tree is a skewed index tree which takes into consideration the access probability of each data item, where the more popular data is stored at a higher level of the tree which has a shorter path from the root node. Thus, it minimizes the average tuning time in the search process. However, almost all existing works discussed Huffman tree on multichannel environment [17, 52]. It is hard to compare the performance of Huffman-tree index with other single-channel indexing methods, because when it comes to multichannel data broadcast, how to allocate index and data will produce heavy impact on the performance of the indexing techniques. A certain allocation method could be helpful to specific indexing structure, but at the same time it might reduce the efficiency of another indexing scheme. Recently, Zhong et al. [74] proposed an alphabetic Huffman-tree distributed index in the single-channel data broadcast environment, which minimizes both average access time and average tuning time. The experiments show that it outperforms the B⁺-tree distributed indexing approach. Besides Huffman-tree index, Imielinski et al. [34] presented hash-based scheme. Another work by Yao et al. [68] proposed MHash scheme to facilitate skewed data access probabilities and reduce access latency.

5.1.1 Flexible Index

As Imielinski et al. [34] proposed, flexible index simply divides the data file into p segments and provides indices to help the clients “navigate,” so as to reduce the tuning time. The parameter p makes this scheme *flexible* since it can be adjusted to allow users choosing between either good tuning time or good access time.

In flexible index, data records are sorted in ascending order. All the data buckets are divided into p groups called data segments, numbered from 1 to p , the first bucket of which stores the *control index* and possibly the data records if space allows. Control index is a binary index used for locating the data bucket which contains the given key.

Figure 6 shows an example of flexible indexing with 66 data buckets. Let $p = 9$, with the length of eight buckets for all data segments except the last one. The first bucket of data segment contains the index. Three examples of such buckets are

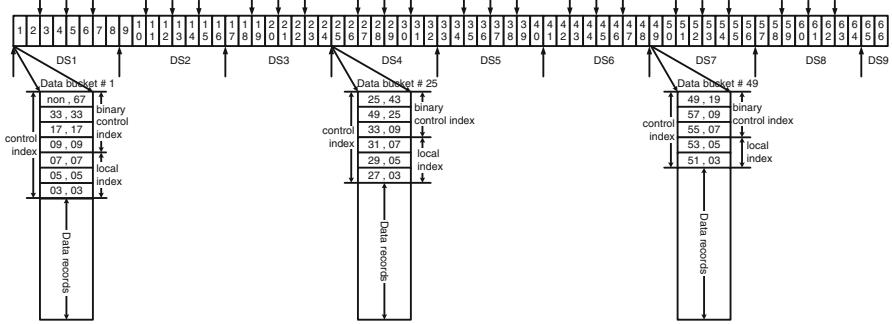

Fig. 6 An example of flexible index

shown in [Fig. 6](#). Each index entry is a pair of the key value and the *offset* (*offset* means the relative distance from this current bucket to that pointed bucket), which tells the clients when to tune in again to find the requested data.

For instance, as shown in [Fig. 6](#), the index of the data bucket #25 indicates that for all key values smaller than 25, the client should tune to the bucket #1 of the next *bcast* that is 43 buckets away (in this case the client missed the key and has to wait for the next broadcast). If the key is greater than 49, the client has to tune in again to bucket #49 (which the offset # = 25 points to). That data bucket will provide another index to help the client continue searching. Not all data buckets contain the index, and that the index information is distributed among different data buckets.

The control index is divided into two parts: the *binary control index* and the *local index*. The *binary control index* has $\lceil \log_2 i \rceil$ tuples, where i is the number of data segments in front of (including) this one. The k th tuple contains the key of the first data item of the $\lfloor \log_2 i / 2^{k-1} \rfloor + 1$ th data segment and an offset to the first data bucket of that data segment. The *local index* has m tuples. Parameter m depends on how many tuples a bucket can hold, the access time desired, etc. The local index further partitions a data segment into $m + 1$ data subsegments D_1, D_2, \dots, D_{m+1} , where the k th tuple contains the key of the first data item of D_{m+1-k} and an offset to the first data bucket of D_{m+1-k} .

Following is the access protocol of flexible indexing scheme [34] for a record with key K .

1. Initial probe, get the offset to the next data segment, and go to doze mode.
2. Tune in again to the designated data segment. (1) If the search key K is less than the first tuple's first field in the binary control index, then go to doze mode for the offset time (as the second field indicates) and repeat step 2; else (2) search the rest entries of the binary control index to check if K is greater than or equal to each tuple's first field. If so, follow the pointer of the first such tuple and repeat step 2; else (3) search the local index and check if K is greater than or equal to each tuple's first field. If so, follow the pointer of the first one of such tuples, tune in at the designated bucket and go to step 3.

3. Search the following $L_data_segment/(m + 1)$ buckets and sequentially locate K, where $L_data_segment$ indicates the length of a data segment.

In general, as shown in [34], the average tuning time using the flexible indexing technique is $(\sum \lceil \log_2 i \rceil + Data / (2 \times (m + 1))) / p$, $\forall 1 \leq i \leq p$, and Data denotes the size of the entire broadcast. The average access time using flexible indexing is $0.5 \times (File + p \times (\lceil \log_2 p \rceil + m) / n) \times (1 + p) / p$.

Later on, Yu et al. [71] extended the flexible indexing method with another parameter, the index base r , and proposed a parameterized flexible indexing scheme (PFIInd), which can be used to tune the trade-off between access efficiency and energy conservation based on the specific requirements of clients.

5.1.2 (1, m) Index and Distributed Index

Imielinski et al. [35] also developed a method for efficient multiplexing of data file with clustering index, called distributed index, which becomes one popular air indexing approach and was extended by many other researchers to meet different system requirements. Before introducing distributed index, this section starts with a simple index allocation method called (1, m) index.

(1, m) Index. (1, m) indexing scheme is an index allocation approach that broadcasts each index m times during one broadcasting cycle, in front of every fraction $(1/m)$ of the file, as illustrated in Fig. 7.

The first bucket of each index segment contains a tuple. The first field of this tuple is the attribute value of the last record in one *bcast*, and the second field is the offset to the next *bcast*. This tuple is used for guiding clients to the next *bcast*, if they missed the required record in the current *bcast*. Here is the access protocol of (1, m) indexing scheme [35] for the request with attribute value K :

1. Initial probe: tune into the broadcast channel, and get the pointer to the next index segment.
2. Go to doze mode and tune back to the broadcast channel to get the index segment.
3. Follow the index to determine when the data bucket of the first record with attribute value K will be broadcasted, and then follow the pointers to direct successive probes (client may doze between two successive probes).
4. Tune in again when the first record with attribute K is broadcasted and download all the records with attribute K .

Data denotes the average file size, and Index indicates the total number of buckets in the index tree. Let C denote the coarseness of the attribute. As shown in [35], the tuning time of (1, m) indexing method is $1 + k + C$. The access latency of (1, m) indexing method is

$$\frac{1}{2} \times \left((m + 1) \times Index + \left(\frac{1}{m} + 1 \right) \times Data \right) + C. \quad (14)$$

Optimum m . In order to minimize the latency for the (1, m) indexing, there is a formula to compute the optimum m (denoted as m^*), which is obtained by

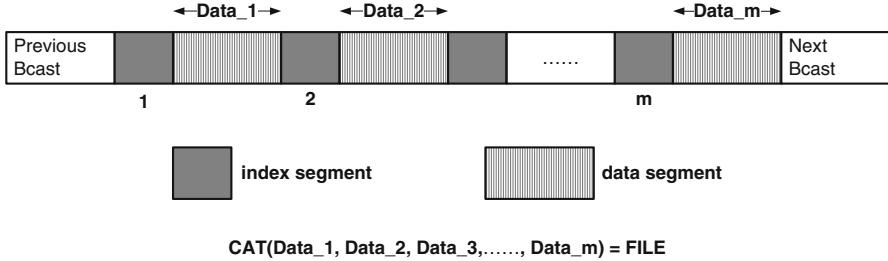

Fig. 7 An example of $(1, m)$ indexing

differentiating the formula of access latency with respect to m , equating it to zero and solving for m .

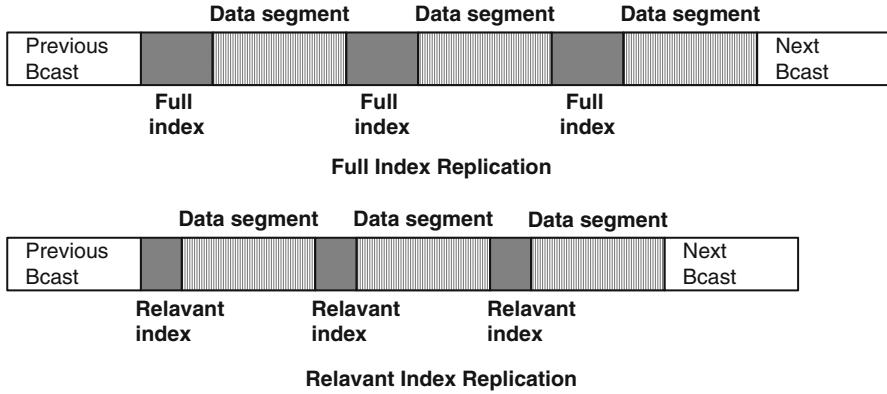

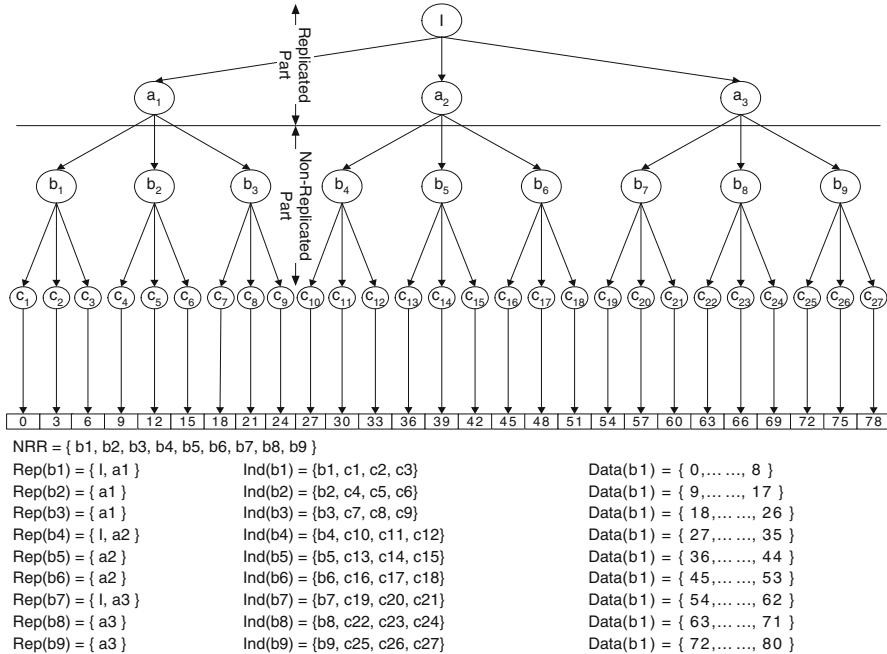

$$m^* = \sqrt{\frac{\text{Data}}{\text{Index}}}. \quad (15)$$

Therefore, just divide the file into m^* data segments and broadcast each segment after each index segment on that channel.

Distributed Index. $(1, m)$ indexing scheme could be improved by cutting down the replication times of an index. Distributed index is such approach that index is partially replicated, since the portion of index that indexes the following data segment is not necessary to be replicated. Figure 8 shows the difference between full index replication as in $(1, m)$ indexing scheme and the relevant index replication as in distributed index [35].

Distributed index takes an index tree T and subdivides it into two parts: the replicated part and the non-replicated part. Replicated part consists of the top r levels of T , and non-replicated part contains the bottom $(k - r)$ levels. Index nodes on the $(r + 1)$ th level are *non-replicated roots*, denoted by NRR. Any index subtree rooted at non-replicated root in NRR appears only once in one *bcast*, in front of the data segments it indexes. On the other hand, the replication times of each index node in the replicated part are equal to the number of its children.

As in [35], I indicates the root of T . B represents an index bucket in NRR, and B_i means the i th index bucket in NRR. $\text{Path}(C, B)$ is the path sequence from index bucket C to (excluding) index bucket B. $\text{Data}(B)$ shows the set of data buckets indexed by B. $\text{Ind}(B)$ indicates the part of T below (including) B. $\text{LCA}(B_i, B_k)$ represents the least common ancestor of B_i and B_k . $\text{NRR} = B_1, B_2, \dots, B_t$, and $\text{Rep}(B_1) = \text{Path}(I, B_1)$, where B_1 is the first bucket in NRR. $\text{Rep}(B_i) = \text{Path}(\text{LCA}(B_{i-1}, B_i), B_i)$ for $i = 2, \dots, t$. Thus, $\text{Rep}(B)$ indicates the *replicated part* of the path from the root to index segment B, while $\text{Ind}(B)$ refers to the *non-replicated part*. Figure 9 shows the values of Rep, Ind, and Data for each index buckets in NRR. The *bcast* contains a sequence of triples: $\langle \text{Rep}(B), \text{Ind}(B), \text{Data}(B) \rangle \forall B \in \text{NRR}$.

**Fig. 8** Index distribution**Fig. 9** An example of the index tree for distributed index

Control index is stored in those indices of replicated part. Suppose P_1, P_2, \dots, P_r is the sequence of buckets in $\text{Path}(I, B)$. $\text{Last}(P_i)$ indicates the attribute value in the last record indexed by P_i . $\text{NEXT}_B(i)$ represents the offset to the next occurrence of P_i (Fig. 10). Let l be the attribute value in the last record before B, and let begin be the offset to the next bcast. Control index in P_i have the following i tuples [35]:

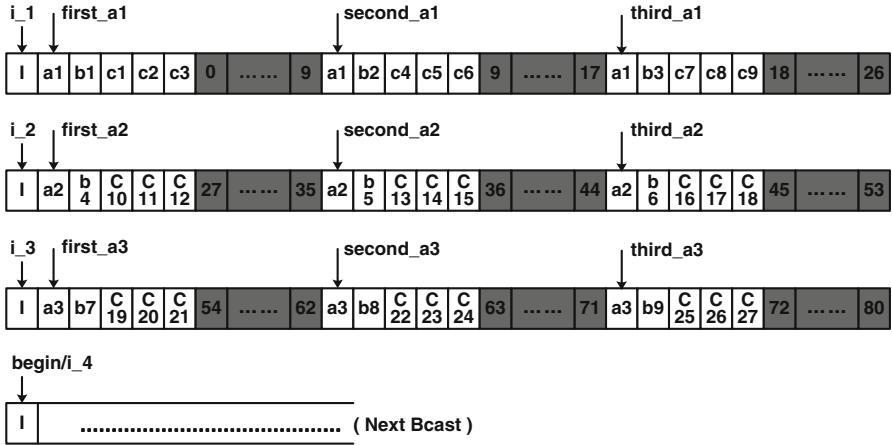

Fig. 10 An example of distributed index

```
[I, begin]
[Last(P2), NEXTB(1)]
[Last(P3), NEXTB(2)]
...
[Last(Pi), NEXTB(i - 1)]
```

An example of the control index is illustrated in Fig. 11. Control index of bucket P_i is used in this way: for the required data with key value of K , if $K < 1$, then the client is directed to the next *bcast*. If $K \geq 1$, then $(K > \text{Last}(P_j))$ is checked to find the smallest j . If $j \leq i$, then follow $\text{NEXT}_B(j - 1)$ to the next occurrence of P_i ; otherwise search the rest of the index in bucket P_i .

Here is the access protocol [35] for a data record with key value K :

1. Initial probe: tune into the *bcast*, and get the pointer to the next control index.
2. Go to the designated bucket with control index. Based on K and the control index, determine whether to do the following:
 - (a) Wait for the next *bcast* and go to step 3.
 - (b) Look for the appropriate higher level index, following one of the “NEXT” pointers, and go to step 3.
3. Follow the designated index and pointers to check when the first data bucket with key value K will be broadcasted, and doze between two successive probes.
4. Tune in again to download all the data with key value K .

The tuning time of distributed indexing is bounded by $2 + k + C$ as shown in [35]. The access time of distributed index is

$$\frac{1}{2} \times \left(\frac{\text{Index} - \text{Index}[r]}{\text{Level}[r + 1]} + \frac{\text{Data}}{\text{Level}[r + 1]} + \text{Data} + \text{Index} + \Delta\text{Index}_r \right) + C. \quad (16)$$

Control Index at first_a1	NON, NON 26, i_2	Control Index at first_a3	53, begin 80, i_4
Control Index at second_a1	8, begin 26, i_2	Control Index at second_a3	62, begin 80, i_4
Control Index at third_a1	17, begin 26, i_2	Control Index at third_a3	71, begin 80, i_4
Control Index at first_a2	26, begin 53, i_3	Control Index at i_2	26, begin
Control Index at second_a2	35, begin 53, i_3	Control Index at i_3	53, begin
Control Index at third_a2	44, begin 53, i_3		

Fig. 11 An example of control index

Optimizing the Number of Replicated Levels. The authors proposed that optimizing the number of r is related to minimizing the access time. Choose r such that the following expression is minimal:

$$\Delta \text{Index}_r + \left(\frac{\text{Index} - \text{Index}[r]}{\text{Level}[r+1]} + \frac{\text{Data}}{\text{Level}[r+1]} \right). \quad (17)$$

Evaluate the above expression (Eq. 17) for a given index tree with r ranging from 1 to the number of levels in the tree. The value of r which results in the minimal value for (Eq. 17) is the optimal number of replicated levels.

5.1.3 Huffman-Tree Index

Among traditional indexing structures, alphabetic Huffman tree is another important tree-based indexing technique, which has been applied to the wireless broadcast environment ever since the last decades. It is an efficient indexing technique because it takes into consideration the access probabilities of data items when constructing the Huffman tree. The popular data with higher access probability resides closer to the root in Huffman tree, which helps clients reduce search time when traversing from the root. However, almost all existing Huffman-tree indexing methods were discussed under multichannel broadcasting environment, which makes it hard to compare the performance between Huffman tree and other single-channel air indexing methods. Recently, Zhong et al. [74] proposed a novel Huffman-tree-based distributed indexing scheme (HTD) on single-channel broadcasting environment. They applied the feature of distributed indexing onto Huffman-tree indexing, which is an innovative idea that has not been considered before. The experiment results show that under a uniform communication environment, HTD outperforms B⁺-tree distributed indexing (BTD) and can replace BTD in most existing wireless data broadcast systems.

Data Item Key	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
Frequency	23	4	12	10	17	31	15	21	29	19	7	12	16	14	20	48

Fig. 12 An example data set of Huffman-tree distributed indexing

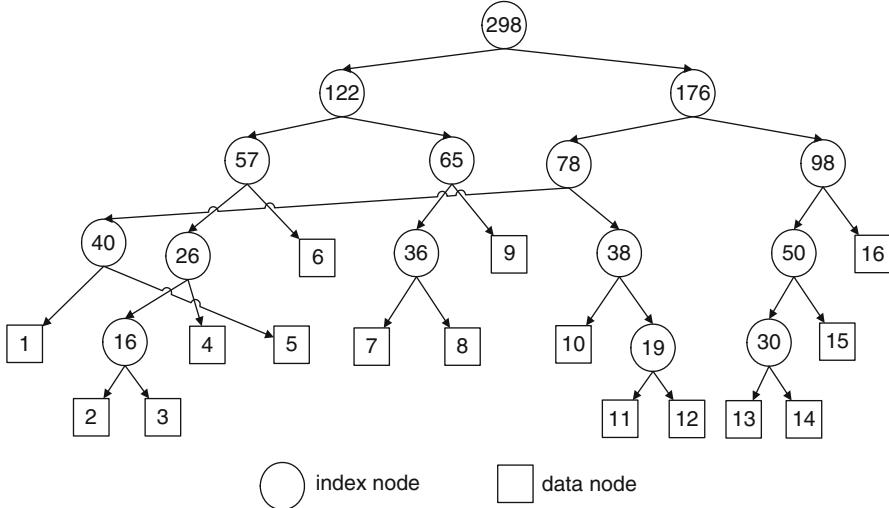

Fig. 13 The first step of constructing T_0

Here is the construction of Huffman-tree-based distributed indexing scheme (HTD). The structure of index bucket and data bucket of HTD is almost the same as that of BTD. The first stage is to construct a k -ary alphabetic Huffman tree as in [52]. Figure 12 gives an example of the data set and the corresponding access frequencies. The construction process of alphabetic Huffman tree is illustrated in Figs. 13 and 14.

Stage 1: choose data nodes d_i, d_j to merge when:

1. There are no data nodes between d_i and d_j .
2. The sum of their frequencies is the minimum.
3. They are the leftmost pair of nodes among all candidates.

Create a new index node d'_i with frequency equal to the sum of d_i 's and d_j 's. Replace d_i and d_j with d'_i in the construction sequence. This first stage produces tree T_0 without alphabetic ordering of the data nodes. Figure 13 gives an example, where the frequencies of each index node are shown inside the circle as index key values.

Stage 2: record the level of each data node of T_0 as L_i for data d_i , while the root node is level 1. After this, rearrange pointers from bottom to the root, such that for each level the leftmost two nodes have the same parent, and then the next two, so on, and so forth. Generate an alphabetic Huffman tree T like this, while keeping the level of each node in T_0 , as shown in Fig. 14.

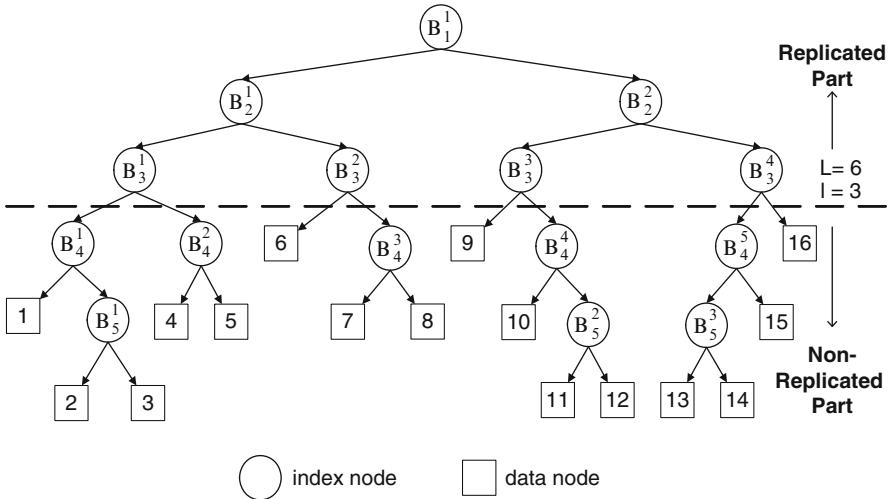

Fig. 14 The final Huffman-tree T

To construct k -ary Huffman tree, just extend this algorithm by merging at most k nodes in stage 1 and combining up to k nodes in stage 2.

After generating the alphabetic Huffman tree T , cut it at level l , and perform a distributed traversal as in distributed indexing method. The index nodes above cutting level l are *control index*, and index nodes below l are *search index*. Next, append control tables onto control index in the same way as distributed indexing.

The major differences between Huffman-tree and B^+ -tree indexing are that (1) the positions of leaf nodes are different and that (2) the subtree sizes below l are different. There might be data items above l in a Huffman tree, depending on which level is chosen for l , because data items are not restricted to reside at bottom level of Huffman tree. Also the sizes of subtrees below l may vary a lot in Huffman tree, but for B^+ -tree the subtrees have similar sizes.

The final broadcast sequence \mathbb{B} of this example is shown in Fig. 15. Control table contains a number of entries, each of which is a tuple of *key value* and *offset*. Here is the access protocol of Huffman-tree-based distributed indexing: when searching in a control table, client compares the *key value* of the first entry in control table with the request key value K :

- If request key K is less than or equal to the first key in control table, wait until the root of the next bcast.
- If request key is greater, go on to compare the next entry in control table.
 - Turn to doze mode for *offset* time if request key K is not greater than the next key in control table.
 - Otherwise, continue comparing with the rest entries of control table until finding such an entry, or go to default bucket (the next index) if not found.

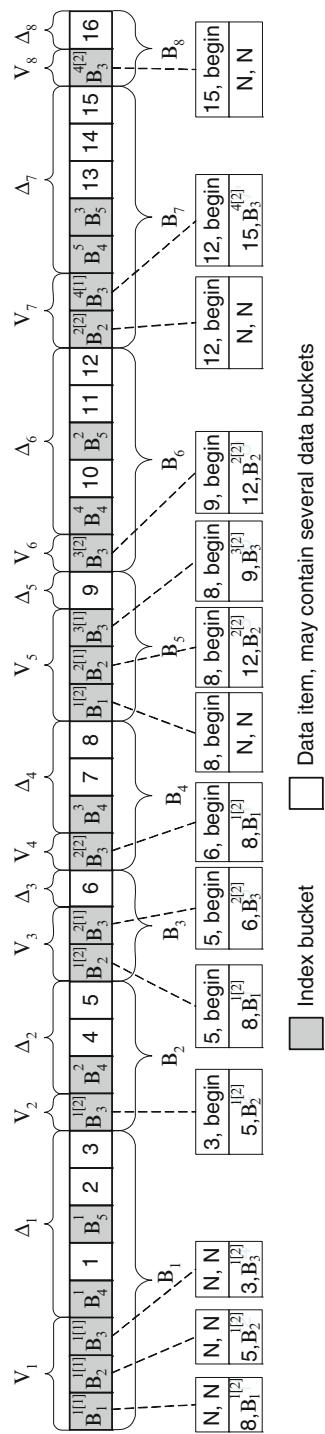

Fig. 15 The broadcast sequence of Huffman-tree distributed indexing

As proven in [74], the expected average access time of alphabetic Huffman-tree-based distributed indexing scheme is

$$E(AL) = \frac{1}{\|\mathbb{B}\|} \sum_{i=1}^R \left(\sum_{w=1}^{R-2} \left(\frac{v_i + \delta_i}{2} + \sum_{j=i+1}^{i+w-1} (v_j + \delta_j) + v_{i+w} + \frac{\delta_{i+w}}{2} \right) P_{(i+w)\%R} (v_i + \delta_i) + \left(\frac{v_i + \delta_i}{2} \right) P_i v_i + \sum_{i=1}^R (v_i + \delta_i) P_i \delta_i \right). \quad (18)$$

The expected average tuning time for alphabetic Huffman-tree-based distributed indexing scheme is

$$E(TT) = \frac{2 \sum_{i=1}^R v_i + (2+r)|D| + 3 \sum_{i=1}^R \delta_i}{r \|\mathbb{B}\|} + \sum_{i=1}^{|D|} \left(\frac{l}{2r} + \frac{1}{r}(L_i - l) + s_i \right) p_i. \quad (19)$$

5.1.4 Exponential Index

Xu et al. [65] proposed the *exponential index*, which facilitates replication by sharing links in different search trees to minimize storage overhead and allows clients to start searching at any index node. Exponential index can be adjusted to optimize the access time with the tuning time bounded by a given limit, and vice versa. The nature of distributed structure makes it easy to handle link errors. When dealing with data updates, exponential index works well, especially for applications where the non-key values may change but the search key values do not change often.

Exponential index was created based on clustered broadcasting, which means that data items are broadcasted in ascending order of their attribute values. Figure 16 shows an example of exponential index, that a server broadcasts stock information periodically. Each bucket stores one stock item in its data part and some index information in its index table. The index table contains four entries, each of them is a tuple $\{distInt, maxKey\}$, where distInt indicates the distance range, whose size grows exponentially, and maxKey is the maximum key value of these buckets. The first entry of index table shows the next bucket. For each $i > 1$, the i th entry indicates the bucket segments 2^{i-1} to $2^i - 1$ away of totally 2^{i-1} buckets. Thus, the $(i-1)$ th and i th entries' maxKey values give the range of buckets indexed by the i th entry. Here in this example the sizes of the indexed segments exponentially increase by a base of 2.

Exponential index has a linear and distributed structure, which enables searching from any index bucket. An index link is shared by different index buckets. In addition, by adjusting the exponential base, the indexing overhead can be controlled. Exponential index could be generalized by changing the index base to any value $r \geq 1$. The i th entry of an index table describes the maximum key value of buckets that are $\lfloor \sum_{j=1}^{i-2} r^j + 1 \rfloor = \lfloor \frac{r^{i-1}-1}{r-1} + 1 \rfloor$ to $\lfloor \sum_{j=1}^{i-1} r^j \rfloor = \lfloor \frac{r^i-1}{r-1} \rfloor$ away.

To reduce the indexing overhead, each group of I buckets are merged into a *data chunk*, and the exponential index is built for each chunk. Therefore, the size and the number of index tables are decreased. Furthermore, index links are constructed

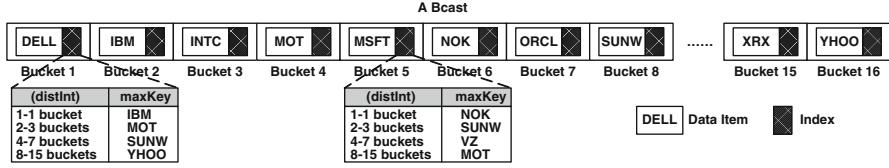

Fig. 16 An example of exponential index

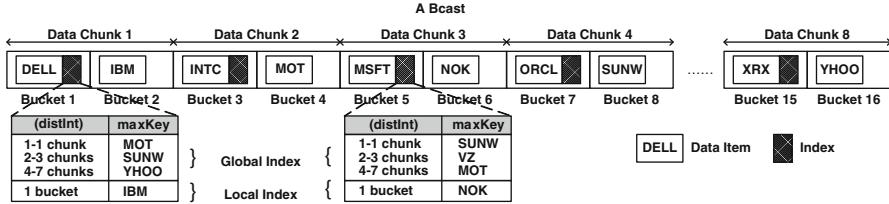

Fig. 17 An example of generalized exponential index

for all buckets within each chunk, called *local index*. Those index entries directing to other data chunks are named *global index*. An example of such generalized exponential index is shown in Fig. 17, where the index base r and the chunk size I are both set to 2. Algorithm 11 presents the searching algorithm of exponential index [65].

Two major parameters for exponential index are index base r and chunk size I , which offer the flexibility between access time and tuning time. Generally, decreasing index base r leads to the increasing number of index entries and indexing overhead, while tuning time decreasing with r . If the chunk size I is larger, the tuning time becomes less, but the initial probing time might be longer.

As shown in [65], the initial probing time plus half of the length of *bcast* makes the average access latency:

$$E(d) = \frac{I}{2} + \frac{IC}{2}. \quad (20)$$

The average tuning time is

$$E(t) = \frac{I-1}{I} + \frac{B(I-1)}{B(I-1) + B'} + \frac{1}{C} \sum_{l=0}^{C-1} t(l). \quad (21)$$

Here $t(l)$ is the tuning time for a chunk that is l chunks away [65]:

$$t(l) = \begin{cases} 1, & \text{if } l = 0; \\ t(l-x) + 1, & \text{if } l > 0, \end{cases} \quad (22)$$

where x is the maximum value in the set of $\{1, 2, \lfloor r+2 \rfloor, \dots, \lfloor \frac{r^{nc}-1}{r-1} \rfloor + 1\}$ that is less than or equal to l .

Algorithm 11 Index searching algorithm for exponential index

```

1: wait for the first bucket of next chunk to be broadcasted;
2: for each data item in the bucket do
3:   if it is the requested data then
4:     stop searching and finish the query;
5:   end if
6: end for
7: check local index in the index table;
8: if the requested data is within the key range of the  $i$ th entry then
9:   go to doze mode until the  $i$ th bucket appears, retrieve data and finish the query;
10: end if
11: check global index in the index table;
12: if the requested data is within the key range of the  $i$ th entry then
13:   go to doze mode for  $(\lfloor \frac{r^{i-1}-1}{r-1} + 1 \rfloor \cdot I - 1)$  buckets until the first bucket of the  $(\lfloor \frac{r^{i-1}-1}{r-1} + 1 \rfloor)$ th chunk appears, and repeat this search process;
14: end if

```

5.1.5 Hashing Schemes

Hashing-based schemes do not require additional index to be broadcasted together with the data. Hashing parameters are included in the *control part* of data buckets, which helps in reducing access latency and tuning time. Control part for the first N buckets contains the following:

1. Hash function $h(K)$
2. Shift: the pointer to a bucket with key K that $h(K) = \text{address(Bucket)}$

In most cases the hashing function is not perfect, and there might be collisions. The colliding records will be stored immediately after the bucket assigned to them, pushing the rest of the file “down,” and create offsets for those buckets. Imielinski et al. [34] proposed two hashing protocols: hashing A and hashing B.

The access protocol of hashing A [34] for record with key K is like this:

1. Initial probe, read the control data from the current bucket, and calculate $h(K)$.
2. If *Current bucket #* < $h(K)$, then go to *doze mode* and tune in again to slot $h(K)$; Else wait till the next *bcast*, and repeat protocol again.
3. At $h(K)$, get the *Shift* value, go to *doze mode* and tune in again after *Shift* number of buckets.
4. Listen until either the record with key K is found (success) or with key L ($h(L) \neq h(K)$) is found (failure).

[Figure 18a](#) is an example of searching key $K = 15$ in the file, hashed Modulo 4. Initial probe is at the second bucket. Follow the hashing function, client first goes to bucket four which may contain key $K = 15$ if there is no overflow. However, the keys are shifted. Client reads the shift value, goes to doze mode, and tunes in again later. It must look at all the overflow buckets of that bucket to find the key $K = 15$. [Figure 18b](#) shows the cases when client needs to wait for the next bcast, which may occur due to either the data miss or the directory miss.

Hashing A was further extended to hashing B, which significantly reduced the directory miss by a minor modification of the hashing function. Let d be the size of the minimum overflow chain. The hashing function h was modified as follows [34]:

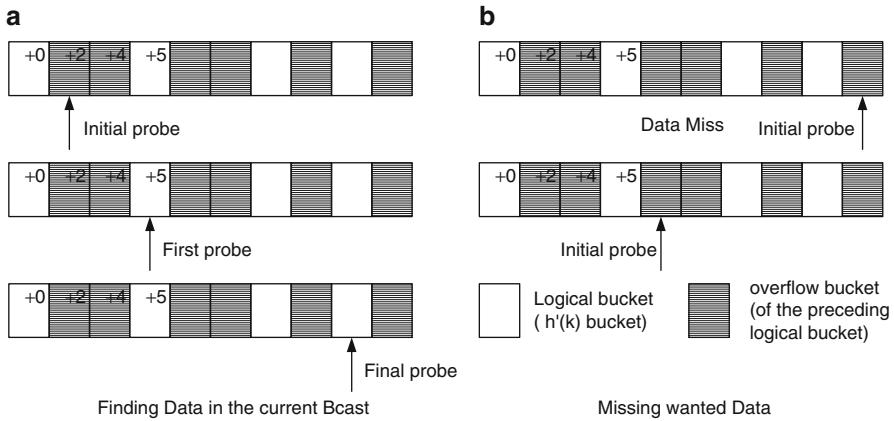

Fig. 18 An example of Hashing A (the numbers in the *upper right* corner of some buckets indicate the shift value in the control part)

$$h'(K) = \begin{cases} h(K), & \text{if } h(K) = 1. \\ (h(K) - 1)(1 + \min_overflow) + 1, & \text{if } h(K) > 1. \end{cases}$$

The new hashing function h' takes into consideration the shift caused by overflow. Figure 19 shows the improvement of hashing B. The reduction is substantial if the sizes of the overflow chains do not differ much. When the sizes of overflow chain are same for all buckets, h' becomes the perfect hashing function. However, perfect hashing function does not guarantee the minimal access latency.

Let $Displacement(h, K)$ denote the distance between the physical bucket where K resides ($Physical_bucket(k)$) and the designated bucket for k ($h'(k)$): $Displacement(h, K) = Physical_bucket(K) - h'(k)$. As presented in [34], the expected access time of hash B is obtained by calculating the access time for each key K and then averaging it out. The expected access time “per key” is combined with two factors:

1. Data miss occurs if the initial probe is between the designated bucket and the physical bucket. The client has to wait an extra *bcast*. Thus,

$$(Displacement(h, K)/Data(h)) \times (Data(h) + 1/2 \times Displacement(h, K)).$$

2. If the initial probe occurs outside the displacement area, it has to wait on average between the $Displacement(h, K)$ and the file size. Then,

$$(1 - (Displacement(h, K)/Data(h))) \times (Data(h) + Displacement(h, K))/2.$$

The sum of expected access latency per key divided by total number of keys becomes the expected access latency. For tuning time, the more logical buckets, the lower the tuning time. When the number of logical buckets grows, the tuning time could go down to 3 [34].

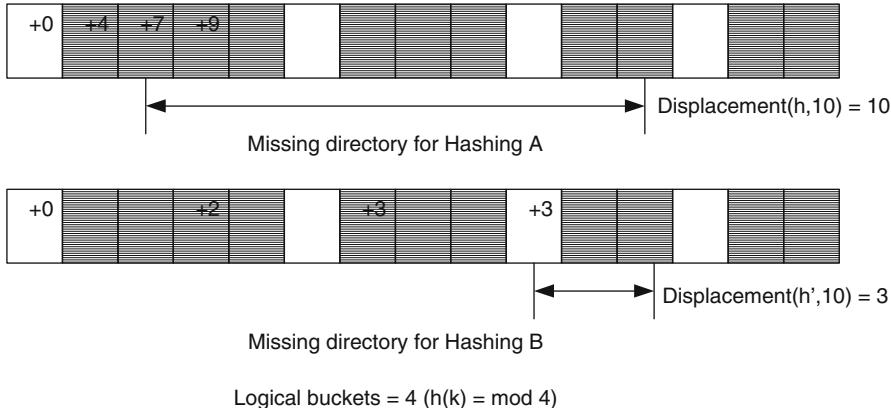

Fig. 19 Displacement comparison

Later, Yao et al. [68] proposed MHash, which optimizes both tuning time and access latency. MHash uses a two-argument hash function $H(k, l)$, which allows each data to be mapped to a number of slots. Popular items are broadcast more frequently, which enables non-flat broadcast to reduce access time. The authors refined MHash by investigating the design of hash function, and analyzed the optimal bandwidth allocation for MHash indexing. They generated hash functions that produce broadcast schedules without unoccupied slots. Such a hole-free hash function was constructed by injecting an offset. MHash reduces access latency and tuning time, since it enables non-flat broadcast, properly spacing the instances of each data, and optimally allocates the bandwidth among data items. Under skewed access distribution, MHash achieves the access latency that is close to the optimal broadcast scheduling.

5.2 Indexing in Multichannel Broadcasting Environment

Multichannel broadcasting techniques enable further reduction of access time by partitioning data onto multiple channels. Several works [10, 15, 48, 49, 69] deal with efficient data allocation for multichannel data broadcast systems. Furthermore, various indexing techniques and index allocation methods have been developed for multichannel data broadcast. Due to the feature of multichannel broadcasting, how to efficiently allocate index has attracted more attentions.

There exist two popular categories of index allocation techniques. One approach is to interleave index with data on multiple channels. Examples of such approach include [6, 46, 70]. In [6], Amarmend et al. derived external indices from the scheduled data to determine which channel broadcasts the required data, and allocate them over upper channels. They also extended the exponential index as the local index for each channel. Lo et al. [46] used a k -ary search tree as the

index tree and discussed the optimal data and index allocation problem on multiple broadcast channels. In [70], indices are striped over multiple channels in such a way that index levels are sequentially broadcasted in sub-strips at certain frequencies. Hsu et al. [24] extended the distributed indexing scheme on multiple channels. Vijayalakshmi et al. [59] presented a hashing scheme for information access through multiple channels in which hash functions are used to index broadcast information across multiple channels.

Another approach is to assign certain channels as designated index channels and others as data channels. Jung et al. [38] gave a tree-structured index allocation method with replication over multiple broadcast channels. Their allocation method designed index blocks based on the number of index channels, which contain null elements. Waluyo et al. [60] proposed a global indexing scheme in which each index channel has a different part of the entire index tree while preserving its overall structure, with replicated tree nodes among index channels. Wang and Chen [61] proposed an index allocation method named TMBT for multichannel data broadcast, which creates a virtual distributed index for each data channel and multiplexes them on the index channel.

So far, almost all literature on multichannel data broadcast have the assumption that all channels are synchronized, that is, all channels have the same throughput and they begin and finish a broadcast cycle at the same time.

Shivakumar et al. [52] discussed the construction of Huffman tree that is similar to Huffman code construction. Chen et al. [17] proposed algorithms for constructing the skewed Huffman tree. However, there exists a problem that the clients may fail to find the desired data item by traversing the Huffman tree. Another kind of Huffman tree proposed in [26], called alphabetic Huffman tree, serves as a binary search tree, which is further extended to k -ary search tree in [52], so that a tree node will fit in a wireless packet of any size by adjusting the fanout of the tree. In [51], Shivakumar and Venkatasubramanian proposed an unbalanced index tree allocation method based on alphabetic Huffman tree, which partitioned the multiple channels into data channels and index channels. They assigned one index channel to each level of the index tree, which might be inefficient when the number of index channels is less than the depth of the index tree.

Jung et al. [38] studied an efficient alphabetic Huffman-tree index allocation method for broadcasting data with skewed access frequencies over multiple physical channels. The rest of Sect. 5.2 will introduce their method in detail.

To cope with the two major problems of previously proposed indexing allocation methods that (1) require equal size for both index and data and (2) the performance degrades when the number of given physical channels is not enough, the proposed tree-structured index allocation method minimizes the average access time by broadcasting the hot data and their indices more frequently than the less hot data and their indexes over the dedicated index and data channels.

Here are the assumptions in [38]. Let DC_i denote the i th data channel. Let $L(v)$ denote node v 's level number in an alphabetic Huffman tree. IL_1 is the first ordered list that consists of the index sequence along the path from the root to the data in DC_1 . Then, IL_i ($2 \leq i \leq$ the number of data channels) denotes the i th ordered

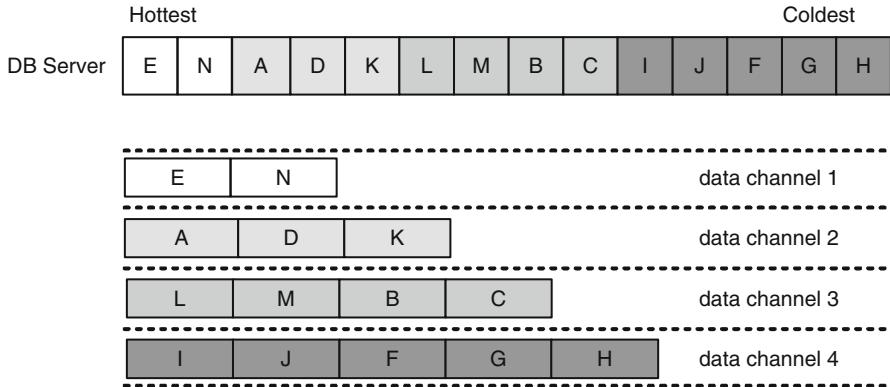

Fig. 20 An example of data broadcast schedule

list, excluding the index nodes in IL_j for $j = 1, \dots, i - 1$. Each ordered list $IL_i = \langle I_1, I_2, I_3, \dots, I_q \rangle$ satisfies two requirements:

1. $L(I_1) \leq L(I_2) \leq L(I_3) \leq \dots \leq L(I_q)$
2. When $L(I_j) = L(I_{j+1})$, index node I_j is on the left of I_{j+1} in the index tree.

Indexes in IL_i point to the hotter (more popular) data than indices in IL_{i+1} , since data at DC_i are hotter than data at DC_{i+1} . Thus, to minimize the access latency, indices in IL_i are broadcasted as many times as the corresponding data in DC_i . Let DX_i denote the number of data items in channel DC_i . LCM means the least common multiple of $DX_1, DX_2, \dots, DX_{ND}$, where ND is the number of data channels. Then, the repetition frequency that IL_i has to be broadcasted is $RF_i = \text{LCM}/DX_i$ [38].

An example of an alphabetic Huffman tree with data nodes {A, B, C, D, E, F, G, H, I, J, K, L, M, N} of Fig. 20 is shown in Fig. 21. The set of index nodes is $\{1, 2, 3, \dots, 11, 12, 13\}$. The hottest data are E and N, and the oldest data are F and G, since they reside at the highest and lowest level of the tree, respectively.

Figure 22 shows the examples of IL_i and RF_i from that Huffman tree of Fig. 21. Here, for data nodes (A, D, K) in channel DC_2 , the corresponding ordered list of index is $IL_2 = \langle 4, 5, 6, 7 \rangle$. $RF_2 = 20$ means the indices in IL_2 will be repeated for 20 times in one index broadcast cycle.

Given $RF_1, RF_2, RF_3, \dots, RF_{ND}$, the normalized repetition frequencies are $NRF_1 = RF_1/RF_{ND}, NRF_2 = RF_2/RF_{ND}, \dots, NRF_{ND} = RF_{ND}/RF_{ND}$ [38]. And the value of NRF_i is rounded off.

Figure 23 illustrates the index blocks for the index ordered lists $\langle 1, 2, 3 \rangle, \langle 4, 5, 6, 7 \rangle, \langle 8, 9 \rangle$, and $\langle 10, 11, 12, 13 \rangle$ of the Huffman tree shown in Fig. 21. Since the number of index channels is 2, the size of each member of index block should be 2, and each member's element is not related to each other with an ancestor-descendent relationship in the tree. Figure 24 shows the index allocation method on 2 index channels for the index blocks of Fig. 23. This index allocation method could also be extended to k channels.

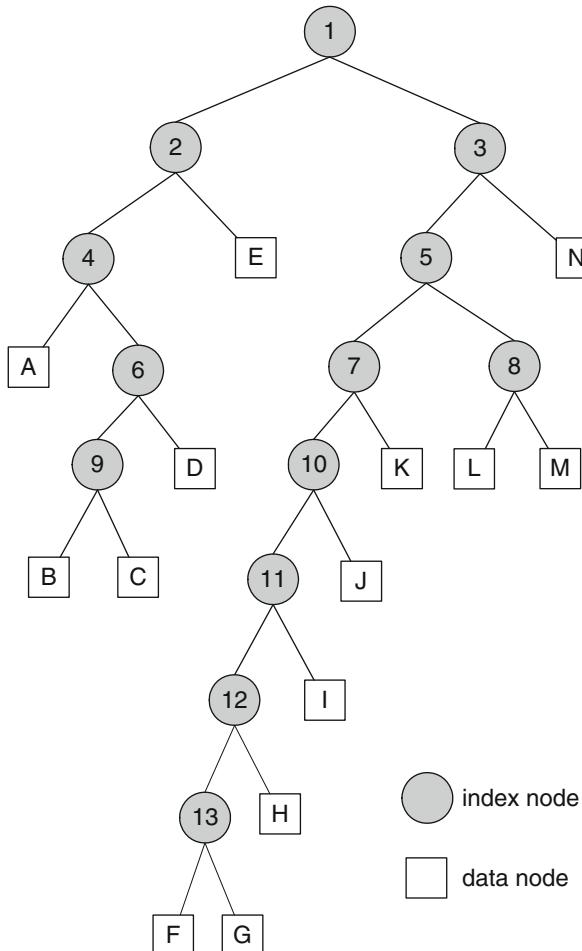

Fig. 21 An example of alphabetic Huffman tree

4 Data Channels						
E	N					IL ₁ :<1, 2, 3> RF ₁ = 60/2=30
A	D	K				IL ₂ :<4, 5, 6, 7> RF ₂ = 60/3=20
L	M	B	C			IL ₃ :<8, 9> RF ₃ = 60/4=15

Fig. 22 The index list and repetition frequencies

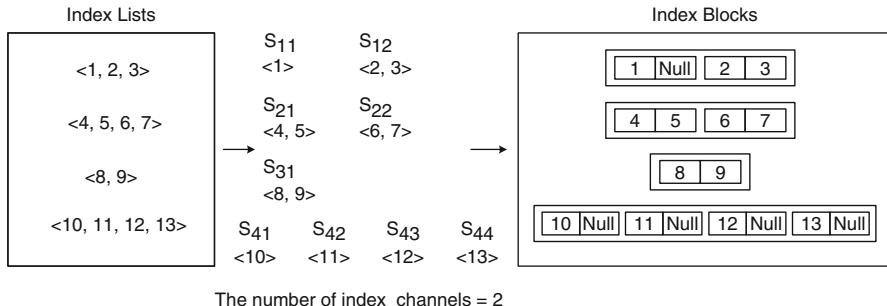

Fig. 23 The example of index blocks

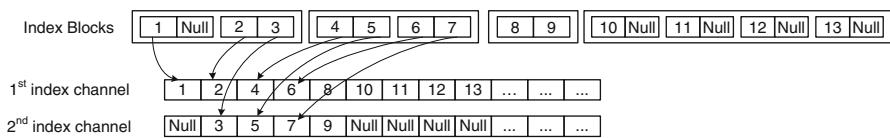

Fig. 24 Allocation of indices on two index channels

[Figure 25](#) gives an example of broadcasting with two index channels and four data channels in the system. The gray boxes represent the index nodes pointing to indices, while the white boxes with letters represent the index nodes pointing to data. Assume that data node size is ten times larger than index node size and that a client requests data E which is broadcasted on data channel 1. The client first tunes into index channel 1 to get the root of the tree, and then traverses the index tree to reach the index node pointing to data E. Assume that when $t = 14$, the index node 2 is being broadcasted over index channel 1, which has the information of data E. With the location of E, the client goes to doze mode until E arrives, and then downloads data E.

In [38], the average access time of alphabetic Huffman-tree indexing allocation method for multichannel environment is as follows:

$$\begin{aligned}
 AveAT = & \frac{ISize}{2 \cdot c_i \cdot NRF_1} \sum_{j=1}^{c_d} NRF_j \cdot |IL_j| + \frac{ISize}{c_i} \sum_{j=1}^{c_d} \left[\left\{ \sum_{k=1}^{j-1} |IL_k| + \frac{|IL_j|}{2} \right. \right. \\
 & \left. \left. + \frac{1}{NRF_j} \cdot \sum_{k=1}^{j-1} |IL_k| \cdot (NRF_k - NRF_j) \right\} \cdot \frac{NRF_j}{NRF} \right] \\
 & + \frac{DSize}{2} \sum_{j=1}^{c_d} \frac{NRF_j}{NRF} \cdot n_j. \tag{23}
 \end{aligned}$$

As shown in [38], given c physical channels, the optimal number of index channels c_i and the number of data channels c_d can be determined by the above Eq. (23).

	t=0	t=10	t=20	t=30	
index channel 1	... E A D L J I H F M G M M G M ...	E A D L J I H F M G M M G M	E A D L J I H F M G M M G M	E A D L M ...	
index channel 2	... N K B C N K B C N K B C ...	N K B C N K B C	N K B C N K B C	N K N K B C ... C ...	
data channel 1	... E ...	N	E	...	
data channel 2	... A ...	D	K	A	
data channel 3	... L ...	M	B	C	
data channel 4	... I ...	J	F	G	

Fig. 25 The final *bcast* over index channels and data channels

Just compute a set of *AveATs* for all possible values of c_i and c_d , and then choose the pair with minimal *AveAT*. Since the time complexity of computing *AveAT* is $O((c_d)^2)$ and $c_d < c$, then the time complexity of this method is $O(c^3)$. Although the optimal split might need to be recomputed with the changes of data set, it is not a big issue since the time complexity $O(c^3)$ is low.

6 Coverage Optimization for Data Broadcast

Coverage optimization is a special topic for data broadcasting problem in wireless communications. Usually, this topic deals with data broadcast and data transmission problems in wireless ZigBee networks [20, 53], wireless/mobile Ad-Hoc networks [64], cellular networks [75], heterogeneous overlayed wireless networks [30], and other types of data broadcast services. Most of the coverage problems are discussing whether the data broadcast service provider guarantees reliable coverage for a certain area or region and how to make the broadcast system more energy efficient, time efficient, or fault tolerant (more reliable). As described in previous sections, the researches for data broadcast are cross-disciplinary works among multimedia technology [43], wireless networking [22], data engineering [18], and other related fields [29]. Accordingly, majority of the studies on coverage optimization belong to wireless networking. This type of problems can be converted into combinatorial optimization problem and most of them are NP-hard problems reducible to known NP problems, which cannot be solved in polynomial time unless $P = NP$ [23]. Therefore, to solve this type of problems, people usually design approximation algorithms and heuristic approaches to provide the near-optimal solutions.

This section will briefly introduce several existing problems and optimization methods of coverage optimization for data broadcast in wireless communications. The organization of this section is shown as follows: Sect. 6.1 will describe the mathematical modeling and problem definition of coverage optimization, Sect. 6.2 will introduce the classification and reduction of this problem, while Sects. 6.3–6.5 will illustrate different variants of coverage optimization for data

broadcast and its corresponding solutions. Finally, Sect. 6.6 will give a summary for coverage optimization and some discussions for the future directions.

6.1 Mathematical Modeling and Problem Definition

To formally define coverage optimization problems for data broadcast, the problem formulation and reduction have to be introduced. More specifically, as shown in Fig. 26, in a typical data broadcast system, one or more base stations (BSs) (also called “nodes” in combinatorial geometry) will continually broadcast information among a certain area/region. Within this area/region, there are hundreds/thousands of fixed-line or mobile clients that have the requirements for these information. As a consequence, how to economically, efficiently, and reliably cover the whole area such that each client can successfully receive the required messages/data streams becomes an important issue for all service providers.

In mathematical description, given an area A in Euclidean space, a group of nodes $N = \{n_1, \dots, n_k\}$, each node n_i covers a certain area described as $V(n_i)$. Each node can also communicate with other nodes in this area. In A , there are $T = \{t_1, \dots, t_m\}$ clients. In different mathematical models, $V(n_i)$ has different representations. If considering signal interference like interrupt, collision, and contention $V(n_i)$ usually denotes a circle whose center is n_i . If each n_i has the same capability, then the whole graph becomes a unit disk graph (UDG) otherwise the graph is a disk graph (DG). Figures 27 and 28 are examples of UDG and DG correspondingly. If not considering signal interference, then $V(n_i)$ usually represents a Voronoi division with the following definition:

$$V(n_i) = \bigcap_{1 \leq j \leq k, j \neq i} \{p : |p - n_i| \leq |p - n_j|\}.$$

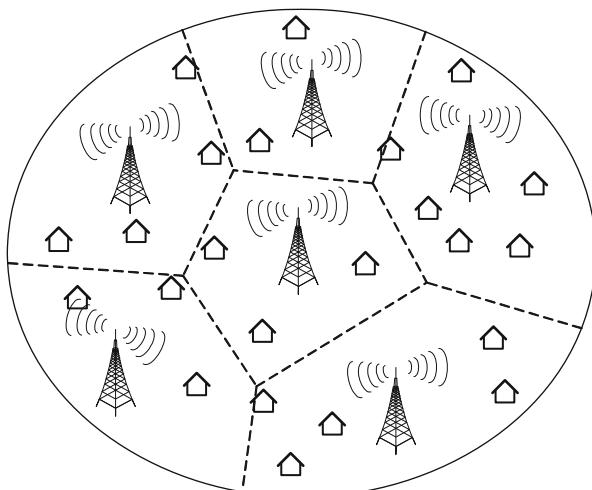

Fig. 26 An example of coverage for data broadcast

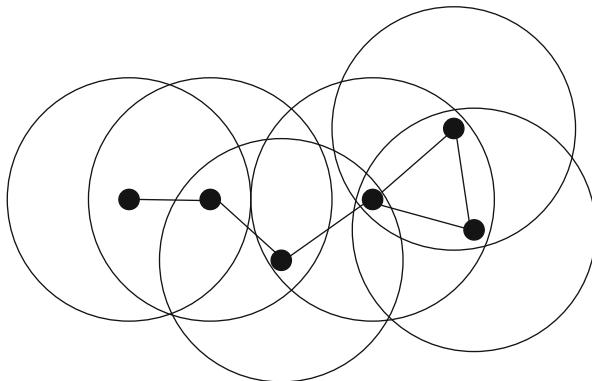

Fig. 27 Unit disk graph model for wireless network

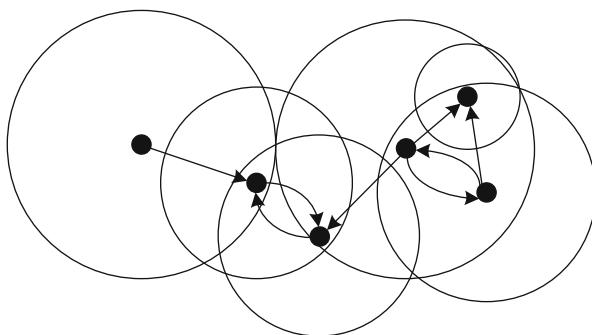

Fig. 28 Disk graph model for wireless network

It means that each BS n_i only charges for its domain $V(n_i)$. Such graph is named as Voronoi graph (VG). An easy example can be seen from Fig. 26, in which the dashed lines represent the boundary of covered area $V(n_i)$ for each n_i in this case.

The problems of coverage optimization are usually defined according to the above given factors. They can be reduced as a minimization-optimization problem with a coverage constraint and some cost constraint together. The next subsection will discuss the classification and reduction of coverage problem.

6.2 Classification and Reduction

There are two types of coverage problems. If not considering the data transmission among nodes, the object of coverage optimization is as follows:

1. Cover the whole area A using the minimum cost (defined as *region coverage*).
2. Cover the target set T using minimum cost (defined as *target coverage*).

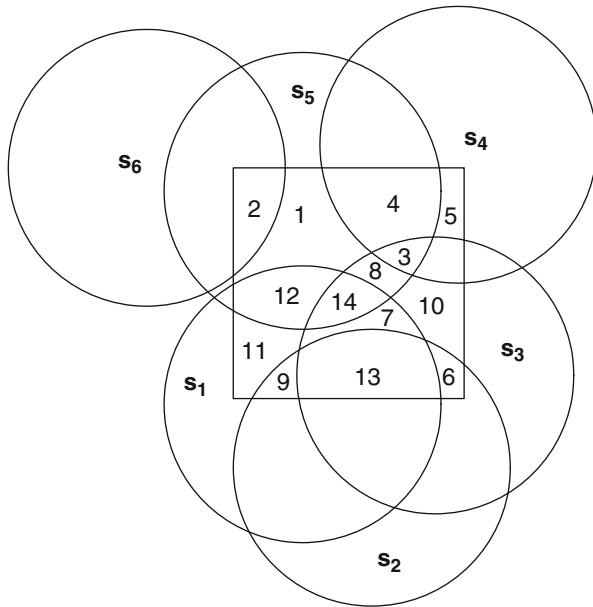

Fig. 29 An example to reduce region coverage to target coverage

Here the cost can be defined as a customized function, according to different requirements in different scenarios.

The region coverage problem can be simply converted to the target coverage problem in UDG or DG [72]. [Figure 29](#) is an example to illustrate this reduction. The square in [Fig. 29](#) is the potential region for broadcasting. For each point in this area, let A denote the set of nodes that can cover this point. Partition the area into different parts, each with different node coverage sets. As a consequence, area coverage problem can be reduced to target coverage problem when considering each part as a target. This problem can further reduced to a set cover problem. Consider each small division as a target mark it with a number from 1 to 14, and then insert covered targets into each set of sensors. Say, $S_1 = \{7, 9, 11, 12, 13, 14\}$, $S_2 = \{6, 9, 13\}$, $S_3 = \{3, 6, 7, 8, 10, 13, 14\}$, $S_4 = \{3, 4, 5\}$, $S_5 = \{2, 1, 3, 4, 8, 12, 14\}$, and $S_6 = \{2\}$. The coverage problem can be reduced to the problem of finding a minimum set cover from S_i to cover $T = \{1, \dots, 14\}$.

In VG, target coverage is widely studied, since due to the definition of Voronoi division, area A has already been divided into different parts, and each part is dominated by some node.

If further considering the data transmission among nodes, then the coverage problems are more complicated. It will either involve the traditional broadcast tree optimization, or deal with selecting a subset of broadcasting sources to reduce the

energy consumption and latency cost. Moreover, based on different requirements from real world applications, there are additional constraints or benefits for coverage optimizations, for example the multilingual message broadcast service, the TV data streaming requirements, the multichannel data broadcast, and the multi-input multi-output (MIMO) antenna technologies. The following subsections will introduce specific coverage optimization problems according to various system models and various client requirements.

6.3 Cell Broadcasting Scheme to Support Multilingual Service

This subsection will describe a coverage problem for cell broadcast to support multi-lingual service [75]. It solves a coverage problem named EEML-CB, which is described as follows:

Definition 9 The *energy-efficient multilingual cell broadcasting (EEML-CB) problem* can be described as

Given: $\mathbf{C} = \{c_1, \dots, c_n\}$ as client set, $\mathbf{BS} = bs_1, \dots, bs_m$ as set of broadcast stations, $\mathbf{H} = \{h_1, \dots, h_n\}$ as the index of the BS communicating with c_i , $\mathbf{L} = \{l_1, \dots, l_k\}$ as language set, $\mathbf{CL} = \{cl_i^q\}$ as client acceptable language set, \mathbf{W} as language weight set, R_{\max} as the maximum broadcasting radius, and A as target area. For each bs_j , assign an efficient strategy S_j , containing several couples as $\langle l_q, r_q^j \rangle$, which means that bs_j should broadcast language l_q with distance r_q^j .

Find: A minimum energy consumption strategy $\mathbf{S} = \{s_j\}, (0 \leq j \leq m)$ for every BS, such that each client c_i can receive at least one copy of the required messages with its acceptable languages.

In short, this topic deals with a target coverage problem for each BS specifically. Within $V(n_i)$ for each node, there locates a group of customers with different language requirements. Sending messages in different language will result different weights. And the object of this topic is trying to assign a minimum energy-cost schedule for the BS, such that all the clients within its domain can receive as least one copy of message in its acceptable language set.

The authors first proved that EEML-CB is a NP-hard problem, by reducing it to an instance of set cover problem, and then provide the inter linear programming (ILP) as follows:

$$\begin{aligned} \min & \sum_{j=1}^m \sum_{q=1}^k E_j^q \\ \text{s.t. } & \sum_{q=1}^k x_i^q \geq 1 && \forall c_i; \\ & x_i^q \leq cl_i^q && \forall c_i, l_q; \\ & A \cdot (d_i^{h_i})^2 \cdot w_q \cdot x_i^q \leq E_{h_i}^q, && \forall c_i, l_q; \\ & d_i^{h_i} \cdot x_i^q \leq r_{h_i}^q, && \forall c_i, l_q. \end{aligned}$$

Algorithm 12 Smart multi-lingual cell broadcasting (SMCB)**Input:** $C, BS, H, L, CL, W, r_{\max}$ and A .**Output:** S and E .

- 1: For each bs_j , select its client set C_j .
- 2: Find the farthest client $c_i \in C_j$ with its least weight language l_q . Assign $r_j^q = d_i^j$. Mark this client.
- 3: Mark clients whose acceptable language set includes l_q .
- 4: Repeat steps 2–3 until no client left unmarked in C_j .

The objective of this ILP model is to minimize the total energy consumption for a BS. The first two constraints guarantee that each client receives at least one language from its accepted language set. The third constraint calculates the energy consumption for each language, while the last one guarantees that for each given language, the energy is large enough for the BS to cover all target clients.

The ILP is acceptable in small-scale networks. However, when network size grows, the time consumption of ILP grows exponentially. Therefore, the authors designed another greedy algorithm shown as follows:

The main idea of this algorithm is to find the farthest client for a BS, broadcast with its least weight acceptable language l_q , and then remove all clients accepting l_q . Repeat this greedy step until no client is left without getting a copy of the content.

Finally, they evaluated the performance of their designs by numerical experiments. The ILP was solved by CPLEX 7.0 for small-scale network, while the greedy algorithm was tested by simulation for large-scale network, with 5 base stations, 100,000 clients, and 50 languages. The results proved the efficient of their design. Their heuristic saves more than 50 % of the energy consumed by traditional broadcasting scheme without any optimizations.

6.4 Coverage Prediction and Optimization for Digital Broadcast

Digital terrestrial broadcasting services (e.g., DVB-T and DAB) are proving a big success in Europe, as improved service quality, low setup costs, and increased content offered by the broadcasters attract more viewers and listeners to these new platforms. In order to reach their target subscriber levels, digital operators not only face the challenge of making their content attractive but also need to know more accurately the quality of terrestrial coverage they can provide to their potential customers. DVB/DAB requires higher prediction accuracy than traditional analogue networks because digital services are planned with tighter margins on the signal strength and interference. This subsection will introduce new prediction models that offer higher accuracy and which can be used to optimize digital broadcasting networks [12].

Accordingly, broadcasters for DVB/DAB services need optimize their new digital networks to provide the following:

- Accurate modeling of the impact of new digital services on analogue availability.
- Prediction of the coverage that can be provided by a new digital network.

- Selection of channels to best accommodate digital services.
- Creation of efficient and effective networks to achieve migration from analogue.
- Optimization of digital networks to maximize the number of customers.

To meet these requirements, the authors provided a high-accuracy coverage prediction models to estimate the maximum coverage of their service, and optimize the following parameters for their network to deliver the best possible coverage.

- Selection of site locations.
- Antenna heights.
- Antenna types and orientations.
- Channel selection.

This model can provide higher accuracy than traditional semiempirical models, yet can be computed in a reasonable timescale with a lower requirement on data accuracy than full 3D deterministic solvers. It relies on three important elements:

1. *High-resolution data*, representing the locations and heights of terrain and buildings in built-up areas, and medium-resolution data for more open, rural areas. They are usually collected by *stereo aerial photography*, *laser interferometry*, or *satellite collection*. The authors for this model require only a raster of terrain heights, avoiding the need to process the data into a vector form that represents the full geometry of the buildings.
2. *Propagation prediction algorithms*, to account for the improved data. The main mechanism for predicting the attenuation of signals across obstructions such as buildings and hills is multiple diffraction. The authors use *slope diffraction* to produce solutions that are as accurate as much more complex techniques in short run times. If radio wave propagation occurs over a clearly defined path (the great-circle path) between the transmitter and receiver, then it is necessary to account for the finite width of buildings and the possibility of off-path propagation around building edges.
3. *Optimized model*, to be implemented efficiently in order to make the most of available computing resources. It also includes (a) the extraction of suitable path profiles to suit the requirements of the model (b) post processing of the prediction results to include the effects of antenna radiation patterns, and (c) computation of the availability, based on the relevant planning margins.

The authors also provided example predictions on behalf of a digital broadcaster. The measurements covered a large area consisting of 6 km^2 , served by a transmitter approximately 30 km away. Field-strength measurements on four channels were made at a height of 10 m using a vehicle equipped with a pump-up mast. An average of 20 measurements per square kilometer were made, resulting in a total set of 468 measurements. In order to assist with the prediction process, the authors have also developed a unique automated network planning and optimization service, known as *SmartPlan*, and have used it successfully in real networks. Their results prove that this model has consistently performed well and has proved to be very effective in (a) reducing the standard deviation of the prediction error, and (b) significantly increasing the hit rate. It has already been used in real situations, either to address optimization issues in existing networks or to choose the optimum parameters for a new network.

6.5 Data Delivery Optimization in Multi-system Heterogeneous Overlayed Wireless Network

This subsection will employ data broadcast on multisystem heterogeneous overlayed wireless networks, due to the development of 4G networks [30]. The authors provided detailed two-step construction for data broadcast system and proved the efficiency of their algorithms by simulations. The system model can be described as follows:

Consider a multisystem heterogeneous overlayed network $N = \{N_1, N_2, \dots, N_{|N|}\}$ consisting of $|N|$ subnetworks, and suppose these subnetworks are ordered by the sizes of their coverage areas in ascending order. Each N_i allocates C_i channels to provide the data broadcast service, and the bandwidth of each channel is B_i . The data program contains $D = \{D_1, D_2, \dots, D_{|D|}\}$ data items. Each D_i has data size s_i and access probability p_i . For instance, Fig. 30a is a general system model of multisystem heterogeneous overlayed networks, while Fig. 30b is a practical example with regional-area subnetwork, metropolitan-area subnetwork, and campus-area subnetwork.

According to the phenomenon that wireless networks with larger coverage areas are usually of higher connection fee and of lower bandwidth than those with smaller coverage areas, the authors want to build a communication system with lowest cost such that all the subscribers can receive the required messages with minimum access time within the corresponding coverage area.

The main idea for data broadcast system in this type of wireless network is as follows: they divided broadcast data program into several subsets D_{cut_i} for subnetwork N_i , such that the largest service area will broadcast the whole data set, while other subnetworks will be viewed as supplements to reduce the minimum overall access time. Each subnetwork will only broadcast a subset of D correspondingly. As a consequence, the problem of broadcast program generation on heterogeneous overlayed wireless networks can be formulated as follows:

Definition 10 (Data broadcast in multi-coverage network) Given a multisystem heterogeneous wireless network $N = \{N_1, N_2, \dots, N_{|N|}\}$, the number of allocated channels C_i in each subnetwork N_i , the number of data items, and the access probabilities and sizes of all data items, for each subnetwork N_i , determine:

1. Which data items will be broadcast in subnetwork N_i (i.e., a proper cutting configuration).
2. How these data items are broadcast in subnetwork N_i (i.e., one proper broadcast program for each subnetwork),

such that the overall average access time for subscribers within the service area will be minimized.

To solve this problem, the authors firstly designed an algorithm named *bruteforce* to enumerate and select the best cutting configuration and the corresponding broadcast programs for all subnetworks. When evaluating one cutting configuration, they generate one broadcast program for each subnetwork by executing algorithm

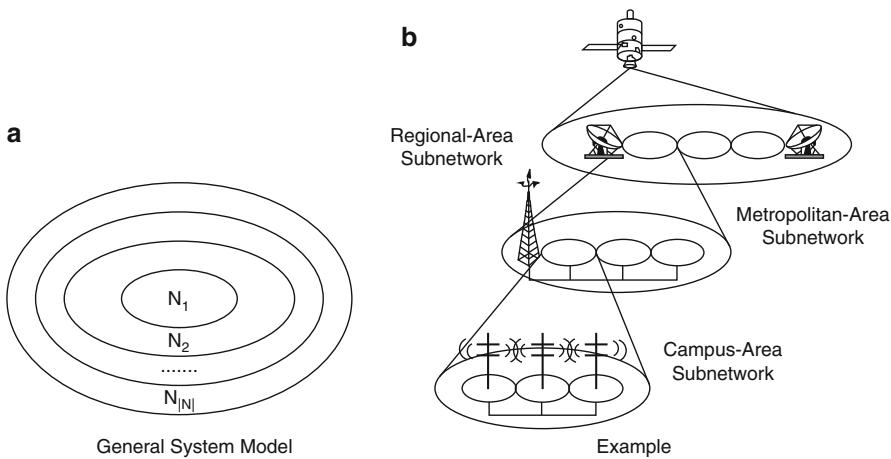

Fig. 30 Multisystem heterogeneous wireless networks

BPG-Single (a single-system network algorithm for data allocation) once so that the average access time of the subnetwork is minimized. Due to the high time complexity of this exhausted search, they next provided a heuristic algorithm named *layeredcutting* to determine a suboptimal cutting configuration and the corresponding broadcast programs for all subnetworks.

Layeredcutting is a two-phase algorithm consisting of inter-network data allocation phase and intra-network data allocation phase. The objective of inter-network data allocation phase is to determine a proper cutting configuration so that the overall average access time of the whole multisystem network is minimized. Then, in intra-network data allocation phase, layeredcutting will generate one broadcast program for each subnetwork according to the resultant cutting configuration. It is an iterative algorithm which merges several subnetworks and determines the value of one cutting point in each iteration. The threshold is the probability estimation of each subnetwork for each data item.

In each iteration, inter-network-data-allocation uses a divide-and-conquer procedure named *test-and-prune* to determine cut_i , and then returns all cut_i group, while intra-network-data-allocation applies execute algorithm BPG-Single on subnetwork N_j and returns broadcast programs of all subnetworks, which become the final broadcast program.

The authors proved that the time complexity of layered-cutting is $O(|N| \times (\log |D| + O(\text{BPG}_{\text{Single}})))$. They also illustrated their heuristics by simulation with 1,000 data items, following a Zipf distribution with parameter θ . There are $|N|$ subnetworks, and the rate between the sizes of the service areas of subnetwork N_i and subnetwork N_{i+1} is equal to 0.8. Finally, according to their simulation results, algorithm layered-cutting is able to efficiently generate broadcast programs of high quality for a multisystem heterogeneous overlayed wireless network and cover the whole service area.

6.6 Summary

To summarize, this section describes the coverage optimization for data broadcast in wireless communications. Coverage problems are introduced in different types of networks like wireless ZigBee networks, wireless/mobile ad hoc networks, cellular networks, and heterogeneous overlayed wireless networks. Firstly, the formal definition of coverage optimization is presented, including the prerequisite factors, the classification, relation among various types of coverage problems, and many possible variants. The researches of coverage optimization belong to wireless networking field. These problems can be reduced to some known NP problem and cannot be easily solved in polynomial time unless $P = NP$. Next, several coverage problems are discussed in details, including the problem formulation, the construction of approximation or heuristic algorithms, and the performance of the solutions.

Future study of coverage optimization could get benefit from the latest technologies, especially the new ideas and technologies in the 4G wireless networks. Moreover, researchers can combine knowledge from different disciplines and think about the requirements from the server side and client side wisely. Even for the same number of BS's with the same capacity, different clients/service providers may have different requirements about the coverage issues. Clients always want to receive their requests quickly and correctly, while servers always hope to provide a reliable and efficient service. Therefore, the coverage problem is always a critical issue for data broadcast system, which makes coverage optimization an active and interesting research topic in both theoretical and practical fields.

7 Conclusion

This chapter discusses various optimization problems in all aspects of data broadcasting. Scheduling is a big topic in data broadcast. In order to reduce response time, push-based broadcast systems need optimized off-line data scheduling (or allocation) algorithms to organize broadcast programs; on-demand broadcast systems need optimized and efficient online scheduling algorithms to decide broadcast contents in real time, while clients may also need scheduling algorithms to decide the downloading sequence of multiple data items. Energy optimization in wireless data broadcast systems relies on good index schemes. Index design should be customized based on different features of broadcast data. Coverage optimization is also an important research area of data broadcast.

Within this big picture, it also introduces different techniques during algorithm design to handle different features of data, communication environment, and user type. For example, data can be homogeneous or heterogeneous; broadcast can be on single channel or on multiple channels; request can be for single data item or multiple data items; and clients may have deadlines on responses to their requests.

Data broadcasting is a mature topic with a new life. Existing research works on data broadcast establish a solid foundation for further research in this area.

On the other hand, with the fast development of mobile communication techniques, new problems are keeping emerging waiting to be solved by future researchers. Hope this chapter can be a good guide for them to better understand the area and an inspiration for new questions and research topics.

Abstract

This chapter introduces and elaborates four major issues in online social networks. First, it describes the problem of maximizing the spread of influence in social networks and the problem of computing the spread. It shows that the problem of maximizing influence is NP-hard and the problem of computing the spread is #P-hard. It also presents a number of algorithms for finding approximations to the problem of influence maximization. Second, it describes the problem of detecting network communities and presents a few heuristic algorithms. In particular, it introduces and elaborates a new algorithm that uses random walkers to find communities effectively and efficiently. Third, it discusses how to collect data from online social networks and it presents the recent work on data collection. Forth, it discusses how to measure influence (friendship) in online social networks and elaborates the recent results on the location-based three-layer friendship modeling.

1 Introduction

Influence maximization (IM) is a combinatorial optimization problem in social sciences with important applications. Kempe et al. [20] formulated and studied IM as a discrete optimization problem and subsequently published additional results in [21]. Since then, a number of researchers have investigated the problem from different angles, including Kumura and Saito [23], Leskovec et al. [26], Narayanan and Narahari [32], and Chen et al. [6–8].

Domingos and Richardson [10] and Richardson and Domingos [38] were among the first to study the social influence problem from the algorithmic standpoint in connection to viral marketing. Suppose a company wants to promote a new product to a large group of people. To do so, the company plans to offer free samples to a small group of selected individuals who are more influential than the others, with the hope that these key individuals will help spread the information of the product to the largest number of individuals through their influence. How to find such key individuals motivated the study of the problem of influence maximization, which finds a small set of most influential individuals.

Social networking in the cyber space has become increasingly popular in recent years. Online social networks (OSNs), such as Facebook and MySpace, provide

a convenient platform for users to interact with each other through the Internet. Studying IM in the setting of OSNs may help reveal how social activities would take place in the electronic world. On the other hand, conducting research on OSNs has an added advantage: it is easier to collect data from OSNs than physical social networks. For example, one could either develop a crawler to collect information by crawling through the targeted OSN [11, 12] or simply use data dumps or the Application Programming Interface provided by the service provider. This chapter is focused on OSNs, but some of the results may also apply to general social networks.

To measure influence of one individual to another, an immediate solution is to determine how close the relationship would be between them. In OSNs, a user can declare other users as friends, even though they may not know each other personally. This chapter follows the notion of online friendships. Thus, one way to measure how influential an individual would be is to determine how many friends they have. The individual with the largest number of friends may be considered as the most influential individual. On the other hand, this individual may not have the most influence on a specific friend. For example, Alice is considered as the most influential individual because she has the largest number of friends, including Bob. But Bob is only a casual friend of Alice. Bob, on the other hand, has a close long-time friend Christie whom he trusts. Thus, Christie would be more influential to Bob than Alice. Simply going through the data collected from OSNs, however, it is difficult to differentiate such level of friendships, and so most studies still rely on the loose concept of online friendships adopted by OSNs.

Related to the problem of influence maximization is the problem of finding network communities. A network community is a collection of nodes within which connections are dense, while connections between communities are sparse. Finding communities in online social networks, biological networks, metabolic networks, and other large-scale networks has important applications, and it has been studied intensively and extensively in computer science, mathematics, biology, and other disciplines. Intuitively, network communities are formed as a subset of nodes with similar characteristics. In an OSN, a community may form from users with similar hobbies or interests. For example, users who like classical music may form a community; users who are interested in iPhone, iPad, and other Apple products may form another community. If a company wants to advertise a new product to as many people as possible effectively and efficiently, it would naturally want to choose communities with a keen interest in similar products. This chapter describes a number of heuristic algorithms for finding network communities, including a new algorithm that uses random walkers to search for communities. This algorithm was recently devised by Li et al. [28], which has only been reported in a technical report.

Studying how users are connected through OSNs would help to measure influence of OSN users. Intuitively, people sharing mutual interests, being geographically close to each other, or belonging to the same social communities are more likely to become friends. This chapter elaborates multilayer metrics recently devised by Li and Chen [27] to quantitatively model these intuitive friendships.

Social networks are often modeled as a weighted directed graph $G(V, E)$, where nodes represent individuals and edges represent relationships and interactions between individuals. To study social influence, each edge $u \rightarrow v$ is associated with a weight $p(u, v) \in [0, 1]$ that quantifies the level of influence on v by u . Such graphs are referred to as *influence graphs*. Node v is said to be node u 's neighbor if $u \rightarrow v \in E$.

Influence maximization seeks a small set of nodes that will influence the maximum number of nodes in the given influence graph. Kempe et al. [20] introduced two stochastic cascade models, also known as diffusion models, for studying the problem of influence maximization. They are *independent cascade* (IC) and *linear threshold* (LT), where each node in the graph is either active or inactive. Initially, both models specify an initial set of active nodes, referred to as *seed set*, while the rest of the nodes are inactive. Once a node is made active, meaning that it has been successfully influenced by its active neighbors, it will remain active throughout the entire process. The process of both models proceeds at discrete steps. Discrete steps are also referred to as rounds or iterations.

In the IC model, each active node u is only given one chance to activate each of its currently inactive neighbor v with the success probability $p(u, v)$, where $u \rightarrow v \in E$. This formulation is motivated by Goldenberg et al.'s work on viral marketing [16, 17]. If v has multiple active neighbors, their attempts to activate v are sequenced in an arbitrary order. In particular, if u is newly activated in round i , $u \rightarrow v \in E$, v is inactive, and u is given a chance to activate v in round $i + 1$, then v is activated by u with probability $p(u, v)$. If u succeeds, then v becomes active at time $i + 1$. If u fails to activate v , then u cannot activate v in subsequent rounds. The process continues until no more activations are possible.

In the LT model, each node $v \in V$ satisfies the following inequality:

$$\sum_{u \rightarrow v \in E} p(u, v) \leq 1.$$

At the beginning, each node v chooses a threshold value $\lambda_v \in [0, 1]$ uniformly and independently at random. An inactive node v becomes *active* in round i if

$$\sum_{\substack{u \rightarrow v \\ u \text{ is active}}} p(u, v) \geq \lambda_v.$$

The process continues until no more activations are possible. As noted by Kempe et al. [20], selecting thresholds at random is the only reasonable choice when the exact influence to v from its neighbors is unknown from the given data set.

This chapter is organized as follows. Section 2 defines the IM problem, shows that it is NP-hard for the independent cascade and linear threshold models, shows that the influence spread of an initial seed set is #P-hard for both models, and provides algorithms to approximate the IM problem. It also introduces other influence models. Section 3 introduces a number of heuristic algorithms for finding network communities. Section 4 describes how to collect data from online social networks. Section 5 discusses how to determine friendships. Section 6 concludes the chapter.

2 Influence Spread

Let S be an initial set of active nodes in G and $I_G(S)$ the expected number of active nodes at the end of the process in an influence model (IC or LT). Function I_G is referred to as the *influence function* of S and the value of $I_G(S)$ the *influence spread* of S , or simply *spread*.

2.1 Formulation

The *influence maximization* problem can be formulated as follows:

Influence maximization (IM)

Input: An influence graph $G(V, E)$ and a positive integer k .

Output: An initial seed set S of k nodes such that $I_G(S)$ is maximized for all k -node initial seed set.

The decision version of IM is defined below:

Decisional influence maximization (DIM)

Input: An influence graph $G(V, E)$ and positive integers k and N .

Question: Does there exist an initial seed set S of k nodes such that $I_G(S) \geq N$?

It is straightforward to see that if IM is polynomial-time computable, then so is DIM. But DIM is NP-complete for both the IC and LT models. Thus, IM is NP-hard on both models.

Counting how many k -node seed sets S that will maximize $I_G(S)$ is at least as hard as solving IM. Moreover, even computing the value of $I_G(S)$ for a fixed seed set S is #P-hard for both the IC and LT models.

Given a seed set S , computing the exact value of $I_G(S)$ is referred to as the *influence spread computation (ISC)* problem, formulated as follows:

Influence spread computation (ISC)

Input: An influence graph $G(V, E)$ and a seed set $S \subseteq V$.

Output: $I_G(S)$.

2.2 NP-completeness

The following results were obtained by Kempe et al. [20].

Theorem 1 ([20]) *DIM is NP-complete for both of the IC model and the LT model.*

Proof First consider the IC model. The goal is to construct a polynomial-time reduction from a known NP-complete problem to DIM for the IC model. The set cover (SC) problem is a suitable NP-complete problem for this purpose. Given a collection of subsets S_1, \dots, S_n of set $U = \{u_1, \dots, u_m\}$, SC decides whether there

exist k subsets such that the union of these sets is equal to U . Without loss of generality, assume that $k < m < n$.

Given an instance of SC, construct a directed bipartite graph $(V_1, V_2; E)$ of $m + n$ nodes such that each subset S_i corresponds to a unique node $i \in V_1$ and each element v_j corresponds to a unique node $j \in V_2$, where i and j are connected by a directed edge $i \rightarrow j \in E$ with weight $p_{ij} = 1$ if $v_j \in S_i$. Because $p_{ij} = 1$, the activation of a node is deterministic. It is straightforward to see that the instance of SC is positive if and only if there is a k -node seed set $S \subseteq U_1$ such that $I_G(S) \geq m + k$.

Thus, SC is polynomial-time reducible to DIM.

Now consider the LT model. The goal is to construct a polynomial-time reduction from a known NP-complete problem to DIM for the LT mode. The vertex cover (VC) problem is a suitable NP-complete problem for this purpose. Given an n -node undirected graph G and an integer k , VC decides whether there is a k -node set C such that every edge has at least one endpoint in C . Converting G to a directed graph by directing every edge in G to both directions and setting $p(u, v) = 1$ for every edge $u \rightarrow v$, it is straightforward to see that there exists a k -node set C to cover G if and only if $I_G(A) = n$. Thus, VC is polynomial-time reducible to DIM. This completes the proof. \square

2.3 #P-Hardness

The following result was obtained by Chen et al. [7].

Theorem 2 ([7]) *ISC for the IC model is #P-hard.*

Proof It suffices to show that if ISC is solvable in polynomial time for the IC model, then so is a known #P-complete problem. The two-terminal-network-reliability problem is an appropriate problem, which was shown to be #P-complete by Valiant [40]. This will establish that ISC is #P-hard.

The two-terminal-network-reliability problem is to count, on a given directed graph $G = (V, E)$ and two nodes $\{s, t\} \subseteq V$, the number of subgraphs in which there is a path from s to t . This is equivalent to computing the probability that there is a path from s to t under the condition that each edge in E has an independent probability of 1/2 to be selected and an independent probability of 1/2 to be discarded. Let $S = \{s\}$ and $p(e) = 1/2$ for all $e \in E$. Compute $I_1 = I_G(S)$. Next, add a new node $t' \notin G$ and a directed edge $t \rightarrow t'$ to obtain a new graph $G' = (V \cup \{t'\}, E \cup \{t \rightarrow t'\})$. Let $p(t, t') = 1$. Compute $I_2 = I_{G'}(S)$. By assumption, both I_1 and I_2 are polynomial-time computable and so is $I_2 - I_1$. Let $p(S, v, G)$ denote the probability that node v is influenced by the seed set S in G . Since t influences t' deterministically, it is straightforward to see that $I_2 = I_G(S) + p(S, t, G)$. Therefore, $p(S, t, G) = I_2 - I_1$ is the probability that s is connected to t , and it is polynomial-time computable. This completes the proof. \square

To show that ISC for the LT model is also #P-hard, it helps to consider the distribution over sets reachable from S via certain types of edges. Recall that in the LT model, each node v receives an influence weight $p(u, v) \geq 0$ from node u for $u \rightarrow v \in E$. Suppose that v selects at most one such incoming edge at random with probability $p(u, v)$ and selects no edges with probability $1 - \sum_u p(u, v)$. The selected edge $u \rightarrow v$ in this way is referred to as a *live* edge and the other edges as *blocked* edges. It can be shown that the distribution over active sets (i.e., sets of active nodes) by running the LT process starting from S is equivalent to the distribution over sets of nodes reachable from S via live-edge paths. A live-edge path is a path where all edges on the path are live edges.

To motivate the proof idea, consider a simple case that G is an acyclic graph. In an acyclic graph, nodes can be listed in a fixed topological ordering: v_1, v_2, \dots, v_n , such that all edges are from nodes of smaller indexes to nodes of larger indexes. It suffices to look at the distribution over active sets following this order. For each node v_i , suppose that the distribution over active subsets of its neighbors is already determined. Following the LT process, the probability that v_i will become active, given that a subset S_i of its neighbors is active, is equal to

$$\sum_{u \rightarrow v_i \in E} p(u, v_i).$$

This is the probability that the live incoming edge selected by v_i lies in S_i , and so it is straightforward to show that the two processes produce the same distribution over active sets by a simple induction on nodes in this order. For general graphs G , however, such an ordering of the nodes may not exist. Instead, an induction will be carried out over the number of rounds of the LT process. The following lemma was shown by Kempe et al. [20].

Lemma 1 ([20]) *For a given initial seed set S in an influence graph G , the distribution over active sets from S under the LT process is the same as that over sets reachable from S via live-edge paths.*

Proof Let S_i be the set of active nodes at the end of round i under LT process ($i = 0, 1, 2, \dots$), where $S_0 = S$. If node v has not become active by the end of round i , then the probability that it becomes active at round $i + 1$ equals the probability that the total influence from $S_i - S_{i-1}$ exceeds the threshold, given that its threshold was not exceeded already. This probability is

$$P_{u,v} = \frac{\sum_{u \in S_i - S_{i-1} \text{ & } u \rightarrow v \in E} p(u, v)}{1 - \sum_{u \in S_{i-1} \text{ & } u \rightarrow v \in E} p(u, v)}.$$

The following procedure can be used to identify reachable sets from the initial seed set S : Starting from the set S , for each node v with at least one edge $u \rightarrow v \in E$ and $u \in S$, if one of these edges becomes live, then v is reachable from S , resulting

in a new set S'_1 of reachable nodes from S . Repeat the same procedure recursively on edges from S'_1 to obtain a new reachable set S'_2 , from S'_2 obtain S'_3 . If node v is not yet reachable by the end of round i , then the probability that it will become reachable in round $i + 1$ is equal to the probability that its live edge comes from $S_i - S_{i-1}$, given that its live edge has not come from any of the earlier sets, which is equal to $\sum_{u \in S_i - S_{i-1} \text{ & } u \rightarrow v \in E} p(u, v) / (1 - \sum_{u \in S_{i-1} \text{ & } u \rightarrow v \in E} p(u, v))$. This is the same as $P_{u,v}$. Thus, a straightforward induction over LT rounds can establish that the live-edge process produces the same distribution over active sets by the LT process. This completes the proof. \square

The following result was obtained by Chen et al. [8].

Theorem 3 ([8]) *ISC for the LT model is #P-hard.*

Proof It suffices to show that if $I_G(S)$ is polynomial-time computable, then so is the problem of counting simple paths (CSP) in a directed graph. CSP is to count, given a directed graph $G = (V, E)$, the total number of simple paths in G , which was shown to be #P-complete by Valiant [40].

Given an influence graph G , construct a new influence graph $G' = (V', E')$ by adding a new node $s \notin G$ and connecting s to all the nodes in V . That is, the node s is a source node. Let d be the maximum in-degree of any node in G' . Assign a weight of $p(e) = w \leq 1/d$ to each edge $e \in E'$, where w is a constant, and it will be determined later. Clearly, for any node $v \in V'$,

$$\sum_{u \rightarrow v \in E'} p(u, v) \leq 1,$$

and so the weight requirement of the LT model is satisfied. Let the initial seed set be $S = \{s\}$. By assumption, $I_{G'}(S)$ is polynomial-time computable.

Let \mathcal{P} denote the set of all simple paths starting from $s \in G'$. It follows from Lemma 1 that

$$I_{G'}(S) = \sum_{\pi \in \mathcal{P}} \prod_{e \in \pi} p(e).$$

Let B_i be the set of simple paths of length i in \mathcal{P} , for $i = 0, 1, \dots, n$, and let $b_i = |B_i|$. Then

$$I_{G'}(S) = \sum_{i=0}^n \sum_{\pi \in B_i} \prod_{e \in \pi} p(e) = \sum_{i=0}^n \sum_{\pi \in B_i} w^i = \sum_{i=0}^n w^i b_i.$$

With the above equation, set w to $n + 1$ different values w_0, w_1, \dots, w_n , where $n = |V|$. For each value w_i , by assumption, $I_{G'}(S)$ is polynomial-time computable. Note that this process produces a set of $n + 1$ linear equations with b_0, \dots, b_n variables. The coefficient matrix M of these equations is a Vandermonde matrix

with $M_{ij} = w_i^j$ for $i, j = 0, \dots, n$. The system of these equations therefore has a unique solution and is easy to compute.

Finally, notice that for each $i = 1, \dots, n$, there is a one-to-one correspondence between paths in B_i and simple paths of length $i - 1$ in graph G . Therefore, $\sum_{i=1}^n b_i$ gives the answer to the total number of simple paths in graph G . This completes the proof. \square

2.4 Approximations

Approximation algorithms for the IM problem are based on the observation that the influence function I_G for both the IC and LT models is a *submodular* function.

2.4.1 Submodularity

A submodular function f is a function that maps a subset of a finite ground set U to a nonnegative real number satisfying the following inequality:

$$(\forall A \subseteq B \subseteq U)(\forall x \in U - B) : f(A \cup \{x\}) - f(A) \geq f(B \cup \{x\}) - f(B).$$

A function f is *monotone* if for all $A \subseteq B : f(B) \geq f(A)$.
Submodular greedy algorithm (SGA) [9]:

1. Given a function $f : 2^U \rightarrow R^+ \cup \{0\}$.
2. Initially set $S \leftarrow \emptyset$.
3. Repeat the following for k times:
 - Choose $u \in U - S$ such that $f(S \cup \{u\})$ is the largest among all possible u 's.
 - Set $S \leftarrow S \cup \{u\}$.
4. Return S .

The following result was shown by Nemhauser et al. [33] and is well known. Its proof is omitted.

Lemma 2 ([33]) *Let f be a monotone submodular function. Let S be a k -element set obtained from SGA. Let S^* be a set that maximizes the value of f over all k -element sets. Then $f(S) \geq (1 - 1/e)f(S^*)$. That is, S is a $(1 - 1/e)$ -approximation to S^* .*

It is straightforward to see that I_G is monotone. It can be shown that I_G is submodular for the IC model and the LT model, which implies that the algorithm stated in Lemma 2 provides a $(1 - 1/e)$ -approximation ratio to IM.

Lemma 3 ([20]) *The influence function I_G is submodular for the IC model.*

Proof Consider a point in the IC process when node u , just becoming active, attempts to activate its neighbor v with a success probability $p(u, v)$.

The outcome of this random event may be thought of as the outcome of flipping an independent coin of bias probability $p(u, v)$. Because coin flips are independent, it does not matter whether the coin was flipped at the moment when v becomes active or it was flipped at the very beginning of the whole process and is being revealed now. Thus, assume that for each edge $u \rightarrow v$ in G , a coin of bias probability $p(u, v)$ is flipped at the very beginning of the process, independently of the coins for all other edges, and the result is stored for later use in the event that u is activated and v is inactive.

Flipping coins in advance, edges in G with coin flips indicate that an activation will be successful and declared live. The remaining edges are declared blocked. Fix the outcomes of the coin flips and then initially activate a seed set S . It is clear how to determine the full set of active nodes at the end of the cascade process [20]: A node x ends up active if and only if there is a live-edge path from some node in S to x . Consider the probability space in which each sample point specifies one possible set of outcomes for all the coin flips on the edges.

Let X denote one sample point in this space. Let $I_{G,X}(S)$ denote the total number of nodes activated by the process when S is the initial seed set and X the set of outcomes of all coin flips on edges. Because X is fixed, it is straightforward to see that $I_{G,X}(S)$ can be deterministically expressed as follows. Let $R(u, X)$ denote the set of all nodes reachable from u on a live-edge path. Thus, $I_{G,X}(S)$ is the number of nodes that can be reached on live-edge paths from any node in S , and so it is equal to the cardinality of the union $\cup_{u \in S} R(u, X)$.

For each fixed outcome X , the function $I_{G,X}(S)$ is submodular. To see this, let S and T be two sets of nodes such that $S \subseteq T$, and consider the quantity $I_{G,X}(S \cup \{u\}) - I_{G,X}(S)$. This is the number of elements in $R(u, X)$ that are not already in the union $\cup_{u \in S} R(u, X)$. It is at least as large as the number of elements in $R(u, X)$ that are not in the (bigger) union $\cup_{u \in T} R(u, X)$. It follows that

$$I_{G,X}(S \cup \{u\}) - I_{G,X}(S) \geq I_{G,X}(T \cup \{u\}) - I_{G,X}(T).$$

Since the expected number of nodes activated is just the weighted average over all outcomes, it implies that

$$I_G(S) = \sum_X \text{Prob}[X] \cdot I_{G,X}(S).$$

But a nonnegative linear combination of submodular functions is also submodular, and hence I_G is submodular, which completes the proof. \square

To show that I_G is submodular for the LT model, one may try to use a similar technique of the proof of [Lemma 3](#). For example, it may be reasonable to consider the behavior of the process after all node thresholds have been chosen. Unfortunately, for a fixed choice of thresholds, the number of activated nodes may not be a submodular function of the initial seed set. Thus, a more subtle technique is needed.

Lemma 4 ([20]) *The function I_G is submodular for the LT model.*

Proof Recall that each node v has an influence weight $p(u, v)$ from its neighbor u , where $\sum_{u \rightarrow v \in E} p(u, v) \leq 1$. Without loss of generality, extend this notation by letting $p(u, v) = 0$ if u is not v 's neighbor. Suppose that v picks at most one live edge $u \rightarrow v \in E$ with probability $p(u, v)$ and declares the rest of the edges blocked with probability $1 - \sum_{u \rightarrow v \in E} p(u, v)$. It follows from Lemma 1 that the LT model is equivalent to the reachability via live-edge paths. Similar to the proof of Lemma 3, it can be shown that I_G is submodular for the LT model. This completes the proof. \square

It follows from Lemmas 2–4 that if the influence function I_G is polynomial-time computable for the IC and LT models, then SGA is polynomial-time computable and provides a $(1 - 1/e)$ -approximation ratio to IM. However, computing $I_G(S)$ is #P-hard for both the IC and LT models, and so in general, I_G is unlikely to be polynomial-time computable. (There are some exceptions. For example, Chen et al. [8] showed that for the LT model, I_G can be computed in linear time for acyclic influence graph G .) Thus, one would naturally want to obtain a good estimate of I_G , which is justified by the following extension of Lemma 2, with a straightforward modification of the same proof as in [33].

Lemma 5 ([20]) *Let f be a monotone submodular function. Let S^* be a set that maximizes the value of f over all k -element sets. Suppose that for any $\varepsilon > 0$, there is a $\gamma > 0$ such that S is a k -element set obtained from SGA based on a g that is a $(1 + \gamma)$ -approximation to f . Then $g(S) \geq (1 - 1/e - \varepsilon)f(S^*)$. That is, S is a $(1 - 1/e - \varepsilon)$ -approximation to S^* .*

Kempe et al. [20] used Monte-Carlo simulations to obtain a close estimate of, on a given seed set S , the influence spread $I_G(S)$ with a large number of runs, resulting in high time complexity.

How to obtain a good estimate of $I_G(S)$ efficiently remains a challenge. Instead of finding close approximations to $I_G(S)$, researchers have devised new algorithms without needing to evaluate $I_G(S)$ (e.g., see [6–8, 26]). Research in this line typically follows two directions: (1) improving the time complexity of submodular greedy algorithm and (2) devising heuristics.

Presented below is an example of improving the time complexity of SGA. Note that each edge $u \rightarrow v$ in an influence graph $G = (V, E)$ is determined once whether it is activated with probability $p(u, v)$. Let G' be an induced subgraph of G as follows: Determine, for each $u \rightarrow v$ in the graph, whether it is selected and remove all edges that are not selected from G . Let $R_{G'}(S)$ denote the set of nodes reachable from S in G' . Performing a linear traverse of G' , depth first or breadth first, one can obtain $R_{G'}(S)$ and $|R_{G'}(\{u\})|$ for all $u \in V$.

The following greedy algorithm was devised by Chen et al. [6].

NewGreedyIC(G, k)

1. Set $S \leftarrow \emptyset$ and r a positive integer (e.g., $r = 20,000$)
2. Repeat the following steps for k times
3. Set $s_u \leftarrow 0$ for all $u \in V - S$
4. Repeat the following steps for r times
5. Construct G' by removing each edge $u \rightarrow v$ from G with probability $1 - p(u, v)$
6. Compute $R_{G'}(S)$
7. For each $u \in V - S$:
8. If $u \notin R_{G'}(S)$ then set $s_u \leftarrow s_u + |R_{G'}(S)|$
9. Set $s_u \leftarrow s_u/r$ for all $u \in V - S$
10. Set $s \leftarrow \arg \max_{u \in V - S} \{s_u\}$
11. Set $S \leftarrow S \cup \{s\}$
12. Output S

It is straightforward to see that *NewGreedyIC*(G, k) runs in $O(kr|E|)$ time. Simulation results [6] confirm that *NewGreedyIC*(G, k) produces an initial seed set S with an influence spread that is very close to what is produced by SGA, but is much more efficient.

For an example of heuristics, consider a simple degree discount for the IC model. According to the experimental results obtained by Kempe et al. [20], selecting nodes with maximum outgoing degrees as seeds could lead to larger influence spread than other previously known heuristics but still smaller than that of SGA. Chen et al. [6] presented a *degree discount heuristics* for the IC model based on this observation, but they discounted an edge from the degree. In particular, suppose that $u \rightarrow v \in E$ and u has been activated as a seed. To consider whether v should be included as a seed by looking at its degree, the edge $v \rightarrow u$ will not be counted in the degree. Simulations show the degree discount heuristics, when properly tuned, can achieve almost the same influence spread as SGA in significantly shorter time.

2.5 Other Influence Models

In addition to the IC and LT influence models, other influence models have also been proposed, including weighted cascade (WC) [20], maximum influence arborescence (MIA) [7], and local directed acyclic graph influence (LDAGI) [8]. The WC and MIA models are related to the IC model, while the LDAGI model is related to the LT model.

In the WC model, if u is activated in round i and $u \rightarrow v \in E$, then v is activated by u in round $i + 1$ with probability $1/d_v$, where d_v is the degree of node v . Similar to the IC model, each neighbor of v may activate v independently. Thus, if an inactive node v has m neighbors activated in or before the round i , the probability that v is activated in round $i + 1$ is $1 - (1 - 1/d_v)^m$.

In the MIA model, the calculation of the influence from one node to another node depends on the *maximum influence path* (MIP). In particular, given an influence graph $G = (V, E)$ and two nodes u and v , let $P_G(u, v)$ denote the set of all paths from u to v in G . Let $P = \langle u = u_1, u_2, \dots, u_m = v \rangle$ be a path from u to v . Define the propagation probability of P , denoted by $\text{pp}(P)$, as follows:

$$\text{pp}(P) = \prod_{i=1}^{m-1} p(u_i, u_{i+1}).$$

Let $\text{MIP}_G(u, v)$ denote the path from u to v with the largest propagation probability. That is,

$$\text{MIP}_G(u, v) = \arg \max_{P \in P_G(u, v)} \{\text{pp}(P)\}.$$

Given an influence threshold λ , define the *maximum influence in-arborescence* of node u , denoted by $\text{MIIA}(u, \lambda)$, as follows:

$$\text{MIIA}(u, \lambda) = \cup_{u \in V, \text{pp}(\text{MIP}_G(u, v)) \geq \lambda} \text{MIP}_G(u, v).$$

The *maximum influence out-arborescence* of u , denoted by $\text{MIOA}(u, \lambda)$, is as follows:

$$\text{MIOA}(u, \lambda) = \cup_{v \in V, \text{pp}(\text{MIP}_G(v, u)) \geq \lambda} \text{MIP}_G(v, u).$$

Given an initial seed set S , let the *activation probability* of any node $v \in \text{MIIA}(u, \lambda)$, denoted by $\text{aps}_S(v, \text{MIIA}(u, \lambda))$, be the probability that v is activated when S is the seed set and influence is propagated in $\text{MIIA}(u, \lambda)$.

In the MIA model, let I_G denote the influence spread of S , defined as

$$I_G(S) = \sum_{u \in V} \text{aps}_S(v, \text{MIIA}(u, \lambda)).$$

As in the IC model, it is straightforward to show the following result.

Theorem 4 *It is NP-hard to compute a k -node seed set S such that $I_G(S)$ is maximized for the MIA model. On the other hand, I_G is submodular and monotone, and so MIP can be approximated by SGA within a $(1 - 1/e)$ -approximation ratio.*

For more information on efficient greedy algorithms, the reader is referred to [7].

In the LDAGI model, each node v in G is associated with a local DAG $\text{LADG}(v)$, a subgraph of G containing v . Given a seed set S , it is assumed that the influence from S to v is only propagated within $\text{LADG}(v)$ according to the LT model. Let $\text{aps}_S(v)$ be the activation probability of v when influence is propagated within $\text{LADG}(v)$. Then the influence spread of S in the LDAG influence model, denoted by $I_G(S)$, is given by

$$I_G(S) = \sum_{v \in V} \text{aps}_S(v).$$

As in the LT model, it is straightforward to show the following result.

Theorem 5 *It is NP-hard to compute a k -node seed set S such that the influence spread $I_G(S)$ is maximized for the LDAGI model.*

For more information of efficient greedy algorithms, the reader is referred to [8].

3 Finding Communities

This section introduces and elaborates a number of heuristic algorithms for finding communities, including a new algorithm of low complexity, which uses random walkers to search for communities. This algorithm has only been reported in a technical report [28]. Simulation results show that the random walker method is both effective and efficient in finding network communities.

The existing algorithms for finding network communities can be roughly categorized into graph-partitioning-based algorithms and hierarchical clustering-based algorithms [35]. The Kernighan–Lin algorithm (K–L, in short) is one of the most popular graph-partitioning algorithms, and the agglomerative method and the divisive method are the common hierarchical clustering-based algorithms.

3.1 Graph-Partitioning-Based Algorithms

On a given (weighted) graph $G = (V, E)$ and a positive integer k , the graph partitioning problem tries to partition V into k subsets such that the size difference of any two subsets is at most 1 and the number of edges (or the summation of edge weights) between different components is minimized. This is an NP-hard problem. Graph partitioning has important applications in task scheduling under multiprocessor systems, sparse matrix reordering, parallelization of neural net simulations, particle calculation, and VLSI design, to name just a few. The K–L algorithm is a popular heuristic algorithm in VLSI design, which could be used to obtain rough network communities.

3.1.1 The Kernighan–Lin Algorithm

Let $G = (V, E)$ be a weighted graph with a weight function $w : E \rightarrow R$ that maps each edge to a real value. Initially, the algorithm partitions V at random into two subsets V_0 and V_1 such that their size difference is at most 1. Let

$$w(V_0, V_1) = \sum_{u \in V_0, v \in V_1} w(u, v)$$

denote the cost of the partition. For each node $u \in V_i$ ($i = 0, 1$), let E_u denote the external weight of u on edges from u to nodes in the other set, that is,

$$E_u = \sum_{v \in V_i \oplus 1} w(u, v),$$

where $0 \oplus 1 = 1$ and $1 \oplus 1 = 0$. Let I_u denote the internal weight of u within V_i , that is,

$$I_u = \sum_{v \in V_i} w(u, v).$$

Let $D_u = E_u - I_u$ be the difference between the external and internal weights of u . For each edge $(u, v) \in E$ with $u \in A$ and $v \in B$, let $I_{u,v} = D_u + D_v$. Swap u with v and obtain a new $I'_{u,v}$. Then

$$I_{u,v} - I'_{u,v} = D_u + D_v - 2w(u, v).$$

The heuristic of the K-L algorithm swaps nodes between $u \in V_0$ and $v \in V_1$ iteratively to maximize $I_{u,v} - I'_{u,v}$. The time complexity of the K-L algorithm is $O(|V|^3)$.

3.2 Hierarchical Clustering-Based Algorithms

The basic idea of the hierarchical clustering-based method is to find relations between nodes in the network and then extract communities from the network by adding or deleting edges.

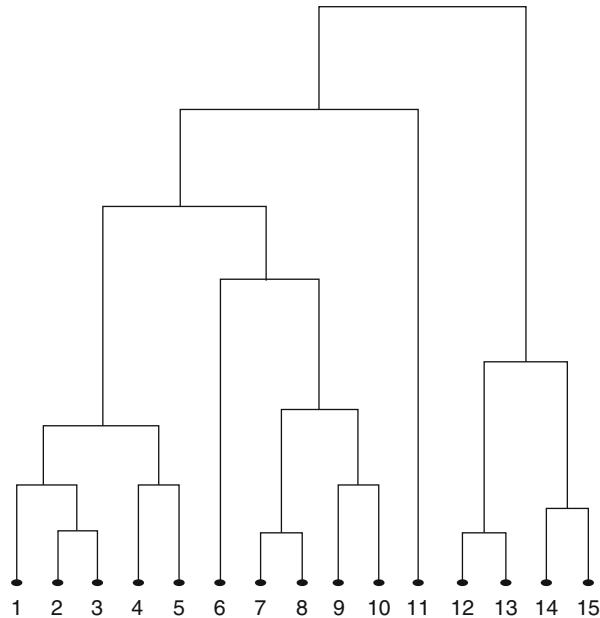

The hierarchical clustering method can be further divided into two subcategories: the agglomerative method and the divisive method. The agglomerative method follows a bottom-up approach. It starts with a completely disconnected network with no edges and proceeds in iterations. In each iteration, an edge is added based on a chosen measure. Pairs of clusters are merged as the algorithm moves up the hierarchy.

The divisive method follows a top-down approach. It starts from the original network and proceeds in iterations. In each iteration, it deletes an edge and splits a current subgraph recursively as the algorithm moves down the hierarchy.

The process of a hierarchical clustering method results in a tree structure known as “dendrogram” shown in Fig. 1.

3.2.1 The Agglomerative Method

This method uses a chosen measure of “structural similarity” of two nodes in the graph. The use of a different similarity measure may result in different communities. Such a similarity measure could either represent metrics of similarities or the strength of connection between nodes. For instance, one may use the distance between two points in a two-dimensional space as a similarity measure. In this case, using different notions of distance, such as the Euclidean distance, Manhattan distance, and maximum distance, gives rise to different variants of the similarity measure. A commonly used similarity measure is based on the comparison of

Fig. 1 The dendrogram

the neighboring nodes. More specifically, if two nodes have the same set of neighbors (or similar sets of neighbors), then they are considered “structurally equivalent” (or “structurally similar”) and should belong to the same community. For example, in an online social network, two persons in a friendship network are considered structurally equivalent if they have exactly the same set of friends [34]. But structural equivalence is rare in reality. Thus, structural similarities are often used instead. In particular, the following “Euclidean distance” [4] is often used to measure the similarity of two nodes u and v in a network. This Euclidean distance is not the same “Euclidean” commonly known:

$$x_{u,v} = \sqrt{\sum_{z \neq u,v} (a_{u,z} - a_{v,z})^2}, \quad (1)$$

where $a_{u,z} = 1$ if z is connected to u , and 0 otherwise. Clearly, if $x_{u,v} = 0$, then u and v have the exact same set of neighbors.

The agglomerative method adds edges from the network in iterations to increase the values of $x_{u,v}$. As more edges are added, connected subsets begin to form, which represent the forming of network communities. The components produced at each iteration are always subsets of other structures. The tree diagram, that is, the dendrogram, can be used to represent these subsets. Horizontal slices of the tree at a given level indicate the communities that exist above and below the value of the dissimilarity.

Running the agglomerative method requires a predetermination of how large each community should be. This is a drawback for finding natural communities.

3.2.2 The Divisive Method

Different from the agglomerative method that starts from a completely disconnected network and keeps adding edges to it in iteration, the divisive method starts from the original network and keeps deleting edges iteratively. The algorithm introduced by Girvan and Newman [13] is one of the most popular ones. The Girvan and Newman algorithm defines “edge betweenness” of an edge as the number of shortest paths between the two end nodes of the edge. If the network contains communities within which nodes are highly connected and between which nodes are sparsely connected, then all the shortest paths between different communities must go through one of these few edges between communities. Thus, at least one of the edges connecting communities will have a high edge betweenness. Removing such an edge, the groups of nodes are separated from one another, which may help reveal the underlying community structure of the network. Thus, the dendrogram is created from root to leaves. The Girvan and Newman algorithm involves intensive computation. For each iteration, the time complexity of calculating the betweenness of all existing edges in the network is $O(|V||E|)$. In the worst case, $O(|E|)$ edges may finally be removed, and so the worst-case running time is $O(|V||E|^2)$.

3.3 The Random Walker Algorithm

This section describes the random walker (RW) algorithm devised by Li et al. [28]. Different from the early algorithms, this algorithm uses random walkers to search for communities.

Given a graph $G = (V, E)$, the RW algorithm first generate, for each node, a number of walkers equal to its degree. The node for which a walker is generated is referred to as the *owner node* of the walker. Each walker is labeled with its owner node. The node where a walker is currently located is referred to as the *current node* of the walker. The RW algorithm runs in iterations. In each iteration, each walker chooses from two possible actions to proceed with certain probability. That is, with probability p_{move} , the walker chooses a node from the neighboring nodes of its current node and moves to it. With probability $p_{\text{jump}} = 1 - p_{\text{move}}$, it jumps back to its owner node.

Run the algorithm for a few iterations, where the number of iterations t is a parameter chosen by the user who runs the algorithm. When the algorithm stops, each node will have a certain number of walkers. If two nodes have the same set of walkers (or similar sets of walkers), then they are considered structurally equivalent (or structurally similar), and so they should belong to the same community. The algorithm uses the Pearson correlation to measure similarity of two nodes [34]. For any node u and v , if when the algorithm stops node u has a walker from node v , let $a_{u,v} = 1$; otherwise, let $a_{u,v} = 0$. The Pearson correlation of node u and v , denoted

by $x(u, v)$, is given below:

$$x_{u,v} = \frac{\sum_k (a_{u,k} - \mu_u)(a_{v,k} - \mu_v)/n}{\sigma_u \sigma_v}, \quad (2)$$

where

$$\begin{aligned} n &= |V|, \\ \mu_u &= \frac{1}{n} \sum_k a_{u,k}, \\ \sigma_u &= \frac{1}{n} \sum_k (a_{u,k} - \mu_u)^2 \end{aligned}$$

are the mean and variance of node u .

A larger value of $x_{u,v}$ would indicate that node u and v are more likely to be in the same community. The RW algorithm forms communities one at a time according to the similarities of nodes. In particular, it starts from an empty set S . It selects a pair of nodes with the highest similarity among all possible pairs that has not been selected and adds them to S . Next, expand S by repeatedly selecting new nodes in the remaining set of nodes, until a certain halting criterion is met. The halting criterion can be that either the size of the community constructed reaches a predefined threshold or the similarity between arbitrary node in the community and any node outside the community is smaller than a predefined threshold. Save S as a community and repeat the same process for the remaining nodes to find the next community, assuming that the nodes added into S will not belong to any other community. The RW algorithm stops after all nodes are considered. It is evident that the time complexity of the algorithm is $O(t(|V| + |E|))$.

Extensive simulation using both halting criteria was executed, which show that the RW algorithm is highly effective. The accuracy of the RW algorithm is computed as follows:

$$\text{Avg. accuracy} = \frac{1}{N_r} \sum_{i=1}^{N_r} \sum_{i=1}^{N_c} \frac{f^i}{s^i},$$

where N_r is the total number of simulation runs, N_c the number of communities, f^i the number of members that were correctly found for community i , and s^i the size of the community i .

For example, one set of simulations runs on two types of graphs of 1,000 nodes, with five communities of equal size. The edges in the first type are constructed with $p_{\text{low}} = 0.05$ and $p_{\text{high}} = 0.9$, while in the second type with $p_{\text{low}} = 0.1$ and $p_{\text{high}} = 0.75$. Each simulation runs for $t = 5$ iterations with $p_{\text{travel}} = p_{\text{jump}} = 0.5$. For the first type of graphs, the RW algorithm achieves on average near 100% accuracy using both halting criteria, where the size threshold is set to 200 and the similarity threshold is set to 2.0. In the second graph, the algorithm achieves on

average near 100 % accuracy if the first halting criterion is used, where the threshold of the community size is set to 200. If the second halting criterion is used, where the similarity threshold is set to 1.5, the RW algorithm achieves on average 93 % accuracy.

4 Data Collection from OSNs

Online social networks are popular platforms for people to connect, share information, and interact with each other. There have been intensive efforts to measure and analyze various characteristics of online social networks in recent years, including topological characteristics, user behaviors, and interactions between users.

Popular OSNs, such as Facebook and Twitter, are continuously growing to garner hundreds of millions of users. The sheer size of these OSNs and the dynamics of user activities make it impractical to measure the entire network. As a result, researchers often collect a small but representative sample of the network to study the properties of the network and test their algorithms.

This section reviews some of the recent studies on the measurement and analysis of OSNs, describes the graph sampling methods that have been used to collect data over OSNs, and presents an example of collecting data from MySpace with interesting statistical results.

4.1 Measuring and Analyzing OSNs

Mislove et al. [31] carried out a large-scale study on measuring and analyzing the structure of multiple online social networks, including Flickr, YouTube, LiveJournal, and Orkut. Their results confirmed that these OSNs are small world and scale free, and the degree distributions satisfy the power law. They also offered the following observations: (1) The in-degree of user nodes tends to match the out-degree. (2) Each OSN contains a densely connected core of high-degree nodes. (3) This core links small groups of strongly clustered, low-degree nodes at the fringes of the network.

Ahn et al. [1] measured and compared the structures of the following three online social networking services: Cyworld, MySpace, and Orkut, with respect to the degree distributions, clustering coefficients, degree correlations, and average path length. Krishnamurthy et al. [22] identified distinct classes of Twitter users and their behaviors, geographic growth patterns, and size of the network.

Gauvin et al. [11] measured and analyzed the gender-specific user publishing characteristics on MySpace using the technique of uniform sampling. They showed that there are recognizable patterns with respect to profile attributes, user interactions, temporal usages, and blog contents for users of different genders. In particular, gender neutral profiles (most of them are music bands, TV shows, and other commercial sites) differ significantly from normal male and female profiles for several publishing patterns. Caverlee and Webb [5] analyzed the frequencies of

words occurred in MySpace wall posts according to genders and ages. They looked at various statistics of male and female profiles in MySpace, including the degree distribution of friends, user demographics, language, and privacy preference.

Chun et al. examined the question of whether interactions between OSN users would follow the declaration of friends using the guestbook logs of Cyworld, the largest OSN in Korea. They constructed an activity network that reflected the online interactions between users and found that its structure is similar to the friend relationship network. However, when only reciprocated links are considered, the degree correlation distribution exhibited much more pronounced assortativity than the friends network. Wilson et al. [41] studied the relationship between friends and publishers and whether social links (social network friendships) were valid indicators of real user interaction in Facebook. They built a graph based on user interactions (i.e., messages exchanged between users). They observed that the interaction graph has much lower average node degree than the Facebook friends graph.

Benevenuto et al. [3] studied user workloads on four popular OSNs: Orkut, MySpace, Hi5, and LinkedIn. They analyzed key features of the social network workloads such as how frequently people were connected to social networks and for how long, as well as the types and sequences of activities that users conducted on these sites. They showed that browsing, which cannot be inferred from crawling publicly available data, accounted for 92 % of all user activities. Consequently, compared to using only crawled data, considering silent interactions like browsing friends' pages increases the measured level of interactions among users.

4.2 Sampling Methods of OSNs

A number of graph sampling methods have been adopted and developed for measuring large-scale OSNs. These methods can be classified into the categories of breadth-first search, random walk, and uniform sampling, among others.

4.2.1 Breadth-First Search (BFS)

The breadth-first-search traversal method was commonly used in recent measurement studies of OSNs (see, e.g., [1, 31, 41]). It is a classic graph search algorithm that begins from an initial seed node and explores all the neighboring nodes. The process is repeated, and at each iteration the earliest explored but not-yet-visited node is selected and its neighbors are explored. It is easy to see that the BFS method will discover all nodes within some distance from the seed node, but the sampled nodes are constrained within the connected component of the seed node. An incomplete BFS will cover and yield a full view (all nodes and edges) of some particular region in the graph. While the resulting sample graph readily enables the study of topological properties of the network (e.g., clustering coefficient, community structure), it is known that BFS introduces a bias toward nodes with high degrees [2, 25].

Kurant et al. [24] quantified the degree distribution bias of BFS sampling. For a random graph $\text{RG}(p_k)$ with a given (and arbitrary) degree distribution p_k , the node degree distribution expected to be observed by BFS as a function of the fraction of covered nodes (q_k) is given by

$$q_k = \frac{p_k(1 - (1 - t(f))^k)}{\sum_l p_l(1 - (1 - t(f))^l)}, \quad (3)$$

where $t(f)$ is the time that a fraction f of the nodes is covered, whose numerical value is straightforward to find.

The bias of BFS monotonically decreases with increasing fraction of sampled nodes f , and there is no bias when BFS is complete ($f = 1$). Kurant et al. also showed that, for $\text{RG}(p_k)$, all commonly used graph traversal techniques (breadth-first search, depth first search, forest fire, and snowball sampling) lead to the same bias. Given a biased sample; they also showed how to correct the bias by deriving an unbiased estimator of the original node degree distribution.

4.2.2 Random Walk

The random walk technique, successfully used for the World Wide Web (WWW) [19] and peer-to-peer network (P2P) [15, 36, 39] sampling, has been recently applied to OSN sampling [14]. In the classic random walk approach [29], a random walker starts from a node (u) and visits its neighboring nodes uniformly at random. The process continues and the given graph is sampled by the random walker. Denote the degree of node u by d_u , the probability that a node v is chosen as the next-hop node is given as follows:

$$P_{u,v} = \begin{cases} \frac{1}{d_u} & \text{if } v \text{ is a neighbor of } u, \\ 0 & \text{otherwise.} \end{cases} \quad (4)$$

For a network with m edges, the steady-state distribution of the random walker being at a node v is

$$\pi(v) = \frac{d_v}{2m}. \quad (5)$$

A linear bias exists on high-degree nodes. Nodes with higher degrees will be visited more often than those with lower degrees in proportion to the node degree. To correct this bias, one can apply the Metropolis–Hastings algorithm [18, 30] to make the random walk converge to a desired probability distribution. In particular, it can be shown that the following transition probability achieves the uniform distribution among nodes [24]:

$$P_{u,w} = \begin{cases} \frac{1}{d_u} \min\left(1, \frac{d_u}{d_v}\right) & \text{if } v \text{ is a neighbor of } u, \\ 1 - \sum_{y \neq u} P_{u,y} & \text{if } v = u, \\ 0 & \text{otherwise.} \end{cases} \quad (6)$$

It can be seen from the above equation that, to correct the degree bias in the classic random walk, the probability of visiting a node has been adjusted to reduce the transition to high-degree nodes.

In a random walk, the accuracy of estimating an underlying characteristic depends on the graph structure and the characteristic being estimated. The estimates may be inaccurate when the random walker gets “trapped” in a certain region of the graph. To mitigate this problem, one can start multiple independent random walks (MultipleRW) in different parts of the network [14]. This will reduce the chance of the sampling process being “trapped” in a region and has the advantage of being amenable to parallel implementation from different machines or different threads in the same machine. However, it was shown [37] that the MultipleRW approach may fail to reduce estimation errors. Starting vertices of MultipleRW in a component proportional to the number of edges of the component is a key factor to determine the accuracy of MultipleRW. While this approach can successfully mitigate estimation errors caused by disconnected components, it is not clear how it can be implemented in realistic OSNs such as MySpace and Facebook.

Ribeiro and Towsley [37] devised a new m -dimensional random walk sampling method called Frontier sampling. It performs m -dependent random walks in a graph. Starting from a collection of m randomly sampled vertices, the Frontier sampling method preserves all of the important statistical properties of a regular random walk (e.g., nodes are visited with a probability proportional to their degrees). For a given sampling budget of B steps, let c be the cost of randomly sampling a node. The sampling algorithm is given as follows:

Frontier Sampling

- 1 $n \leftarrow 0$ (n is the number of steps)
2. initialize $L = (v_1, \dots, v_m)$ with m randomly chosen nodes (uniformly)
3. **repeat**
4. select $u \in L$ with probability $d_u / \sum_{v \in L} d_v$
5. select an outgoing edge of u , (u, v) , uniformly at random
6. replace u by v in L and add (u, v) to the sequence of sampled edges
7. $n \leftarrow n + 1$
8. until $n \geq B - mc$

In Frontier sampling, while nodes are visited with a probability proportional to their degree, it can be shown that the joint steady-state distribution (the joint distribution of all m nodes) is closer to being uniform (the starting distribution) than k -independent random walkers, for any $k > 0$. This property has the potential to dramatically reduce the transient period of random walks. In simulations using real-world graphs, Frontier sampling can indeed effectively mitigate the large estimation

errors caused by disconnected or loosely connected components that can “trap” a random walker and distort the estimated graph characteristic in a variety of scenarios.

4.2.3 Uniform Node Sampling

As the name suggests, the uniform node sampling technique samples all the nodes in a graph uniformly and independently. There is no inherent measurement bias regardless of the distribution of the user IDs. When applicable, uniform node sampling can be used to establish the “ground truth” of the network properties and has the advantage of sampling disconnected graphs. Several recent studies have used the uniform node sampling technique to measure the network properties of MySpace and Facebook [11, 14].

For the uniform node sampling to work, however, an OSN must allow access to user profiles using unique numeric IDs. As such, it does not serve as a general solution for OSN sampling. Also, this approach may become highly inefficient when the space of user IDs is large and sparsely occupied, which was observed in both MySpace and Facebook [11, 14]. Since access to OSNs is often rate limited, the sparse distribution of the ID space will significantly increase the time to collect the data required for sampling.

4.3 MySpace Data Collection and Analysis

When sampling an online social network, the walker (a.k.a. crawler) collects the user profile information such as age, gender, education, work, location, friends/followers, and blogs, among others. The exact information that can be obtained from a user profile depends on the specific OSN design and the user’s privacy setting. The study carried out by Gauvin et al. on MySpace [11] provides an example of collecting and analyzing data of OSNs.

MySpace is a major online social networking site. Since launched in 2004, it has attracted a large number of users. Typical MySpace users are teenagers, music bands, artists, and commercial sites. MySpace is particularly popular among young people and music communities. Each MySpace user owns a profile containing basic personal information including name, age, gender, and location. A user profile whose owner’s gender is neither female nor male is treated as a gender “neutral” profile. A neutral profile in the data sets occurs when the gender is not specified. Many of the gender neutral profiles were commercial sites for music bands and TV shows. Despite the importance of these profiles, Gauvin et al. were the first to look at the publishing tendencies of gender neutral, commercial profiles.

In particular, Gauvin et al. [11] developed a crawling tool to sample MySpace, uniformly at random, to collect user profile attributes (name, gender, age, location, friends, among other things) and their corresponding blog information. Six million possible user profiles were randomly sampled between September 2008 and May 2009. When blogs for these random profiles were found, each blog was scanned to obtain the publisher profile attributes, the time stamp, and the content information.

A profile may be public (the default option) or private depending on its privacy setting. Private profiles only share the owner's name, gender, age, and location. No blog or friend information could be retrieved from these sites. As a result, the analysis was limited to the blogs posted on public profiles. The results of this data collection process produced 546,829 public and 68,141 custom profiles of which 92,653 sets of blogs were obtained and 1,867,299 blogs were collected. The number of blogs contained within a randomly scanned profile ranged from 0 to 85,643. To determine the publisher characteristics, 1,768,884 profiles were scanned.

4.4 Member Profile Patterns

4.4.1 Age, Gender, and Privacy

In the collected data set, female, male, and neutral profiles constitute, respectively, 52.8 %, 37.7 %, and 9.5 % of the total valid IDs. A larger percentage of female users (57.1 %) were privacy aware than male users (39.2 %). Almost all (99.999 %) gender neutral profiles were public as they were typical commercial sites trying to attract people to visit their pages.

[Figure 2](#) shows the age distribution of private account profiles. The majority of profile owners declared their ages in the range of 15–30. Beyond this range the distribution falls off rapidly, only to increase around age 69 and age 100 due to a

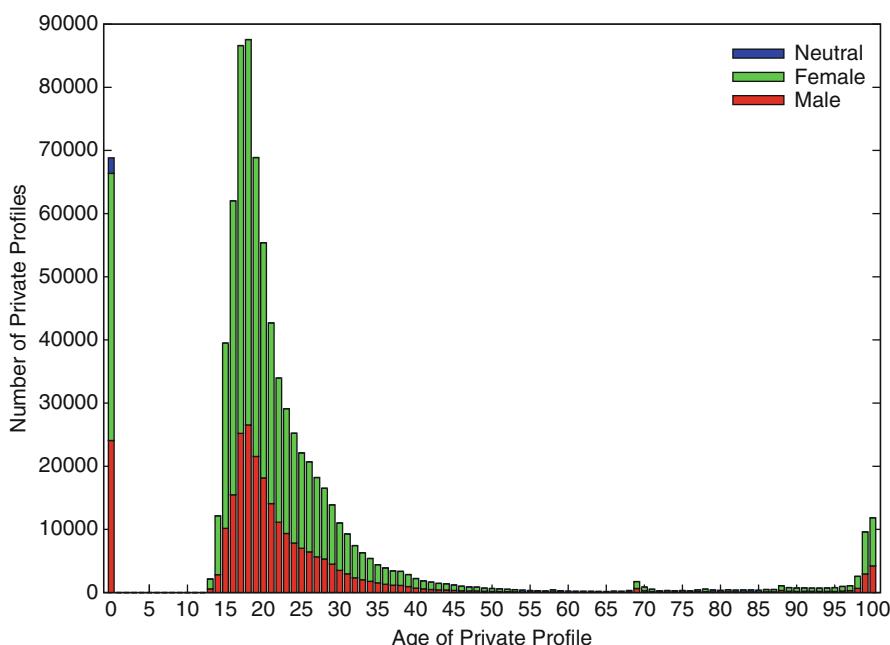

Fig. 2 MySpace private account and age distribution

common practice among underage users to elude the age restriction by selecting an exaggerated age.

Two age groups deserve a special mention. The first is the absence of ages from 1 to 12. MySpace protects users in this age group and does not create their profiles. The second is the age group under 16. MySpace automatically sets user profiles in this group to be private. This restricts the information that can be obtained for these sites. It can be noted that there was a large number of zero-age profiles. This is probably because accounts of underage owners were kept private. Also note that the data collected do contain some user profiles with ages under 16. This is contradictory to the current MySpace policy. This inconsistency may be the result of MySpace's policy change, where an old policy may actually allow users under age of 16 to publish their ages.

4.4.2 Publishers Versus Friends

In an online social network, friend relationships do not necessarily reflect real online interactions between users. The data sets depict an interesting relationship between the total number of friends of a user and the number of friends that actually publish on the user's blog wall.

[Figure 3](#) plots two sets of complementary cumulative distribution functions (CCDF), one set corresponding to the number of friends and the other corresponding to the number of distinct publishers among those friends. In each set, a CCDF is obtained for each profile gender: female, male, and neutral.

It can be seen that the friendship and publisher distributions for male and female profiles exhibit similar behaviors except at the tail, where the female distribution extends farther and the male distribution falls off sharply. The distributions for gender neutral profiles lie above the male and female distributions. This indicates that neutral profiles tend to have more friends and publishers than normal male and female profiles. This trend is consistent with the observation that neutral profiles were generally music bands or other commercial sites with a large number of friends publishing comments on the music, movie, or product being promoted.

[Figure 4](#) plots the number of distinct publishers versus the number of friends of MySpace users. It is observed that for most users, as the number of friends increases, only a small fraction of the users actually interact with each other through blogs. This is consistent with the observations made in [41] for Facebook users.

Interestingly, the publisher-versus-friend plots for male and female profiles nearly coincide with each other, while the plot for gender neutral profiles falls far below. This indicates that although gender neutral profiles tend to have more friends than normal male and female profiles, an even smaller fraction of these friends actually write on their blog walls. A possible explanation for this difference is that many users befriend commercial sites just to browse or receive information from the sites. The relationships between friends and gender neutral commercial sites are less "active" than those between normal users. It is worth noting that some profiles contain more distinct publishers than friends. This is a result of profile owners removing friends from their profiles and occurs rather rarely.

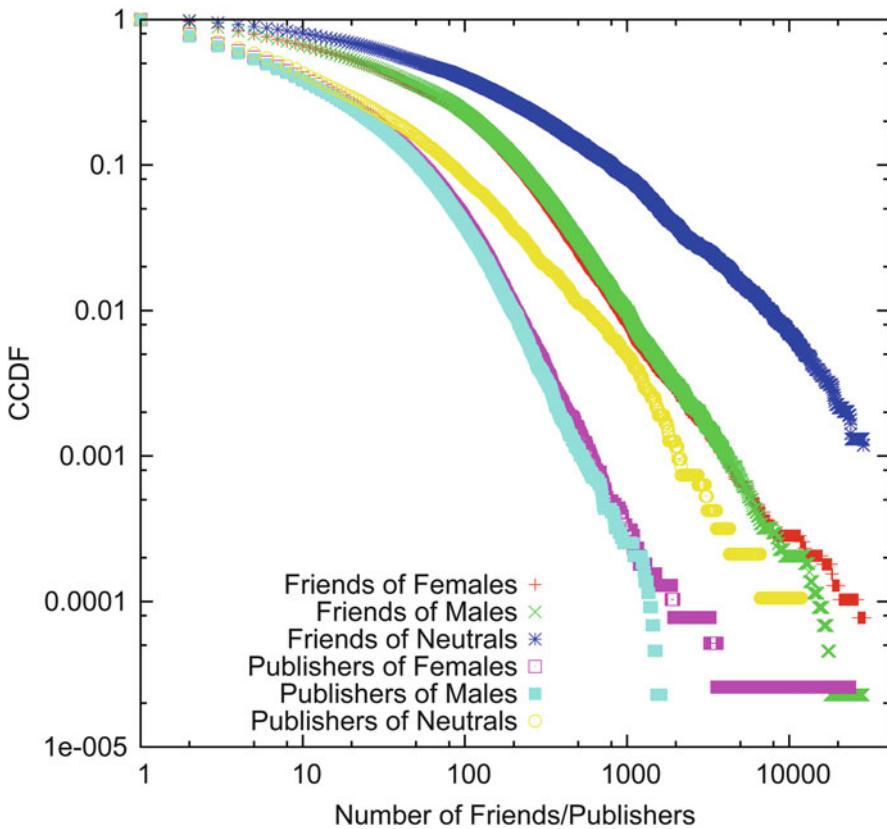

Fig. 3 Distribution of number of friends and publishers

4.4.3 Profile Owner and Publisher Age Difference

Figure 5 shows a density graph of the ages of publishers versus those of the profile owners. It can be observed that the density is greatest along the diagonal line (zero age difference between publishers and profile owners) and drops quickly as the age difference increases. This indicates that users tend to interact with friends of similar ages. A large fraction (75 %) of publishing activities occurs between people within a 5-year age difference. The shape of the age difference distribution can be described by an exponential function $f(x) = a \exp(b\|x\|)$, where $a = 0.334$ and $b = -0.470$, for age differences between 0 and 8 years. The shape of known distributions is unlikely to match the distribution of age differences larger than 8, likely because a fraction of the young users tend to lie about their age. Note that the other small islands in the figure are artifacts caused by the following two groups of users: underage users below 14 whose age information is not available and set to 0 and users with exaggerated ages around 69 and 100.

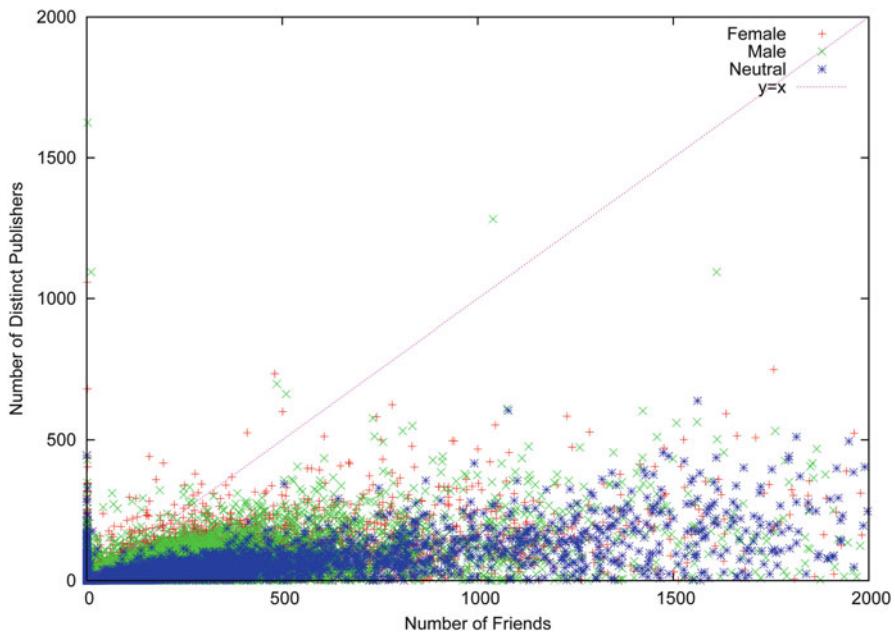

Fig. 4 Distribution of friends versus publishers

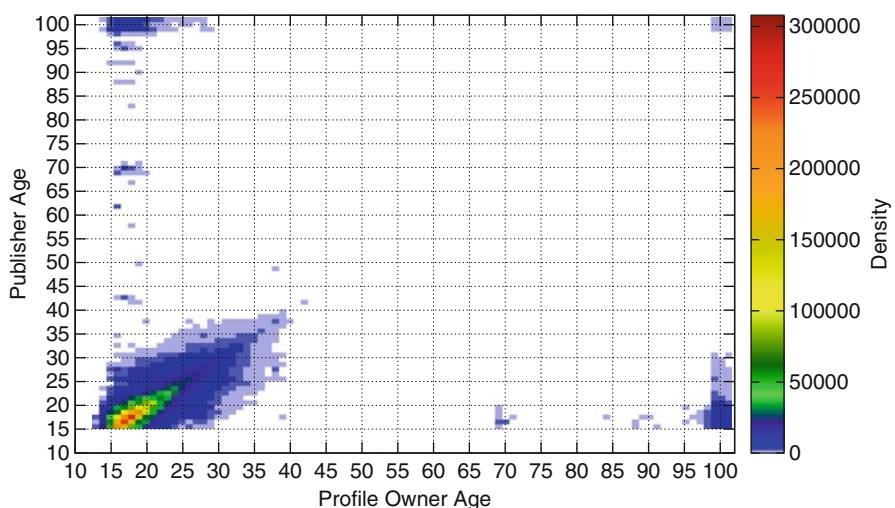

Fig. 5 Publisher age versus owners

4.5 Temporal Usage Patterns

Three specific elements of time are analyzed. They are time of day, day of week, and monthly usage patterns, as shown in Fig. 6.

All blog posting times are normalized to the local wall-clock time of the individual profiles. It can be observed from Fig. 6a that there is a significant increase in publishing activity from morning to afternoon, with the peak usage time at 10pm and a significant drop at midnight. The low activity between midnight and 12pm may reflect the times of rest and busiest time for labor in the day as far as school and work are concerned. As for the daily publishing pattern characterized in Fig. 6b, weekdays have a higher degree of activity than weekend days. Gender analysis for diurnal publishing patterns does not indicate any significant pattern difference between genders.

The total number of blogs and content per day for each month was also collected. The reason for gathering this information was to ascertain whether trends in publishing patterns can be used to predict the load of a social network server and determine peak usage times. This information may be used to determine false positives during spam detection and other security filtering policies. Many months displayed evenly distributed activities on each day where the daily blog counts did not deviate by more than 200 blogs for the collection set analyzed. There were some months (February, November, December), however, that stood out with respect to predicting publishing patterns, mainly due to the specific calendar events within the months. An example is given in Fig. 6c for February, which is a low publishing month in general, but there is a sharp contrast between the publishing activities on the 14th and those on other days. Similar high publishing activities are observed for other major calendar events including New Years Day, Mother's Day, 4th of July, Halloween, Thanksgiving, and Christmas.

4.6 Blog Content Patterns

A blog's entry contains four types of content, namely, words, hyper-references (HREFs), images, and objects. In most cases the objects were ColdFusion scripts or other animated objects. ColdFusion objects allow users to create animated objects used to make their profiles more attractive. Each blog is a composition of these four content types. The inclusion and makeup of these different content types is a reflection of each individual's writing style. The goal is to determine if specific content patterns can be identified.

Figure 7 depicts the complementary cumulative distribution functions (CCDF) of the counts of words, HREFs, images, and objects in a blog entry. It can be seen that the counts of these content types decay roughly according to power laws in certain regimes. In a blog entry, word count dominates the counts of other types. Object count is the smallest among all types. HREF and image counts are similar to each other and lie somewhere in-between. Of course, the counts of the different content types do not reflect their actual sizes (bytes). The size of an image is typically

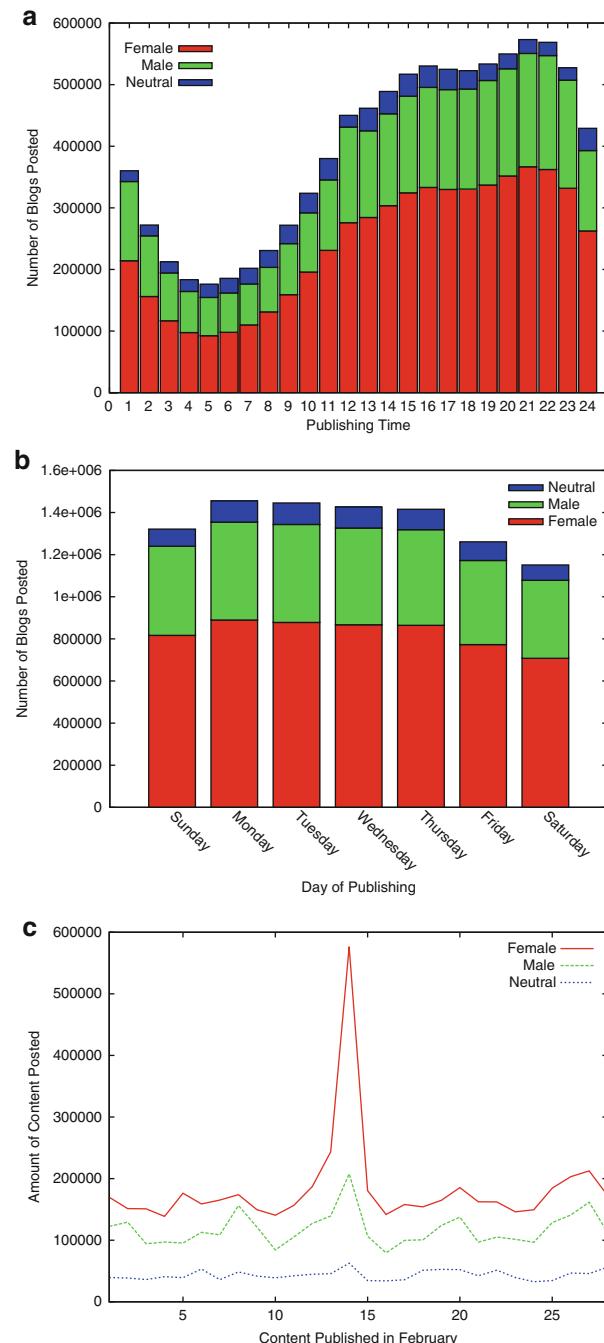

Fig. 6 Temporal publishing patterns. (a) Hourly pattern. (b) Daily pattern. (c) February daily pattern

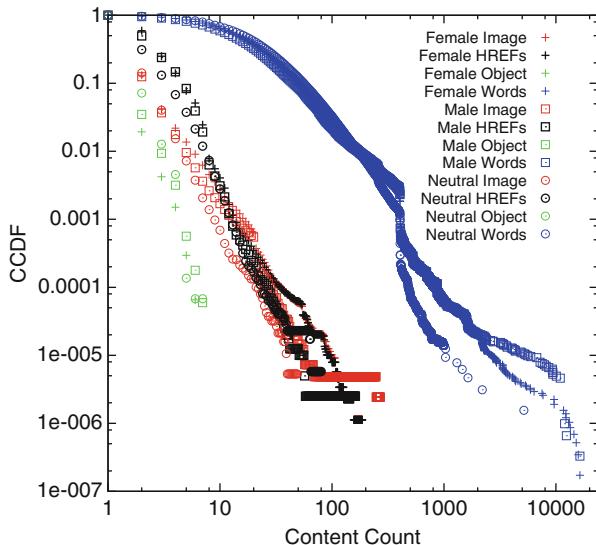

Fig. 7 Gender content publishing

significantly larger than that of a word. In general, users tend to post short messages. For example, only 10 % of the blog entries contain more than 50 words; 4 % of the blog entries contain 3 or more images. The use of objects is even less frequent.

There are a number of recognizable patterns with respect to the count of these content types across different genders. The word count distribution of gender neutral profiles drops off drastically around word count 410. This may be due to the need of a commercial site to have very specific and focused contents (e.g., advertisements) that fit people's attention spans. Another recognizable pattern is that females tend to publish more HREFs (hyperlink references) and images than male and neutral profiles.

5 Multilayer Friendship Modeling in Location-Based OSNs

How users are connected through an online social network is an interesting question. Intuitively, the formation of online friendship may reflect to certain degree the real-world counterpart. People who have mutual interests, are geographically close, or belong to the same social communities (e.g., churches, volunteer groups, and special interest groups) are more likely to become friends. The challenge is to devise adequate metrics to represent this intuitive understanding with a quantitative model. While there are a number of studies on structural properties of social networks, such as the distribution of node degrees, friendships (or connections) between users may be modeled with other user attributes.

In the context of influence maximization, a quantitative friendship model can provide an interesting perspective for studying influence propagation in OSNs, for the strength of the friendship often reflects the likelihood of how people influence each other. For example, for any two people who are OSN friends, it would be reasonable to combine their behaviors, such as whether they would buy the similar products or like the same brands, with the friendship model to come up with an empirical influence propagation model. For any two people who are not OSN friends, it would be useful to predict the possibility and the strength of their connection if they will ever become friends. Such information would be useful to find the most influential individuals in the network.

This section presents a friendship model for Brightkite, a location-based OSN. The primary service mode of Brightkite is to let users post and share updates with their friends or with the public. A user update could be a text note with a 140-character cap, a photo, or a check-in to announce a location. The user performs a check-in when they come to a new location. This is the typical usage scenario of Brightkite. All note and photo updates will be associated with the location of the user's latest check-in. Brightkite assumes that the user stays at the same location until they perform another check-in somewhere else.

To study how Brightkite users share location and how they become connected, Li and Chen [27] collected Brightkite user updates posted from March 21, 2008, to December 15, 2009. There were 4,460,161 updates posted by 70,337 users. They also collected each user's profile and friend list. They then built a three-layer friendship model to correlate the relationship between friend connections with attributes of their profiles, social graphs, and mobility patterns. For convenience, this model is referred to as the *three-layer friendship* (TLF) model. To validate the TLF model, they used new friend connections during the 168 days after the training data were collected. They showed that the TLF model can better predict user friendships than the classical naive Bayes and J48 tree algorithms.

5.1 A Multilayer Friendship Model

In social communities, friend connections have strong correlations to the social graph structures, profile attributes of individuals, and geographic locations. For social graph structures, the social distance between friends can be used to derive the empirical model of connections. For the profiles of individuals, the common interests between friends can be used to infer their friendships, which are reflected to some degree by the Brightkite tags in user profiles. For the geographic locations, it was observed that friends tend to send updates within a small geographic range with high probability. The TLF model exploits the correlations of friendship distance, tag attributes, and mobility patterns.

In a social network $G_s(V_s, E_s)$ where each node v_s denotes a user and each edge e_s denotes the friendship between two nodes. For any node (user) pair (a, b) , its attribute(s) can be calculated. Given the attribute values of two users, the empirical probability of them being friends can be computed as follows: Assuming that m_v is the attribute value, let $P_f(m_v)$ denote the probability of value m_v for friend pairs and

$P_{\text{nf}}(m_v)$ denotes the probability of value m_v for non-friend pairs. Using the *Bayes' rule* of conditional probability, the probability $P(ab|m_v)$ of existence of an edge between the two users (meaning they are friends) while observing attribute value m_v is

$$P(ab|m_v) = \frac{P(m_v|ab) \times P(ab)}{P(m_v)}, \quad (7)$$

where $P(m_v|ab)$ denotes the conditional probability that the attribute value m_v occurs given that (a, b) is a pair of friends, $P(ab)$ denotes the probability that node a and node b are friends, and $P(m_v)$ denotes the probability that m_v occurs in all possible pairs. Thus,

$$P(m_v|ab) = P_f(m_v), \quad (8)$$

$$P(ab) = \frac{|E_s|}{C_{|V_s|}^2}, \quad (9)$$

$$P(m_v) \cong P_{\text{nf}}(m_v), \quad (10)$$

where $C_{|V_s|}^2$ denotes all possible user pairs.

Equation 10 is satisfied because $C_{|V_s|}^2$ is much larger than $|E_s|$. In the social graph retrieved on April 14, 2009, $|E_s| = 175,309$ and

$$C_{|V_s|}^2 = 50,842 \times 50,842 / 2 \cong 1.29 \times 10^9.$$

The probability of m_v in non-friend pairs is approximately equal to that in all possible pairs. It follows from Eqs. 8–10 that Eq. 7 becomes

$$\begin{aligned} P(ab|m_v) &= \frac{P_f(m_v) \times |E_s|}{P_{\text{nf}}(m_v) \times C_{|V_s|}^2} \\ &= F(m_v) \times \frac{|E_s|}{C_{|V_s|}^2}. \end{aligned} \quad (11)$$

Let $F(m_v)$ denote the *ranking factor* defined as follows:

$$F(m_v) = \frac{P_f(m_v)}{P_{\text{nf}}(m_v)}. \quad (12)$$

Since $|E_s|/C_{|V_s|}^2$ is a constant for all user pairs, to determine which pair has a higher probability to become friends, it suffices to calculate $F(m_v)$ and compare its value over different user pairs.

Identifying the existing 175,309 friend pairs from the data set, it is straightforward to compute $P_f(m_v)$ using this empirical data. Since the number of non-friend pairs is huge, it would be hard to explore the entire sample space. Instead, Li and Chen [27] randomly selected 340,000 non-friend pairs and calculated $P_{nf}(m_v)$ from these samples.

In the real world, a single attribute is insufficient to recommend user's friendship. For example, potential friends could share the same tag(s) because of mutual interest(s), but may never send updates in nearby locations. Thus, if one only uses the location-based attribute, it would be difficult to accurately model the pair relationship. Instead, Li and Chen selected three attributes (details later) to calculate the probability of friends. Let P_1 , P_2 , and P_3 denote the probabilities that were calculated by three different attributes, respectively, and if they are independent, then

$$\begin{aligned} P(ab|m_{v1,v2,v3}) &= 1 - (1 - P_1) \cdot (1 - P_2) \cdot (1 - P_3) \\ &= 1 - (1 - P_1 - P_2 + P_1 \cdot P_2) \cdot (1 - P_3) \\ &= P_1 + P_2 + P_3 + O(P^2) - O(P^3) \\ &\cong P_1 + P_2 + P_3. \end{aligned} \quad (13)$$

The values of $O(P^2)$ and $O(P^3)$ are extremely small, and so they can be ignored. For Eq. 11,

$$|E_s|/\mathbf{C}_{|V_s|}^2 = 1.36 \times 10^{-4}$$

in the current social graph, and each rank factor $F(m_v)$ is usually no more than 300.

Ignoring the constant value, user friendship can be ranked by comparing the summation of the ranking factors of the three attributes:

$$F = F_1 + F_2 + F_3. \quad (14)$$

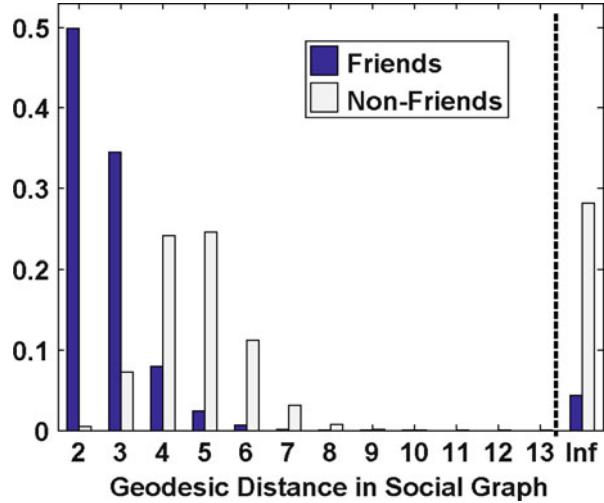

The three attributes used in this calculation will be discussed below. Note that in Eq. 14, if one or two attributes are missed, the model is still valid.

5.1.1 The Social Graph Layer

In the constructed social graph $G_s(V_s, E_s)$ obtained from Brightkite, where $|V_s| = 50,842$ and $|E_s| = 175,309$, each node v_s is a Brightkite user and each edge e_s represents a pair of friends. Since the "friendship" in Brightkite is mutual,¹ G_s is an undirected graph. Define the *friends distance* $DS_{i,j}$ of v_i and v_j in Eq. 15, where $e_{i,j}$ is the link between v_i and v_j :

¹At the time of retrieving the data trace, a friendship in Brightkite was mutual. Starting from December 2009, friendships were changed to directional. In other words, like Twitter, each user has a "friends list" and "fans list" corresponding to the "following" and "follower."

Fig. 8 Histogram of distance DS of friends/non-friends in the social graph

$$DS_{i,j} = \text{geodesic_distance}(v_i, v_j) \text{ in } G'_s(V_s, E_s - e_{i,j}). \quad (15)$$

In Eq. 15, geodesic distance is the shortest path of two nodes in the social graph. Equation 15 means if v_i and v_j are friends, then remove the existing edge between i and j and calculate their geodesic distance in the resulting social graph.

Figure 8 depicts the histogram of normalized DS including non-friend pairs (the bar at the left-hand side) and friend pairs (the bar at the right-hand side). It turns out that the distance of more than 49.9 % friend pairs was 2 and more than 34.5 % was 3. On the other hand, the distance of less than 7.8 % non-friend pairs was less than 4, and 28.2 % of non-friend pairs were disconnected nodes in the social graph, which suggested that the social graph in Brightkite was quite sparse.

The ranking factor of the social graph layer was calculated by dividing the friend pairs' proportion by non-friend pairs' proportion (Eq. 12). Consider the situations that the ranking factor is larger than 1 and ignore the other situations. Then

$$F_s(m_s) = \begin{cases} 94.81 & m_s = 2 \\ 4.75 & m_s = 3 \\ 0 & \text{others.} \end{cases} \quad (16)$$

5.1.2 Tag Graph Layer

To model the relationship between friendships and users' tags, Li and Chen [27] selected 1,000 popular tags to build a tag graph, denoted by $G_t(V_t, E_t)$. Since Brightkite allows users to use any words as their tags, it makes sense to only focus on the popular tags to obtain statistical results. The graph G_t is an undirected *complete* graph, and each node corresponds to a tag word. Connect each pair of tags with a nonnegative value w_t as weight to indicate the closeness of them, which is defined as follows:

$$\begin{aligned}
w_{t_1,t_2} &= \frac{P_f(t_1, t_2)}{P_a(t_1, t_2)} \\
&= \frac{P_f(t_1, t_2)}{P_a(t_1) \cdot P_a(t_2) + P_a(t_2) \cdot P_a(t_1)} \\
&= \frac{P_f(t_1, t_2)}{2 \cdot P_a(t_1) \cdot P_a(t_2)},
\end{aligned} \tag{17}$$

where $P_f(t_1, t_2)$ denotes the probability that tag t_1 and tag t_2 are shared by friends in all friend pairs. This probability can be calculated by first counting the number of pairs, where one user had tag t_1 and the other had tag t_2 , to get $CNT_f(t_1, t_2)$, then dividing it by the total number of friend pairs $|E_s|$. That is,

$$P_f(t_1, t_2) = \frac{CNT_f(t_1, t_2)}{|E_s|} \tag{18}$$

Note that t_1 and t_2 could be the same.

Let $P_a(t_1, t_2)$ denote the probability that for one user pair, one user has tag t_1 and the other has tag t_2 , in all possible user pairs, and $P_a(t_1)$ denote the probability that tag t_1 occurs in all users. The probability $P_a(t_1)$ can be calculated by first counting the number of users who used tag t_1 in all users to get $CNT_a(t_1)$ and then dividing it by the total number of users $|V_s|$. That is,

$$P_a(t_1) = \frac{CNT_a(t_1)}{|V_s|} \tag{19}$$

To rank how close tags are to each other, let

$$w_{t_1,t_2} = \frac{CNT_f(t_1, t_2)}{CNT_a(t_1) \cdot CNT_a(t_2)}, \tag{20}$$

which represents the weight of the tag pair of t_1 and t_2 . If neither t_1 nor t_2 is on the list of top 1,000 tags, then let $w_{t_1,t_2} = 0$. It turns out that the tag pairs with the highest weight are *music* versus *photography* and *photography* versus *travel*. The tag pairs with the lowest weight are *film* versus *php* and *linux* versus *snowboarding*.

Let user i 's tag list be $(t_{i1}, t_{i2}, \dots, t_{iM})$ and user j 's tag list be $(t_{j1}, t_{j2}, \dots, t_{jN})$. Define the tag metric $m_{t(i,j)}$ as follows:

$$m_{t(i,j)} = \sum_{n=1}^N \sum_{m=1}^M w_{t_{im}, t_{jn}}. \tag{21}$$

Figure 9 shows the histogram of tag metrics including both friend pairs (the bar on the right-hand side) and non-friend pairs (the bar on the left-hand side). It turns out that for most metric values, the tag metric distribution of friend pairs is

Fig. 9 Histogram of tag metric M_t of friends and non-friends

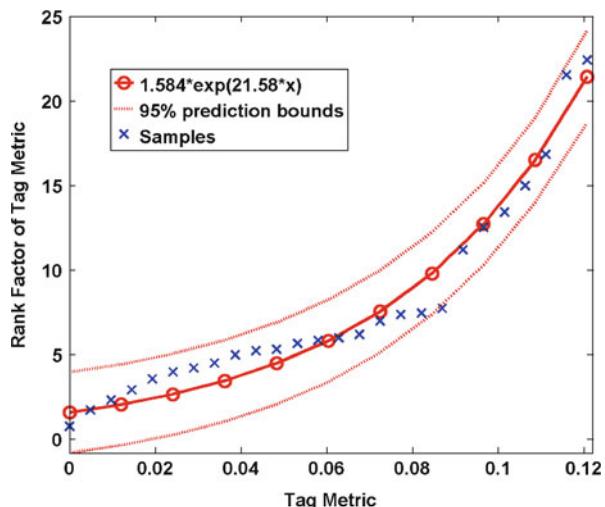

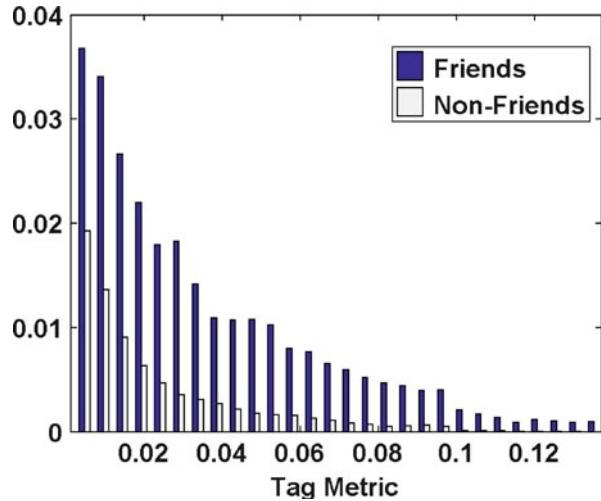

Fig. 10 Rank factor of tag metric

larger than that of non-friend pairs, especially in large value ranges, which means that friend pairs tend to share closer tags. The ranking factor of tag metric can be calculated as follows:

$$F_t = \frac{P_f(m_t)}{P_{nf}(m_t)}. \quad (22)$$

Figure 10 shows samples of F_m by cross markers. To guarantee the statistical significance of $P_{nf}(m_t)$, the tag count was required to be at least 50 for each sample in the figure. That is, values of $P_{nf}(m_t)$ for $m_t > 0.12$ were ignored. An exponential function was applied to fit the samples for producing a fitting function, shown as the

line of points. The two dotted lines depict the 95 % prediction bounds by the fitting function. When the tag metric is larger than 0.1, the values of the samples tend to be infinitely large, and so an arbitrary large number, 100, was assigned.

The function F_t can be denoted by

$$F_t(m_t) = \begin{cases} 0 & m_t = 0 \\ 1.584 \times e^{(21.58 \times m_t)} & 0 < m_t \leq 0.12 \\ 100 & 0.12 < m_t. \end{cases} \quad (23)$$

5.1.3 Location Graph Layer

To calculate location similarities among users, the conterminous 48 states in the USA were split into smaller regions based on population. Cities with large population were also divided into several regions. For a countryside with fewer people, a region may cover tens of square miles. [Figure 11](#) depicts a splitting example. The population data of the year 2000 from the US Census Bureau was used in the splitting,² which includes 36,269 cities in the USA. In particular, the conterminous 48 states were viewed as a rectangle, and the total population was counted. If the population was larger than the threshold of 50,000, split the rectangle both vertically and horizontally, resulting in four smaller rectangles evenly. Keep splitting each region until there is no more region with population larger than the threshold or there is only a single city in the region.

Count for each user how many updates fell into each region. The summation of two users' update counts in the same region indicates their location similarity, which is the metric for the location layer. Formally, let c_{in} denote the update count of user i in region n ; then the location metric of user i and user j , denoted by $m_l(i,j)$, can be calculated as follows:

$$m_l(i, j) = \sum_n \text{sng}(c_{in}) \times \text{sng}(c_{jn}) \times (c_{in} + c_{jn}), \quad (24)$$

where $\text{sng}(\cdot)$ is a sign function defined below:

$$\text{sng}(x) = \begin{cases} 1 & \text{if } x > 0 \\ 0 & \text{otherwise.} \end{cases} \quad (25)$$

[Figure 12](#) shows the probability density function of the location metric for both friend pairs and non-friend pairs. The friend pairs tend to have smaller values of the location metric. To keep the statistical significance, samples with location metric larger than 500 were ignored, for there were few non-friend pairs in this range.

Similar to the tag metric, define the ranking factor of location metric as follows:

$$F_l = \frac{P_f(m_l)}{P_{nf}(m_l)}. \quad (26)$$

²<http://www.census.gov/>.

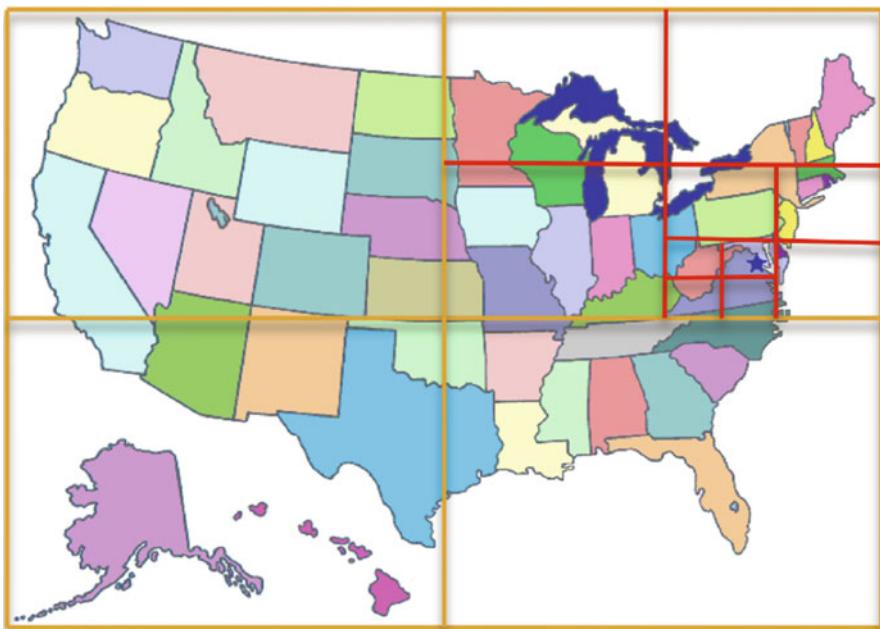

Fig. 11 An example of map splitting

Fig. 12 Probability distribution of location metric 1

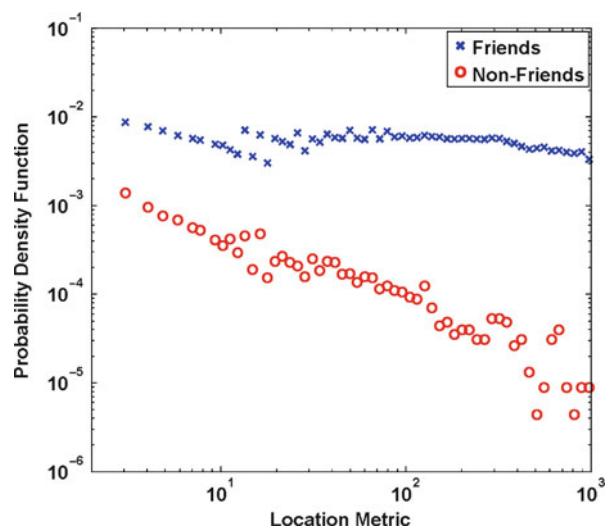

Fig. 13 Rank factor of location metric 1

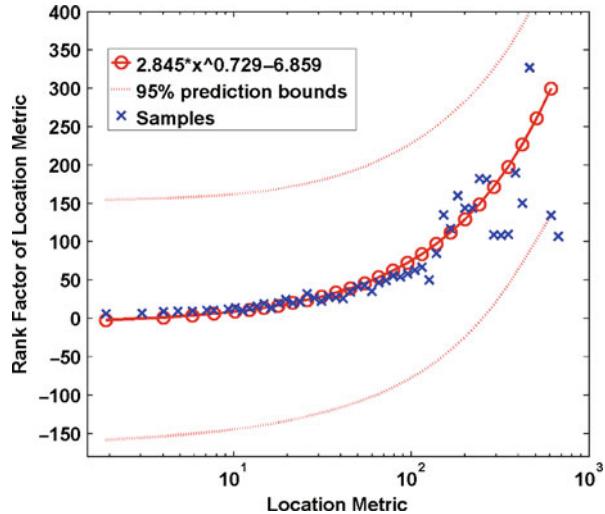

Figure 13 depicts the samples of F_l by cross markers. The power law function was used to fit the samples for producing a fitting function, shown as the line of points. The two dotted lines show the 95 % prediction bounds by the fitting function. The situations where $m_l > 500$ were ignored for statistical significance, and an arbitrary large number, 300, was assigned for $m_l > 500$.

$$F_l(m_l) = \begin{cases} 0 & m_l < 4 \\ 2.845 \times m_l^{0.729} - 6.859 & 4 \leq m_l \leq 500 \\ 300 & m_l > 500. \end{cases} \quad (27)$$

Lacking population data outside the USA, another location metric was used to calculate the user pairs who posted updates outside of the United States.

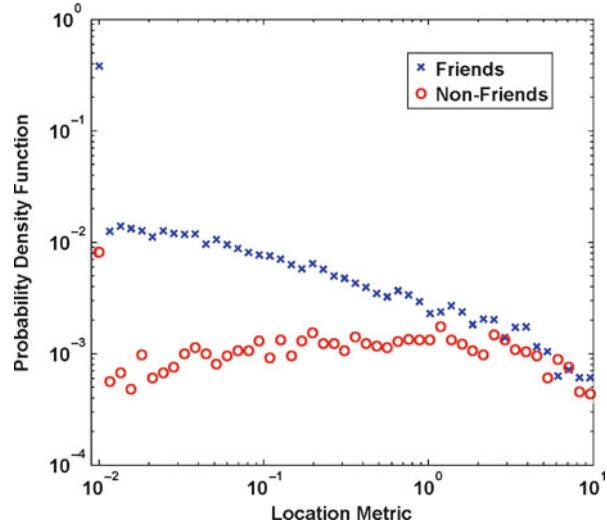

Assuming that user i sent updates in the locations $(l_{i1}, l_{i2}, \dots, l_{iN})$ and each location contained a number of updates $(c_{i1}, c_{i2}, \dots, c_{iN})$, respectively, let $\text{Dist}(l_1, l_2)$ denote the geographical distance of locations l_1 and l_2 .

Define the location metric $m'_{l(i,j)}$ between user i and j as follows:

$$m'_{l(i,j)} = \min_{\forall m \in (1, M), \forall n \in (1, N)} \left(\frac{\text{Dist}(l_{im}, l_{jn})}{c_{im} + c_{jn}} \right) \quad \text{when, } \text{Dist}(l_{im}, l_{jn}) < 30. \quad (28)$$

Equation 28 ignores the location pairs whose distance is larger than 30 miles. That is, the geographical correlation of two locations that are 30 miles away is ignored. The location metric is the minimum value of update distance divided by the summation of update times in the two locations. The user pair (A, B) is viewed closer than the user pair (C, D) if (A, B) has more updates than (C, D) , even if their

Fig. 14 Probability of location metric 2

update distances are the same. More updates for (A, B) mean that A and B could be neighbors or they worked in nearby locations. On the other hand, few updates for (C, D) mean that they happened to visit the same place and were not close as (A, B) .

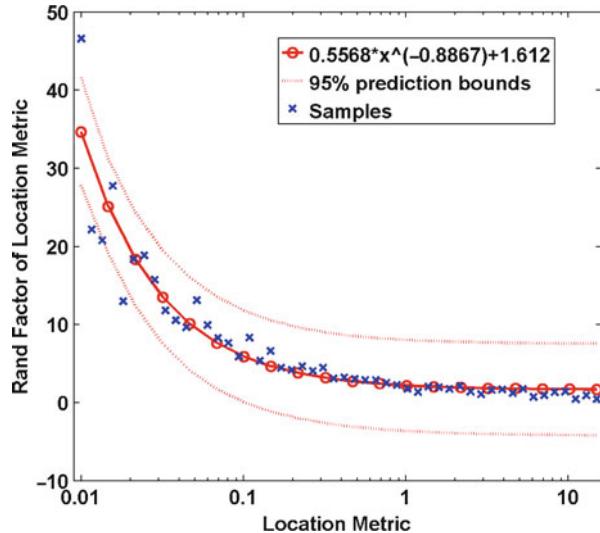

Figure 14 shows the probability density function of the location metric for both friend pairs and non-friend pairs. The friend pairs tend to have smaller values for the location metric.

Figure 15 shows the samples of F_l by cross markers. The power law function was used to fit the samples for producing a fitting function, shown as the point-line. The two dotted lines show the 95 % prediction bounds by the fitting function. The situations where $m'_l > 14$ were ignored because in these situations $F'_l < 1$. An arbitrary large number, 100, was assigned for $m'_l < 0.01$:

$$F'_l(m'_l) = \begin{cases} 100 & m'_l < 0.01 \\ 0.5568 \times m'^{-0.8867}_l + 1.612 & 0.01 \leq m'_l \leq 14 \\ 0 & m'_l > 14. \end{cases} \quad (29)$$

It can be seen that the second location metric is not as good as the first one, since it considers the two closest update locations and ignores the others. On the other hand, the first location metric reflects all update closeness between any two users. Finally, if the majority of updates of both users were in the conterminous 48 states of the USA, the first location metric was used; otherwise, the second location metric was used.

Fig. 15 Rank factor of location metric 2

5.2 Friendship Ranking

Given a user pair, its friendship ranking can be calculated as follows:

$$F(m_s, m_t, m_l) = F_s(m_s) + F_t(m_t) + F_l(m_l). \quad (30)$$

A larger value of $F(m_s, m_t, m_l)$ indicates that the two users would have a higher probability to be friends. For any given user, the system can calculate the friendship ranking value with other users and returns a list of high rank users as recommended friends to that user.

5.3 Evaluation

The proposed friendship model was validated using the changes of friends lists from April 14, 2009, to October 4, 2009. A total of 19,092 new friend pairs were found. Then randomly select another 200,000 non-friend pairs that have no overlaps with the 340,000 non-friend model training pairs. The two groups of user pairs were test sets for model evaluation.

Figure 16 shows the distributions of the ranking values of the two test sets. It is obvious that the distribution of ranking values of friend pairs and non-friend pairs is different. Given a threshold of 3, there were 93.01 % friend pairs whose ranking value is larger than 3. On the other hand, there were 86.32 % non-friend pairs whose ranking value is smaller than the threshold.

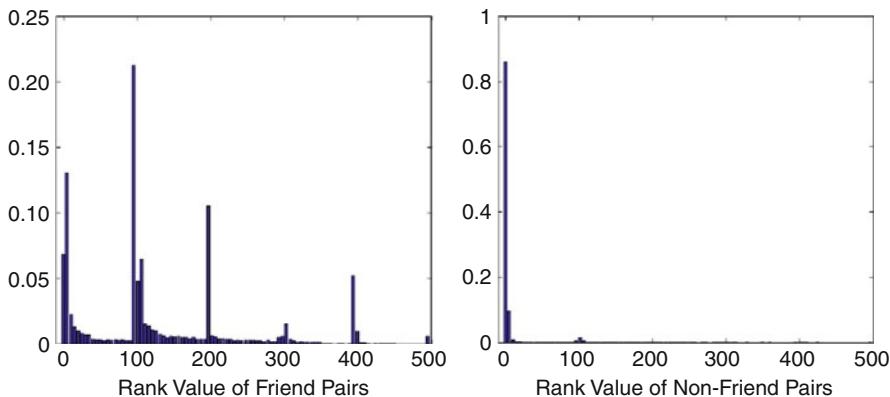

Fig. 16 Histogram of ranking value

5.3.1 Model Prediction Results

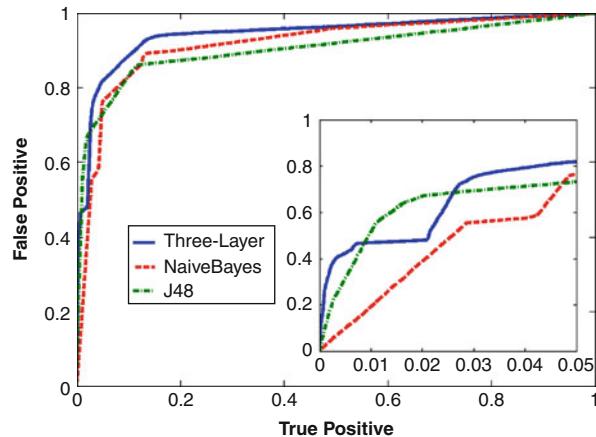

One of the applications of this friendship model is friend recommendation. Given a large user set (there were over 70,000 users in Brightkite, for example), one can use this model to rank all users against a specified user and present a recommended user list to the user as suggested friends based on the ranking values. On the other hand, this model can also be used to predict friendship in user pairs. To evaluate the model, if most of user pairs with high ranking value indeed became friends after a period of time, then the model is valid and effective.

The receiver operating characteristic (ROC) curve was used to compare the ranking performance of the proposed model with other classical data mining algorithms, as shown in Fig. 17. The ranking performance can also be considered as accuracy of prediction.

To plot the ROC curve, first calculate the ranking values of all test sets (19,092 new friend pairs + 200,000 non-friend pairs) and sort them in decreasing order of ranking values. If two pairs have the same ranking value, their order is random. Going through from top to bottom in the sorted list, draw points in the ROC figure from original point (0,0). If the current ranked user pair is indeed a friend, move the cursor along the y -axis with the normalized distance $\Delta y = 1/19,092$ and draw a point. If the current ranked user pair is not a friendship, move along the x -axis with distance $\Delta x = 1/200,000$ and draw a point. After drawing a point, check the next user pair and repeat the process until no more data is left. Viewing the ranking result as friendship prediction, the x -axis denotes the false positives and y -axis denotes the true positives.

For perfect friendship ranking, all the true friend pairs should aggregate at the top of the ranking values, the ROC curve thus yields the line from original point (0,0) to the upper left corner (0,1) and to the upper right corner (1,1). A completely random ranking, however, would give a diagonal line from the left bottom to the top right corner.

Fig. 17 ROC curves of friendship ranking

The non-diagonal solid line is the ROC curve for the proposed model. It can be seen that there were more than 80 % true friend pairs against about 10 % false positives. In other words, by using the friendship ranking, about 80 % friend pairs aggregate at the top 10 % of the data set.

The performance of the three-layer friendship model is superior to the classical data mining algorithms. In particular, the standard probabilistic naive Bayes classification algorithm and the C4.5 revision 8 decision tree learner algorithm (J48) were carried out on the same data sets used by the three-layer friendship model. Figure 17 also depicts the performance of these two algorithms, where the dashed line denotes the performance of naive Bayes algorithm and the dotted line denotes the performance of the J48 decision tree algorithm. The ROC area was calculated to quantify the overall performance, which is the area below the ROC curve. Of course, the ROC area of the perfect ranking is 1 and the random ranking is 0.5. Table 1 shows the comparison results of the three algorithms. Though the results are close, the three-layer model has a larger ROC area than the other two models, indicating better performance.

For a friend recommendation application, it is more interesting to compare user pairs for *high ranking values*. This is because when a recommended list of friends is provided to a user, they would probably only browse the top, say 100, suggestions and ignore the rest. Considering more than 70,000 users in Brightkite, the top 1 % or even top 0.1 % recommended users are the most important.

To show the performance of the three algorithms in the part of high ranking values, it suffices to show a sub-figure of magnifying ROC curves in Fig. 17. This figure includes the three ROC curves of the x -axis from 0 to 0.05. The three-layer friendship model shows a superior performance over the other two algorithms in most cases, where J48 is better than naive Bayes.

Table 2 shows the detailed numbers on the friend-pair prediction against different non-friend pairs (false positive rate). Each row indicates prediction results of the three algorithms in a given top user pairs. For example, the second row of Table 2

Table 1 The ROC area of three algorithms

	Multilayered	Naive Bayes	J48 tree
	0.906	0.882	0.869

Table 2 Predication performance comparisons

Top	Friend pairs number and percentage			J48 tree
	Multilayer	Naive Bayes		
10,000	8,672	86.7 %	6,498	65.0 %
5,000	4,804	96.1 %	3,277	65.5 %
1,000	982	98.2 %	639	63.9 %
500	487	97.4 %	324	64.8 %
100	98	98.0 %	68	68.0 %
50	49	98.0 %	37	74.0 %

indicates that in the top 100 user pairs with high ranking values, the three-layer model successfully predicted 98 friend pairs, which means that in those ranked list, there are 98 true friend pairs in the top 100 ranked pairs and the true friend pairs percentage is 98 %. At the same time, the J48 tree found 90.0 % true friend pairs and the naive Bayes found only 68.0 %. In the third row from bottom of [Table 2](#), the three-layer model successfully predicted 487 true friend pairs in the top 500 ranked pairs. Though the three algorithms have close overall prediction performance, [Table 1](#) shows that the three-layer friendship model achieved better prediction accuracy than the other two classical algorithms, especially for the part of high ranking values.

5.3.2 Location Metric

To explore the relationship between location-based metric and user friendship for location-based OSNs, the ROC area of the proposed model without the location layer was calculated. That is, the model has only two layers: the social graph and tag graph. The ROC area is 0.758, which incurs substantial performance reduction compared with the three-layer model. [Figure 18](#) shows the comparison of two ROC curves.

Additionally, one can use the *information gain* to quantify the impact of different attributes to friendship prediction. In addition to the three attributes of distance, tags, and locations, one may also calculate the information gain of gender difference and age difference in friendship prediction. [Table 3](#) shows the results.

It shows that the location-based metric provided comparable information gain as the social graph distance in friendship prediction. The tag metric has smaller information gain than the other two metrics, possibly for the reason that a large number of users used tags out of the top 1,000 popular ones, and so their tag metrics become zero. The gender and age attributes, however, provide few information gain

Fig. 18 Comparison of ROC curves with/without location metric

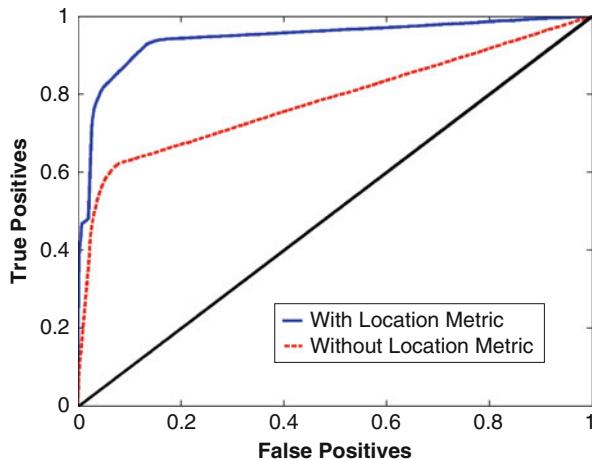

Table 3 Information gain of different attributes

Attributes	Info. gain
Social dist.	0.549
Loc. metric	0.405
Tag metric	0.034
Gender diff	0.020
Age diff	0.011

and so do not help predict friendship. One of a possible reason is that a large number of users hide such information for privacy consideration.

6 Conclusion

This chapter introduces and describes four major issues in the application research of online social networks. They are influence maximization, community detection, data collection, and multilayer friendship modeling. The first two are combinatorial optimization problems. The last two study how to collect data and determine friendships, which are needed for studying the first two issues from a holistic point of view. For each issue, this chapter provides theoretical results and approximation algorithms. Online social networks provide a new platform of rich applications for fruitful research of combinatorial optimizations.

Abstract

Data collection is an important operation of wireless sensor networks (WSNs). The performance of data collection can be measured by its achievable *network capacity*. Most existing works focus on the capacity of *unicast*, *multicast*, or/and *snapshot data collection* (SDC) in single-radio single-channel wireless networks, and no works dedicatedly consider the *continuous data collection* (CDC) capacity for WSNs under the protocol interference model. In this chapter, firstly, a *multipath scheduling* algorithm for SDC in single-radio multichannel WSNs is proposed. Theoretical analysis of the multipath scheduling algorithm shows that its achievable network capacity is at least $\frac{W}{2\lceil(1.81\rho^2+c_1\rho+c_2)/H\rceil}$, where W is the channel bandwidth, H is the number of available orthogonal channels, ρ is the ratio of the interference radius over the transmission radius of a node, $c_1 = \frac{2\pi}{\sqrt{3}} + \frac{\pi}{2} + 1$, and $c_2 = \frac{\pi}{\sqrt{3}} + \frac{\pi}{2} + 2$, which is a tighter lower bound compared with the previously best result which is $\frac{W}{8\rho^2}$ (Chen et al. (2010) Capacity of data collection in arbitrary wireless sensor networks. In: IEEE INFOCOM, San Diego, USA). For CDC, an intuitive method is to pipeline existing SDC methods. However, such an idea cannot actually improve the network capacity. The reason for this failure is discussed and a novel *pipeline scheduling* algorithm for CDC in dual-radio multichannel WSNs is proposed. This pipeline scheduling algorithm significantly speeds up the data collection process and achieves a capacity of

$$\begin{cases} \frac{nW}{12M \left\lceil \frac{3.63\rho^2 + c_3\rho + c_4}{H} \right\rceil}, & \text{if } \Delta_e \leq 12 \\ \frac{nW}{M\Delta_e \left\lceil \frac{3.63\rho^2 + c_3\rho + c_4}{H} \right\rceil}, & \text{if } \Delta_e > 12 \end{cases},$$

where n is the number of the sensors, M is a constant value and usually $M \ll n$, Δ_e is the maximum number of the leaf nodes having a same parent in the routing tree (i.e., data collection tree), $c_3 = \frac{8\pi}{\sqrt{3}} + \pi + 2$, and $c_4 = \frac{8\pi}{\sqrt{3}} + 2\pi + 6$. Furthermore, for completeness, the performance of the proposed pipeline scheduling algorithm in single-radio multichannel WSNs is also analyzed, which shows that for a long-run CDC, the lower bound of the achievable asymptotic network capacity is

$$\begin{cases} \frac{nW}{16M \left\lceil \frac{3.63\rho^2 + c_3\rho + c_4}{H} \right\rceil}, & \text{if } \Delta_e \leq 12 \\ \frac{nW}{M(\Delta_e + 4) \left\lceil \frac{3.63\rho^2 + c_3\rho + c_4}{H} \right\rceil}, & \text{if } \Delta_e > 12 \end{cases}.$$

Extensive simulation results indicate that the proposed algorithms improve the network capacity significantly compared with existing works.

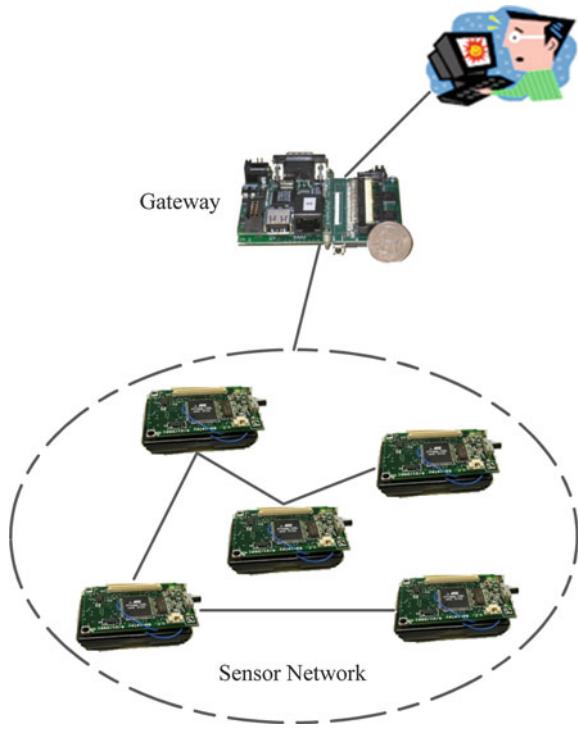

1 Introduction

Wireless sensor networks (WSNs) as shown in Fig. 1, consisting of small nodes with sensing, computation, and wireless communication capabilities, attract many interests from the research community recently.

Generally speaking, WSNs are deployed for monitoring and controlling systems where human intervention is not desirable or feasible. Therefore, WSNs are widely used in many applications [2, 15, 34]:

- *Disaster relief applications.* A typical scenario is wildfire detection, where a WSN consisting of sensor nodes that are equipped with thermometers and can determine their own locations (relative to each other or in absolute coordinates) is deployed. In such an application, sensor nodes should be cheap enough to be considered disposable since a large number is necessary.
- *Environment monitoring.* WSNs can be used to monitor environments. For instance, with respect to monitor chemical pollutants, a possible application is monitoring garbage dump sites. The main advantage of WSNs here is the long-term and unattended monitoring.
- *Intelligent buildings.* Buildings waste vast amounts of energy because of inefficient monitoring of humidity, ventilation, and/or air conditioning usage. A better, real-time, and high-resolution monitoring of temperature, airflow, humidity, and other physical parameters in a building by means of WSNs can considerably increase the comfort level of inhabitants and reduce the energy consumption.
- *Facility management.* In the management of facilities larger than a single building, WSNs also have a wide range of possible applications. Simple examples include keyless entry applications where people wear badges that allow a WSN to check which person is allowed to enter which areas of a larger company site. This example can be extended to the detection of intruders.
- *Machine surveillance and structural health monitoring (SHM).* One idea is to fix sensor nodes to difficult-to-reach areas of machinery where they can detect vibration patterns that indicate the need for maintenance.
- *Precision agriculture.* Applying WSNs to agriculture allows precise irrigation and fertilizing by placing humidity/soil composition sensors into the fields.
- *Medicine and health care.* The use of WSNs in healthcare applications is potentially very beneficial. Possibilities range from postoperative and intensive care, where sensors are directly attached to patients.
- *Logistics.* In several different logistics applications, it is conceivable to equip goods with simple sensors that allow a simple tracking of these objects during transportation or facilitate inventory tracking in stores or warehouses.
- *Traffic control.* Sensors embedded in the streets or road sides can gather information about traffic conditions at a much finer-grained resolution. Such deployed sensors could also interact with the cars to exchange danger warnings about road conditions or traffic jams ahead.

Fig. 1 A wireless sensor network (WSN)

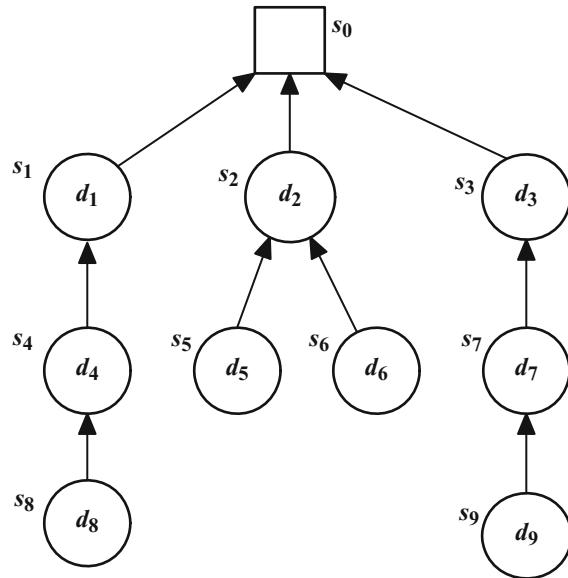

2 Problems, Motivations, and Main Contributions

As mentioned in the previous section, WSNs are mainly used for gathering data from the physical world. Data gathering can be categorized as *data aggregation* [1, 28, 33, 44, 57], which obtains aggregated values from WSNs, e.g., maximum, minimum, or/and average value of all the data, and *data collection* [11, 12, 31, 32, 46, 65, 66], which gathers all the data from a network without any data aggregation. For data collection, the union of all the sensing values from all the sensors at a particular time instance is called a *snapshot* [12, 31]. The problem of collecting all the data of one snapshot is called *snapshot data collection* (SDC). Similarly, the problem of collecting multiple continuous snapshots is called *continuous data collection* (CDC).

Taking the WSN shown in Fig. 2 as an example, this WSN consists of one sink node denoted by s_0 and nine sensors denoted by s_i ($1 \leq i \leq 9$). Assume the data value (packet) produced at sensor s_i ($1 \leq i \leq 9$) at a particular time instance is d_i ($1 \leq i \leq 9$) as shown in Fig. 2. Then, the set $\{d_i \mid 1 \leq i \leq 9\}$ is called a snapshot. In a data aggregation task, if the aggregation function is $\max(\cdot)$,¹ then

¹Under the $\max(\cdot)$ function, the maximize value of a snapshot will be collected by the sink, i.e., $\max(\{d_1, d_2, \dots, d_n\}) = d_{\max}$ such that $d_{\max} \in \{d_1, d_2, \dots, d_n\}$ and for $\forall d_i \in \{d_1, d_2, \dots, d_n\}$, $d_{\max} \geq d_i$.

Fig. 2 Explanation of *data aggregation and data collection*

only the maximize value of set $\{d_i \mid 1 \leq i \leq 9\}$ will be collected by the sink s_0 . On the other hand, in a data collection task, all the nine values of set $\{d_i \mid 1 \leq i \leq 9\}$ will be collected by the sink s_0 .

Different from wired networks, WSNs suffer from the interference problem, which degrades the network performance. Consequently, *network capacity*, which can reflect the achievable data transmission rate, is usually used as an important measurement to evaluate network performance. Particularly, for a data collection WSN, the average data receiving rate at the sink during the data collection process, referred to as *data collection capacity* [12, 31] (formally defined in Sect. 4.2), is used to measure its achievable network capacity, i.e., data collection capacity reflects how fast data have been collected by the sink. In this chapter, the snapshot and continuous data collection problems (formally defined in Sect. 4.2), as well as their achievable capacities in single/dual-radio multichannel WSNs, are studied.

After the first work [24], extensive works emerged to study the network capacity issue for variety of network scenarios, e.g., multicast capacity [40, 41, 48], unicast capacity [52, 53], broadcast capacity [42], and SDC capacity [11, 12, 46, 66]. Most of the previous studies on network capacity are for single-radio single-channel WSNs [4, 8–12, 20, 22, 24, 40, 41, 46, 48, 51–53, 55, 59, 60, 63, 66], where a network consists of a number of nodes which have only one radio and all the nodes communicate over a common single channel. Because of the inherent limitations of such networks, transmissions suffer from the *radio confliction* problem [13, 23, 37, 47, 56] and the *channel interference* problem [3, 6, 7, 14, 16–19, 21, 25, 29, 29, 35–37, 43, 45, 49, 54, 61, 64] seriously. This degrades network performance significantly. The radio confliction problem is caused by the fact that each node is equipped with only one radio, which means a node can only work on a *half-duplex* mode, i.e., this node cannot receive and transmit data simultaneously. The channel

Fig. 3 A dual-radio sensor node [30, 38]

interference problem is caused by all the nodes working over a common channel. When one node transmits data, all the other nodes within its interference radius cannot receive any other data and all the other transmissions that interfere with this transmission cannot be carried out simultaneously.

Fortunately, many current off-the-shelf sensor nodes are capable of working over multiple orthogonal channels, e.g., IEEE 802.11 b/g standard supports 3 orthogonal channels and IEEE 802.11a standard supports 13 orthogonal channels [5, 13], respectively, which can greatly mitigate the channel interference problem. Furthermore, with the development of hardware technologies and the decreasing of hardware cost, a sensor node can be equipped with multiple radios. As shown in Fig. 3, it is a dual-radio sensor node developed by HLJU and HIT [30, 38]. This helps with solving the radio confliction problem. Therefore, multi-radio multichannel WSNs currently begin to attract more and more interests from researchers [13, 23, 37, 47, 56].

Different from the previous works which investigate the capacity issues for single-radio single-channel WSNs, this chapter studies the network capacity problem for both CDC and SDC in dual-radio multichannel WSNs under the *protocol interference model*. Similarly as [12], in this chapter, the *data collection capacity* is defined as the average data rate at the sink to continuously receive data from sensor nodes. Two channel scheduling algorithms for both CDC and SDC are proposed, respectively. Meanwhile, the results obtained in this chapter can be extended to WSNs under the *physical interference model* [42]. The motivation of the work in this chapter lies on the fact that dual-radio multichannel WSNs can make nodes work in a *full-duplex* manner without incurring high hardware cost, while the channel interference problem can be mitigated significantly. Most of the previous works focus on addressing the SDC capacity problem, while the work in this chapter is the dedicated one investigating the CDC capacity problem in detail under the protocol interference model. Besides, the work in this chapter is suitable for dual-radio multichannel WSNs. The main contributions of this chapter are as follows:

- For the SDC problem in single-radio multichannel WSNs, a new *multipath scheduling* algorithm is proposed. Furthermore, theoretical analysis of the multipath scheduling algorithm shows that this algorithm can achieve the order-optimal network capacity $\Theta(W)$ and has a tighter lower bound $\frac{W}{2\lceil(1.81\rho^2+c_1\rho+c_2)/H\rceil}$ compared with the previously best result in [12], which is $\frac{W}{8\rho^2}$, where W is the channel bandwidth, H is the number of available orthogonal channels in a WSN, ρ is the ratio of the interference radius over the transmission radius of a node, $c_1 = \frac{2\pi}{\sqrt{3}} + \frac{\pi}{2} + 1$, and $c_2 = \frac{\pi}{\sqrt{3}} + \frac{\pi}{2} + 2$.

- Currently, there are no solutions dedicated for the CDC capacity problem. Therefore, a novel *pipeline scheduling* algorithm that combines *compressive data gathering* (CDG) [46] and *pipeline* together is proposed, which significantly improves the CDC capacity for dual-radio multichannel WSNs. Theoretical analysis shows that the achievable asymptotic network capacity of this pipeline scheduling algorithm in a long-run is

$$\begin{cases} \frac{nW}{12M \left\lceil \frac{3.63\rho^2 + c_3\rho + c_4}{H} \right\rceil}, & \text{if } \Delta_e \leq 12 \\ \frac{nW}{M\Delta_e \left\lceil \frac{3.63\rho^2 + c_3\rho + c_4}{H} \right\rceil}, & \text{if } \Delta_e > 12 \end{cases},$$

where n is the number of the sensors in a WSN, M is a constant value determined by the correlations of the data in a snapshot and usually $M \ll n$, Δ_e is the maximum number of the leaf nodes having a same parent in the routing tree (i.e., data collection tree), $c_3 = \frac{8\pi}{\sqrt{3}} + \pi + 2$, and $c_4 = \frac{8\pi}{\sqrt{3}} + 2\pi + 6$. A straightforward upper bound of data collection of a dual-radio WSN is $2W$, since a dual-radio sink can simultaneously receive two data packets at most. Whereas, thanks to the benefit brought by the pipeline technique and CDG, analysis shows that the proposed pipeline scheduling algorithm can even achieve a capacity higher than $2W$.

- For completeness, the performance of the proposed pipeline scheduling algorithm in single-radio multi-channel WSNs is also examined, denoted by the *single-radio-based pipeline scheduling* algorithm. Theoretical analysis shows that for a long-run CDC, the lower bound of the achievable asymptotic network capacity of the single-radio-based pipeline scheduling algorithm for single-radio multi-channel WSNs is

$$\begin{cases} \frac{nW}{16M \left\lceil \frac{3.63\rho^2 + c_3\rho + c_4}{H} \right\rceil}, & \text{if } \Delta_e \leq 12 \\ \frac{nW}{M(\Delta_e + 4) \left\lceil \frac{3.63\rho^2 + c_3\rho + c_4}{H} \right\rceil}, & \text{if } \Delta_e > 12 \end{cases}.$$

- The simulation results indicate that the proposed algorithms have a better SDC capacity compared with the previously best works. Particularly, when $\rho = 2$ and $H = 3$, for SDC in a WSN with 4,000 nodes, the improvements of the capacity of the proposed multipath scheduling algorithm are 74.3 and 29 % compared with BFS [12] and SLR [6], respectively. For CDC in a WSN with 10,000 nodes, the proposed pipeline scheduling algorithm achieves a capacity 7.6 times of that of CDG [46], 22.8 times of that of BFS [12], and 19.4 times of that of SLR [6], respectively.

The rest of this chapter is organized as follows: Sect. 3 summarizes the advances in studying network capacity issues for wireless networks. Section 4 introduces the interference model, the network model, and the preliminaries. The multi-channel scheduling algorithm for SDC in single-radio multichannel WSNs is proposed and analyzed in Sect. 5. Section 6 presents a novel pipeline scheduling algorithm for CDC and its theoretical achievable asymptotic network capacity. For completeness, the performance of the pipeline scheduling algorithm in single-radio multichannel WSNs is also analyzed in Sect. 6. The simulations to validate the performance of the proposed algorithms are shown in Sect. 7. Section 8 concludes this chapter and points out possible future research directions.

3 Capacity Issues in Wireless Networks

In this section, the advances in studying network capacity issues for wireless networks are surveyed and summarized. At the end of this section, the differences between the work in this chapter and existing works are also compared.

3.1 Capacity for Single-Radio Single-Channel Wireless Networks

Following the seminal work [24] by Gupta and Kumar, extensive works emerged to study the network capacity issue. The works in [4, 8, 9, 22] focus more on the MAC layer to improve the network capacity. In [8], the network capacity with random-access scheduling is investigated. In this work, each link is assigned a channel access probability. Based on which some simple and distributed channel access strategies are proposed. Another similar work is [9], in which the authors studied the capacity of CSMA wireless networks. The authors formulated the models of a series of CSMA protocols and study the capacity of CSMA scheduling versus TDMA scheduling. They also proposed a CSMA scheme which combines a backbone-peripheral routing scheme and a dual carrier-sensing and dual-channel scheme. In [22], the authors considered the scheduling problem where all the communication requests are single-hop and all the nodes transmit at a fixed power level. They proposed an algorithm to maximize the number of links in one time slot. Unlike [22], the authors in [4] considered the power-control problem. A family of approximation algorithms were presented to maximize the capacity of arbitrary wireless networks.

The works in [40, 41, 48, 52, 53, 59] study the multicast and/or unicast capacity of wireless networks. The multicast capacity for wireless ad hoc networks under the protocol interference model and the Gaussian channel model is investigated in [40, 41], respectively. In [40], the authors showed that the network multicast capacity is $\Theta\left(\sqrt{\frac{n}{\log n}} \cdot \frac{W}{k}\right)$ when $k = O\left(\frac{n}{\log n}\right)$ and is $\Theta(W)$ when $k = \Omega\left(\frac{n}{\log n}\right)$, where W is the bandwidth of a wireless channel, n is the number of the nodes in a network, and k is the number of the nodes involved in one multicast session. In [41], the authors showed that when $k \leq \theta_1 \frac{n}{(\log n)^{2\alpha+6}}$ and $n_s \geq \theta_2 n^{1/2+\beta}$, the

capacity that each multicast session can achieve is at least $c_8 \frac{\sqrt{n}}{n_s \sqrt{k}}$, where k is the number of the receivers in one multicast session; n is the number of the nodes in the network; n_s is the number of the multicast sessions; θ_1 , θ_2 , and c_8 are constants; and β is any positive real number. Another similar work [48] studies the upper and lower bounds of multicast capacity for hybrid wireless networks consisting of ordinary wireless nodes and multiple base stations connected by a high-bandwidth wired network. Considering the problem of characterizing the unicast capacity scaling in arbitrary wireless networks, the authors proposed a general cooperative communication scheme in [52]. The authors also presented a family of schemes that address the issues between multi-hop and cooperative communication when the path loss exponent is greater than 3. In [53], the authors studied the balanced unicast and multicast capacity of a wireless network consisting of n randomly placed nodes and obtained the characterization of the scaling of the n^2 -dimensional balanced unicast and $n2^n$ -dimensional balanced multicast capacity regions under the Gaussian fading channel model. A more general (n, m, k) -casting capacity problem was investigated in [59], where n , m , and k denote the total number of the nodes in the network, the number of destinations for each communication group, and the actual number of communication group members that receive information, respectively. In [59], the upper and lower bounds for the (n, m, k) -cast capacity were obtained for random wireless networks.

In [29], the authors investigated the network capacity scaling in mobile wireless ad hoc networks under the protocol interference model with infrastructure support. In [64], the authors studied the network capacity of hybrid wireless networks with directional antenna and delay constraints. Unlike previous works, the authors in [36] studied the capacity of multi-unicast for wireless networks from the algorithmic aspects, and they designed provably good algorithms for arbitrary instances. The broadcast capacity of wireless networks under the protocol interference model is investigated in [35], where the authors derived the upper and lower bounds of the broadcast capacity in arbitrary connected networks. When the authors in [45] studied the data gathering capacity of wireless networks under the protocol interference model, they concerned the per source node throughput in a network where a subset of nodes send data to some designated destinations while other nodes serve as relays. To gather data from WSNs, a multi-query processing technology is proposed in [14]. In that work, the authors considered how to obtain data efficiently with data aggregation and query scheduling. Under different communication organizations, the authors in [17] derived the many-to-one capacity bound under the protocol interference model. Another work that studied the many-to-one capacity issue for WSNs is [49], where the authors considered to use data compression to improve the data gathering efficiency. They also studied the relation between a data compression scheme and the data gathering quality. In [19], the authors studied the scaling laws of WSNs based on an antenna-sharing idea. In that work, the authors derived the many-to-one capacity bounds under different power constraints. In [61], the authors studied the multicast capacity of MANETs under the physical interference model, called MotionCast. They considered the network capacity of MANETs in two particular situations, which are the LSRM (local-based speed-restricted) model and the GSRM (global-based speed-restricted) model.

The multi-unicast capacity of wireless networks is studied in [18] via percolation theory. By applying percolation theory, the authors obtained a tighter capacity bound for arbitrary wireless networks.

The SDC capacity of WSNs is studied in [10–12, 31, 46, 51, 66]. In [66], the authors considered the collision-free delay-efficient data-gathering problem. Furthermore, they proposed a family of path scheduling algorithms to collect all the data to the sink and obtained the network capacity through theoretical analysis. The authors of [12, 31] extended the work of [66]. They derived tighter upper and lower bounds of the capacity of data collection for arbitrary WSNs. Luo et al. [46] is a work studying how to distribute the data collection task to the entire network to achieve load balancing. In that work, all the sensors transmit the same number of data packets during the data collection process. In [10, 11, 32], the authors investigated the capacity of data collection for WSNs under the protocol interference model and the physical interference model, respectively. They proposed a grid partition method which divides the network into small grids to collect data and then derived the network capacity. The worst-case capacity of data collection of a WSN is studied in [51] under the physical and protocol interference models.

The capacity and energy efficiency of wireless ad hoc networks with multi-packet reception under the physical interference model are investigated in [60]. With the multi-packet reception scheme, a tight bound of the network capacity is obtained. Furthermore, the authors showed that a trade-off can be made between increasing the transport capacity and decreasing the energy efficiency. In [63], a scheduling partition method for large-scale wireless networks is proposed. This method decomposes a large network into many small zones, and then localized scheduling algorithms which can achieve the order optimal capacity as a global scheduling strategy are executed in each zone independently. A general framework to characterize the capacity of wireless ad hoc networks with arbitrary mobility patterns is studied in [20]. By relaxing the “homogeneous mixing” assumption in most existing works, the capacity of a heterogeneous network is analyzed. Another work [55] studies the relationship between the capacity and the delay of mobile wireless ad hoc networks, where the authors studied how much delay must be tolerated under a certain mobile pattern to achieve an improvement of the network capacity.

3.2 Capacity for Multichannel Wireless Networks

Since wireless nodes can be equipped with multiple radios, and each radio can work over multiple orthogonal channels, multi-radio multichannel wireless networks attract many research interests recently [3, 21, 25, 43]. In [21], the authors studied the data aggregation issue in multichannel WSNs under the protocol interference model. Particularly, they designed a constant factor approximation scheme for data aggregation in multi-channel WSNs modeled by unit disk graphs (UDGs). Unlike [21], this chapter studies the snapshot/continuous data collection capacity issue for WSNs. In [3, 25, 43], the authors investigated the joint channel assignment and routing problem for multi-radio wireless mesh networks, software-defined radio

networks, and multichannel ad hoc wireless networks, respectively. They focused on the channel assignment and routing issues, while in data collection, especially continuous data collection, one focuses on how to solve the data accumulation problem at the sensors near the sink to improve the achievable network capacity.

The issue of the capacity of multichannel wireless networks also attracts a lot of attention [6, 7, 16, 37, 54]. In [6, 7], the authors studied the connectivity and capacity problem of multichannel wireless networks. They considered a multi-channel wireless network under constraints on channel switching, proposed some routing and channel assignment strategies for multiple unicast communications and derived the per-flow capacity. The multicast capacity of multi-channel wireless networks is studied in [54]. In this work, the authors represented the upper bound capacity of per multicast as a function of the number of the sources, the number of the destinations per multicast, the number of the interfaces per node, and the number of the available channels. Subsequently, an order-optimal scheduling method is proposed under certain circumstances. In [16], the authors first proposed a multichannel network architecture, called MC-MDA, where each node is equipped with multiple directional antennas, and then obtained the capacity of multiple unicast communications, under arbitrary and random network models. The impact of the number of the channels, the number of the interfaces, and the interface switching delay on the capacity of multichannel wireless networks is investigated in [37]. In this work, the authors derived the network capacity under different situations for arbitrary and random networks.

3.3 Remarks

Unlike the above-mentioned works, this chapter has the following two main characteristics. First, most of the above-mentioned works are specifically for single-radio single-channel wireless networks, while the work in this chapter considers the network capacity for dual-radio multichannel WSNs. Second, the work in this chapter is the dedicated one that investigates the network capacity for CDC in detail under the protocol interference model, whereas most of the previous works study the network capacity for multicast or/and unicast and etc. For the works that study the data collection capacity of wireless networks, they focus on the SDC problem which is a special case of CDC. Compared with them, the methods proposed in this chapter are more universal.

4 Network Model and Preliminaries

In this section, the interference model, the network model, and the assumptions are described; the routing tree used for data collection is constructed; and some necessary preliminaries are made. For the frequently used notations in this chapter, they are listed in [Table 1](#).

Table 1 Notations used in this chapter

Notation	Description
$G(V, E)$	The network topology graph, V is the set of all the nodes, E is the set of all the possible links
n	The number of sensors in a WSN
ρ	The interference radius
$\lambda_1, \dots, \lambda_H$	The H available orthogonal channels
W	The bandwidth of a channel
b	The size of a data packet
t	A time slot
τ	The time consumption of snapshot/continuous data collection
N	The number of snapshots in a continuous data collection task
Υ	The snapshot/continuous data collection capacity
D/C	The set of dominators/connectors
G'	The graph constructed by the nodes in D
L'	The radius of G'
T	The data collection tree
$\mathfrak{R}(A)$	The conflicting graph of A
$\Delta(\cdot)/\delta(\cdot)$	The maximum/minimum degree of a graph
Δ_e	The maximum number of leaf nodes having a same parent in T
$\delta^*(\cdot)$	The inductivity of a graph
β_r	The number of the dominators within a half-disk with radius r
SDC	Snapshot data collection
CDC	Continuous data collection
CDG	Compressive data gathering
STS	Super time slot
CDS	Connected dominating set

4.1 Interference Model

When model the interference in wireless networks, three interference models are frequently used: the *protocol interference model* [12, 31], the *physical interference model* [11], and the *generalized physical interference model* [1, 41]. Assume u and v are two nodes in a wireless network and u is transmitting some data to v . Furthermore, assume \mathcal{T} is set of all the nodes that transmit data to some nodes concurrently with u . Then, the transmission of u and v under these three interference models will be introduced respectively in the following.

4.1.1 Protocol Interference Model

Under the protocol interference model, u can successfully transmit data to v only if

$$\forall w \in \mathcal{T}, w \neq u, \quad \|w - v\| \geq (1 + \theta) \cdot r, \quad (1)$$

where w is any node transmitting data concurrently with u , $\|\cdot\|$ is the Euclidian distance between two nodes, $\theta \geq 0$ is a constant value, and r is the communication radius of the nodes in a wireless network.

4.1.2 Physical Interference Model

Under the physical interference model, u can successfully transmit data to v only if the signal-to-interference-plus-noise ratio (SINR) value at v associated with u is no less than a threshold value as follows:

$$\Lambda(u, v) = SINR_{u,v} = \frac{P_u \cdot \|u - v\|^\eta}{N_0 + \sum_{w \in \mathcal{T}, w \neq u} P_w \cdot \|w - v\|^\eta} \geq \gamma, \quad (2)$$

where P_u (respectively, P_w) is the transmission power of u (respectively, w), $\eta > 2$ is the path loss exponent, N_0 represents the ambient noise, and γ is the threshold SINR value.

4.1.3 Generalized Physical Interference Model

Under the generalized physical interference model, the data receiving rate at v from u is given by

$$\mathcal{R}_{u,v} = W \cdot \log(1 + \Lambda(u, v)), \quad (3)$$

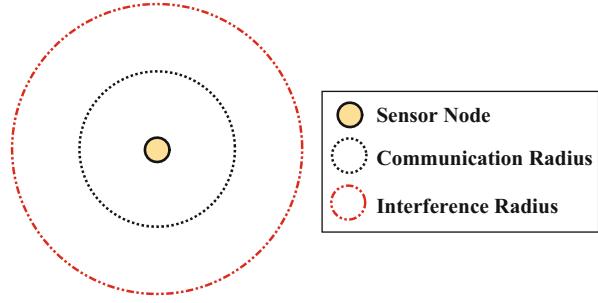

where W is the bandwidth of the channel on which u transmits data to v .

In this chapter, the snapshot and continuous data collection, as well as their achievable capacities, in single/dual-radio multichannel WSNs are investigated under the protocol interference model.

4.2 Network Model

In this chapter, a WSN consisting of n sensors and one sink is considered and represented by a connected undirected graph $G = (V, E)$, where V is the set of all the nodes in the network and E is the set of all the possible links among the nodes in V . Every sensor in the WSN produces one data packet in a snapshot. Each sensor has two radios and each radio has a fixed transmission radius normalized to one and a fixed interference radius, denoted by ρ , $\rho \geq 1$, as shown in Fig. 4. Since the protocol interference model is used, for any receiving node v , v can receive a data packet successfully from a transmitting node u if $\|u - v\| \leq 1$ and there is no other node s satisfying $\|s - v\| \leq \rho$ and trying to transmit a data packet simultaneously over the same channel with u . Furthermore, two links are *interfering links* if at least one transmission over them will fail if they transmit data simultaneously. Each radio can work over H orthogonal channels, denoted by $\lambda_1, \lambda_2, \dots, \lambda_H$, respectively. A fixed data-rate channel model [12] is adopted in this chapter, which means each sensor can transmit at a rate of W bits/second over a wireless channel. The size of every

Fig. 4 Communication radius vs. interference radius

data packet transmitted in the network is set to be b bits. All the transmissions are assumed to be synchronized and the size of a time slot is $t = b/W$ seconds.

The problems studied in this chapter are further formally defined as follows. For a WSN consisting of n sensors and one sink, every sensor produces a data packet with b bits at a particular time instant. The union of all the n data packets produced by the n sensors at a particular time instant is called a *snapshot*. The process to collect all the data of a snapshot to the sink is called *snapshot data collection* (SDC). The *SDC capacity* is defined as $\Upsilon = \frac{nb}{\tau}$, where τ is the time used to collect all the data of a snapshot to the sink, i.e., SDC capacity reflects the average data receiving rate at the sink during SDC. Similarly, the process to collect all the data of N continuous snapshots is called *continuous data collection* (CDC). The *CDC capacity* is defined as $\Upsilon = \frac{Nnb}{\tau}$, where τ now is the time consumption to collect all the data of these N snapshots to the sink, i.e., CDC capacity reflects the average data receiving rate at the sink during CDC. In this chapter, the SDC and CDC problems for WSNs, as well as their achievable network capacities, are studied.²

4.3 Routing Tree

G is a unitdisk graph representing a WSN. The sink s_0 is defined as the *center* of G . The *radius* of G with respect to s_0 is the maximum depth of the *breadth-first search* (BFS) tree rooted at s_0 . For a subset U of V , U is a *dominating set* (DS) of G if every node in V is either an element of U or adjacent³ to at least one node in U . If the subgraph of G induced by U is connected, then U is called a *connected dominating set* (CDS) of G . Since a CDS can serve as a virtual backbone of a WSN, it receives a lot of attention [26, 27, 39, 57, 58, 62] recently.

²In the following of this chapter, the snapshot/continuous data collection capacity and network capacity are used interchangeably without confusion.

³In this chapter, if two nodes u and v are said adjacent/connected, that means u and v are within the communication range of each other, i.e., $\|u - v\| \leq 1$.

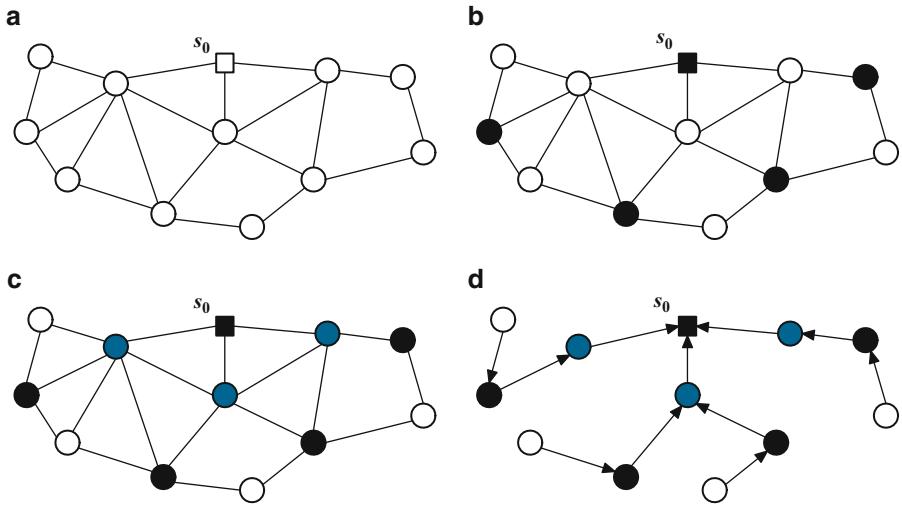

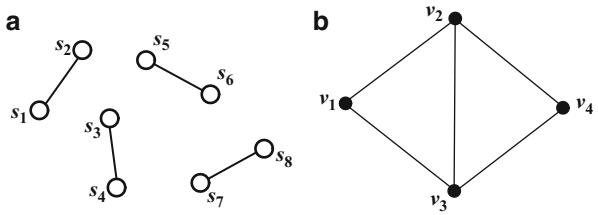

Fig. 5 The construction of a CDS based routing tree. s_0 is the sink. The *black nodes* in (b) are *dominators*, and the *blue nodes* in (c) are *connectors*

Taking the WSN shown in Fig. 5a as an example, a CDS-based routing tree T is built as shown in Fig. 5d using the method proposed in [57]. T is rooted at the sink and can be built according to the following steps. First, construct a BFS tree on G beginning at the sink and obtain a *maximal independent set* (MIS) D according to the search sequence. As shown in Fig. 5b, the set of all the black nodes is an MIS of the network shown in Fig. 5a. Note that D is also a DS of G and an element in D is called a *dominator*. Clearly, every dominator is out of the communication range of any other dominators. Let G' be a graph on D in which two nodes in D linked by an edge if and only if these two nodes have a common neighbor in G . Obviously, sink s_0 is in G' and also s_0 is defined as the center of G' . Suppose that the radius of G' with respect to s_0 is L' and the union of dominators at level l ($0 \leq l \leq L'$) is denoted as set D_l . Note that $D_0 = \{s_0\}$. Second, choose nodes, also called *connectors*, to connect all the nodes in D to form a CDS. Let S_l ($0 \leq l \leq L'$) be the set of the nodes adjacent to at least one node in D_l and at least one node in D_{l+1} and compute a minimal cover $C_l \subseteq S_l$ for D_{l+1} . Let $C = \cup_0^{L'-1} C_l$ and therefore $D \cup C$ is a CDS of G . As shown in Fig. 5c, the blue nodes are connectors chosen to connect the dominators in D . Meanwhile, the union of the dominators and connectors in Fig. 5c forms a CDS of the network shown in Fig. 5a. Finally, for any other node u , also called a *dominatee*, not belonging to $D \cup C$, choose the nearest dominator as u 's parent node. Thus, the routing tree T is obtained. For instance, the tree shown in Fig. 5d is the obtained routing tree for the network shown in Fig. 5a.

For each link in T , assign it a direction from the child node to the parent node along the data transmission flow to the sink as shown in Fig. 5d. Furthermore,

Fig. 6 (a) A link set and (b) its corresponding conflicting graph

the receiving node, i.e., the parent node, of a link is called a *head*. Similarly, the transmitting node, i.e., the child node, of a link is called a *tail*. Suppose that A is a set of links of T . The corresponding *conflicting graph* of A is denoted by $\mathfrak{R}(A) = (V_A, E_A)$, where each link in A is abstracted to a node in V_A and two nodes in V_A form an edge in E_A if the corresponding two links of these two nodes are interfering links. Taking the four links shown in Fig. 6a as an example, suppose $\iota_1 = (s_1, s_2)$, $\iota_2 = (s_3, s_4)$, $\iota_3 = (s_5, s_6)$, and $\iota_4 = (s_7, s_8)$. Let $\mathbb{I}(\iota_i)$ ($1 \leq i \leq 4$) denote the set of interfering links with ι_i and assume

- $\mathbb{I}(\iota_1) = \{\iota_2, \iota_3\}$;
- $\mathbb{I}(\iota_2) = \{\iota_1, \iota_3, \iota_4\}$;
- $\mathbb{I}(\iota_3) = \{\iota_1, \iota_2, \iota_4\}$;
- $\mathbb{I}(\iota_4) = \{\iota_2, \iota_3\}$.

Then, the corresponding conflicting graph of $\{\iota_1, \iota_2, \iota_3, \iota_4\}$ is shown in Fig. 6b, where ι_i is abstracted to v_i .

Lemma 1 in [57] can be used to derive some useful results of the routing tree T .

Lemma 1 ([57]) Suppose that O (respectively, O') is a disk (respectively, halfdisk) with radius r and U is a set of points with mutual distances of at least one. Then the number of the points α_r in a disk and the number of the points β_r in a half-disk are

$$\alpha_r = |U \cap O| \leq \frac{2\pi}{\sqrt{3}}r^2 + \pi r + 1 \quad (4)$$

and

$$\beta_r = |U \cap O'| \leq \frac{\pi}{\sqrt{3}}r^2 + \left(\frac{\pi}{2} + 1\right)r + 1. \quad (5)$$

From Lemma 1, Wan et al. in [57] derived the following properties of the routing tree T :

- For each $0 \leq l \leq L' - 1$, each connector in C_l is adjacent to at most four dominators in D_{l+1} .
- For each $1 \leq l \leq L' - 1$, each dominator in D_l is adjacent to at most 11 connectors in C_l .
- $|C_0| \leq 12$.

4.4 Vertex Coloring Problem

For a graph $G = (V, E)$, the *maximum degree* (respectively, *minimum degree*) of G is denoted by $\Delta(G)$ (respectively, $\delta(G)$). The *minimum degree* of G is denoted by $\delta(G)$. A subgraph of G on $U \subseteq V$ is denoted by $G(U)$. The *inductivity* of G is defined as $\delta^*(G) = \max_{U \subseteq V} \delta(G(U))$. A *vertex coloring* of G is a scheme of coloring all the vertices in G such that no two adjacent vertices share the same color. The *chromatic number* $\chi(G)$ of G is the least number of colors used to color G . Deciding the lower bound of $\chi(G)$ is a well-known NP-complete problem. However, the upper bound of $\chi(G)$ has been derived in *graph theory* [50, 57]. The following lemma was proven in [50, 57].

Lemma 2 $\chi(G) \leq 1 + \delta^*(G)$ and a vertex coloring scheme, called first-fit coloring, for G using at most $1 + \delta^*(G)$ colors can be found in polynomial time.

Given a link set A of T , the channel assignment problem for A can be abstracted to the vertex coloring problem for its corresponding conflicting graph $\mathfrak{R}(A)$. If the tail (respectively, head) of every link in A is a dominator, then Lemma 3 in [57] gives the upper bound of $\delta^*(A)$.

Lemma 3 [57] $\delta^*(A) \leq \beta_{\rho+1} - 1$.

Lemma 3 implies that in the worst case, at most $\beta_{\rho+1}$ channels may be assigned to all the links in A without channel interference by a first-fit coloring method.

5 Capacity of Snapshot Data Collection

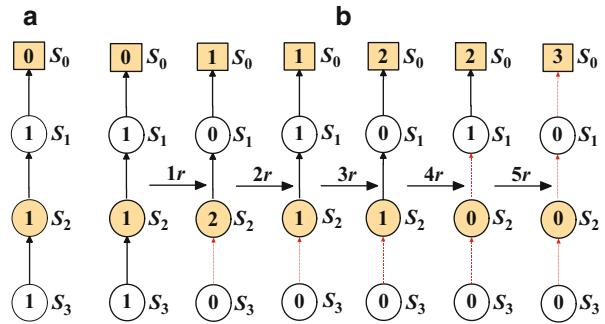

In this section, the traditional SDC problem is investigated first, a scheduling algorithm for this problem is proposed in single-radio multichannel WSNs, and the achievable capacity of the proposed algorithm is analyzed. Subsequently, the proposed algorithm is discussed further, and the reason that the proposed algorithm and most existing works cannot improve the CDC capacity of a network in order by the pipeline technology is also pointed out.

Since at any time slot, the sink can receive data from at most one neighboring sensor; therefore, the upper bound of the SDC capacity is W [12, 31]. Aiming at this upper bound, a scheduling algorithm for SDC which is order-optimal and has a tighter lower bound than the previously best result [12] is designed.

5.1 Scheduling Algorithm for Snapshot Data Collection

The idea of *single-path scheduling* has been used in [12, 66] to collect data for a WSN. However, their methods have a looser bound of the SDC capacity. In this

Fig. 7 (a) A single path and (b) its scheduling ($r = \text{round}$)

subsection, a new *multipath scheduling* algorithm based on the routing tree T built in Sect. 4 is designed, which is proven to have a better performance. Firstly, how to schedule a single path is studied. Subsequently, how to extend the single-path scheduling scheme to the scheduling of multipath in the routing tree T is investigated.

For simplicity of discussion, the concept of a *round* is defined. A *round* is a period of time which consists of multiple continuous time slots (the size of a round will be studied in Lemma 5 of the next subsection). Take the path, shown in Fig. 7a as an example to explain the idea of the single-path scheduling scheme. In Fig. 7a, the path, denoted by P consists of one sink s_0 and three sensors s_1, s_2 , and s_3 , where s_0 and s_2 are dominators, s_1 is a connector, and s_3 is a dominatee. The value marked in each node is the number of the data packets at this node to be transmitted during a time slot. At the initial time, every sensor on P has one data packet and there is no data packet at s_0 . P_o denotes the set of links on P whose heads are dominators and whose tails have at least one data packet to be transmitted. P_e denotes the set of links on P whose tails are dominators and whose tails have at least one data packet to be transmitted. For the path shown in Fig. 7a, $P_o = \{(s_3, s_2), (s_1, s_0)\}$ and $P_e = \{(s_2, s_1)\}$. P can be scheduled according to the following two steps and repeat them until all the data packets have been collected by s_0 .

Step 1: In an odd round, schedule every link in P_o once, i.e., assign a dedicated channel and one dedicated time slot to each link in P_o .

Step 2: In an even round, schedule every link in P_e once, i.e., assign a dedicated channel and one dedicated time slot to each link in P_e .

The detailed scheduling in Step 1 can be done in the following way: first, for any link $\ell_i \in P_o$, let $\mathbb{I}_{P_o}(\ell_i) = \{\ell_j | \ell_j \in P_o, \ell_i \text{ and } \ell_j \text{ are interfering links}\}$; second, sort the links in P_o according to $|\mathbb{I}_{P_o}(\ell_i)|$ ($1 \leq i \leq |P_o|$) in a nondecreasing order, where $|\cdot|$ denotes the cardinality of a set, and denote the resulting link sequence as $\{\ell'_1, \ell'_2, \dots, \ell'_{|P_o|}\}$; and finally, during the i -th ($1 \leq i \leq \lceil \frac{|P_o|}{H} \rceil$) time slot of a round, let the j -th ($(i-1)H < j \leq iH$) link in P_o work on channel $\lambda_{j \% H + 1}$. Here, sort the links in P_o first and subsequently assign channels based on the *first-fit coloring* scheme in Lemma 2. Furthermore, according to Lemmas 2 and 3,

the channel assignment plan for the links in P_o is interference/collision-free. The detailed scheduling in Step 2 is similar to that of Step 1.

The scheduling process of P in Fig. 7a is shown in Fig. 7b. During the first (odd) round, links (s_3, s_2) and (s_1, s_0) are scheduled and the data packets at s_3 and s_1 are transmitted to their parent nodes. After the first round, s_3 has no data packet to transmit. During the second (even) schedule, link (s_2, s_1) is scheduled and s_2 transmits one data packet to its parent node. This schedule process continues until all the data packets on path P has been transmitted to s_0 .

Now, consider the scheduling of the routing tree T built in Sect. 4. Suppose that there are m leaf nodes in T denoted by $s_1^l, s_2^l, \dots, s_m^l$, respectively. The path from leaf node s_i^l ($1 \leq i \leq m$) to the sink s_0 is denoted by P_i . Two paths P_i and P_j are said *intersecting* if they have at least one common node besides the sink node. Assume path P_i and path P_j are intersecting, and the lowest common ancestor of s_i^l (P_i) and s_j^l (P_j), i.e., the common node of P_i and P_j having the largest number of hops from the sink, is called an *intersecting point* of P_i and P_j . If path P_i intersects with other paths, the route from s_i^l to the nearest intersecting point of P_i is called a *sub-path*, denoted by F_i . Otherwise, F_i is actually P_i .

Taking the routing tree \widehat{T} shown in Fig. 8a as an example, \widehat{T} consists of one sink denoted by s_0 and ten sensor nodes denoted by s_i ($1 \leq i \leq 10$). \widehat{T} has three leaf nodes s_1, s_2 , and s_3 , which correspond to paths P_1, P_2 , and P_3 , respectively. In \widehat{T} , P_1 and P_2 are intersecting and their intersecting point is s_5 . Nevertheless, P_1 and P_3 , as well as P_2 and P_3 , are not intersecting since they have no common node beside the sink s_0 . For P_1 , the route from s_1 to s_5 is the sub-path of P_1 , denoted by F_1 . For P_3 , since it is not intersecting with any path, F_3 is P_3 itself.

To schedule multiple paths on the routing tree T , a *multipath scheduling* algorithm as shown in Algorithm 1 is proposed. In Algorithm 1, \mathcal{P} is the set of paths that has been scheduled simultaneously in a round, \mathcal{S} is the set of links from multiple paths that can be scheduled in a round, rd_i/rd_j indicates the number of available rounds that has been assigned to path P_i/P_j , and P_o^i/P_o^j (respectively, P_e^i/P_e^j) is the set of links on P_i/P_j whose heads (respectively, tails) are dominators and whose tails have at least one data packet to be transmitted. From Algorithm 1, one can see that lines 2–10 are used to schedule path P_i according to the single-path scheduling algorithm. Lines 11–20 are used to find other paths that can be scheduled simultaneously with P_i according to the single-path scheduling algorithm at the same round.

The proposed multipath scheduling algorithm is further explained by the routing tree \widehat{T} shown in Fig. 8a. Assume the interference radius $\rho = 1$, i.e., the interference radius is equal to the transmission radius, which implies that each *round* consists of two time slots. Furthermore, $\mathcal{I}(s_i)$ ($1 \leq i \leq n$) is used to denote the set of sensor nodes that cannot be transmitted data simultaneously with s_i . For the nodes in \widehat{T} , assume

- $\mathcal{I}(s_1) = \{s_4, s_5, s_6, s_7, s_8\}$;
- $\mathcal{I}(s_2) = \{s_6, s_7\}$;
- $\mathcal{I}(s_3) = \{s_9, s_{10}\}$;

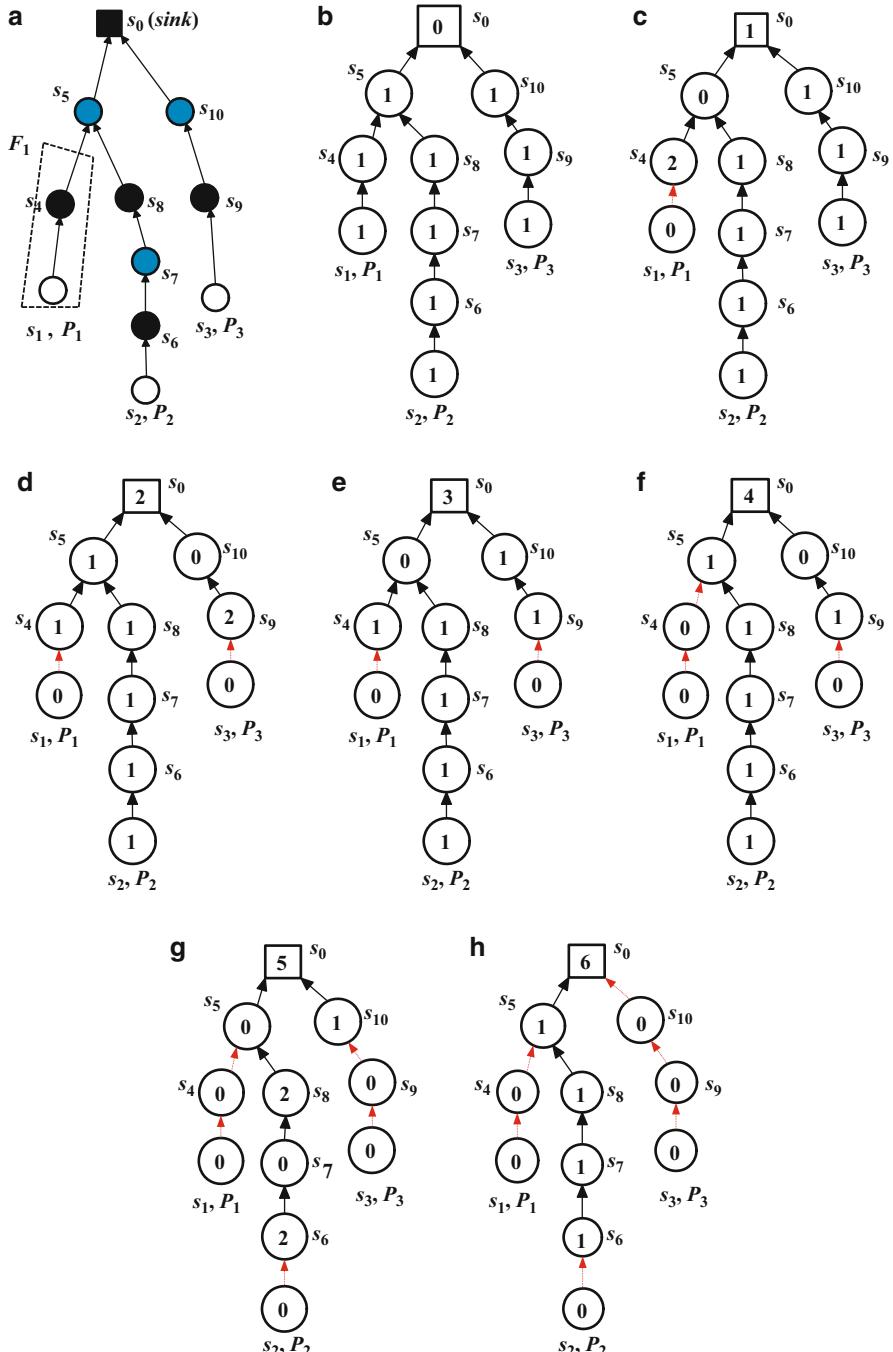

Fig. 8 A routing tree and its scheduling. In (a), the *black nodes* are dominators, the *blue nodes* are connectors, and the other nodes are dominatees. In (b)–(h), the number inside each node is the number of data packets at this node. The *red links* are the links removed from the data collection tree according to [Algorithm 1](#)

```

- $\mathcal{I}(s_4) = \{s_1, s_5, s_7, s_8\};$
- $\mathcal{I}(s_5) = \{s_1, s_4, s_7, s_8, s_{10}\};$
- $\mathcal{I}(s_6) = \{s_1, s_2, s_7, s_8\};$
- $\mathcal{I}(s_7) = \{s_1, s_2, s_4, s_5, s_6, s_8\};$
- $\mathcal{I}(s_8) = \{s_1, s_4, s_5, s_6, s_7\};$
- $\mathcal{I}(s_9) = \{s_3, s_{10}\};$
- $\mathcal{I}(s_{10}) = \{s_3, s_5, s_9\}.$

Additionally, for path P_1 , P_2 , and P_3 ,

- $P_o^1 = \{(s_1, s_4), (s_5, s_0)\};$
- $P_e^1 = \{(s_4, s_5)\};$
- $P_o^2 = \{(s_2, s_6), (s_7, s_8), (s_5, s_0)\};$
- $P_e^2 = \{(s_6, s_7), (s_8, s_5)\};$
- $P_o^3 = \{(s_3, s_9), (s_{10}, s_0)\};$
- $P_e^3 = \{(s_9, s_{10})\}.$

At the beginning of [Algorithm 1](#), the network is shown in [Fig. 8b](#) with the number inside each node denoting the number of data packets at this node. According to the algorithm, during the first round, P_o^1 is scheduled, and path P_2 will not be scheduled since it is intersecting with P_1 . P_3 also will not be scheduled since the link (s_{10}, s_0) in P_o^3 and the link (s_5, s_0) in P_o^1 are not interference/confliction-free. Thus, after the first round, the network situation is shown in [Fig. 8c](#). During the second round, P_e^1 will be scheduled. Now, all the links in P_e^1 and all the links in P_o^3 are interference/confliction-free.⁴ Hence, P_1 and P_3 can be scheduled simultaneously at the second round. After the second round, the network situation is shown in [Fig. 8d](#). Similarly, according to [Algorithm 1](#), the network after the third, the fourth, the fifth, and the sixth round is shown in [Fig. 8e–h](#), respectively. Finally, for \widehat{T} shown in [Fig. 8a](#), it will take 13 rounds to collect all the data packets to the sink by the multipath scheduling algorithm. By contrast, it will take 18 rounds to collect all the data packets to the sink by the single-path scheduling algorithm.

5.2 Capacity Analysis

In this subsection, the achievable network capacity of the proposed multi-path scheduling algorithm is analyzed. The upper bound of the SDC capacity is W which has been explained. Consequently, the lower bound of the SDC capacity is focused on. In the worst case, all the paths in the routing tree T are intersecting, i.e., they have a common intersecting point, which means only one path can be scheduled at any time. In order to derive the lower bound of the capacity of the multipath scheduling algorithm, the number of the rounds needed to finish the scheduling of one single path is first investigated and then the number of the time slots in each round is studied. [Lemma 4](#) gives the maximum number of the rounds used for the scheduling of one single path.

Lemma 4 *For a single-path P of length L in T , it takes at most $2L - 1$ rounds to collect all the data packets on P at the sink node.*

Proof Suppose that the node sequence on P is $s_1, s_2, \dots, s_L, s_0$, where s_1 is the leaf node (dominatee) and s_0 is the sink node. Considering the building process of T , each link in P has either a dominator head or a dominator tail. According to the scheduling scheme of a single path, during the first (odd) round, the links in P_o are scheduled, which implies that each nondominator with at least one data packet transmits this data packet to its parent node. After the first round, the sink receives one data packet and all the other dominators of the links in P_o have two data packets to be transmitted. During the second (even) round, the links in P_e are scheduled, which implies that every dominator in P_e transmits one data packet to its

⁴Here, P_o^3 is considered instead of P_e^3 because for path P_3 , the current round is the first available round.

parent node. As a result, the sensor s_i ($2 \leq i \leq L$) has exactly one data packet to be transmitted and a new odd-even scheduling round begins. In summary, after every two rounds, the sink receives one data packet and the length of the data collection path decreases by 1. Since the length of P is L and s_0 is the destination of all the data packets which does not have to transmit any data, it takes at most $2L - 1$ rounds to collect all the data packets on P . \square

From [Lemma 4](#), it is straightforward to obtain the number of the rounds used to collect all the data on the sub-path F of P as shown in [Corollary 1](#).

Corollary 1 *For the sub-path F of length L_s in P , it takes at most $2L_s$ rounds to collect all the data packets on F .*

Proof The proof of [Corollary 1](#) is similar to that of [Lemma 4](#). Note that the intersecting point is not a sink node in this case and thus it needs one round to transmit its data packet. \square

By [Lemma 4](#) and [Corollary 1](#), the number of the rounds used to collect the data packets on a path is obtained. The maximum number of the time slots in a round is as follows.

Lemma 5 *In the single-path scheduling algorithm, a round has at most $\left\lceil \frac{\beta_{\rho+1}}{H} \right\rceil$ time slots, where $\beta_{\rho+1}$ is the number of the dominators in a halfdisk with radius $\rho + 1$ and H is the number of available orthogonal channels.*

Proof During every odd (respectively, even) round, the scheduled links are links in P_o (respectively, P_e). Since the heads (respectively, tails) of links in P_o (respectively, P_e) are dominators, all the links in P_o (respectively, P_e) can be scheduled in one time slot with at most $\beta_{\rho+1}$ channels in polynomial time by [Lemmas 3](#) and [2](#). Now, the considering WSN has H available channels, which means the scheduling can be finished within $\left\lceil \frac{\beta_{\rho+1}}{H} \right\rceil$ time slots. Therefore, the lemma holds. \square

Now, the lower bound of the achievable capacity of the multipath scheduling algorithm can be obtained as shown in [Theorem 1](#).

Theorem 1 *The capacity Υ at the sink of T of the multipath scheduling algorithm is at least $\frac{W}{2\lceil(1.81\rho^2+c_1\rho+c_2)/H\rceil}$, where $c_1 = \frac{2\pi}{\sqrt{3}} + \frac{\pi}{2} + 1$ and $c_2 = \frac{\pi}{\sqrt{3}} + \frac{\pi}{2} + 2$, which is orderoptimal.*

Proof Suppose that T has m paths and the length of each path is L_i ($1 \leq i \leq m$). In the worst case, all the m paths cannot be scheduled concurrently. Then by [Lemma 4](#), [Corollary 1](#), and [Lemma 5](#), the total time τ used to collect all the data packets of T at the sink is at most $t \cdot \sum_{i=1}^m 2L_i \left\lceil \frac{\beta_{\rho+1}}{H} \right\rceil$. According to the multipath scheduling

algorithm, for any path P_i , the time used to collect data packets on P_i is equal to the time used to collect data packets on the corresponding sub-path F_i of P_i .⁵ Therefore,

$$\tau \leq t \cdot \sum_{i=1}^m 2L_i \left\lceil \frac{\beta_{\rho+1}}{H} \right\rceil \quad (6)$$

$$= t \cdot \sum_{i=1}^m 2|F_i| \left\lceil \frac{\beta_{\rho+1}}{H} \right\rceil \quad (7)$$

$$= 2t \left\lceil \frac{\beta_{\rho+1}}{H} \right\rceil \sum_{i=1}^m |F_i|. \quad (8)$$

Since the number of the links in T is equal to the number of the sensors in T , $\sum_{i=1}^m |F_i| = n$. Then, $\tau \leq 2nt \left\lceil \frac{\beta_{\rho+1}}{H} \right\rceil$. Therefore, the capacity

$$\Upsilon = \frac{nb}{\tau} \geq \frac{nb}{2nt \left\lceil \frac{\beta_{\rho+1}}{H} \right\rceil} \quad (9)$$

$$= \frac{b}{2t \left\lceil \frac{\beta_{\rho+1}}{H} \right\rceil} = \frac{W}{2 \left\lceil \frac{\beta_{\rho+1}}{H} \right\rceil}. \quad (10)$$

From Lemma 1,

$$\beta_{\rho+1} \leq \frac{\pi}{\sqrt{3}}(\rho+1)^2 + \left(\frac{\pi}{2} + 1\right)(\rho+1) + 1 \quad (11)$$

$$= \frac{\pi}{\sqrt{3}}\rho^2 + \left(\frac{2\pi}{\sqrt{3}} + \frac{\pi}{2} + 1\right)\rho + \frac{\pi}{\sqrt{3}} + \frac{\pi}{2} + 2 \quad (12)$$

$$\approx 1.81\rho^2 + c_1\rho + c_2, \quad (13)$$

where $c_1 = \frac{2\pi}{\sqrt{3}} + \frac{\pi}{2} + 1$ and $c_2 = \frac{\pi}{\sqrt{3}} + \frac{\pi}{2} + 2$. This implies

$$\Upsilon \geq \frac{W}{2 \left\lceil \frac{\beta_{\rho+1}}{H} \right\rceil} \geq \frac{W}{2 \left\lceil \frac{1.81\rho^2 + c_1\rho + c_2}{H} \right\rceil}. \quad (14)$$

⁵From lines 2–10 in Algorithm 1, the scheduling of path P_i is stopped when all the data packets on the sub-path F_i have been collected by the sink. As shown in Fig. 8f, g, after all the data packets on F_1 (the sub-path of P_1) have been collected by the sink, the scheduling of data transmission on P_2 is beginning. Additionally, based on the definition of a sub-path, F_3 in Fig. 8 is P_3 itself since P_3 does not intersect with any path. Therefore, the time used to collect data packets on P_i is equal to the time used to collect data packets on the corresponding sub-path F_i of P_i .

Since H is a constant and the upper bound of Υ is W [12, 31], Υ is orderoptimal. \square

From [Theorem 1](#), it is known that the achievable capacity of the multi-path scheduling algorithm is orderoptimal, and it also has a tighter lower bound compared with the previously best result in [12], which has a lower bound of $\frac{W}{8\rho^2}$.

5.3 Discussion

When address the CDC problem, an intuitive idea is to pipeline the existing SDC operations [12]. Nevertheless, such an idea cannot achieve a better performance. This is because the sink can receive at most one data packet at a time slot. By pipeline, data transmissions at the nodes far from the sink are really accelerated. However, the fact that a sink can receive at most one data packet at each time slot makes the data accumulated at the nodes near the sink. Finally, the network capacity cannot be improved even with pipeline. This motivates people to investigate new methods for CDC.

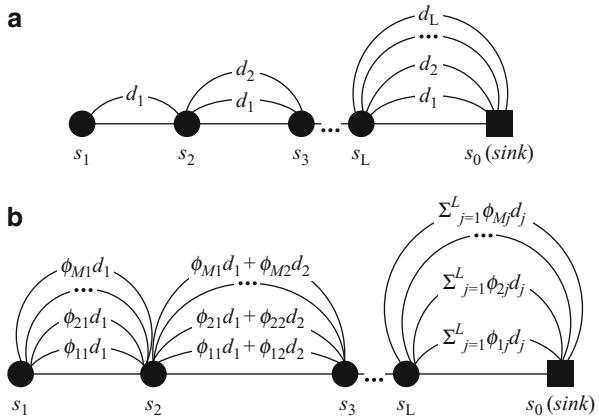

6 Capacity of Continuous Data Collection

Since multipath scheduling algorithm and existing works with pipeline cannot improve the capacity of CDC, in this section, a novel *pipeline scheduling* algorithm based on *compressive data gathering* (CDG) [46] is proposed in dual-radio multichannel WSNs, which augments the CDC capacity significantly. Here, dual-radio multichannel WSNs are considered because dual radios can make a *half-duplex* single-radio node work in a *full-duplex* mode, i.e., a dual-radio node can receive and transmit data simultaneously with the two radios over different channels. Furthermore, the full-duplex working mode is in favor of pipeline. For completeness, the achievable network capacity of the pipeline scheduling algorithm (a little modification is needed) in single-radio multichannel WSNs is also analyzed.

6.1 Compressive Data Gathering (CDG)

CDG is first proposed in [46] for SDC in single-radio single-channel WSNs. The basic idea of CDG is to distribute the data collection load uniformly to all the nodes in the entire network. Take the data collection on a path consisting of L sensors s_1, s_2, \dots, s_L and one sink s_0 as shown in [Fig. 9](#) [46] as an example to explain CDG. In [Fig. 9](#), the data packet produced at sensor s_j ($1 \leq j \leq L$) is d_j . In the basic data collection shown in [Fig. 9a](#), s_1 transmits one data packet d_1 to s_2 , s_2 transmits two data packets d_1 and d_2 to s_3 , and finally all the data packets on the path are transmitted to s_0 by s_L . Obviously, nodes near the sink have more transmission load compared with nodes far from the sink in the basic data collection. To balance the transmission load, the authors in [46] proposed the CDG method as shown in [Fig. 9b](#).

Fig. 9 Comparing of (a) basic data collection and (b) CDG [46]

Instead of transmitting the original data directly, \$s_1\$ multiplies its data with a random coefficient \$\phi_{i1}\$ (\$1 \leq i \leq M\$) and sends the \$M\$ results \$\phi_{i1}d_1\$ to \$s_2\$. Upon receiving \$\phi_{i1}d_1\$ (\$1 \leq i \leq M\$) from \$s_1\$, \$s_2\$ multiplies its data \$d_2\$ with a random coefficient \$\phi_{i2}\$ (\$1 \leq i \leq M\$), adds it to \$\phi_{i1}d_1\$, and then sends \$\phi_{i1}d_1 + \phi_{i2}d_2\$ as one data packet to \$s_3\$. Finally, \$s_L\$ does the similar multiplication and addition and sends the result \$\sum_{j=1}^L \phi_{ij}d_j\$ (\$1 \leq i \leq M\$) to \$s_0\$. After \$s_0\$ receives all the \$M\$ data packets, \$s_0\$ can restore the original data packets based on the compressive sampling theory [46]. By CDG, all the sensors send \$M\$ data packets to their parent nodes, which achieves the goal to uniformly distribute the data collection task to the entire network. The number of the transmitted data packets is \$O(n^2)\$ in Fig. 9a and is \$O(NM)\$ in Fig. 9b, and usually \$M \ll n\$ for large-scale WSNs. Therefore, CDG reduces the number of the transmitted data packets. Considering WSNs are usually large-scale networks, then \$M \ll n\$, the number of sensors in a WSN [46].

6.2 Pipeline Scheduling

Thanks to the benefit brought by CDG, the CDC problem can be addressed with the pipeline technique. From the building process of the routing tree \$T\$, it is known that the nodes in \$T\$ can be divided into sets by levels \$D_e, D_{L'}, C_{L'-1}, D_{L'-1}, C_{L'-2}, \dots, D_1, C_0, D_0 = \{s_0 | s_0 \text{ is the sink}\}\$ in a bottom-up way, where \$D_e\$ is the set of all the dominatees, i.e., leaf nodes, \$D_i\$ (\$0 \leq i \leq L'\$) is the set of the dominators at the \$i\$-th level, and \$C_i\$ (\$0 \leq i \leq L' - 1\$) is the set of the connectors at the \$i\$-th level. Since every node has two radios, one radio can be dedicated to receive data and the other dedicated to transmit data. Therefore, the nodes at every level can receive and transmit data simultaneously over different channels. Consequently, for a CDC task consisting of \$N\$ snapshots, a *pipeline scheduling* algorithm is proposed as follows:

Step 1: All the nodes in \$D_e\$ transmit the data packets of the \$j\$-th (\$1 \leq j \leq N - 1\$) snapshot to their parent nodes in the CDG way, i.e., for every node \$s \in D_e\$, \$s\$ multiplies its data with \$M\$ random coefficients, respectively, and sends the \$M\$ products to its parent node. After all the data packets of the \$j\$-th

snapshot have been transmitted successfully, the nodes in D_e immediately transmit the data packets of the $(j + 1)$ -th snapshot in the CDG way.

- Step 2: After all the nodes in D_l ($1 \leq l \leq L'$) receive all the data packets of the j -th snapshot from their childlevel, they send the data packets of the j -th snapshot to their parent nodes in the CDG way, i.e., every node $s \in D_l$ combines its data packet of the j -th snapshot with the received data packets of the j -th snapshot and sends the M new data packets to its parent node. After all the data packets of the j -th snapshot have been transmitted successfully, the nodes in D_l immediately transmit the data packets of the $(j + 1)$ -th snapshot to their parent nodes in the CDG way, if they have received all the data packets of the $(j + 1)$ -th snapshot from their childlevel.*
- Step 3: After all the nodes in C_l ($0 \leq l \leq L' - 1$) receive all the data packets of the j -th snapshot from their childlevel, they send the data packets of the j -th snapshot to their parent nodes in the CDG way, i.e., every node $s \in C_l$ combines its data packet of the j -th snapshot with the received data packets of the j -th snapshot and sends the M new data packets to its parent node. After all the data packets of the j -th snapshot have been transmitted successfully, the nodes in C_l immediately transmit the data packets of the $(j + 1)$ -th snapshot in the CDG way if they have received all the data packets of the $(j + 1)$ -th snapshot from their child-level.*

- Step 4: The sink restores the data of a snapshot in the CDG way after it receives all the data packets of this snapshot.*

Steps 1–4 provide the general frame of the proposed pipeline scheduling scheme. Now, how to prevent radio confliction and channel interference in Steps 1–3 is explained as follows. If two or more nodes have the same parent node, they are called *sibling* nodes. In Steps 1–3, radio confliction may arise if two or more sibling nodes send data to their parent node simultaneously even over different orthogonal channels. This is because every sensor only has one radio dedicated to receiving data. Suppose that there are at most Δ_e (respectively, Δ_d and Δ_c) nodes in D_e (respectively, D_l ($1 \leq l \leq L'$) and C_l ($1 \leq l \leq L' - 1$)) which have the same parent node. Usually, $\Delta_e < \Delta(T)$ except in one-hop WSNs, where any sensor is just one hop away from the sink, $\Delta_e = \Delta(T)$. Then, $\Delta_d \leq 4$ and $\Delta_c \leq 11$. (Note that $|C_0| \leq 12$.) (See Sect. 4.3.) To avoid confliction, the nodes in D_e (respectively, D_l ($1 \leq l \leq L'$) and C_l ($1 \leq l \leq L' - 1$)) can be partitioned into Δ_e (respectively, Δ_d and Δ_c) subsets to guarantee that each node belongs to one subset and no sibling nodes belong to the same subset. Then, when scheduling the nodes of each level, these subsets can be scheduled in a certain order. For the nodes in C_0 , they can be scheduled in a certain order, e.g., the nodes with small IDs are scheduled with high priority.

Different from the multipath scheduling algorithm, in which a sensor sends one data packet over a link in one time slot, the CDG way is employed in the pipeline scheduling algorithm, where a sensor sends M data packets for a snapshot. Thus, the concept of a *super time slot* (STS) which consists of M time slots is introduced. In an STS, a sensor can send M data packets over a channel for a snapshot. For the links working simultaneously, the channels and STSs can be assigned in the similar manner of the multipath scheduling algorithm.

6.3 Capacity Analysis

In this subsection, the achievable network capacity of the proposed *pipeline scheduling* algorithm is analyzed.

Lemma 6 indicates the inductivity (defined in Sect. 4.4) of the corresponding conflicting graph of the links scheduled simultaneously in the pipeline scheduling algorithm, which is used to obtain the upper bound of the number of the necessary channels to schedule these links.

Lemma 6 Suppose that A is the set of the links in T scheduled simultaneously in the pipeline scheduling algorithm and $\mathfrak{R}(A)$ is the corresponding conflicting graph of A , then, $\delta^*(\mathfrak{R}(A)) \leq 2\beta_{\rho+2} - 1$, where $\delta^*(\mathfrak{R}(A))$ is the inductivity of $\mathfrak{R}(A)$ and $\beta_{\rho+2}$ is the number of the dominators within a halfdisk of radius $\rho + 2$.

Proof Since the sibling nodes at every level have been divided into different subsets and different subsets are scheduled in a certain order, there is no radio confliction among the links in A . Furthermore, for any link in A , either the tail or the head of this link is a dominator according to the building process of the routing tree T . Suppose that A' is a subset of A and e is the link in A' whose tail, denoted by $t(e)$, or head, denoted by $h(e)$, is the bottommost dominator among all the dominators in A' . Then, it can be proven that the number of the links interfered with e , i.e., $\delta(\mathfrak{R}(A'))$, is at most $2\beta_{\rho+2} - 1$ case by case as follows:

Case 1: $t(e)$ is a dominator. In this case, assume that e' is another link in A' interfered with e and $t(e')$ is a dominator. Since $t(e)$ is the bottommost dominator, the necessary condition for e and e' to be interfering links is that $t(e')$ locates at the upper halfdisk centered at $t(e)$ with radius $\rho + 1$. On the other hand, if $h(e')$ is a dominator, then the necessary condition for e and e' to be interfering links is that $h(e')$ locates at the upper halfdisk centered at $t(e)$ with radius $\rho + 2$. By Lemma 1, the number of the dominators within a halfdisk of radius $\rho + 2$ is at most $\beta_{\rho+2}$. Since every dominator in A' is associated with at most two links, there are at most $2\beta_{\rho+2}$ links within the halfdisk of radius $\rho + 2$ centered at $t(e)$. Therefore, $\delta(\mathfrak{R}(A')) \leq 2\beta_{\rho+2} - 1$, where minus 1 means e is also in the halfdisk. As a result, $\delta^*(\mathfrak{R}(A)) = \max_{A' \subseteq A} \delta(\mathfrak{R}(A')) \leq 2\beta_{\rho+2} - 1$.

Case 2: $h(e)$ is a dominator. By the similar method as in case 1, it can be proven that the conclusion also holds in this case. \square

Based on the result of Lemma 6, the number of the STSSs used to schedule all the links in A can be determined as follows.

Lemma 7 For the links of set A in Lemma 6, one can use $\left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$ STSSs to schedule them without channel interference.

Proof By Lemma 6, $\delta^*(\mathfrak{N}(A)) \leq 2\beta_{\rho+2} - 1$. By Lemma 2, one can use $1 + \delta^*(\mathfrak{N}(A)) \leq 2\beta_{\rho+2}$ channels to schedule all the links in A in one STS simultaneously. Now, a WSN has H channels, which implies all the links in A can be scheduled in $\left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$ STSs of H links in each STS. \square

From the pipeline scheduling algorithm, it is known that the transport of subsequent snapshots has sometime overlap with the transport of preceding snapshots. Therefore, in the following, the time used to collect the data packets of the first snapshot is firstly analyzed since it is the base of the pipeline, and then the achievable capacity of the entire pipeline is analyzed.

Theorem 2 *The number of the time slots used to collect the data packets of the first snapshot by the pipeline scheduling algorithm is at most $M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 15L' + 1)$.*

Proof In Step 1 of the pipeline scheduling algorithm, the nodes in D_e are partitioned into Δ_e subsets and scheduled in a certain order. By Lemma 7, each scheduling uses at most $\left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$ STSs. Consequently, Step 1 needs at most $\Delta_e \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$ STSs to finish the scheduling for the first snapshot. In Step 2 (respectively, Step 3), the nodes in D_l ($1 \leq l \leq L'$) (respectively, C_l ($1 \leq l \leq L' - 1$)) are partitioned into Δ_d (respectively, Δ_c) subsets and scheduled in a certain order. Since, $\Delta_d \leq 4$ (respectively, $\Delta_c \leq 11$), Step 2 (respectively, Step 3) needs at most $4L' \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$ (respectively, $11(L' - 1) \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$) STSs to finish the scheduling for the first snapshot. Furthermore, it needs at most $12 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$ STSs for C_0 to transmit the data packets for the first snapshot to the sink. In summary, the total number of the STSs used for the first snapshot is at most

$$\Delta_e \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil + 4L' \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil + 11(L' - 1) \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil + 12 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil \quad (15)$$

$$= \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 4L' + 11L' - 11 + 12) \quad (16)$$

$$= \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 15L' + 1). \quad (17)$$

Since every STS has M time slots, then the number of the time slots used for the first snapshot is at most $M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 15L' + 1)$. \square

On the basis of the result in [Theorem 2](#), one can obtain the time slots used to collect all the data packets of N continuous snapshots for the pipeline scheduling algorithm as shown in [Theorem 3](#).

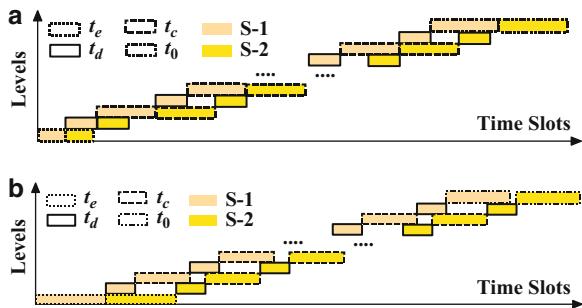

Theorem 3 *The time slots used for the pipeline scheduling algorithm to collect N continuous snapshots are at most*

$$\begin{cases} M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 15L' + 12N - 11), & \text{if } \Delta_e \leq 12 \\ M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (N\Delta_e + 15L' + 1), & \text{if } \Delta_e > 12 \end{cases}.$$

Proof From the proof of [Theorem 2](#), it takes the nodes in D_e (respectively, D_l ($1 \leq l \leq L'$), C_l ($1 \leq l \leq L' - 1$), and C_0) at most $\Delta_e \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$ (respectively, $4 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$, $11 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$, and $12 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$) STSs to transmit data packets for a snapshot. In order to obtain the upper bound of the number of the time slots used, assume the STSs used by nodes in D_e (respectively, D_l ($1 \leq l \leq L'$), C_l ($1 \leq l \leq L' - 1$), and C_0) are $\Delta_e \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$ (respectively, $4 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$, $11 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$, and $12 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$) in the following proof. Then, [Theorem 3](#) can be proven by cases.

Case 1: $\Delta_e \leq 4$. For clearness, the transmission of two snapshots S-1 and S-2 shown in [Fig. 10a](#) is used as an example for explanation. In [Fig. 10a](#), the vertical axis denotes the levels in the routing tree T and the horizontal axis denotes time slots. $t_e = \Delta_e \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$, $t_d = 4 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$, $t_c = 11 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$, and $t_0 = 12 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$, respectively. From [Fig. 10a](#), it is known that the nodes at the D_e -level begin to send data packets of S-2 immediately after they send out the data packets of S-1. Since $\Delta_e \leq 4$, after the nodes at the $D_{L'}$ -level receive all the data packets of S-2, they may still be busy with the transmission of the data packets of S-1. Nevertheless, from the $C_{L'-1}$ -level to the D_1 -level, the pipeline can be utilized in a maximum degree, which implies whatever the data packets of S-1 or the data packets of S-2, they can be sent immediately. After the data packets of S-2 are sent from the nodes at the D_0 -level to the nodes in C_0 , they may have to wait for a while at the nodes of the C_0 -level, since the transmission for the data packets of S-1 may last for as long as $12 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$ STSs. This implies the sink will receive all the data packets of S-2 in $12 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$ STSs after it receives all the data packets of S-1. According to the description of the pipeline scheduling algorithm, the subsequent snapshots will be transmitted in the same way, which implies the sink will receive all the data packets of a snapshot within at most every $12 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$ STSs, after it receives the data packets of the first

Fig. 10 Data transport in (a) Case 1 and (b) Case 4

snapshot which takes at most $M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 15L' + 1)$ time slots by **Theorem 2**. As a result, the number of time slots used to collect the data packets of N continuous snapshots by the pipeline scheduling algorithm is at most

$$M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 15L' + 1) + (N - 1) \cdot 12M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil \quad (18)$$

$$= M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 15L' + 1 + 12N - 12) \quad (19)$$

$$= M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 15L' + 12N - 11). \quad (20)$$

Case 2: $4 < \Delta_e \leq 11$ and *Case 3:* $\Delta_e = 12$. These two cases can be proven by the similar method used in Case 1. The number of the time slots used to collect the data packets of N continuous snapshots is also at most $M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 15L' + 12N - 11)$.

Case 4: $\Delta_e > 12$. Take the data transmission of two snapshots shown in Fig. 10b as an example to show the proof in this case. The notations in Fig. 10b are the same as those in Fig. 10a. Since $\Delta_e > 12$, the pipeline can be utilized in a maximum degree at the $D_{L'}$ -level and continue to the C_0 -level. Then, the sink can receive all the data packets of a subsequent snapshot every $\Delta_e \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$ STSSs after it receives the data packets of the first snapshot. Therefore, the number of the time slots used to collect the data packets of N continuous snapshots is at most

$$M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 15L' + 1) + (N - 1) \cdot \Delta_e M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil \quad (21)$$

$$= M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 15L' + 1 + (N - 1)\Delta_e) \quad (22)$$

$$= M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (N\Delta_e + 15L' + 1). \quad (23)$$

As a conclusion, [Theorem 3](#) is true. \square

[Theorem 3](#) shows the number of the time slots used to collect N continuous snapshots. It is prepared to derive the achievable capacity of the pipeline scheduling algorithm. The lower bound of the achievable CDC capacity in a long-run is given in [Theorem 4](#).

Theorem 4 *For a long-run CDC, the lower bound of the achievable asymptotic network capacity of the pipeline scheduling algorithm is*

$$\begin{cases} \frac{nW}{12M \left\lceil \frac{3.63\rho^2 + c_3\rho + c_4}{H} \right\rceil}, & \text{if } \Delta_e \leq 12 \\ \frac{nW}{M\Delta_e \left\lceil \frac{3.63\rho^2 + c_3\rho + c_4}{H} \right\rceil}, & \text{if } \Delta_e > 12 \end{cases},$$

where $c_3 = \frac{8\pi}{\sqrt{3}} + \pi + 2$ and $c_4 = \frac{8\pi}{\sqrt{3}} + 2\pi + 6$.

Proof [Theorem 4](#) can be proven by two cases.

Case 1: $\Delta_e \leq 12$. In this case the number of the time slots used to collect N continuous snapshots is at most $M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 15L' + 12N - 11)$ as proven in [Theorem 3](#). Therefore, the lower bound of the capacity of the pipeline scheduling algorithm is

$$\frac{N \cdot nb}{tM \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 15L' + 12N - 11)} \quad (24)$$

$$= \frac{nb}{tM \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil \left(\frac{\Delta_e}{N} + \frac{15L'}{N} + 12 - \frac{11}{N} \right)} \quad (25)$$

$$= \frac{nW}{M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil \left(\frac{\Delta_e}{N} + \frac{15L'}{N} + 12 - \frac{11}{N} \right)}. \quad (26)$$

When $N \rightarrow \infty$, the above equation approaches to $\frac{nW}{12M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil}$. From [Lemma 1](#),

$$2\beta_{\rho+2} \leq 2 \left[\frac{\pi}{\sqrt{3}} (\rho + 2)^2 + \left(\frac{\pi}{2} + 1 \right) (\rho + 2) + 1 \right] \quad (27)$$

$$= \frac{2\pi}{\sqrt{3}}\rho^2 + \left(\frac{8\pi}{\sqrt{3}} + \pi + 2\right)\rho + \frac{8\pi}{\sqrt{3}} + 2\pi + 6 \quad (28)$$

$$\approx 3.63\rho^2 + c_3\rho + c_4, \quad (29)$$

where $c_3 = \frac{8\pi}{\sqrt{3}} + \pi + 2$ and $c_4 = \frac{8\pi}{\sqrt{3}} + 2\pi + 6$. This implies the asymptotic network capacity in this case is $\frac{nW}{12M\lceil(3.63\rho^2+c_3\rho+c_4)/H\rceil}$.

Case 2: $\Delta_e > 12$. The lower bound of the asymptotic network capacity in this case is $\frac{nW}{M\Delta_e\lceil(3.63\rho^2+c_3\rho+c_4)/H\rceil}$, which can be proven by the similar method as in Case 1. \square

In a dual-radio multichannel WSN, since every node has two radios, the upper bound of the network capacity is $2W$. This is because the sink can receive at most two data packets in one time slot. From [Theorem 4](#), when $\Delta_e \leq 12$ and $M \leq \frac{n}{24\lceil(3.63\rho^2+c_3\rho+c_4)/H\rceil}$, or $\Delta_e > 12$ and $M \leq \frac{n}{2\Delta_e\lceil(3.63\rho^2+c_3\rho+c_4)/H\rceil}$, the achievable CDC capacity of the pipeline scheduling algorithm is greater than $2W$. By checking the reasons carefully, it can be found that the pipeline scheduling and CDG are responsible for this improvement. By forming a CDG-based pipeline, the time overlap of gathering multiple continuous snapshots conserves a lot of time, which accelerates the data collection process directly and significantly. These two reasons are also validated by the simulation results in [Sect. 7](#).

Furthermore, it can be found that the pipeline scheduling algorithm is more effective for large-scale WSNs, since large-scale WSNs incur large size routing trees, which are more suitable for pipeline. The pipeline scheduling algorithm is also more effective for a long-time CDC, which can also be seen from [Theorem 4](#).

6.4 Capacity of the Pipeline Scheduling Algorithm in Single-Radio Multichannel WSNs

For completeness, the achievable network capacity of the pipeline scheduling algorithm in single-radio multichannel WSNs is also analyzed in this subsection. Now, since each sensor node has one radio, some modifications of the pipeline scheduling algorithm are made as follows. For the nodes in D_e , D_l ($1 \leq l \leq L'$), and C_l ($1 \leq l \leq L' - 1$), instead of transmitting the data packets of the $(j+1)$ -th ($j \geq 1$) snapshot immediately after transmitting the data packets of the j -th snapshot, they wait until their parent nodes have transmitted all the data packets of the j -th snapshot successfully. (Note that the transmission of the data from the first snapshot does not have the waiting process.) For convenience, the modified pipeline scheduling algorithm is referred to as the *single-radio-based pipeline scheduling* algorithm. Then, by the similar proof technique shown in [Theorem 2](#), the following lemma can be proven.

Lemma 8 *The number of the time slots used to collect the data packets of the first snapshot by the single-radio-based pipeline scheduling algorithm for single-radio multichannel WSNs is at most $M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 15L' + 1)$.*

On the basis of [Lemma 8](#), the number of time slots used to collect all the data packets of N continuous snapshots by the single-radio-based pipeline scheduling algorithm is shown in [Theorem 5](#).

Theorem 5 *The time slots used by the single-radio-based pipeline scheduling algorithm to collect N continuous snapshots for single-radio multi-channel WSNs are at most*

$$\begin{cases} M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 15L' + 16N - 15), & \text{if } \Delta_e \leq 12 \\ M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (N\Delta_e + 15L' + 4N - 3), & \text{if } \Delta_e > 12 \end{cases}.$$

Proof Similar as the analysis in the proof of [Theorem 3](#), when $\Delta_e \leq 12$, the sink will receive all the data packets of a snapshot within every $12 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil + 4 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil = 16 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$ STSSs after it receives the data packets of the first snapshot, which implies that the number of time slots used to collect the data packets of N continuous snapshots by the single-radio-based pipeline scheduling algorithm is at most

$$M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 15L' + 1) + (N - 1) \cdot 16 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil \quad (30)$$

$$= M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 15L' + 16N - 15). \quad (31)$$

Similarly, when $\Delta_e > 12$, the sink will receive all the data packets of a snapshot within every $\Delta_e \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil + 4 \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil = (\Delta_e + 4) \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil$ STSSs after it receives the data packets of the first snapshot, which implies the number of time slots used to collect the data packets of N continuous snapshots by the single-radio-based pipeline scheduling algorithm is at most

$$M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (\Delta_e + 15L' + 1) + (N - 1) \cdot (\Delta_e + 4) \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil \quad (32)$$

$$= M \left\lceil \frac{2\beta_{\rho+2}}{H} \right\rceil (N\Delta_e + 15L' + 4N - 3). \quad (33)$$

□

Table 2 Comparison of the multipath scheduling algorithm, the pipeline scheduling algorithm, and the best existing works

Therefore, based on [Theorem 5](#), the lower bound of the achievable CDC capacity of the single-radio-based pipeline scheduling algorithm in a long-run is shown in [Theorem 6](#).

Theorem 6 *For a long-run CDC, the lower bound of the achievable asymptotic network capacity of the single-radio-based pipeline scheduling algorithm for single-radio multichannel WSNs is*

$$\begin{cases} \frac{nW}{16M \left\lceil \frac{3.63\rho^2 + c_3\rho + c_4}{H} \right\rceil}, & \text{if } \Delta_e \leq 12 \\ \frac{nW}{M(\Delta_e + 4) \left\lceil \frac{3.63\rho^2 + c_3\rho + c_4}{H} \right\rceil}, & \text{if } \Delta_e > 12 \end{cases},$$

where $c_3 = \frac{8\pi}{\sqrt{3}} + \pi + 2$ and $c_4 = \frac{8\pi}{\sqrt{3}} + 2\pi + 6$.

Proof By the similar technique in the proof of [Theorem 4](#) and based on [Theorem 5](#), the results of this theorem hold. \square

From [Theorems 4](#) and [5](#), the capacity improvement ratio of the pipeline scheduling algorithm for multi-radio WSNs compared with the single-radio-based pipeline scheduling algorithm for single-radio WSNs is $\frac{4}{3}$ when $\Delta_e \leq 12$, or $\frac{\Delta_e + 4}{\Delta_e}$ when $\Delta_e > 12$.

In a sum, the achievable network capacities of the proposed algorithms are compared with the most recently published algorithms for data collection, and the result is shown in [Table 2](#).

7 Simulations and Results Analysis

In this section, simulations are conducted to verify the performances of the proposed algorithms through implementing them with the C language. For all the simulations, assume every WSN has one sink, and all the sensor nodes of each WSN are randomly distributed in a square area and the communication radius of each node is normalized to one. Suppose the network MAC layer works with TDMA, i.e., the network time can be slotted. Every node produces one data packet in a snapshot and the size of a data packet is normalized to one. Every available channel has the same bandwidth normalized to one. For any two different channels, suppose they are orthogonal, i.e., the communications initialized over any two channels have no wireless interference. Furthermore, assume a data packet can be transmitted over a channel within a time slot.

The compared algorithms are BFS [12], SLR [6], and CDG [46]. BFS is an SDC algorithm based on a *breadth-first search* tree and the scheduling is carried out path by path [12]. BFS is specifically proposed for single-radio single-channel WSNs. In the following simulations, BFS is extended to the dual-radio multichannel scenario for fairness. SLR is a *straight-line routing* method for multi-unicast communication in multichannel wireless networks with channel switching constraints [6]. For data collection, SLR works by setting every sensor having a unicast communication with the sink simultaneously. The channel switching constraints in SLR are also removed in the following simulations for fairness. Furthermore, the pipelined versions of BFS and SLR (i.e., add the pipeline technique to the data transmission in BFS and SLR), referred to as BFS-P and SLR-P, respectively, are also implemented, when evaluating the performance of the proposed pipeline scheduling algorithm. The basic idea of CDG is discussed in Sect. 6. The proposed *multipath scheduling* algorithm for SDC is referred to as MPS and the proposed *pipeline scheduling* algorithm for CDC is referred to as PS in the following discussions.

In the remainder of this section, the achievable capacities of MPS and PS are investigated through three groups of simulations, respectively. In the simulations, H is the number of the available channels, ρ is the interference radius, n is the number of the sensors in a WSN, AR refers to the square area where a WSN is deployed, and N is the number of the snapshots in a CDC task.

7.1 Performance of MPS

The SDC capacities of MPS, BFS, and SLR in different network scenarios are shown in Fig. 11. In Fig. 11a, the capacity of every algorithm increases when the number of the available channels increases. This is because more available channels enable more concurrent transmissions, which accelerates the data collection process resulting in a higher capacity. After the number of the available channels arrives at 4, the capacities of BFS and SLR almost maintain the same level. This is because four channels are enough to prevent channel interference. However, radio confliction becomes the main barrier of a higher capacity at this time. MPS achieves a

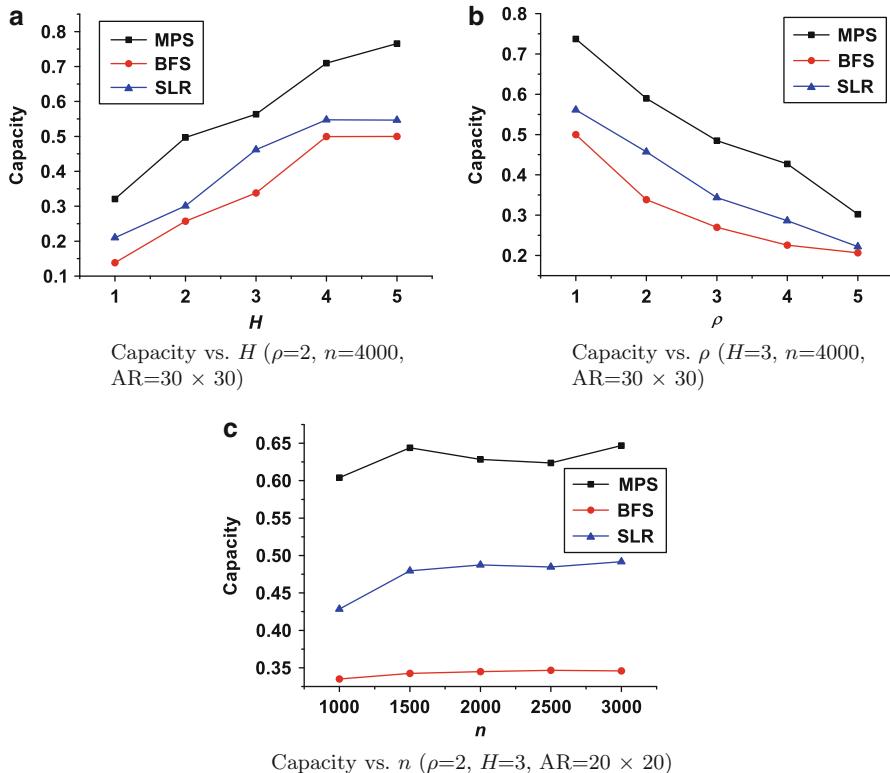

Fig. 11 SDC capacity

higher capacity compared with BFS and SLR. This is because MPS simultaneously schedules all the paths without radio confliction (except at the sink). Since radio confliction on a single path can be avoided easily, MPS can simultaneously schedule all the links without radio confliction on multiple paths, which implies that MPS can make use of channels in a maximum degree. Whereas, BFS just schedules links without radio confliction on one path every time and SLR schedules all the transmission links simultaneously, which leads to serious radio confliction. On average, MPS achieves 77.49 and 41.95 % more capacity than BFS and SLR, respectively.

The effect of the interference radius on the capacity is shown in Fig. 11b. With the increase of the interference radius, more transmission interference occurs, which leads to the decrease of the capacities of all the algorithms. Nevertheless, MPS still achieves the largest capacity since it simultaneously schedules multiple paths without radio confliction, which suggests a nice trade-off between BFS and SLR. On average, MPS achieves 67.45 and 37.37 % more capacity than BFS and SLR, respectively.

The effect of the number of the sensors on the capacity is shown in Fig. 11c. It can be seen that the number of the sensors in a network has a little impact on the capacities of MPS and SLR and almost no impact on the capacity of BFS. There are two reasons for this result. First, BFS is a single-path scheduling algorithm. Whatever the number of the sensors is, it schedules only one path every time. Second, the number of the channels is fixed to 2 in all of these three algorithms. This implies that whatever the number of the sensors is, they can simultaneously schedule at most two interfering links without radio confliction. On average, MPS achieves 83.51 and 32.87 % more capacity than BFS and SLR, respectively.

7.2 Performance of PS

The CDC capacities of PS, CDG, BFS-P, BFS, SLR-P, and SLR in different network scenarios are shown in Fig. 12. Figure 12a (respectively, Fig. 12b, c) and Fig. 12d (respectively, Fig. 12e, f) are the same except the achievable capacity of PS in Fig. 12d (respectively, Fig. 12e, f) is not shown. This is mainly for conveniently and clearly checking the achievable capacities of CDG, BFS-P, BFS, SLR-P, and SLR.

Figure 12a, d reflect the effect of the number of the available channels on the achievable CDC capacity. As explained before, the capacities of all the algorithms increase as more and more channels are available. This is because more channels can prevent channel interferences among concurrent transmission links. PS has a much higher capacity compared with the other five algorithms. This is because by forming a CDG-based pipeline, the time overlap of gathering multiple continuous snapshots conserves a lot of time, which accelerates the data collection process directly and significantly in PS. Furthermore, PS collects data in the CDG way, which can reduce the overall data transmission times. This also explains why CDG has a higher capacity compared with BFS and SLR. From Fig. 12d, it can also be seen that BFS-P and SLR-R have higher network capacities than BFS and SLR, respectively. This is because the use of the pipeline technique can accelerate the data collection process. On average, PS achieves a capacity of 8.22 times of that of CDG, 17.1 times of that of BFS-P, 21.94 times of that of BFS, 13.17 times of that of SLR-P, and 18.39 times of that of SLR, respectively.

The effect of the interference radius on the capacity is shown in Fig. 12b, e. With the increase of the interference radius, a transmission link will interfere with more and more other transmission links, which leads to the decrease of capacity whatever algorithm it is. PS has the highest capacity among all the algorithms since it works with pipeline and CDG. On average, PS achieves a capacity of 7.31 times of that of CDG, 15.9 times of that of BFS-P, 20.43 times of that of BFS, 12.53 times of that of SLR-P, and 16.08 times of that of SLR, respectively.

The effect of the number of the sensors on the capacity is shown in Fig. 12c, f. The increase of the number of the sensors has a little impact on BFS and SLR, and the reasons are similar to those explained in the previous subsection. Whereas, the capacities of PS and CDG have some improvement with more sensors in a WSN.

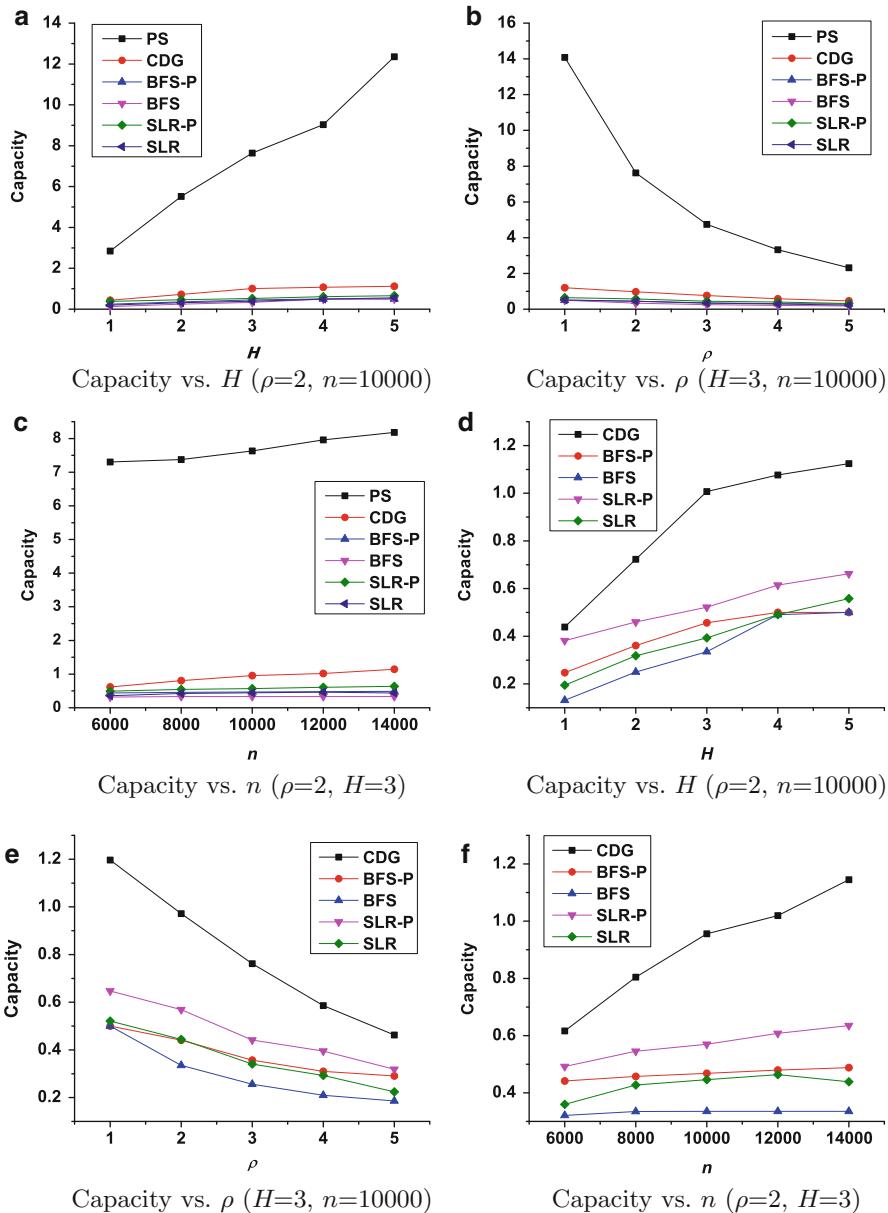

Fig. 12 CDC capacity in different scenarios (AR = 50 × 50, N = 1,000, M = 100)

This is because PS and CDG are more effective for large-scale WSNs. On average, PS achieves a capacity of 8.77 times of that of CDG, 15.48 times of that of BFS-P, 23.15 times of that of BFS, 12.49 times of that of SLR-P, and 18.06 times of that of SLR, respectively.

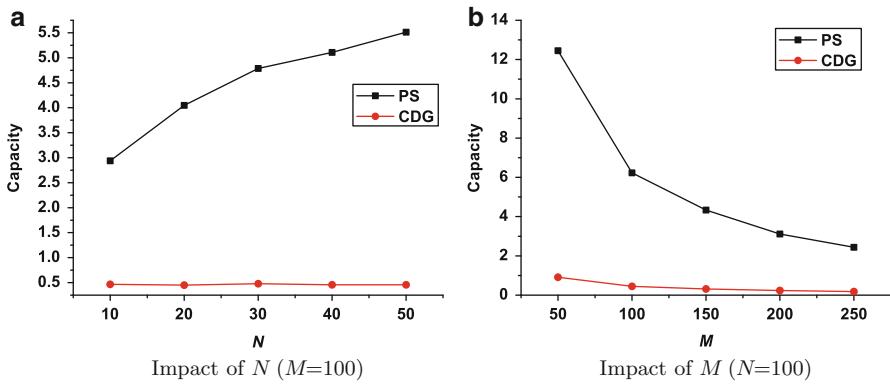

Fig. 13 The impacts of N and M to PS and CDG ($\rho = 2$, $H = 3$, $n = 5,000$, AR = 50×50)

7.3 Impacts of N and M

In this subsection, the impacts of the number of the snapshots and the value of M to the capacities of PS and CDG are investigated. As shown in Fig. 13a, with the increase of N in a CDC task, PS achieves about 87.54 % more capacity. This is straightforward from the analysis in Sect. 6. Since PS employs the pipeline technology, the transmissions of continuous snapshots are overlapped, which can significantly reduce the time used to collect all the snapshots data. With more snapshots in a CDC task, the capacity of PS approaches closer and closer to its theoretical asymptotic capacity. For CDG, the number of the snapshots has little impact on its capacity.

Since the performance of CDG depends on the value of M , the capacities of both PS and CDG decrease about 80 % with the increase of the value of M as shown in Fig. 13b. This is because a bigger M implies that more data packets have to be transmitted for every sensor, and longer transmission time for each snapshot is resulted. Nevertheless, considering that the value of M is usually much less than n , PS can still achieve a high capacity.

8 Conclusion

Motivated by the fact that there exist no works dedicated on studying the capacity of continuous data collection for WSNs under the protocol interference model, this problem in dual-radio multichannel WSNs is investigated in this chapter. A *multipath scheduling* algorithm for the snapshot data collection problem is first proposed. Theoretical analysis of the multi-path scheduling algorithm shows that its achievable network capacity is at least $\frac{W}{2\lceil(1.81\rho^2+c_1\rho+c_2)/H\rceil}$, where W is the channel bandwidth, H is the number of available orthogonal channels, ρ is the ratio of the

interference radius over the transmission radius of a node, $c_1 = \frac{2\pi}{\sqrt{3}} + \frac{\pi}{2} + 1$, and $c_2 = \frac{\pi}{\sqrt{3}} + \frac{\pi}{2} + 2$. For the continuous data collection problem, it is found that pipeline with the existing snapshot data collection methods cannot actually improve the network capacity. The reason of this is analyzed, and then a novel continuous data collection method, the *pipeline scheduling* algorithm, for dual-radio multichannel WSNs is proposed. This method speeds up the data collection process significantly. Theoretical analysis of the pipeline scheduling algorithm shows that the achievable asymptotic network capacity is

$$\begin{cases} \frac{nW}{12M \left\lceil \frac{3.63\rho^2 + c_3\rho + c_4}{H} \right\rceil}, & \text{if } \Delta_e \leq 12 \\ \frac{nW}{M\Delta_e \left\lceil \frac{3.63\rho^2 + c_3\rho + c_4}{H} \right\rceil}, & \text{if } \Delta_e > 12 \end{cases},$$

where n is the number of the sensors, M is a constant value and usually $M \ll n$, Δ_e is the maximum number of the leaf nodes having a same parent in the routing tree (i.e., data collection tree), $c_3 = \frac{8\pi}{\sqrt{3}} + \pi + 2$, and $c_4 = \frac{8\pi}{\sqrt{3}} + 2\pi + 6$. Furthermore, for completeness, the performance of the proposed pipeline scheduling algorithm in single-radio multichannel WSNs is also analyzed, which shows that for a long-run CDC, the lower bound of the achievable asymptotic network capacity is

$$\begin{cases} \frac{nW}{16M \left\lceil \frac{3.63\rho^2 + c_3\rho + c_4}{H} \right\rceil}, & \text{if } \Delta_e \leq 12 \\ \frac{nW}{M(\Delta_e + 4) \left\lceil \frac{3.63\rho^2 + c_3\rho + c_4}{H} \right\rceil}, & \text{if } \Delta_e > 12 \end{cases}.$$

Simulation results indicate that the proposed algorithms improve the network capacity significantly compared with existing works.

The future work of this chapter can be conducted according to the following directions:

- First, in this chapter, the snapshot and continuous data collection problems are studied for single/dual-radio multichannel WSNs. It is expected to extend the work in this chapter to general multi-radio multichannel WSNs to study the achievable capacities of snapshot and continuous data collection.
- Second, the WSNs considered in this chapter are randomly deployed. It is expected to further investigate the snapshot/continuous capacity in arbitrary WSNs.
- Third, the parameter M is crucial for the performance of the pipeline scheduling algorithm. Although the authors in [46] indicated that $M = 3K \sim 4K$ is usually

sufficient for CDG, where K is a value determined by the correlations of the data of a snapshot and $K \ll n$, it is also expected to derive the function relation between M and n for random WSNs, as well as arbitrary WSNs, in the future work.

- Finally, to study the snapshot and continuous capacities for arbitrary WSNs under the *general physical interference model* will be another future research direction.

Abstract

Packing circles in a circle is a classic mathematical problem, which has been studied for a long time. Recently, this problem received a great deal of applications in the study of wireless networks. Those applications are related to many combinatorial optimization problems raised in wireless networks. In analyzing approximation algorithms for those combinatorial optimization problems, it is required to establish an upper bound for the number of untouched unit circles which can be packed into a circle of radius r , where a unit circle is a circle with diameter one. This bound can be easily derived from some classic bounds for the number of unit circles packed into a circle. Moreover, analysis of those approximation algorithms also promoted some new problems about packing circles in circles. In this chapter, a state of the art on the developments in this research direction is presented.

Keywords

Circle packing • Wireless networks

1 Introduction

A circle is *unit* if its diameter is one. What is the minimum radius $r(k)$ of a circle which can contain k nonoverlapping unit circles?

Kravitz [31] presented an upper bound of $r(k)$ for $k = 2, \dots, 16$ in 1967, and for $2 \leq k \leq 4$, the bound is trivially optimal. The optimality of Kravitz's bound is proved for $5 \leq k \leq 7$ by Graham [20] in 1968 and for $8 \leq k \leq 9$ by Piri [45] in 1969. In the same paper, Piri also determined the value of $r(10)$ which indicates that Kravitz's bound is not optimal for $k = 10$. Meanwhile, Piri [45] made a conjecture on optimal packings for $11 \leq k \leq 19$. His conjecture is proved for $k = 11$ by Melissen [40], for $k = 12$ by Fodor [13], for $k = 13$ by Fodor [14], and for $k = 19$ by Fodor [12]. Those values of $r(k)$ are as follows:

$$r(1) = 0.5,$$

$$r(2) = 1,$$

$$r(3) = 0.5 + \frac{1}{\sqrt{3}} = 1.077 \dots,$$

$$r(4) = (1 + \sqrt{2})/2 = 1.207 \dots,$$

$$r(5) = \left(1 + \sqrt{\frac{10 + 2\sqrt{5}}{5}}\right)/2 = 1.350 \dots,$$

$$r(6) = 1.5,$$

$$r(7) = 1.5,$$

$$r(8) = (1 + \csc(\pi/7))/2 = 1.652 \dots,$$

$$\begin{aligned}
r(9) &= \left(1 + \sqrt{4 + 2\sqrt{2}}\right)/2 = 1.806\dots, \\
r(10) &= 1.906\dots, \\
r(11) &= (1 + \text{scs}(\pi/9))/2 = 1.961\dots, \\
r(12) &= 2.014\dots, \\
r(13) &= (2 + \sqrt{5})/2 = 2.228\dots, \\
r(19) &= (1 + \sqrt{2} + \sqrt{6})/2 = 2.431\dots.
\end{aligned}$$

For $k = 14, 16, 17, 20$, Goldberg [18] improved the conjectured value of $r(k)$, and Reis [47] gave a further improvement for $k = 17$ and some dense packings for $21 \leq k \leq 25$. Graham et al. [23] found the best known packing for $26 \leq k \leq 65$. Graham and Lubachevsky [22] and Lubachevsky and Graham [36] gave dense packings for some families of infinitely many values of k . Lv and Huang [37] and Lubachevsky [35] designed computer programs to find dense packing for general k .

Tarnai and Miyazaki [51] found interesting connections between circle packing, sacred lotus, and Japanese Buddhist art. There also exist relationships between optimal packing and optimal codes [7, 21]. Recently, more and more applications of circle packing are found in the analysis of approximation algorithms for optimization problems in wireless sensor networks. In this chapter, a state of the art on the developments in this research direction is presented.

2 An Inequality

Let X be a compact convex region on the Euclidean plane. Suppose X contains a set V of centers of n nonoverlapping unit circles. Then

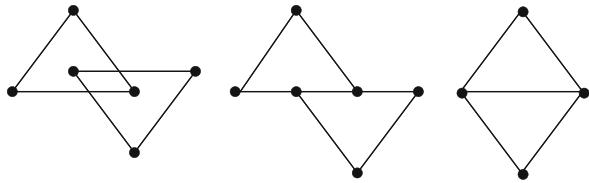

$$n \leq \frac{2}{\sqrt{3}}A(X) + \frac{1}{2}P(X) + 1,$$

where $A(X)$ and $P(X)$ denote the area and the perimeter of X , respectively. This inequality was conjectured by H. Zassenhaus in 1947 (see [59]) and independently proved by Groemer [24] in 1960 and Oler [44] in 1961. Folkman and Graham [15] extended this inequality to simplicial complex.

A point is a zero-dimensional simplex, a straight line segment is a one-dimensional simplex, and a triangle is a two-dimensional simplex. In general, a *simplex* is a polytope with the minimum number of vertices among all the polytopes of a certain dimension. For example, a tetrahedron is a three-dimensional polytope with the minimum number of vertices and hence a three-dimensional simplex.

Any simplex is the convex hull of its vertices. The convex hull of any subset of vertices in a simplex S is also a simplex, which is called a *face* of simplex S . A family Δ of simplexes is called a *simplicial complex* if it satisfies the following two conditions:

Fig. 1 Three families of simplexes

- (a) For $S \in \Delta$, every face of S is in Δ .
- (b) For $S, S' \in \Delta$, $S \cap S'$ is a face for both S and S' .
From (a) and (b), it is easy to see the following:
- (c) For $S, S' \in \Delta$, $S \cap S'$ is also a simplex in Δ .

In Fig. 1, there are three families of simplexes. While the first two are not simplicial complexes, the last one is.

For any simplex A , $|A|$ denotes the number of vertices in A . Thus, $|A| - 1$ is the dimension of A . The *Euler characteristic* of a simplicial complex Δ is defined by

$$\chi(\Delta) = \sum_{A \in \Delta, A \neq \emptyset} (-1)^{|A|-1}.$$

Let $m(A)$ denote the area of A for two-dimensional simplex A and the length of A for one-dimensional simplex A . For one-dimensional simplex A , let $\varepsilon(A, \Delta)$ denote the number of two-dimensional simplexes in Δ having A as a face. For simplicial complex Δ in the Euclidean plane, it is easy to see from (b) that $\varepsilon(A, \Delta) \leq 2$. When $\varepsilon(A, \Delta) = 1$, A is on the boundary of the union of the simplexes in Δ . When $\varepsilon(A, \Delta) = 2$, A is in the interior of the union of the simplexes in Δ . In terms of these terminologies, a definition can be given for the area $A(\Delta)$ and the perimeter $P(\Delta)$ of a simplicial complex Δ in the Euclidean plane:

$$A(\Delta) = \sum_{A \in \Delta, |A|=3} m(A)$$

and

$$P(\Delta) = \sum_{A \in \Delta, |A|=2} (2 - \varepsilon(A, \Delta))m(A).$$

The inequality of Folkman and Graham [15] is as follows:

Theorem 1 (Folkman-Graham [15]) *Let Δ be a simplicial complex in the Euclidean plane. Suppose for any two distinct vertices x and y in Δ , $\|xy\| \geq 1$. Then*

$$|\Delta| \leq \frac{2}{\sqrt{3}}A(\Delta) + \frac{1}{2}P(\Delta) + \chi(\Delta)$$

where $|\Delta|$ is the number of vertices in Δ and $\|xy\|$ is the Euclidean distance between x and y .

To prove this inequality, the following two lemmas were proved first.

Lemma 1 Let a, b, c be the lengths of the three edges of a triangle Δ . Suppose $a \geq b \geq c \geq 1$. Then

$$\frac{4}{\sqrt{3}}A(\Delta) + a \geq b + c.$$

Proof By Hero's formula,

$$\begin{aligned} A(\Delta) &= \frac{1}{4}\sqrt{(a+b+c)(a+b-c)(a-b+c)(-a+b+c)} \\ &\geq \frac{1}{4}\sqrt{(a+b+c)(-a+b+c)} \\ &\geq \frac{1}{4}\sqrt{3c(-a+b+c)} \\ &\geq \frac{1}{4}\sqrt{3(-a+b+c)^2} \\ &= \frac{\sqrt{3}}{4}(-a+b+c). \end{aligned}$$

The inequality of the lemma follows. \square

Lemma 2 Let $BCDE$ be a quadrilateral in the Euclidean plane with area A and perimeter P . Suppose the length of every diagonal of $BCDE$ is not less than the length of every edge of $BCDE$ and the length of every edge is at least one. Then

$$\frac{4}{\sqrt{3}}A - P + 2 \geq 0.$$

Proof Without loss of generality, assume $\angle B + \angle D \leq \pi$. Note that in this case, one must have $A = A(\triangle BCE) + A(\triangle CDE)$. Since diagonal CE is the longest edge in $\triangle BCE$ and in $\triangle DEC$, one has $\angle B \geq \pi/3$ and $\angle D \geq \pi/3$. Hence, $\pi/3 \leq \angle B \leq 2\pi/3$ and $\pi/3 \leq \angle D \leq 2\pi/3$. Therefore,

$$\begin{aligned} A &= \frac{1}{2}(|BC| \cdot |BE| \cdot \sin \angle B + |DC| \cdot |DE| \cdot \sin \angle D) \\ &\geq \frac{\sqrt{3}}{4}(|BC| \cdot |BE| + |DC| \cdot |DE|). \end{aligned}$$

Thus,

$$\begin{aligned} \frac{4}{\sqrt{3}}A - P + 2 \\ \geq |BC| \cdot |BE| + |DC| \cdot |DE| - (|BC| + |BE| + |DC| + |DE|) + 2 \end{aligned}$$

$$\begin{aligned}
&= (|BC| - 1)(|BE| - 1) + (|DC| - 1)(|DE| - 1) \\
&\geq 0.
\end{aligned}$$

The lemma is proved. \square

Now, it is ready to prove [Theorem 1](#).

Proof of Theorem 1. The proof uses an induction on the number of one-dimensional simplexes contained in Δ . First, suppose Δ contains no one-dimensional simplex. Then $A(\Delta) = P(\Delta) = 0$ and $\chi(\Delta)$ is equal to the number of vertices. Therefore, the Folkman-Graham inequality is true.

Next, suppose Δ contains k one-dimensional simplexes and $k \geq 1$. Assume that for every simplicial complex with less than k one-dimensional simplexes, the Folkman-Graham inequality holds. Let $\text{union}(\Delta)$ denote the union of simplexes in Δ . Then it is easy to see that for two simplicial complexes Δ and Γ , if $\text{union}(\Delta) = \text{union}(\Gamma)$, then $A(\Delta) = A(\Gamma)$ and $P(\Delta) = P(\Gamma)$. Furthermore, one also has $\chi(\Delta) = \chi(\Gamma)$, since the Euler characteristic $\chi(\Delta)$ depends only on $\text{union}(\Delta)$ (see, e.g., [46]). Therefore, it suffices to show the validity of Folkman-Graham inequality for a specific simplicial complex among the simplicial complexes with the same union. Without loss of generality, suppose that Δ is the one having the minimum total length of one-dimensional simplexes among those simplicial complexes with the same union and the same number of one-dimensional simplexes as Δ has.

Consider a one-dimensional simplex σ in Δ with the longest length. There are three cases in the following.

Case 1. $\varepsilon(\sigma, \Delta) = 0$. In this case, $\Delta - \{\sigma\}$ is a simplicial complex and $P(\Delta - \{\sigma\}) = P(\Delta) - 2m(\sigma)$. Therefore, by induction hypothesis,

$$\begin{aligned}
|\Delta| &= |\Delta - \{\sigma\}| \\
&\leq \frac{2}{\sqrt{3}}A(\Delta - \{\sigma\}) + \frac{1}{2}P(\Delta - \{\sigma\}) + \chi(\Delta - \{\sigma\}) \\
&= \frac{2}{\sqrt{3}}A(\Delta) + \frac{1}{2}P(\Delta) - m(\sigma) + \chi(\Delta) + 1 \\
&\leq \frac{2}{\sqrt{3}}A(\Delta) + \frac{1}{2}P(\Delta) + \chi(\Delta).
\end{aligned}$$

Case 2. $\varepsilon(\sigma, \Delta) = 1$. Let τ be the two-dimensional simplex in Δ having σ as a face. Let σ' and σ'' be the other two one-dimensional faces of τ . Without loss of generality, assume $m(\sigma') \geq m(\sigma'')$. From the choice of σ , it can be seen that $m(\sigma) \geq m(\sigma') \geq m(\sigma'') \geq 1$. By [Lemma 1](#),

$$\frac{4}{\sqrt{3}}m(\tau) + m(\sigma) \geq m(\sigma') + m(\sigma'').$$

Note that $\Gamma = \Delta - \{\tau, \sigma\}$ is a simplicial complex. By induction hypothesis,

$$\begin{aligned}
& \frac{2}{\sqrt{3}}A(\Delta) + \frac{1}{2}P(\Delta) + \chi(\Delta) \\
&= \frac{2}{\sqrt{3}}A(\Gamma) + \frac{1}{2}P(\Gamma) + \chi(\Gamma) + \frac{2}{\sqrt{3}}(A(\tau) + \frac{1}{2}(m(\sigma) - m(\sigma') - m(\sigma''))) \\
&\geq \frac{2}{\sqrt{3}}A(\Gamma) + \frac{1}{2}P(\Gamma) + \chi(\Gamma) \\
&\geq |\Gamma| = |\Delta|.
\end{aligned}$$

Case 3. $\varepsilon(\sigma, \Delta) = 2$. Let τ and τ' be the two-dimensional simplexes in Δ having σ as a face. Let B and D be the two vertices of σ . Suppose C is the third vertex of τ and E is the third vertex of τ' . By (b) of the definition of simplicial complex, it can be seen that $BCDE$ is a convex quadrilateral. It follows that replacing τ and τ' by $\triangle BCE$ and $\triangle DEC$, a simplicial complex can be obtained from Δ which has the same union and the same number of one-dimensional simplexes as Δ has. By the choice of Δ , one has $m(\sigma) = |BD| \leq |CE|$. Since σ has the longest length, the condition of Lemma 2 is satisfied, and thus

$$\frac{4}{\sqrt{3}}(A(\tau) + A(\tau')) - P(\tau \cup \tau') + 2 \geq 0.$$

Note that $\Gamma = \Delta - \{\sigma, \tau, \tau'\}$ is a simplicial complex. By induction hypothesis,

$$\begin{aligned}
& \frac{2}{\sqrt{3}}A(\Delta) + \frac{1}{2}P(\Delta) + \chi(\Delta) \\
&= \frac{2}{\sqrt{3}}A(\Gamma) + \frac{1}{2}P(\Gamma) + \chi(\Gamma) + \frac{2}{\sqrt{3}}(A(\tau) + A(\tau')) - \frac{1}{2}P(\tau \cup \tau') + 1 \\
&\geq \frac{2}{\sqrt{3}}A(\Gamma) + \frac{1}{2}P(\Gamma) + \chi(\Gamma) \\
&\geq |\Gamma| = |\Delta|.
\end{aligned}$$

Summing the above three cases, Theorem 1 is proved. \square

Zassenhaus-Groemer-Oler inequality can be derived from Folkman-Graham inequality.

Corollary 1 (Zassenhaus-Groemer-Oler) *Let X be a compact convex region on the Euclidean plane. Suppose X contains a set V of centers of n nonoverlapping unit circles. Then*

$$n \leq \frac{2}{\sqrt{3}}A(X) + \frac{1}{2}P(X) + 1$$

where $A(X)$ and $P(X)$ denote the area and the perimeter of X , respectively.

Proof Let H be the convex hull of V . By the convexity of X , one has $A(X) \geq A(H)$ and $P(X) \geq P(H)$. Let Δ be a simplicial complex with vertex set V , whose two-dimensional faces form a triangulation of H . Then the union of Δ equals H and $\chi(\Delta) = 1$. By Folkman-Graham inequality,

$$\frac{2}{\sqrt{3}}A(X) + \frac{1}{2}P(X) + 1 \geq \frac{2}{\sqrt{3}}A(\Delta) + \frac{1}{2}P(\Delta) + 1 \geq |\Delta| = |V|.$$

Zassenhaus-Groemer-Oler Inequality follows. \square

The next corollary follows immediately from Zassenhaus-Groemer-Oler inequality.

Corollary 2 *If a circle with radius r contains n nonoverlapping unit circles, then*

$$n \leq \frac{2}{\sqrt{3}}\pi(r - 0.5)^2 + \pi(r - 0.5) + 1.$$

3 Packing Independent Points

In this section, $\|uv\|$ denotes the Euclidean distance between two points u and v .

A set of points in the Euclidean plane is *independent* if the distance between every pair of points in the set is (strictly) larger than one. For packing independent points, one has similar inequalities with the sign “ \leq ” replaced by “ $<$ ”.

Theorem 2 *Let Δ be a simplicial complex in the Euclidean plane with at least one one-dimensional face. Suppose for any two distinct vertices x and y in Δ , $\|xy\| > 1$. Then*

$$|\Delta| < \frac{2}{\sqrt{3}}A(\Delta) + \frac{1}{2}P(\Delta) + \chi(\Delta)$$

where $|\Delta|$ is the number of vertices in Δ .

Proof Notice that under the condition that every pair of vertices has distance strictly larger than one, the inequality sign “ \geq ” can be replaced by sign “ $>$ ” in Lemmas 1 and 2. With these modified lemmas, the proof of Folkman-Graham inequality can be modified to a proof of Theorem 2. \square

Corollary 3 *Let X be a compact convex region on the Euclidean plane. Suppose X contains n independent points. Then*

$$n < \frac{2}{\sqrt{3}}A(X) + \frac{1}{2}P(X) + 1$$

where $A(X)$ and $P(X)$ denote the area and the perimeter of X , respectively.

Corollary 4 If a circle with radius r contains n independent points, then

$$n < \frac{2}{\sqrt{3}}\pi r^2 + \pi r + 1.$$

As one can see from the following sections, Corollary 4 has a lot of applications. But in some other applications, Corollary 4 is far from tight. For example, in the study of wireless sensor networks, the following problem is often considered: Let T be a tree lying in the Euclidean plane with n vertices, satisfying the condition that each edge has length at most one. Let $Q(T)$ be the union of the n disks with radius one and centers at the vertices of T . How many independent points could $Q(T)$ contain? Let $\text{mip}(n)$ denote the maximum number of independent points lying in $Q(T)$ for T over all the trees with n vertices whose maximum edge lengths are at most one. For $n = 1$, Corollary 4 results in $\text{mip}(1) \leq \lfloor (2/\sqrt{3} + 1)\pi + 1 \rfloor = 7$. However, the exact value of $\text{mip}(1)$ is five, determined by Wan et al. in [53].

Lemma 3 (Wan et al. [53]) $\text{mip}(1) = 5$.

Proof Let D_v denote the disk with center v and radius one. Let a_1, a_2, \dots, a_k be the independent points lying in D_v such that va_1, va_2, \dots, va_k are in counterclockwise ordering. Since $\|va_i\| \leq 1$ for $i = 1, 2, \dots, k$ and $\|a_i a_j\| > 1$ for $i \neq j$, one has $\angle a_1 v a_2 > \pi/3, \angle a_2 v a_3 > \pi/3, \dots, \angle a_k v a_1 > \pi/3$. Thus, $2\pi = \angle a_1 v a_2 + \angle a_2 v a_3 + \dots + \angle a_k v a_1 > k\pi/3$. Hence, $k < 6$. This means $\text{mip}(1) \leq 5$.

On the other hand, it is easy to arrange five independent points on the boundary of D_v , which means $\text{mip}(1) \geq 5$. \square

Since the upper bound of $\text{mip}(n)$ plays an important role in analyzing approximation algorithms for the virtual backbone of wireless networks, a lot of works focus on the improvement of $\text{mip}(n)$.

Unlike wired network, there is no fixed infrastructure in a wireless network. In such a circumstance, if all the sensors participate in the transmission, it is not only a waste of energy, but also can cause too much interference such that nodes cannot decode the transmitted information correctly (which is known as *broadcast storm*). To solve this problem, virtual backbone was proposed [3, 8, 49], which corresponds to a connected dominating set in a graph. A *dominating set* (DS) of a graph $G = (V, E)$ is a vertex set D such that every vertex in $V \setminus D$ has at least one neighbor in D . It is a *connected dominating set* (CDS) if $G[D]$, the subgraph of G induced by D , is connected. Using a CDS as the virtual backbone, computations and transmissions are mainly carried out in the CDS, and thus energy is saved; interference is alleviated. Clearly, one expects the size of the CDS to be as small as possible, resulting in the *minimum connected dominating set* problem (MCDS).

A widely used model of homogeneous wireless sensor network is the *unit disk graph* (UDG), for which every vertex corresponds to a sensor on the plane; two vertices are adjacent in the graph if and only if the Euclidean distance between their corresponding sensors is at most a constant which is scaled to one.

Consider the MCDS problem in a unit disk graph (UDG) G . A lot of approximation algorithms follow a two-phase strategy [3, 5, 33, 50, 53]. The first phase constructs a *maximal independent set* (MIS) I (i.e., a set of independent points such that adding any point into it breaks the independency, notice that any MIS is also a DS). The second phase selects a set C of *connectors* such that $D = I \cup C$ is a CDS. The differences of these works lie in how I and C are selected.

To analyze the approximation ratio, consider an optimal solution D^* . If $|I| \leq \beta_1|D^*| + \beta_2$ and $|C| \leq \gamma_1|D^*| + \gamma_2$, then $|D| \leq (\beta_1 + \gamma_1)|D^*| + (\beta_2 + \gamma_2)$, and thus D is a $(\beta_1 + \gamma_1)$ -approximation solution.

Implementation of Lemma 3 for mip(1) already shows that $|I| \leq 5|D^*|$. A lot of improvements on the upper bound were made continually by Funke et al. [16], Gao et al. [17], Wan et al. [53, 54], Wu et al. [58], and Li et al. [33], which will be introduced in the following.

For the ease of statement, some notations should be fixed first. For a positive real number r , use D_w^r to denote the disk centered at node w with radius r . For a node set W , denote by $D_W^r = \bigcup_{w \in W} D_w^r$. Call them as the *r -neighbor area* of w and W , respectively. For an MIS I , denote by $I_w^r = I \cap D_w^r$ and $I_W^r = I \cap D_W^r$ the set of MIS nodes in the r -neighbor area of w and W , respectively. When $r = 1$, the superscript r is omitted and the notations D_W , I_W , and terminology *neighbor area* are used. Thus, $Q(T)$ in the above is exactly $D_{V(T)}$, and $\text{mip}(n)$ is exactly $\max\{|I_{V(T)}| : I \text{ is an MIS and } T \text{ is a tree on } n \text{ nodes in a UDG}\}$. What one is interested in is the spanning tree T of $G[D^*]$ where D^* is an optimal CDS.

Theorem 3 $|I| \leq 4|D^*| + 1$.

Proof The proof makes use of the following observation: Suppose W is a connected node set and w is another node which is connected to W , then

$$|I_{W \cup \{w\}} \setminus I_W| \leq 4 \quad (1)$$

(refer to Fig. 2 for an illustration), that is, connecting a node to an already connected node set increases the number of MIS nodes in the neighbor area by at most four. For an optimal solution D^* , order the nodes as $v_1, v_2, \dots, v_{|D^*|}$ such that for any $i = 1, 2, \dots, |D^*|$, the subgraph of $G[D^*]$ induced by $W_i = \{v_1, v_2, \dots, v_i\}$ is connected. Then

$$|I| = |I_{v_1}| + \sum_{i=2}^{|D^*|} |I_{v_i} \setminus I_{W_i}| \leq 5 + \sum_{i=2}^{|D^*|} 4 = 5 + 4(|D^*| - 1) = 4|D^*| + 1.$$

The upper bound is proved. \square

For $n = 2$, the exact value of $\text{mip}(2)$ has been determined in [58].

Lemma 4 (Wu et al. [58]) $\text{mip}(2) = 8$.

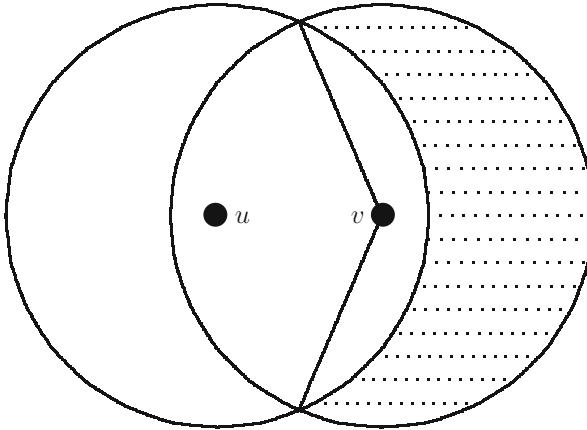

Fig. 2 Adding node v increases the region D_u by the *shaded area* which contains at most four MIS nodes

Proof Let u and v be two points with distance at most one.

First, it was shown that $\text{mip}(2) \leq 8$. Suppose that there exists an independent set I of more than eight points lying in $D_u \cup D_v$. A contradiction will be found through a proof consisting of two parts, each part showing a fact.

Fact 1. The intersection area $A = D_u \cap D_v$ contains exactly one vertex in I .

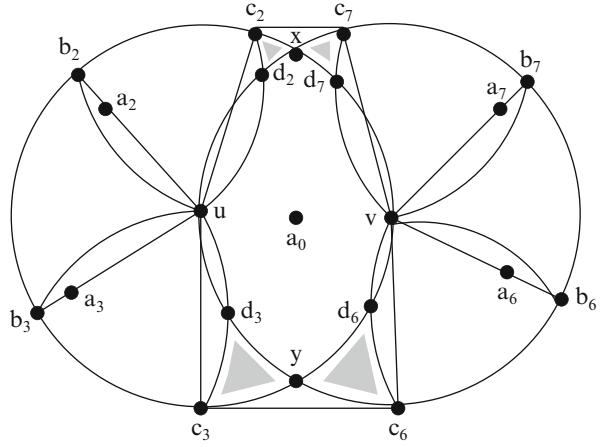

Indeed, suppose A contains k vertices in I . By Lemma 3, $D_u - A$ contains at most $5 - k$ vertices in I and $D_v - A$ contains at most $5 - k$ vertices in I . Thus, $D_u \cup D_v$ contains at most $10 - k$ vertices in I . Hence, by the assumption $|I| \geq 9$, one has $k \leq 1$. To show $k \geq 1$, let x and y be the two intersection points of the boundaries of D_u and D_v . Since $d(u, v) \leq 1$, one has $\angle xvy = \angle yux \geq 2\pi/3$. Thus, $D_u - A$ contains at most four vertices in I , so does $D_v - A$. This means that I contains at most $8 + k$ vertices. Since $|I| \geq 9$, one has $k \geq 1$.

Let a_0 denote the unique point of I lying in $D_u \cap D_v$. As a consequence, each of $D_u - A$ and $D_v - A$ contains exactly four vertices in I and $|I| = 9$. Assume $I = \{a_0, a_1, \dots, a_8\}$, where a_0, a_1, \dots, a_4 lie counterclockwise in D_u and a_0, a_5, \dots, a_8 lie counterclockwise in D_v . Denote by ub_i the radius through a_i for $i = 2, \dots, 4$ and by vb_i the radius through a_i for $i = 5, \dots, 8$. Using radius one, draw four arc-triangles ub_2c_2 , ub_3c_3 , vb_6c_6 , and vb_7c_7 as shown in Fig. 3. Their boundaries intersect the boundary of $D_u \cap D_v$ at d_2, d_3, d_6, d_7 , respectively. Note that none of a_1, a_4, a_5, a_8 can lie in the four arc-triangles ub_2c_2 , ub_3c_3 , vb_6c_6 , and vb_7c_7 and $D_u \cap D_v$. Therefore, a_1, a_4, a_5, a_8 must lie in the four small dark areas xc_2d_2 , yc_3d_3 , yc_6d_6 , and xc_7d_7 , respectively, as shown in Fig. 3.

Fact 2. There exist two small dark areas which are too close to contain two independent vertices. (Therefore, this fact results in a contradiction.)

To show this fact, notice that $\angle b_2ub_3 > \pi/3$ and $\angle c_2ub_2 = \angle b_3uc_3 = \pi/3$. Hence, $\angle c_2uc_3 > \pi$ and $\angle c_3uc_2 < \pi$ (note that $\angle c_3uc_2$ is the one obtained by sweeping c_3u counterclockwise to c_2u). Similarly, $\angle c_7vc_6 < \pi$. Therefore,

Fig. 3 An illustration of the four small dark areas

$\angle uc_2c_7 + \angle c_2c_7v + \angle vc_6c_3 + \angle c_6c_3u > 2\pi$. This means that either $\angle uc_2c_7 + \angle c_2c_7v > \pi$ or $\angle vc_6c_3 + \angle c_6c_3u > \pi$. Without loss of generality, assume the former occurs. Then, it can be shown that the dark area $xc_2d_2 \cup xc_7d_7$ cannot contain two independent points.

To do so, enlarge the area xc_7d_7 by turning the arc-triangle vb_7c_7 around v until vc_7 is parallel to uc_2 (Fig. 4). At this position, quadrilateral c_2uvc_7 becomes a parallelogram so that $\|c_2c_7\| = \|uv\| \leq 1$. It follows that the distance between two points in areas xc_2d_2 and xc_7d_7 cannot exceed $\max(\|c_2c_7\|, \|c_2d_7\|, \|d_2c_7\|, \|d_2d_7\|)$. Moreover, it can be proved that $\|d_2d_7\| \leq \max(\|c_2d_7\|, \|d_2c_7\|)$. In fact, by noticing that $\angle c_7d_7d_2 + \angle d_7d_2c_2 > \pi$, one has either $\angle c_7d_7d_2 > \pi/2$ or $\angle d_7d_2c_2 > \pi/2$. Therefore, either $\|d_2c_7\| > \|d_2d_7\|$ or $\|c_2d_7\| > \|d_2d_7\|$.

Now, to complete the proof of Fact 2, it suffices to prove that $\|c_2d_7\| \leq 1$ and $\|d_2c_7\| \leq 1$. To see $\|c_2d_7\| \leq 1$, make $\|c_2d_7\|$ longer by moving v away from u until $\|uv\| = 1$ (Fig. 5). At this limit position, $\|uv\| = \|vb_7\| = \|b_7d_7\| = \|d_7u\| = 1$. Therefore, uvb_7d_7 is a parallelogram. It follows that $\|d_7b_7\| = \|c_2c_7\| = 1$ and d_7b_7 is parallel to uv and hence parallel to c_2c_7 . Thus, $c_2d_7b_7c_7$ is a parallelogram. Therefore, $\|c_2d_7\| = \|c_7b_7\| = 1$. Similarly, one can show $\|d_2c_7\| \leq 1$.

Fact 2 induces a contradiction, which implies that $\text{mip}(2) \leq 8$.

On the other hand, eight independent points can be easily placed in $D_u \cup D_v$ when $\|uv\| = 1$. This means that $\text{mip}(2) \geq 8$. \square

Making use of Lemma 4, Wu et al. [58] improved the upper bound of $|I|$ as follows:

Theorem 4 $|I| \leq 3.8|D^*| + 1.2$.

Proof In [58], the authors first showed that any unit disk graph has a minimum spanning tree in which every vertex has degree at most five. Let T be such a spanning tree of $G[D^*]$. The upper bound is established by induction on $|T|$, the number

Fig. 4 Turn unit arc-triangle vb_7c_7 until vc_7 parallels uc_2

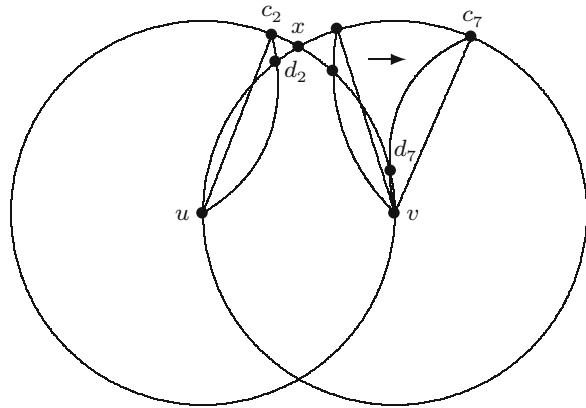

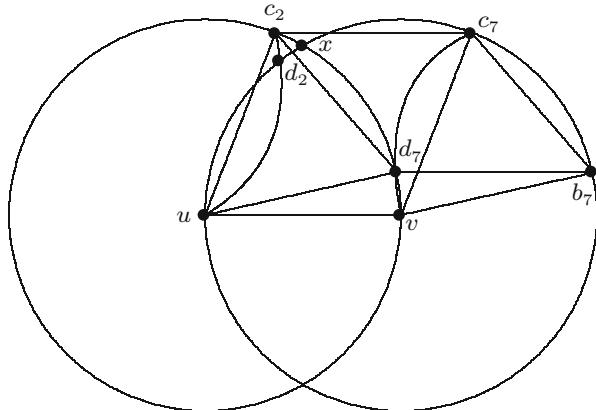

Fig. 5 Move u until $\|uv\| = 1$

of nodes in T . The validity for $|T| = 1$ or 2 follows from [Lemmas 3](#) and [4](#). For $|T| \geq 3$, it is easy to see that T has a non-leaf node v which is adjacent with at most one non-leaf node u (if all the neighbors of v in T are leaves, let u be an arbitrary neighbor of v). Let the remaining neighbors of v be x_1, x_2, \dots, x_k . Then $k \leq 4$. By the induction hypothesis, the neighbor area of $T' = T - \{v, x_1, \dots, x_k\}$ contains at most $3.8(|T| - k - 1) + 1.2$ MIS nodes. Denote $T_0 = T' \cup \{vx_k\}$ and $T_i = T_{i-1} \cup \{vx_i\}$ for $i = 1, 2, \dots, k - 1$. By [Lemma 4](#), it can be seen that $|I_{\{v, x_k\}} \setminus I_u| \leq 7$. By [Lemma 3](#), $|I_{x_i} \setminus I_v| \leq 4$. Thus $|I_{T_0} \setminus I_{T'}| \leq 7$ and $|I_{T_i} \setminus I_{T_{i-1}}| \leq 4$ ($i = 1, 2, \dots, k - 1$). Then, $|I| = |I_{T'}| + |I_{T_0} \setminus I_{T'}| + \sum_{i=1}^{k-1} |I_{T_i} \setminus I_{T_{i-1}}|$ is upper bounded by

$$\begin{aligned} |I| &\leq 3.8(|T| - k - 1) + 1.2 + 7 + 4(k - 1) = 3.8|D^*| + 1.2 + 0.2(k - 4) \\ &\leq 3.8|D^*| + 1.2. \end{aligned}$$

□

From the above analysis, one obtains the feeling that if some nodes in D^* are more compact, then the number of MIS nodes in their neighbor area will be smaller. This intuition is further explored in [54].

Theorem 5 (Wan et al. [54]) $\text{mip}(n) \leq \frac{11}{3}n + \frac{4}{3}$.

Proof A set W of nodes is called a *star* if there exists a node $w \in W$ such that $W \subseteq D_w$. A star containing k nodes is called a k -star. Thus a star is a compact set of nodes, and the larger k is, the more compact the nodes are. It was proved in [54] that any k -star W satisfies

$$|I_W| \leq \frac{11k}{3} + 1. \quad (2)$$

This inequality is obtained by showing that

$$|I_W| \leq \phi_k = \begin{cases} 3k + 2, & \text{for } k \leq 2, \\ \min\{3k + 3, 21\}, & \text{for } k \geq 3, \end{cases}$$

and $\phi_k \leq \frac{11k}{3} + 1$. The intuition for the expression of ϕ_k is that adding a new node into a star increases the number of MIS nodes in the neighbor area by at most 3, and when k is large enough (in fact, when $k > 6$), adding new nodes into the star will no longer increase the number of MIS nodes in the neighbor area.

A *nontrivial star* is a k -star with $k \geq 2$. Decompose D^* into nontrivial stars S_1, S_2, \dots, S_p such that for any $i = 1, 2, \dots, p$, the subgraph of $G[D^*]$ induced by $\bigcup_{j=1}^i S_j$ is connected (this can be done as proved in [54]). By (2),

$$|I_{S_1}| \leq \frac{11|S_1|}{3} + 1.$$

For $i = 2, 3, \dots, p$, let u_i be a node in $\bigcup_{j=1}^{i-1} S_j$ which is adjacent with S_i . Then $(I_{S_i} \setminus \bigcup_{j=1}^{i-1} S_j) \cup \{u_i\}$ is independent. Again by (2),

$$|I_{S_i} \setminus \bigcup_{j=1}^{i-1} I_{S_j}| \leq \frac{11}{3}|S_i|.$$

It follows that

$$|I| = |I_{S_1}| + \sum_{i=2}^p |I_{S_i} \setminus \bigcup_{j=1}^{i-1} I_{S_j}| \leq \frac{11}{3}|D^*| + 1. \quad \square$$

Funke et al. [16] presented a new approach and outlined a proof for

$$\text{mip}(n) \leq 3.453n + 8.291.$$

However, Wan et al. [54] thought that the proof for a key geometric extreme property underlying this claim is missing, and thus the proof is incomplete. Gao et al. [17] proved the key geometric extreme property in detail and found that the proof of Funke et al. actually leads to a better bound.

Lemma 5 (Gao et al. [17]) $\text{mip}(n) \leq 3.453n + 4.839$.

To understand the idea in deducing this bound, it is useful to first look at the deduction of a looser bound:

$$|I| \leq 3.748|D^*| + 5.252. \quad (3)$$

To prove (3), notice that the disks $\{D_u^{0.5} \mid u \in I\}$ are mutually disjoint and they are all contained in $D_{D^*}^{1.5}$. Hence

$$|I| \leq \frac{\text{Area}(D_{D^*}^{1.5})}{\pi \cdot 0.5^2}. \quad (4)$$

To obtain an upper bound for $\text{Area}(D_{D^*}^{1.5})$, notice that adding a disk $D_v^{1.5}$ to a disk $D_u^{1.5}$ increases the 1.5-neighbor area by at most $\pi \cdot 1.5^2 - 2 \left(1.5^2 \arccos \frac{1}{3} - \frac{\sqrt{2}}{2} \right) \approx 2.9435$ (this can be illustrated also by Fig. 2; in this setting, the disks have radius 1.5, and the upper bound is achieved when the distance between nodes u and v is exactly one). Then by an analysis similar to Theorem 3, it can be seen that

$$\text{Area}(D_{D^*}^{1.5}) \leq \pi \cdot 1.5^2 + 2.9435(|D^*| - 1) \approx 2.9435|D^*| + 4.1251. \quad (5)$$

Then inequality (3) follows from (4).

The above deduction is not tight, because the set of disks $\{D_u^{0.5} \mid u \in I\}$ cannot overspread the whole area of $D_{D^*}^{1.5}$; there are a lot of “wasted” fragments the areas of which are counted in $\text{Area}(D_{D^*}^{1.5})$ but have no contribution to $\text{Area}(\bigcup_{u \in I} D_u^{0.5})$.

To overcome this shortcoming, Funke et al. [16] proposed using Voronoi cells instead of disks of radius 0.5 to aid the analysis. For a node $u \in I$, the *Voronoi cell* of u , denoted by $V(u)$, is the set of points on the plane which are closer to u than to the other nodes of I . Call $TV(u) = V(u) \cap D_{D^*}^{1.5}$ as the *truncated Voronoi cell* of u . Clearly, $D_{D^*}^{1.5} = \bigcup_{u \in I} TV(u)$. The advantage is that there is no waste in using truncated Voronoi cell. The key step in the paper [17] is to establish a lower bound:

$$\text{Area}(TV(u)) \geq 0.8525 (\forall u \in I). \quad (6)$$

Replacing the denominator of (4) by 0.8525 and using (5), the upper bound in Lemma 5 is obtained.

In the case that the region $D_{D^*}^{1.5}$ has no holes, Gao et al. [17] proved an upper bound:

$$|I| \leq 3.399|D^*| + 4.874.$$

It was obtained by combining the lower bounds for the truncated Voronoi cells with the Euler's formula. In the case when $D_{D^*}^{1.5}$ has holes, they proved

$$|I| \leq 3.473|D^*| + 4.874.$$

Li et al. [33] improved the approach of Funke et al. [16] and proved the following:

Lemma 6 (Li et al. [33]) $\text{mip}(n) \leq 3.4306n + 4.81854$.

Proof This bound is obtained by further exploring the lower bounds for the areas of the truncated Voronoi cells. The authors partition I into two subsets: $I_1 = \{u \in I \mid D_u^{1/\sqrt{3}} \subseteq D_{D^*}^{1.5}\}$ and $I_2 = I \setminus I_1$. It was proved that

$$\text{Area}(TV(u)) \geq \begin{cases} \sqrt{3}/2, & \text{for } u \in I_1, \\ \sigma, & \text{for } u \in I_2, \end{cases}$$

where $\sigma \approx 0.855$. Hence

$$\text{Area}(D_{D^*}^{1.5}) \geq \frac{\sqrt{3}}{2}|I_1| + \sigma|I_2| = \frac{\sqrt{3}}{2}|I| - \left(\frac{\sqrt{3}}{2} - \sigma\right)|I_2|. \quad (7)$$

Then the authors proved that

$$|I_2| \leq \frac{\text{Peri}\left(D_{D^*}^{1.5-1/\sqrt{3}}\right)}{2(1 - 1/\sqrt{3})}, \quad (8)$$

where Peri represents the perimeter of the region. By induction on $|D^*|$, it can be proved that

$$\text{Peri}\left(D_{D^*}^{1.5-1/\sqrt{3}}\right) \leq 2\left(3 - \frac{2}{\sqrt{3}}\right)\left((|D^*| - 1) \arcsin \frac{1}{3 - 2/\sqrt{3}} + \frac{\pi}{2}\right). \quad (9)$$

Then, the desired upper bound follows from (5), (7), (8), and (9). □

Vahdatpour et al. [52] claimed that they proved

$$\text{mip}(n) \leq 3n + 3. \quad (10)$$

If their proof is correct, then this is best possible because Wan et al. [54] have constructed an example showing that

$$\text{mip}(n) \geq 3n + 3.$$

Unfortunately, an important part of the proof was missing from [52]. Therefore, their result cannot be accepted by many researchers in the literature. What is the important part which was missing from the proof? To explain, the terminology of semi-exclusive neighboring set is needed. Let T be an arbitrary spanning tree of $G[D^*]$ and assume $v_1, v_2, \dots, v_{|T|}$ is an arbitrary traversal of T and v_1 is not a leaf vertex. For any i , $2 \leq i \leq |T|$, the set $U_i = I_{v_i} \setminus I_{\{v_1, \dots, v_{i-1}\}}$ (the subset of MIS nodes which are adjacent with v_i but not adjacent to any of the previous nodes v_1, v_2, \dots, v_{i-1}) is called the *semi-exclusive neighboring set of node v_i* . By (1), one has $|U_i| \leq 4$ for $i = 2, \dots, |T|$.

Vahdatpour et al. tried to prove (10) by using induction on $|T|$. If there exists a leaf vertex v_j with $|U_j| \leq 3$, then the induction hypothesis can be applied on $T - v_j$ to yield $|I_{D^*}| \leq (3(|T|-1) + 3) + 3 = 3|T| + 3$. Hence one may assume that every leaf vertex v_j has $|U_j| = 4$. For each leaf vertex v_j , denote by $f(v_j)$ the first fork vertex (i.e., a vertex of degree at least three in T) that is met when one starts from v_j and goes along the path on T toward the root v_1 . If there exists a vertex v_i between v_j and $f(v_j)$ such that $|U_i| \leq 2$, denote the path on T between v_j and v_i as P . Notice that $T - V(P)$ is still a tree. Hence one can apply the induction hypothesis to $T - V(P)$ to obtain $|I_{D^*}| \leq (3(|T|-t) + 3) + 2 + 3(t-2) + 4 = 3|T| + 3$, where t is the number of nodes on P . What remains is the case that for every leaf vertex v_j , every vertex v_i between v_j and $f(v_j)$ has $|U_i| \geq 3$, and the focus is on the distribution of MIS nodes near a fork vertex. This is the most complicated case, but Vahdatpour et al. did not provide a sufficient argument to deal with it.

Due to the above reason, one can conclude that up to now, the best known upper bound for $\text{mip}(n)$ for general n is the one in Lemma 6 given by Li et al. [33].

In all the above works, geometry is explored deeper and deeper to obtain a tighter bound for the packing of disks with radius 0.5 in the neighbor area of a minimum CDS. The interested readers are referred to the mentioned literatures for the detailed implementation of geometry.

4 Sink Placement in Underwater Sensor Networks

Underwater Sensor Network has a lot of differences from the Terrestrial Sensor Network. It uses acoustic channels instead of radio-frequency signals, which cannot travel far in water. Thus a message which is forwarded through more intermediate nodes will experience a significantly longer data latency. To solve this problem, multiple UnderWater-Sink (UW-Sink) architecture was proposed [1]. Since UW-Sinks are very expensive, it is desirable to use as less UW-Sinks as possible while the number of relays for each sensor can be controlled within a given constant d . This consideration leads to the model of *minimum d -hop sink placement* (MdHSP) problem, the goal of which is to place a minimum number of sinks such that each sensor is at most d -hops away from at least one sink.

Even in UDG, MdHSP problem is NP-hard [29]. However, this problem admits a PTAS in UDG [57]. In the following, the ideas in [29] which gave a constant approximation algorithm for MdHSP are introduced.

A node set I_d of a graph $G = (V, E)$ is a *d-hop independent set* (*dIS*) if any pair of nodes in I_d have hop distance greater than d , it is a *maximal d-hop independent set* (*dMIS*) if any super-set of I_d is no longer a *d-IS*, and it is a *d-hop dominating set* (*dDS*) if every node $v \in V \setminus D$ is at most d -hops away from some node $u \in D$ (v is said to be *d-hop dominated by u*). Clearly, a *dMIS* is also a *dDS*.

Let G be the UDG for the sensors. The algorithm just finds a *dMIS* I_d in G and place a sink at the location of each node in I_d . Clearly, I_d is a solution to *MdHSP*. The authors in [29] proved that I_d approximates the optimal solution within a factor of $O(d)$.

First, they proved that

$$opt_{dDS} \leq 5opt_{MdHSP}, \quad (11)$$

where opt_{dDS} and opt_{MdHSP} are the sizes of a minimum *dDS* and an optimal *MdHSP*, respectively. To show (11), suppose OPT_{MdHSP} is an optimal solution to *MdHSP*. For each $c \in \text{OPT}_{MdHSP}$, find an MIS I_c in $N(c)$, where $N(c)$ is the set of sensors at Euclidean distance at most one from c . Let $I' = \bigcup_{c \in \text{OPT}_{MdHSP}} I_c$. For each node $v \in V$, it is at most d -hops away from some $c \in \text{OPT}_{MdHSP}$. Let (v, w_1, \dots, w_k, c) be a shortest path from v to c , where $k \leq d - 1$. Then w_k is either in I_c or adjacent with a node in I_c . In any case, v is at most d -hops away from some node in I_c . Hence I' is a *dDS* of G , and thus $opt_{dDS} \leq |I'|$. By Lemma 3, one has $|I'| \leq 5opt_{MdHSP}$.

In view of inequality (11), what remains to show is that

$$|I_d| \leq O(d)opt_{dDS} \quad (12)$$

holds for any *dMIS* I_d .

Since a *dMIS* must be an MIS, an upper bound of factor $O(d^2)$ follows easily from Corollary 4: Each node in I_d is *d-hop dominated* by some node in OPT_{dDS} ; nodes which are *d-hop dominated* by $u \in \text{OPT}_{dDS}$ are in the disk centered at u with radius d ; since the nodes in I_d have mutual distances greater than one, Corollary 4 gives

$$|I_d| \leq \left(\frac{2}{\sqrt{3}}\pi d^2 + \pi d + 1 \right) opt_{dDS} = O(d^2)opt_{dDS}.$$

To reduce the order of the factor, an intuitive idea might be that two nodes which are *d-hop independent* are far from each other. Unfortunately, this intuition is not true, as can be seen from Fig. 6. Thus a more elaborated analysis is in need.

For a node u , denote by $I_d(u)$ the set of nodes of I_d which are *d-hop dominated* by u . Divide $I_d(u)$ into two parts: $I_d^{(1)}(u) = \{v \in I_d(u) \mid v \text{ is } \lceil d/2 \rceil\text{-hop dominated by } u\}$ and $I_d^{(2)}(u) = I_d(u) \setminus I_d^{(1)}(u)$. It was proved in [29] that for any node u ,

$$|I_d^{(1)}(u)| \leq 5. \quad (13)$$

$$|I_d^{(2)}(u)| \leq O(d). \quad (14)$$

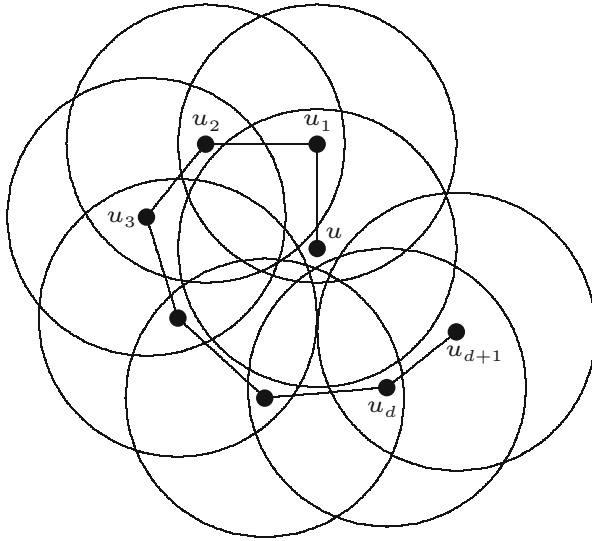

Fig. 6 The node u_{d+1} is d -hop independent with node u ; their Euclidean distance is only a little larger than one

To show (13), for each node $v \in I_d^{(1)}(u)$, let P_v be a shortest path from v to u , and let w_v be the last node on P_v . Then $W(u) = \{w_v \mid v \in I_d^{(1)}(u)\}$ is an independent set. In fact, if this is not true, suppose w_{v_1} is adjacent with w_{v_2} , then there is a path from v_1 to v_2 through edge $w_{v_1}w_{v_2}$ with hop distance at most $2(\lceil d/2 \rceil - 1) + 1 \leq d$, contradicting that v_1 and v_2 are d -hop independent. Thus it follows from Lemma 3 that $|I_d^{(1)}(u)| \leq |W(u)| \leq 5$.

To show (14), for each node $v \in I_d^{(2)}(u)$, let P_v be a shortest path from v to u , say, $P_v = w_0w_1w_2 \dots w_p u$, where $w_0 = v$. Notice that $p \geq \lceil d/2 \rceil$. For each $i = 0, 1, \dots, \lceil d/2 \rceil - 1$, draw a disk $D_{w_i}^{0.5}$ with center w_i and radius 0.5. Denote $A(v) = \bigcup_{i=1}^{\lceil d/2 \rceil - 1} D_{w_i}^{0.5}$. First, notice that $A(v_1) \cap A(v_2) = \emptyset$ for any pair of nodes $v_1, v_2 \in I_d^{(2)}(u)$; otherwise, similarly to the above paragraph, one might obtain a contradiction that there is a path from v_1 to v_2 with hop distance at most d . Second, observe that the disks $D_{w_0}^{0.5}, D_{w_2}^{0.5}, D_{w_4}^{0.5} \dots$ are mutually disjoint since P_v is a shortest path. Thus

$$\text{Area}(A(v)) \geq \left\lfloor \frac{1}{2} \left\lceil \frac{d}{2} \right\rceil \right\rfloor \cdot \pi \cdot (0.5)^2 \geq \frac{(d-3)\pi}{16}.$$

Since $\bigcup_{v \in I_d^{(2)}(u)} A(v)$ is contained in the disk centered at u with radius $d + 0.5$, one has

$$|I_d^{(2)}(u)| \leq \frac{\pi(d+0.5)^2}{(d-3)\pi/16} = O(d).$$

Then, (12) follows from (13) and (14).

Theorem 6 *The MdHSP problem in unit disk graph admits an approximation of factor $O(d)$.*

The above analysis also shows that the *minimum d-Hop dominating set* problem can be approximated within factor $O(d)$, which provides an approximation guarantee for the previous works such as [2], and can also be a step stone for some other more constraint problems such as *minimum connected d-hop dominating set* [43], *minimum d-hop connected d-hop dominating set* [30, 48], and *minimum connected k-fold d-hop dominating set* [32, 60].

5 Data Aggregation Scheduling

In data aggregation problem, a sink node s collects an information from the other nodes. During the aggregation, each node other than the sink combines all the information it receives with its own and sends the combined information only once. For example, to detect a burst of fire, the base station is interested in the highest temperature in a sensed field. Each node in the field detects its local temperature. When a node receives a data sent from another node, it compares the received temperature with the highest temperature stored in it, chooses the higher one, and puts it into the current data as well as the corresponding location. When it has aggregated all the data that are planned to be sent to it, it forwards the aggregated data. It can be seen that the topology of an aggregation can be modeled as an inward arborescence rooted at the sink node, call it as an *aggregation arborescence*.

Because of interference, the aggregation might be delayed. In the *protocol interference model*, node u can receive data from node v only when u is in the transmission range of v and no other nodes are in the interference range of u . Suppose each node has a fixed transmission radius which is scaled to one and an interference radius $\rho > 1$. Then two links u_1v_1 and u_2v_2 *interfere* with each other if either u_1v_2 or u_2v_1 has length at most ρ . A set of links are *interference-free* if they are mutually interference-free.

In an *aggregation schedule*, one has to find an aggregation arborescence and assign time-slots to its links such that (i) a node sends the combined data to its parent only after it has collected all the data from its children and (ii) all the links assigned to a common time-slot are interference-free. The *latency* of the aggregation schedule is the number of time-slots used. The goal of the *minimum-latency aggregation schedule problem* (MLAS) is to find an aggregation schedule with the minimum latency.

Even for the case that $\rho = 1$, the MLAS problem is NP-hard [6]. For a set of nodes V in the plane, let G be the unit disk graph on V . The maximum hop distance from the sink node s to the other nodes is the *radius of G with respect to s* , denoted by R . The approximation algorithms given in [6] and [27] achieve latencies at most $(\Delta - 1)R$ and $23R + \Delta - 18$, respectively, where Δ is the maximum degree of G . In [55], Wan et al. presented three approximation algorithms called SAS, PAS, and EPAS, which produce latencies at most $15R + \Delta - 4$, $2R + \Delta + O(\log R)$, and

$\left(1 + \Theta\left(\log R / \sqrt[3]{R}\right)\right)R + \Delta$. In Sects. 5.1 and 5.2, the main ideas of PAS and EPAS are introduced, respectively.

An aggregation schedule for interference radius $\rho = 1$ is said to be *well separated* if at each time-slot of the schedule, either all the transmitting nodes have mutual distances greater than one or all the receiving nodes have mutual distances greater than one. Using well-separated schedule, Wan et al. [55] introduced a generic method for the aggregation scheduling problem with $\rho > 1$. This method is presented in Sect. 5.3.

Parts of the above works were generalized to many-to-one data aggregation scheduling problem in multichannel multi-hop wireless networks [34].

5.1 Pipelined Aggregation Scheduling (PAS)

A basic step for PAS is the establishment a *single-hop aggregation schedule* from X to Y , where X, Y are two disjoint node sets. The schedule is described in Algorithm 1 called *iterative minimal covering* (IMC), in which data are sent through the links specified by S . In each iteration, a minimal cover C of the remaining node set X' is formed. By the minimality of C , every node $y \in C$ has a *private neighbor* x in X' , that is, y is the only neighbor of x in C . Then xy is the link through which x is set to report its data. The integer $\ell(xy)$ indicates the time-slot assigned to the link xy . It can be seen that

$$\ell(xy) \text{ is no more than the number of neighbors of } y \text{ in } X. \quad (15)$$

By choosing x to be a private neighbor of y , the links with the same label are interference-free.

Algorithm PAS first constructs a connected dominating set (CDS) D of the unit disk graph G . For each node u in $V \setminus D$, assign an arbitrary dominator v as its parent, indicating that u reports data through link uv . In the first phase of the aggregation, data are sent from $V \setminus D$ to D using the single-hop aggregation schedule IMC. By the property in (15), this phase takes at most $\Delta - 1$ time-slots. In the second phase of the aggregation, transmissions are scheduled within the CDS D . In the following, the focus is put on the construction of D and the scheduling within D .

Though the problem of computing a minimum CDS has constant approximations, the CDS D in [55] is constructed in a specific way so that it has stronger properties to be used in analyzing the latency. It starts from constructing a breadth-first-search tree T of G and finds a maximal independent set (MIS) U induced by T in a first-fit manner: order the nodes of T layer by layer as v_1, v_2, \dots, v_n , where $v_1 = s$; set $U = \{v_1\}$ initially; for $i = 2$ to n , add v_i to U if v_i is not adjacent with any node in U . Notice that any MIS of G is also a dominating set of G . After that, more nodes W called *connectors* are added in the following way such that $D = U \cap W$ is a CDS of G : Let H be the graph with node set U ; two nodes in U are adjacent in H if they have a common neighbor in G . Suppose the radius of H

Algorithm 1 IMC

```

1:  $S = \emptyset$ ,  $\ell = 0$ ,  $X' = X$ ,  $Y' = Y$ .
2: while  $X' \neq \emptyset$  do
3:    $\ell = \ell + 1$ .
4:   Let  $C \subseteq Y'$  be a minimal cover of  $X'$ .
5:   for each  $y \in C$  do
6:     Let  $x \in X'$  be a private neighbor of  $y$ .
7:      $S = S \cup \{xy\}$ .
8:      $\ell(xy) = \ell$ .
9:      $X' = X' \setminus \{x\}$ .
10:     $Y' = C$ .
11:   end for
12: end while
13: Output  $S$  and  $\ell$ .

```

with respect to s is R' . It can be seen that $R' \leq R - 1$. For $i = 0, 1, \dots, R'$, let U_i be the set of nodes at distance i from s in H , and let P_i be the set of nodes which are adjacent with some node in U_i and some node in U_{i+1} . Compute a minimal cover $W_i \subseteq P_i$ for U_{i+1} . The connector set $W = \bigcup_{i=1}^{R'-1} W_i$.

Since all the nodes in U are contained in the disk centered at s with radius R , it follows from Corollary 4 that

$$|U| \leq \frac{2\pi}{\sqrt{3}}R^2 + \pi R + 1. \quad (16)$$

Furthermore, since W_i is a *minimal* cover of U_{i+1} , one has $|W_i| \leq |U_{i+1}|$, and thus $|W| \leq |U| - 1$. Hence

$$|U \cup W| \leq \frac{4\pi}{\sqrt{3}}R^2 + 2\pi R + 1. \quad (17)$$

Let $D = U \cap W$. Denote the subgraph of G induced by D as $G[D]$. Clearly, $G[D]$ is connected. Let R_D be the radius of $G[D]$ with respect to s . For $i = 0, 1, \dots, R_D$, let V_i be the set of nodes at distance i from s in $G[D]$. The aggregation arborescence T_D within D is constructed together with a link labeling and a node ranking rank as in algorithm CBFS.

For $0 \leq i \leq R_D$ and $0 \leq j \leq \text{rank}(s)$, let $t_{ij} = (R_D - i) + 44j$. Each link uv of T_D is scheduled to the time-slot $t_{ij} + 4(\ell - 1)$, where i is the depth of u in T_D (i.e., $u \in V_i$), $j = \text{rank}(u)$, and ℓ is the label of the link uv .

It was proved in [55] that the above method gives an aggregation schedule with latency at most $t_{0,\text{rank}(s)}$. Notice that the node ranking produced by CBFS has the property that $\text{rank}(s) \leq \log |D|$. Combining this with (17), $\text{rank}(s) \leq O(\log R)$. Hence, by observing $R_D \leq 2(R - 1)$, one has

$$r_{0,\text{rank}(s)} = R_D + 44 \cdot \text{rank}(s) \leq 2R + O(\log R).$$

Algorithm 2 CBFS

```

1:  $T_D = (D, \emptyset)$ .
2: For each  $u \in V_{R_D}$ ,  $\text{rank}(u) = 0$ .
3: for  $i = R_D$  down to 1 do
4:   Let  $J = \{\text{rank}(v) : v \in V_i\}$ .
5:   for each  $j \in J$  do
6:     Let  $V_{ij} = \{v \in V_i : \text{rank}(v) = j\}$ .
7:     Augment  $T_D$  by applying Algorithm IMC to the sets  $V_{ij}$  and  $V_{i-1}$ .
8:   end for
9:   for each  $u \in V_{i-1}$  do
10:    if  $u$  has no child then  $\text{rank}(u) = 0$ 
11:    else Let  $r$  be the maximum rank of the children of  $u$ .
12:      if  $u$  has only one child with rank  $r$  then  $\text{rank}(u) = r$ 
13:      else  $\text{rank}(u) = r + 1$ .
14:      end if
15:    end if
16:   end for
17: end for
18: Output  $T$  and rank.

```

Taking the first phase of aggregation into account, the latency of the scheduling produced by the algorithm PAS is at most $2R + O(\log R) + \Delta$.

5.2 Enhanced Pipelined Aggregation Scheduling (EPAS)

EPAS uses the same outline as PAS but different set of connectors and different function of time-slot assignment.

The set W of connectors is constructed based on the same MIS U as in PAS, which is induced by the breadth-first-search tree T . For each node v , denote by $p^i(v)$ the i th ancestor of v , that is, $p^i(v)$ is i hops away from v on the path of T from v to s . Fix a positive integer k . Set $W' = \emptyset$ initially. For each node $u \in U \setminus \{s\}$, suppose i is the smallest positive integer such that $p^i(u)$ is in U , add $\{p^j(u) : 1 \leq j \leq \min\{i-1, k\}\}$ into W' . Notice that $\min\{i-1, k\} \geq 1$, and thus by the construction of U , the subgraph $G[U \cup W']$ is connected. In $G[U \cup W']$, construct a shortest path tree T' from s to all the nodes in $U \setminus \{s\}$. Let W be the subset of W' which is contained in $V(T')$.

Since for each node $u \in U \setminus \{s\}$, at most k nodes are added into W' , one has

$$|W| \leq |W'| \leq k(|U| - 1).$$

Combining this with (16),

$$|D| = |U \cup W| \leq (k+1) \left(\frac{2\pi}{\sqrt{3}} R^2 + \pi R \right) + 1. \quad (18)$$

Furthermore, it was proved in [55] that

$$R_D \leq \left(1 + \frac{1}{k}\right) R, \quad (19)$$

where R_D is the radius of the subgraph $G[D]$ with respect to s .

The EPAS uses parameter $k = \Theta(\sqrt[3]{R} / \log R)$ to find a connector set W . Let T_D be the aggregation arborescence of $G[U \cup W]$ constructed by CBFS. Suppose ℓ_0 is the maximum label on the links of T_D . For $0 \leq i \leq R_D$ and $0 \leq j \leq \text{rank}(s)$, let $t_{ij} = (R_D - i) + 3\ell_0 j$. Each link uv of T_D is scheduled to the time-slot $t_{ij} + 3(\ell - 1)$, where i is the depth of u in T_D , $j = \text{rank}(u)$, and ℓ is the label of the link uv .

Similar to PAS, the number of time-slots used by EPAS is at most $t_{0,\text{rank}(s)}$. By (18), (19), and the observation $\text{rank}(s) \leq O(\log R)$,

$$t_{0,\text{rank}(s)} = R_D + 3\ell_0 \text{rank}(s) \leq \left(1 + \Theta\left(\frac{\log R}{\sqrt[3]{R}}\right)\right) R.$$

Taking the first phase of aggregation into account, EPAS produces a schedule with latency at most $\left(1 + \Theta\left(\log R / \sqrt[3]{R}\right)\right) R + \Delta$.

5.3 A Generic Method for $\rho > 1$

Let $\mathcal{S} = \{\mathcal{S}_i : 1 \leq i \leq \ell\}$ be the output of a well-separated schedule using interference radius $\rho = 1$, where ℓ is the latency of the schedule, and \mathcal{S}_i is the set of links scheduled at time-slot i . For each $1 \leq i \leq \ell$, links in \mathcal{S}_i might have interference with respect to $\rho > 1$ and thus need to be further scheduled.

For a link set L , the *conflict graph* of L is the undirected graph $CG(L)$ with vertex set L ; two vertices are adjacent in $CG(L)$ if the corresponding two links interfere with each other. It can be seen that scheduling \mathcal{S}_i into interference-free subsets is equivalent to properly coloring the vertices of $CG(\mathcal{S}_i)$, with each color class corresponding to a set of interference-free links.

Suppose H is a graph to be colored, and $V(H)$ is ordered as v_1, v_2, \dots, v_n . The *first-fit coloring* assigns colors to the vertices sequentially. When vertex v_i is to be colored, it is assigned the first available color, namely, the color with the smallest index which has not been used by any of its previous neighbors. Such a coloring strategy uses at most $\delta^* + 1$ colors, where $\delta^* = \max_{1 \leq i \leq n} \{d_{\text{prev}}(v_i)\}$ and $d_{\text{prev}}(v_i)$ is the number of previous neighbors of v_i in the ordering (also see [39]).

By symmetry, it suffices to consider the case that

the transmitting nodes of \mathcal{S}_i have mutual distances greater than one. (20)

Order the vertices of $CG[\mathcal{S}_i]$ as $u_1 v_1, u_2 v_2, \dots, u_p v_p$ such that the tails u_1, u_2, \dots, u_p of the corresponding links are located from left to right. When

vertex $u_i v_i$ is to be colored in $CG[\mathcal{S}_i]$, all those links corresponding to the previous neighbors of vertex $u_i v_i$ which interfere with link $u_i v_i$ have their tails in the left half of the disk centered at u_i with radius $\rho + 1$. Combining this with (20), Zassenhaus-Groemer-Oler inequality ([Corollary 1](#)) tells us that $u_i v_i$ has at most $\beta_\rho - 1$ previous neighbors, where

$$\beta_\rho = \frac{1}{\sqrt{3}}\pi(\rho + 1)^2 + \left(\frac{\pi}{2} + 1\right)(\rho + 1) + 1.$$

Thus $CG[\mathcal{S}_i]$ can be properly colored with at most β_ρ colors, and thus \mathcal{S}_i can be further scheduled into at most β_ρ interference-free subsets with respect to interference radius $\rho > 1$. The total number of time-slots for the whole scheduling is at most $\beta_\rho \ell$.

Notice that PAS is a well-separated aggregation schedule for $\rho = 1$. Hence the EPAS can produce a schedule with latency at most $\beta_\rho(2R + \Delta + O(\log R))$.

6 Maximum Interference-Free Sets of Links

In a wireless sensor network, interferences are inevitable, which causes delays of transmissions. In a *physical interference model*, when a node u is transmitting at a power p_u , the signal power caught by another node v is

$$cp_v(u) = \frac{p_u}{\|uv\|^\alpha},$$

where $\|uv\|$ is the Euclidean distance between u and v and α is the *path-loss exponent* which is a constant usually between two and six. A node can correctly receive a signal if and only if the *signal-to-interference-plus-noise ratio* (SINR) is above a threshold. To speak it concretely, suppose \mathcal{L} is a set of transmission requests specified by a set of source-destination links. For a link subset $L \subseteq \mathcal{L}$, denote by L^s and L^r the set of source nodes and the set of destination nodes of the links in L , respectively. For a link uv and a vertex set W not containing u , the SINR of uv with respect to W is defined as

$$\text{SINR}(W; uv) = \frac{cp_v(u)}{N + \sum_{w \in W} cp_v(w)}, \quad (21)$$

where N is the ambient noise. Node v correctly receives the message from u if and only if

$$\text{SINR}(L^s; uv) \geq \beta, \quad (22)$$

where L is the set of the other links which are scheduled to transmit at the same time-slot as uv . A subset L of links is said to be *interference-free* if $\text{SINR}(L^s \setminus \{u\}; uv) \geq \beta$ holds for each link $uv \in L$. In other words, links in L can be scheduled to transmit

at the same time-slot such that all the destination nodes of L can correctly receive the messages from their corresponding sources.

Starting with the pioneering work of Gupta and Kumar [26], the capacity of networks with physical interference has been extensively studied in recent years. A lot of works claim the superiority of the physical interference model over the binary interference model [25, 38, 42]. However, because of the nonconvexity and the nonlocality property of the physical interference model, theoretical studies are notoriously hard.

Consider the problem of *maximum interference-free set of links* (MISL), also known as *one-shot scheduling* problem. Given a set \mathcal{L} of transmission requests, the goal is to find a maximum subset L of \mathcal{L} which is interference-free. With uniform power assignment (i.e., every node transmits at a fixed power P), Goussevskaia et al. [19] gave the first constant approximation algorithm for MISL, but their analysis is only valid when the ambient noise $N = 0$. For $N > 0$, Wan et al. [56] gave a constant approximation algorithm in which [Corollary 4](#) is implemented. The following part introduces the major ideas of the algorithm in [56] and how [Corollary 4](#) is integrated in the analysis of the algorithm.

Let $R = \left(\frac{P}{\beta N}\right)^{1/\alpha}$. By (21) and (22), R is the maximum length that a transmission can be done without considering the interferences from the other nodes. A simple calculation shows that $\text{SINR}(W; uv) \geq \beta$ if and only if

$$\beta \frac{\sum_{w \in W} (\|uv\| / \|wv\|)^\alpha}{1 - (\|uv\| / R)^\alpha} \leq 1.$$

In the light of this, Wan et al. defined the *relative interference of a node w ($\neq u$) to the link uv* as

$$RI(w; uv) = \beta \frac{(\|uv\| / \|wv\|)^\alpha}{1 - (\|uv\| / R)^\alpha},$$

and the *relative interference of a set W ($u \notin W$) to uv* as

$$RI(W; uv) = \sum_{w \in W} RI(w; uv).$$

Thus a link set L is interference-free if and only if $RI(L^s \setminus \{u\}; uv) \leq 1$ holds for every link $uv \in L$.

The algorithm uses a parameter $\phi \in (0, 1)$ which is to be chosen to minimize the final approximation ratio. It also makes use of the Riemann zeta function $\zeta(x) = \sum_{j=1}^{\infty} j^{-x}$. For a link uv , denote

$$\rho_{uv, \phi} = 1 + \left(\frac{\beta(16\zeta(\alpha - 1) + 8\zeta(\alpha) - 6)}{\phi(1 - (\|uv\| / R)^\alpha)} \right)^{1/\alpha}.$$

The algorithm is presented in [Algorithm 3](#).

Algorithm 3 Approximation algorithm for MISL

```

1: Let  $\mathcal{S}$  be the set of transmission requests sorted by the increasing order of lengths.
2: Let  $I = \emptyset$ ,  $U = \emptyset$ .
3: while  $\mathcal{S} \neq \emptyset$  do
4:   Let  $uv$  be the first link in  $\mathcal{S}$ .
5:    $\mathcal{S} = \mathcal{S} \setminus \{uv\}$ ,  $I = I \cup \{uv\}$ ,  $U = U \cup \{u\}$ .
6:   Let  $\mathcal{S}' = \{u'v' \in \mathcal{S} : \|u'u'\| < \rho_{\|uv\|,\phi} \cdot \|uv\|\}$ .
7:    $\mathcal{S} = \mathcal{S} \setminus \mathcal{S}'$ .
8:   Let  $\mathcal{S}'' = \{u''v'' \in \mathcal{S} : RI(U; u''v'') > 1 - \phi\}$ .
9:    $\mathcal{S} = \mathcal{S} \setminus \mathcal{S}''$ .
10: end while
11: Output  $I$ .

```

In the algorithm, the transmission requests are sorted by the increasing order of lengths and scanned sequentially. That is, preference is given to those links with shorter lengths. When a link uv is selected into the interference-free set I , the remaining links whose sources are near to u to some extend are discarded (see \mathcal{S}' in line 6), then the remaining links whose relative interferences to uv is greater than $1 - \phi$ are discarded (see \mathcal{S}'' in line 8).

The final output I of [Algorithm 3](#) is indeed an interference-free set of links. In fact, for each link $uv \in I$, denote by I_{uv}^- and I_{uv}^+ the sets of links of I which are chosen before uv and after uv , respectively. Since uv is not discarded as a member of \mathcal{S}'' , one has $RI((I_{uv}^-)^s; uv) \leq 1 - \phi$. The use of \mathcal{S}' ensures that the mutual distances between the nodes in $(I_{uv}^+)^s \cup \{u\}$ are at least $\rho_{\|uv\|,\phi} \cdot \|uv\|$. Wan et al. proved that such a property implies $RI((I_{uv}^+)^s; uv) < \phi$. Then, by the additivity of relative interference, $RI(I \setminus \{uv\}; uv) \leq 1$.

Let

$$\begin{aligned}\rho_0 &= 1 + \left(\frac{\beta(16\zeta(\alpha - 1) + 8\zeta(\alpha) - 6)}{\phi} \right)^{1/\alpha}, \\ \mu_1 &= \left\lfloor \frac{2\pi}{\sqrt{3}} \left(\frac{\rho_0}{\beta^{1/\alpha} - 1} \right)^2 + \pi \frac{\rho_0}{\beta^{1/\alpha} - 1} \right\rfloor + 1, \\ \mu_2 &= 5 \left\lceil \left((1 - \phi)^{-1/\alpha} + 2\beta^{-1/\alpha} \right)^\alpha \right\rceil.\end{aligned}$$

It was proved in [56] that [Algorithm 3](#) has approximation ratio $(\mu_1 + \mu_2 + 1)$. To prove this, suppose $|I| = k$. For $i = 1, 2, \dots, k$, let $u_i v_i$ be the link chosen into I and $\mathcal{S}'_i, \mathcal{S}''_i$ be the sets discarded from \mathcal{S} in the i th iteration. Denote $L' = \bigcup_{i=1}^k \mathcal{S}'_i$ and $L'' = \bigcup_{i=1}^k \mathcal{S}''_i$. Consider an optimal solution OPT. It can be proved that $|\text{OPT} \cap L''| \leq \mu_2 k$ and

$$|\text{OPT} \cap \mathcal{S}'_i| \leq \mu_1 \text{ holds for each } 1 \leq i \leq k. \quad (23)$$

Then the approximation ratio follows from

$$|\text{OPT}| = |\text{OPT} \cap I| + |\text{OPT} \cap L'| + |\text{OPT} \cap I''| \leq (1 + \mu_1 + \mu_2)k.$$

It is in proving (23) that [Corollary 4](#) is used. In fact, Wan et al. proved that the sources of all the links in $\text{OPT} \cap \mathcal{S}'_i$ have mutual distances at least

$$\left(\frac{\beta^{1/\alpha}}{(1 - (\|u_i v_i\|/R)^\alpha)^{1/\alpha}} - 1 \right) \|u_i v_i\|.$$

Combining this with the observation that the sources of all the links in $\text{OPT} \cap \mathcal{S}'$ lie in the disk of radius $\rho_{\|u_i v_i\|, \phi} \cdot \|u_i v_i\|$, [Corollary 4](#) tells us that

$$|\text{OPT} \cap \mathcal{S}'_i| \leq \frac{2\pi}{\sqrt{3}} \left(\frac{\rho_{\|u_i v_i\|, \phi}}{\frac{\beta^{1/\alpha}}{(1 - (\|u_i v_i\|/R)^\alpha)^{1/\alpha}} - 1} \right)^2 + \pi \cdot \frac{\rho_{\|u_i v_i\|, \phi}}{\frac{\beta^{1/\alpha}}{(1 - (\|u_i v_i\|/R)^\alpha)^{1/\alpha}} - 1} + 1.$$

Then inequality (23) follows from an analytic calculation.

7 Diameter Bounded Connected Dominating Sets

Using connected dominating set (CDS) as virtual backbone has a lot of advantages, such as saving energy and reducing interferences. However, there are some other concerns. For example, the probability of message transmission failure increases if a message is sent through a longer path [\[41\]](#). Hence one expects the diameter of the virtual backbone to be as small as possible. In [\[28\]](#), Kim et al. initiated the study on minimum CDS with bounded diameter. Two approximation algorithms were presented in [\[28\]](#) for the unit disk graph (UDG), which were named by the authors as CDS-BD-C1 and CDS-BD-C2, respectively. The former one has a smaller diameter but a larger size of CDS, and the latter one has a smaller size of CDS but a larger diameter.

Both algorithms are based on a breadth-first-search tree T rooted at an arbitrary node s . Suppose T has depth R . It can be seen that

$$\text{Diam}^* \geq R - 2, \quad (24)$$

where Diam^* is the diameter of a CDS D^* with the smallest diameter. In fact, consider two nodes $u, v \in V(G)$ with $\text{dist}_G(u, v) = \text{Diam}(G)$. Let u', v' be the nodes in D^* dominating u, v , respectively (u' may coincide with u if u is in D , the same coincidence may occur for v and v'). Then

$$\text{Diam}^* \geq \text{dist}_{D^*}(u', v') \geq \text{dist}_G(u', v') \geq \text{dist}_G(u, v) - 2 = \text{Diam}(G) - 2 \geq R - 2.$$

For $i = 0, 1, \dots, R$, let L_i be the set of nodes at hop distance i from node s . Find a maximal independent set (MIS) I induced by T by, for example, the

Algorithm 4 Connector 1

```

1:  $C = \emptyset$ .
2: for  $i = 2$  to  $R$  do
3:   for each node  $u \in I \cap L_i$  do
4:     if  $u$  has no neighbor in  $C \cap L_{i-1}$  then
5:       Let  $v$  be a neighbor of  $u$  in  $L_{i-1}$  and add  $v$  into  $C$ .
6:     end if
7:   end for
8: end for

```

first-fit strategy used in Sect. 5 or a coloring strategy as in [28]. Such an MIS has the property that

$$\text{each node } u \in L_i \setminus I \text{ is adjacent with some node in } I \cap (L_{i-1} \cup L_i). \quad (25)$$

Then a set C of connectors is found layer by layer.

First consider CDS-BD-C2. The construction of C is described in Algorithm 4. Notice that since s is an MIS node, there is no MIS nodes in L_1 , and thus the for-loop starts from $i = 2$. By property (25), it is easy to see that $D = I \cup C$ is a CDS.

Theorem 7 *CDS-BD-C2 produces a connected dominating set D with*

$$\begin{aligned} |D| &\leq 6.862\text{opt}^* + 8.638, \\ \text{Diam}(G[D]) &\leq 4(\text{Diam}^* + 1), \end{aligned}$$

where opt^* and Diam^* are the size and the diameter of the optimal solution D^* .

Proof Since in each iteration, at most one node is added into C , one has $|C| \leq |I| - 1$. Thus $|D| \leq 2|I| - 1$ and the first inequality follows from the inequality in Lemma 6.

Denote by r_i the maximum distance of a node in $I \cap L_i$ from s in $G[D]$. By induction on i , it can be proved that

$$r_1 = 1 \text{ and } r_i \leq 2(i - 1) \text{ for } i \geq 2. \quad (26)$$

In fact, it is trivial to see that $r_1 = 1$ and $r_2 = 2$. Suppose $i \geq 3$ and (26) is true for r_1, r_2, \dots, r_{i-1} . Let u be a node in $I \cap L_i$ such that $\text{dist}(s, u) = r_i$. Suppose v is the neighbor of u in $C \cap L_{i-1}$. By property (25), v is adjacent to a node $u' \in I \cap (L_{i-2} \cup L_{i-1})$. Then, it follows from the induction hypothesis that

$$r_i = \text{dist}(s, u) \leq d(s, u') + 2 \leq 2(i - 1) - 2 + 2 = 2(i - 1).$$

In particular, $r_R \leq 2(R - 1)$. Notice that a node which is farthest from s in $G[D]$ must be an MIS node. Hence

$$\text{Diam}(G[D]) \leq 2r_R \leq 4(R - 1). \quad (27)$$

Algorithm 5 Connector 2

```

1:  $C = \emptyset$ .
2: for  $i = 1$  to  $\lfloor R/2 \rfloor$  do
3:   for each node  $u \in I \cap L_{2i}$  do
4:     if  $u$  has no neighbor in  $C \cap L_{2i-1}$  then
5:       Let  $v$  be a neighbor of  $u$  in  $L_{2i-1}$  and add  $v$  into  $C$ .
6:       if  $v$  has no neighbor in  $(I \cup C) \cap L_{2i-2}$  then
7:         Let  $w$  be a neighbor of  $v$  in  $L_{2i-2}$  and add  $w$  into  $C$ .
8:       end if
9:     end if
10:   end for
11:   for each node  $u \in I \cap L_{2i+1}$  do
12:     if  $u$  has no neighbor in  $C \cap L_{2i}$  then
13:       Let  $v$  be a neighbor of  $u$  in  $L_{2i}$  and add  $v$  into  $C$ .
14:     end if
15:   end for
16: end for

```

Then the second inequality follows from (27) and (24). \square

CDS-BD-C1 differs from CDS-BD-C2 in the construction of C which is described in [Algorithm 5](#). The authors in [28] gave a weight function on the node set to specify the priority in selecting the ancestors, which is a heuristic to raise the performance in the simulation. Since this does not affect the theoretical analysis, the algorithm is presented in a simpler form as [Algorithm 5](#).

Theorem 8 *CDS-BD-C1 produces a connected dominating set D with*

$$|D| \leq 10.293\text{opt}^* + 12.457,$$

$$\text{Diam}(G[D]) \leq 3\text{Diam}^* + 5.$$

Proof Again by property (25), the output $D = I \cup C$ is a CDS. Notice that for each MIS node, at most two ancestors are added into C . Hence $|C| \leq 2(|I| - 1)$, and thus $|D| \leq 3|I| - 2$. The first inequality follows from [Lemma 6](#).

Using the same notation r_i as in [Theorem 7](#), it can be proved that for CDS-BD-C1,

$$r_i \leq \left\lfloor \frac{3i - 1}{2} \right\rfloor \text{ holds for } i \geq 1. \quad (28)$$

Notice that $r_1 = 1$ and $r_2 = 2$ satisfy (28). Suppose (28) is true for $r_1, r_2, \dots, r_{2j-1}, r_{2j}$. Let u be a node in $I \cap L_{2j+1}$ with $\text{dist}(s, u) = r_{2j+1}$. Suppose

v is the parent of u in C . Since v is adjacent with some MIS node u' in layer L_{2j} or L_{2j-1} , one has

$$r_{2j+1} = \text{dist}(s, u) = \text{dist}(s, u') + 2 \leq r_{2j} + 2 \leq 3j + 1 = \left\lfloor \frac{3(2j + 1) - 1}{2} \right\rfloor.$$

Next consider a node $u \in I \cap L_{2j+2}$ with $\text{dist}(s, u) = r_{2j+2}$. By line 4–9 of the algorithm, u has an ancestor $w \in (I \cup C) \cap L_{2j}$. If $w \in I$, let $u' = w$; otherwise, let u' be an MIS neighbor of w in layer L_{2j} or L_{2j-1} . Then

$$r_{2j+2} = \text{dist}(s, u) \leq \text{dist}(s, u') + 3 \leq r_{2j} + 3 \leq 3j + 2 = \left\lfloor \frac{3(2j + 2) - 1}{2} \right\rfloor.$$

Thus (28) is true by induction.

It follows that $\text{Diam}(G[D]) \leq 2r_R \leq 3R - 1$. Combining this with (24), the second inequality is proved. \square

8 Routing-Cost Bounded Connected Dominating Sets

Using a connected dominating set (CDS) as the virtual backbone of a network G , energy is saved; interference is alleviated. However, the routing cost might be increased. For a node set D , denote by $d_D(u, v)$ the length of a shortest path between two nodes u and v such that all the internal nodes on this path belong to D (length here means *hop distance*). Consider the example in Fig. 7a, the set D of black nodes is a CDS. One can see that $d_D(A, C) = 4 > 2 = d_G(A, C)$.

Taking the routing cost into consideration, Ding et al. [9] proposed the problem of *minimum routing cost CDS* (MOC-CDS), the goal of which is to find a minimum CDS D with the property that $d_D(u, v) = d_G(u, v)$ holds for any pair of nodes $u, v \in V(G)$. The set of black nodes in Fig. 7b is an MOC-CDS. It was proved in [9] that MOC-CDS cannot be polynomially approximated within factor $(1 - \varepsilon) \ln \Delta$ unless $NP \subseteq DTIME(n^{O(\log \log n)})$, where Δ is the maximum degree of the graph. The authors also gave a $(1 - \ln 2 + 2 \ln \Delta)$ -approximation algorithm.

However, the size of an MOC-CDS might be conspicuously larger than the size of a CDS. To balance the competing considerations of energy saving and routing cost, Du et al. [11] proposed the problem of *guaranteed routing cost CDS*: Given a constant $\beta \geq 1$, the goal is to find a minimum CDS D such that $d_D(u, v) \leq \beta d_G(u, v)$ holds for any pair of nodes $u, v \in V(G)$. Such a CDS is called a β -GOC-CDS. For $\beta = 5$, a constant approximation algorithm was given in [11].

The authors first proved that for any pair of nodes $u, v \in V(G)$, $d_D(u, v) - 1 \leq \beta(d_G(u, v) - 1)$ if and only if for any pair of nodes $u, v \in V(G)$ with $d_G(u, v) = 2$, $d_D(u, v) - 1 \leq \beta$. The necessity is obvious. The sufficiency is established by considering a shortest (u, v) -path in G and sequentially replacing sub-paths of length two by paths of length at most $\beta + 1$ whose internal nodes all belong to D (see the

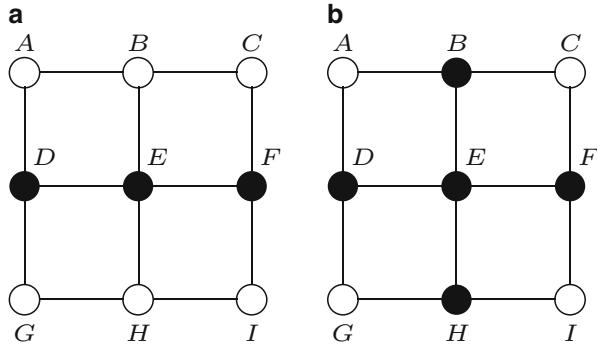

Fig. 7 (a) a CDS, (b) an MOC-CDS

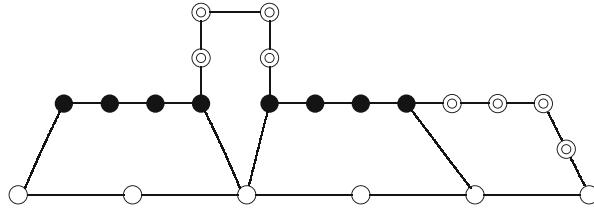

Fig. 8 The *white nodes* are on the shortest path. The *blackened nodes* and the *double-circle nodes* belong to D . First replace sub-paths of length two by the paths whose internal nodes are the blackened ones. Then further replace sub-paths of length two at the intersection points by the paths whose internal nodes are the *double-circle* ones

illustration in Fig. 8). As a consequence, if $d_D(u, v) \leq \beta + 1$ holds for any pair of nodes $u, v \in V(G)$ with $d_G(u, v) = 2$, then D is a β -GOC-CDS.

The algorithm first computes a maximal independent set (MIS) I . Then for every pair of nodes $u, v \in I$ with $d_G(u, v) \leq 4$, the internal nodes of a shortest (u, v) -path are added. Denote the set of the added nodes as C . The output $D = I \cup C$ has the property that for any pair of nodes $u, v \in I$ with $d_G(u, v) \leq 4$, the distance $d_D(u, v) \leq 4$. Consider two nodes $u', v' \in V(G)$ with $d_G(u', v') = 2$. Since I is a dominating set, there exist $u, v \in I$ such that u' is dominated by u and v' is dominated by v . Then $d_G(u, v) \leq 2 + d_G(u', v') = 4$, and thus $d_D(u, v) \leq 4$. Hence $d_D(u', v') \leq 2 + d_D(u, v) \leq 6$. By the arbitrariness of u', v' and the claim in the previous paragraph, D is a 5-GOC-CDS.

To analyze the approximation ratio of the algorithm, the authors first proved that for any node $u \in I$, the number of nodes $v \in I$ with $0 < d_G(u, v) \leq 4$ is at most 80. In fact, using Corollary 4, the upper bound can be reduced to 70: Since any such node v lies in the disk centered at u with radius 4, the number of such nodes is upper bounded by

$$\left\lfloor \frac{2}{\sqrt{3}} \cdot 16\pi + \frac{1}{2} \cdot 8\pi + 1 \right\rfloor - 1 = 70.$$

To bound $|C|$, construct an auxiliary graph H with vertex set I ; two vertices are adjacent in H if their distance is at most four in G . By the above analysis, the maximum degree of H is upper bounded by 70, and thus there are at most $35|I|$ edges in H . Corresponding to each edge in H , at most three nodes are added into C . Hence $|C| \leq 105|I|$, and thus $|D| \leq 106|I|$. By using the inequality in [Lemma 6](#), one has $|I| \leq 3.431 \cdot \text{opt}_{MCDS} + 4.819$, where opt_{MCDS} is the number of nodes in a minimum CDS, which is clearly a lower bound for the size of a minimum GOC-CDS. Then $|D| \leq 363.686 \cdot \text{opt}_{GOC-CDS} + 510.814$, which is a constant approximation solution to the GOC-CDS problem.

Based on the above constant approximation solution, a PTAS was given in [\[10\]](#).

9 Conclusion

In this chapter, an overview of some typical applications of packing circle theory to the wireless network is presented. These applications also propose new challenges to the study on packing circle theory. This chapter aims to serve as a spur to induce more researchers to come forward with valuable contributions.

Abstract

Partition combined with shifting strategy is a powerful method in producing polynomial time approximation scheme (PTAS) for many NP-hard geometric problems. The focus of this chapter is on the ideas and the techniques of partition method which can be applied to high dimensional space, including the basic ideas, the small compensation technique which is used to deal with the requirement of connection, the multilayer partition technique which is used to deal with the situation when the geometric objects are not uniform, and the growing partition technique which does not require the geometric representation of the graph.

1 Introduction

The performance of an approximation algorithm is measured by its time complexity and performance ratio. For an NP-hard problem \mathcal{P} , suppose \mathcal{A} is an approximation algorithm for \mathcal{P} , the performance ratio of \mathcal{A} is

$$PR(\mathcal{A}) = \begin{cases} \sup_{\mathcal{I} \in \mathcal{P}} \frac{apx(\mathcal{I})}{opt(\mathcal{I})}, & \text{if } \mathcal{P} \text{ is a minimization problem;} \\ \sup_{\mathcal{I} \in \mathcal{P}} \frac{opt(\mathcal{I})}{apx(\mathcal{I})}, & \text{if } \mathcal{P} \text{ is a maximization problem,} \end{cases}$$

where the supremum is taken over all instances \mathcal{I} of \mathcal{P} , $apx(\mathcal{I})$ is the value of the solution output by the algorithm when it is applied to instance \mathcal{I} , and $opt(\mathcal{I})$ is the optimal value of instance \mathcal{I} .

A polynomial time approximation scheme (PTAS) is an approximation algorithm such that for any fixed positive real number $\varepsilon > 0$, the algorithm can produce an approximation solution in polynomial time (depending on the size of the input and ε) with performance ration $1 + \varepsilon$. Furthermore, if the running time is polynomial in the size of the input and $1/\varepsilon$, then the algorithm is a fully polynomial time scheme (FPTAS).

In this chapter, partition method is explored to device PTASs for some geometric NP-hard problems in high dimensional space. These problems are all strong NP-hard [4, 8, 18, 20, 25, 28, 31, 33, 39, 45]. Therefore, there are no FPTAS for these problems unless P=NP. Hence, the best approximation algorithm one can expect is a PTAS.

Partition has long been proved to be a powerful method in producing PTAS for many geometric NP-hard problems. It partitions the region into small subregions, finds exact solutions to the small subregions, and combines them together to yield a feasible solution to the original large region. The key observation for this method lies in two aspects. The first is that the exact solution for the problem can be found in time depending on the size of the region, and thus if the sizes of the subregions are bounded by a constant (which is the meaning of “small”), then the problem on the small subregions can be polynomially solvable. The second is that

the solutions for the subregions can be combined into a “feasible” solution to the original large region. The key analysis for the performance ratio of the method lies in the probabilistic observation that the probability for an optimal solution to “cross the boundary region” is very small.

Instead of a comprehensive survey of the large amount of literatures in this rich realm, this chapter focuses on the ideas of the partition method which can produce PTASs for the problems in high dimensional space. For the sake of simplicity, only three-dimensional problems are used as illustrations. However, all the methods introduced in this chapter can be easily adapted to fit higher dimensional problems.

The following sections are organized as follows. In Sect. 2, the history of partition method is briefly introduced. Section 3 works on the minimum unit ball cover problem to illustrate the basic ideas of the partition and shifting strategy. Section 4 introduces some techniques to deal with different problems, including the vacancy technique for the maximum independent set problem and the expansion technique for the minimum dominating set problem. Section 5 introduces the technique used in conquering the minimum connected dominating set problem. Section 6 introduces the idea of multilayer partition which is used to deal with the problems in which the geometric objects have different sizes. In Sect. 7, a partition method of a different taste, which is called growing partition, is introduced. This method does not require the geometric representation of the problems.

2 History of partition method

As early as 1977, Karp [38] has used the probabilistic method to analyze the performance of the partition algorithm for the traveling-salesman problem (TSP). The algorithm partitions the region into small subregions, each of which contains at most a constant number of cities. An optimal tour is constructed within each subregion. And then these subtours are combined to yield a tour through all the cities. Karp showed that with probability 1, the algorithm produces a PTAS for the TSP.

This method was applied to the rectilinear minimum Steiner tree problem by Komlos and Shing [43].

As a derandomization of Karp’s probabilistic analysis, the partition and shifting method was proposed by Baker [5] and Hochbaum and Maass [32].

In solving covering and packing problems on planar graphs, Baker [5] devised a technique to produce PTASs. The class of problems for which this technique provides PTASs includes maximum independent set, maximum tile salvage, partition into triangles, maximum H-matching, minimum vertex cover, minimum dominating set, and minimum edge dominating set on planar graphs. Taking the maximum independent set problem, for example, nodes are assigned to different levels according to their depths from the exterior face. A planar graph is said to be *k*-outerplanar if there is no node of level $> k$ in the graph. The key observation is that for a fixed k , the maximum independent set problem is solvable in linear time on *k*-outerplanar graphs by dynamic programming. In the case that the graph G is not *k*-outerplanar, for each $0 \leq r \leq k$, let G_r be the graph obtained from

G by deleting all those nodes whose levels are congruent to $r \pmod{k+1}$. Then G_r is composed of components of k -outerplanar subgraphs. Solving the problem on each of the components, then the union of the solutions forms an approximation solution A_r to the problem on G_r . Let r_0 be the index such that $|A_{r_0}| = \max\{|A_r| : 0 \leq r \leq k\}$, and let A^* be an optimal solution. Notice that there exists an index $0 \leq r^* \leq k$ such that at most $1/(k+1)$ nodes of A^* are of level r^* . Thus, $|A_{r_0}| \geq |A_{r^*}| \geq (1 - \frac{1}{k+1})|A^*|$. Taking $k = \lceil 1/\varepsilon \rceil$, one obtains a PTAS.

Similar idea was used by Hochbaum and Maass [32] to solve some other covering and packing problems (not only on the plane). It divides the region into small subregions, solves the problem optimally on each subregion, and combines the solutions for the subregions to yield a feasible solution to the original region. Then it shifts the partition one unit at a time to obtain a series of partitions, solves the problem as the above on each of the partitions, and chooses the best one. Hochbaum and Maass illustrated the strategy by solving the problem of ball covering in a d -dimensional space, where the diameters of all the balls are the same. They also remarked that this method can be easily generalized for problems where one covers with objects other than balls. However, the running time will depend exponentially on the ratio D/\tilde{D} , where D is the maximum diameter of the object and \tilde{D} is the maximum side length of a d -dimensional cube which can be contained in a covering object of the considered shape. In some special cases, such as the covering with rectilinear blocks, the ratio D/\tilde{D} can be eliminated from the exponent of the running time.

An application of the above method to the cellular networks can be found in [30], in which Glaßer et al. considered the problem of selecting a base station configuration from a set of possible configurations, such that as much as possible of the traffic is served while interference is kept to a minimum. PTASs were given under the assumption that there is an upper bound for the transmission ranges and a lower bound for the distance between different base stations.

Hunt et al. [34] were the first to implement the partition and shifting strategy to obtain PTASs for many NP-hard problems on unit disk graphs. Unit disk graphs arise naturally in the field of wireless networks. A graph G is a unit disk graph, if every vertex corresponds to a node on the plane; two vertices are adjacent in G if and only if the Euclidean distance between the corresponding nodes is not greater than one. Notice that a unit disk graph is not necessarily a planar graph. Hence, the method used for planar graphs is invalid in this circumstance. The NP-hard problems which were studied in [34] include the maximum independent set problem, the minimum vertex cover problem, and the minimum dominating set problem. Their method is also valid for graphs which can be drawn in an (r, s) -civilized manner, that is, the length of each edge is $\leq r$ and the distance between any two nodes is $\geq s$. Roughly speaking, a graph can be drawn in a civilized manner if the distances between vertices are not too large and the vertices are distributed not too densely.

Requiring connection significantly adds to the difficulty. The first PTAS for the minimum connected dominating set problem on unit disk graph was given by Cheng et al. in [17], in which a new idea was proposed to harmonize the solutions in the subregions. In their algorithm, a constant factor approximation solution D_0 is computed; the shifting strategy is used to select a partition $P(a)$ such that the

number of nodes of D_0 which fall into the boundary region of $P(a)$ is the minimum; then these boundary nodes are combined into the union of the optimal solutions for the subregions. The key idea is to use the boundary nodes to connect otherwise independent connected components of the subregions. However, the analysis of Cheng's algorithm depends on a property which is only valid on the plane. Hence, their method cannot be generalized to higher dimensional space.

Later, Zhang et al. [63] gave a PTAS for the minimum connected dominating set problem on unit ball graphs. Their algorithm is essentially the same as that in [17]. The difference lies in the theoretical analysis, where a new idea of *small compensation* was used. This technique is also valid for some other connection problems, such as the minimum connected vertex cover problem [64].

Some other applications of the partition and shifting strategy can be found in [48, 56, 58], etc.

In an intersection graph G , each vertex corresponds to a geometric object, and two vertices are adjacent in G if and only if the two objects corresponding to them have a non-empty intersection. In particular, if the geometric objects are disks of the same radii on the plane, then the intersection graph is equivalent to a unit disk graph. But if the shapes and the sizes of the geometric objects differ a lot, the difficulty is increased significantly.

In [22, 23], Erlebach et al. developed a new technique called *multilayer partition* to give PTASs for the maximum independent set problem and the minimum vertex cover problem in the intersection graphs in which the geometric objects are disks on the plane with varying radii. Before their work, for the intersection disk graphs with varying radii, the best known approximation algorithms have performance ratio 5 for the maximum independent set problem [47] and $3/2$ for the minimum weight vertex cover problem [46]. The idea in [22, 23] is to divide both the disks and the region into layers, consider an approximate problem in which the disks intersecting the lines of their own level are ignored, show that the approximate problem can be solved polynomially using dynamic programming, and the solution to the approximate problem differs from the solution to the original one by only a small fraction.

A PTAS for the fractional chromatic number problem on intersection disk graphs, using the above PTAS for the minimum weight independent set problem as a subroutine, was obtained by Jansen and Porkolab in [35].

The method is also applicable to the intersection graphs consisting of *fat* objects. Using instead shifted quadtree, Chan [15] described a PTAS for the packing problem which takes $n^{O(1/\varepsilon^{d-1})}$ time and space. Chan also gave a PTAS for the packing problem which takes $n^{O(1/\varepsilon^d)}$ time and linear space. This algorithm uses a completely different idea, by extending Smith and Wormald's separator theorem [55] for highly overlapping objects. Using the separator approach, Chan obtained the first PTAS for the piercing problem for fat objects with varying sizes.

An interesting relation between the intersection graphs and the planar graphs is as follows: every planar graph is a *coin graph*, that is the intersection graph of a set of interior-disjoint disks [42]. Therefore, every planar graph is a special intersection graph, and thus the above works generalized the work for the planar graphs.

The multilayer partition technique is also used by Lev-Tov and Peleg [44] in solving the minimum sum radii cover problem.

For all the above methods, the geometric representation is required, that is the coordinates of the nodes are known. This requirement is both reasonable and realistic, since Breu and Kirkpatrick [12] have proved that the recognition of unit disk graphs is NP-hard, and in the real-world applications, the location information is always given.

A method without requiring the geometric representation was proposed by Nieberg et al. in [51, 52], who gave a PTAS for the maximum independent set problem and a PTAS for the minimum dominating set problem in unit disk graphs. Their idea is to grow a subregion from a node until the boundary of the region is fairly *thin*; remove the nodes which have been searched and repeat this procedure until the region is partitioned into disjoint subregions; then the algorithm uses the union of the optimal solutions to the subregions to approach the optimal solution to the original problem. Something might be lost at the boundary regions. However, since the boundary is very thin, the loss can be controlled within a small fraction of the optimal solution. It was proved that the size of the subregions can be bounded by a constant depending on ε but not on the size of the input graph. As a consequence, the running time of their algorithm is $O(n^{\frac{1}{\varepsilon}} \log^{\frac{1}{\varepsilon}})$ to achieve a $(1 + \varepsilon)$ -approximation.

The growing partition method was also used on the problems with connection requirement. Gfeller and Vicari [29] used it to give a PTAS for the minimum connected dominating set problem in growth-bounded graphs. Roughly speaking, in a growth-bounded graph, the size of any maximum independent set can be controlled. The implementation of the method on the minimum d -Hop connected dominating set problem in growth-bounded graphs was done by Gao et al. in [27]. PTASs for the minimum dominating set and the minimum connected dominating set problems in unit disk graphs were also given by Wiese and Kranakis [61] using growing partition, focusing on the locality of the algorithm.

The partition method has many variations and is extensively used in many other problems. For example, in proving a lower bound for the k -steiner ratio, Du et al. [21] proved a useful lemma for the shifting technique in tree partition. With this lemma, Jiang et al. [36] and Wang et al. [59] designed a PTAS for the tree alignment problem. Wang et al. [60] introduced a new partition of balanced binary trees which results in a more efficient PTAS.

3 The Basic Ideas

The basic idea of the partition and shifting method lies in the following three observations.

3.1 The First Observation: Local Computability

For many geometric problems in a small region with fixed size, it is possible to obtain an optimal solution in polynomial time by exhaust search.

For example, consider the minimum unit ball cover problem (MUBC): a unit ball is a ball with diameter one; given a set of nodes in the space, the goal is to find a minimum number of unit balls to cover all the nodes. Suppose the nodes are enclosed in a cube Q_ℓ with side length ℓ , where ℓ is a fixed integer. Let $p = \lceil \sqrt{3}\ell \rceil$. Divide Q_ℓ into $p \times p \times p$ small cubes such that each small cube has side length at most $1/\sqrt{3}$. Notice that every unit ball whose center lies at the center of a small cube e covers all the nodes in e . Hence, the minimum number of unit balls needed is at most $p^3 = \lceil \sqrt{3}\ell \rceil^3$.

Notice that there are infinitely many choices for the unit balls. However, one can make the number to be finite by considering only *standard positions*. In fact, if there is a node u with a distance more than one from all the other nodes, then one unit ball has to be spent to cover u . If there are two nodes u_1, u_2 within distance one from each other such that they have a distance more than one from all the remaining nodes, then one unit ball has to be spent to cover u_1 and u_2 . In these two cases, such unit balls can be regarded as unique. For a unit ball which encloses at least three nodes, one can shift it to a position such that at least three nodes are on the surface of the unit ball. Such a position is called standard. For simplicity of statement, it is assumed that no three nodes are colinear. Then any three nodes determine at most two standard positions. In fact, suppose u_1, u_2, u_3 are three nodes which can be enclosed in a unit ball. Draw a triangle with u_1, u_2, u_3 as its extremes. On each side of the plane determined by the triangle, one can find a unique position which has distance $1/2$ from each of the three nodes (the positions on the two sides may collapse into one if the circumcenter of the triangle has distance $1/2$ from the three nodes). Then the two unit balls whose centers are located at these two positions are the only standard unit balls determined by u_1, u_2, u_3 . It follows that the number of standard positions is at most $O(n^3)$, where n is the number of nodes in the space.

It is easy to see that there exists an optimal ball cover such that every ball which encloses at least three nodes is in the standard position. Hence, to find an optimal ball cover, one only needs to select some balls from $N = O(n^3)$ candidate balls. By trying out every subset of candidate balls with cardinality at most $\lceil \sqrt{3}\ell \rceil^3$, one can find the desired ball cover in time at most $\binom{N}{1} + \binom{N}{2} + \binom{N}{\lceil \sqrt{3}\ell \rceil^3} = O(N^{\lceil \sqrt{3}\ell \rceil^3})$, which is polynomial in n when ℓ is a constant.

The keys to the success of the above method lie in two properties:

- (i) The number of elements in an optimal solution is bounded above by a polynomial in the size of the region.
- (ii) The locating problem can be transformed to a selecting problem by considering some standard candidates.

3.2 The Second Observation: Divisibility

When a large region is divided into small regions, then for many geometric problems, the union of the optimal solutions in every small region is a feasible solution for the large region. Consider the MUBC problem again. Suppose the n

nodes are enclosed in a cube Q with side length L , where L may be polynomial in n . Use planes to divide Q into smaller cubes Q_ℓ with side length ℓ , where ℓ is a constant. Such smaller cubes are called as *cells*. Solve the MUBC problem on each Q_ℓ as described in Sect. 3.1. Let U be the union of all these local optimal solutions. Clearly U is a ball cover of the n nodes.

3.3 The Third Observation: A Probabilistic Property

When one throws a ball to a square randomly, the probability that the ball hits the boundary lines is zero. If the boundary line is enlarged to a boundary region while the region is still very thin compared to the side length, then the probability that the ball falls into the boundary region is very small. This observation, combining with shifting strategy, leads to the theoretical analysis of the performance ratio for the above divide-and-conquer method.

Let U^* be an optimal solution to the MUBC problem, and consider its restriction in a cell Q_ℓ , that is let $U_{Q_\ell}^*$ be the set of the balls of U^* which have nonempty intersections with Q_ℓ . Clearly, $U_{Q_\ell}^*$ is a ball cover of the nodes in Q_ℓ . In other words, $U_{Q_\ell}^*$ is a feasible solution to the local problem on Q_ℓ . Hence, $|U_{Q_\ell}^*| \geq |U^*(Q_\ell)|$, where $U^*(Q_\ell)$ is the local optimal solution on Q_ℓ . It follows that

$$|U| = \sum |U^*(Q_\ell)| \leq \sum |U_{Q_\ell}^*|, \quad (1)$$

where $U = \bigcup U^*(Q_\ell)$ is the output of the approximation algorithm, and the sum is taken over every cell which contains at least one node to be covered.

The problem is that one ball in U^* might intersect more than one cell, and thus is counted more than once in the right-hand side of (1). Such balls are called as *boundary balls*. Suppose U^* has m boundary balls. Notice that if the side length ℓ is larger than one, then one unit ball intersects at most eight cells. It follows that

$$|U| \leq |U^*| + 7m. \quad (2)$$

Hence, to make the performance ratio small, one expects m to be small. Intuitively, the larger the side length ℓ is, the fewer the number of boundary balls might be. However, this is not necessarily true if the partition is badly chosen such that some planes which are used to divide the region go through too many balls. Nevertheless, by shifting the partition, it is possible to find one such that the number of boundary balls is small.

To state the idea more strictly with mathematical language, suppose the region enclosing all the nodes is $Q = \{(x_1, x_2, x_3) \mid 0 \leq x_i < L, i = 1, 2, 3\}$ (notice that Q is half closed and half open). Let $q = \lceil L/\ell \rceil$. Enlarge Q to $\tilde{Q} = \{(x_1, x_2, x_3) \mid 0 \leq x_i < (q+1)\ell, i = 1, 2, 3\}$. Divide \tilde{Q} into $(q+1) \times (q+1) \times (q+1)$ smaller cubes (called *cells*) with side length ℓ such that for $j_1, j_2, j_3 \in \{0, 1, \dots, q\}$, the (j_1, j_2, j_3) -th cell is $Q_\ell^{j_1 j_2 j_3} = \{(x_1, x_2, x_3) \mid j_i \ell \leq x_i < (j_i + 1)\ell, i = 1, 2, 3\}$ (notice that each cell is also half closed and half open). Denote this partition as $P(0)$.

Algorithm 1 PTAS for MUBC

```

1: for each partition  $P(a)$  do
2:   for each cell  $Q_\ell(a)$  in  $P(a)$  which contains at least one node do
3:     Compute a minimum ball cover  $U_\ell(a)$  of the nodes in  $Q_\ell(a)$ .
4:   end for
5:   Set  $U(a) = \bigcup_{Q_\ell^a} U_\ell(a)$ .
6: end for
7: Choose  $a^*$  such that  $|U(a^*)| = \min\{|U(a)| : a = 0, 1, \dots, \ell - 1\}$ .
8: Output  $U(a^*)$ .

```

For $a = 0, 1, \dots, \ell - 1$, let $P(a)$ be the partition obtained from $P(0)$ by shifting it such that the left-bottom-back corner of $P(a)$ lies at the coordinate $(-a, -a, -a)$. It should be noted that the enlargement of Q guarantees that after shifting, all the nodes to be covered are still enclosed by every partition $P(a)$.

The algorithm is executed as in [Algorithm 1](#).

Since every unit ball can serve as a boundary ball at most once (the assumption that every Q_ℓ is half closed and half open is used here), there must exist a partition $P(\hat{a})$ for which U^* has at most $|U^*|/\ell$ boundary balls. Then by (2) and Step 7 of [Algorithm 1](#), one has $|U(a^*)| \leq |U(\hat{a})| \leq (1 + 7/\ell)|U^*|$. Taking $\ell = \lceil 7/\varepsilon \rceil$, one has $|U(a^*)| \leq (1 + \varepsilon)|U^*|$, which implies that there is a PTAS for the MUBC problem.

4 Some Basic Techniques

To deal with various different conditions requires more techniques. They are illustrated by considering the maximum independent set problem (MIS), the minimum vertex cover problem (MVC), and the minimum dominating set problem (MDS) in a unit ball graph.

In a *unit ball graph* (UBG), each vertex corresponds to a node in the space. Two vertices are adjacent in the graph if and only if the Euclidean distance between the corresponding two nodes is not greater than one. UBGs are widely used in the field of wireless sensor networks. A wireless sensor network is an ad hoc wireless network which consists of a huge amount of static or mobile sensors. The sensors collaborate to sense, collect, and process the raw information of the phenomenon in the sensing area and transmit the processed information to the observers. Suppose the sensors of the network are uniform and have omnidirectional antennas. Then the transmission range of each sensor is a ball, and the transmission radii of all the sensors are the same. For simplicity of statement, the transmission radius can be scaled to one. It is widely adopted that two sensors can communicate if and only if they fall into the transmission ranges of each other, in other words, if and only if the Euclidean distance between them is not greater than one. Thus, in modeling a wireless sensor network, one arrives at an UBG. When all the sensors are distributed on the plane, then a unit ball graph degenerates to a *unit disk graph* (UDG).

A set I of vertices is an *independent set* of graph G if no vertices in I are adjacent in G . A set U of vertices is a *vertex cover* of G if every edge of G has at least one end in U . A set D of vertices is a *dominating set* of G if every vertex in $V(G) \setminus D$ has at least one neighbor in D . For an independent set, one wants its size to be as large as possible, which results in the maximum independent set problem (MIS). For a vertex cover or a dominating set, one wants its size to be as small as possible, which results in the minimum vertex cover problem (MVC) and the minimum dominating set problem (MDS).

There are an abundance of studies on the above problems. For example, see [3, 6, 7, 24, 26, 40, 50, 54] for the MVC problem, and [11, 31, 37, 53] for the MDS problem. In particular, with the rapid progress in wireless networks, the studies are flourishing on the unit disk graphs [2, 10, 14, 16, 17, 19, 47, 49, 57, 62].

Notice that different from the MUBC problem, the above three problems are already selecting problems. Thus, the step of making a locating problem to a selecting problem by using standard positions (as property (ii) of the first observation) can be omitted.

For an UBG, since a cell Q_ℓ of side length $\sqrt{3}/3$ contains at most one vertex from an independent set, and one vertex in Q_ℓ is sufficient to dominate all the other vertices in Q_ℓ , it can be seen that property (i) of the first observation holds for the MIS and the MDS problems. It is well known that a vertex set U is a vertex cover of G if and only if $V(G) \setminus U$ is an independent set of G . Thus, the MVC problem also satisfies property (i). Hence, these three problems can also be solved in polynomial time if the size of the region is a constant.

In terms of the second observation, it is also valid for the MDS problem in UDG. However, it is no longer true for the MIS problem. The trouble occurs at the boundary region: two vertices which belong to the MISs of their own cells might not be independent if they fall into the boundary region of two adjacent cells. The following technique is very useful in dealing with such cases.

4.1 The First Technique: Vacancy

The technique creates a vacant region at the boundary: for each cell Q_ℓ , let $Q_\ell^{(i)}$ contain all those points of Q_ℓ which are at least $1/2$ distance away from the boundary of Q_ℓ (to be more strict, it is assumed that $Q_\ell^{(i)}$ is half closed and half open as for the case of Q_ℓ). Call $Q_\ell^{(i)}$ the *inner region* of Q_ℓ . Let $Q_\ell^{(b)} = Q_\ell \setminus Q_\ell^{(i)}$ and call it the *boundary region* of Q_ℓ . The algorithm for computing an MIS in UDG is executed as in [Algorithm 2](#).

The essential difference of [Algorithm 2](#) from [Algorithm 1](#) lies in Step 3, which computes a local optimal solution for each *inner* region instead of the whole region in a cell. Since nodes in two different inner regions are at least one distance away from each other, it can be seen that the set $I(a)$ as in Step 5 of [Algorithm 2](#) is an independent set.

Algorithm 2 PTAS for MIS

```

1: for each partition  $P(a)$  do
2:   for each cell  $Q_\ell(a)$  in  $P(a)$  whose inner region  $Q_\ell^{(i)}(a)$  contains at least one node do
3:     Compute a maximum independent set  $I_\ell(a)$  of the nodes in  $Q_\ell^{(i)}(a)$ .
4:   end for
5:   Set  $I(a) = \bigcup_{Q_\ell^{(i)}(a)} I_\ell(a)$ .
6: end for
7: Choose  $a^*$  such that  $|I(a^*)| = \max\{|I(a)| : a = 0, 1, \dots, \ell - 1\}$ .
8: Output  $I(a^*)$ .

```

To analyze the performance ratio of [Algorithm 2](#), compare the output $I(a^*)$ with an optimal solution I^* . For a partition $P(a)$, let $I_\ell^*(a)$ be the restriction of I^* on $Q_\ell^{(i)}(a)$. Clearly, $I_\ell^*(a)$ is an independent set of the nodes in $Q_\ell^{(i)}(a)$. Hence,

$$|I_\ell^*(a)| \leq |I_\ell(a)|,$$

where $I_\ell(a)$ is the *maximum* independent set computed in Step 3 of [Algorithm 2](#). Denote by $B(a)$ the union of the boundary regions of $P(a)$, and set $I_B^*(a) = I^* \cap B(a)$. Since each node can fall into at most one of the $B(a)$'s, there exists a partition $P(\hat{a})$ such that

$$|I_B^*(\hat{a})| \leq \frac{|I^*|}{\ell}.$$

It follows that

$$|I^*| = \sum_{Q_\ell^{(i)}(\hat{a})} |I_\ell^*(\hat{a})| + |I_B^*(\hat{a})| \leq \sum_{Q_\ell^{(i)}(\hat{a})} |I_\ell(\hat{a})| + \frac{|I^*|}{\ell} \leq |I(a^*)| + \frac{|I^*|}{\ell},$$

and thus

$$|I^*| \leq \left(1 + \frac{1}{\ell - 1}\right) |I(a^*)|.$$

Taking $\ell = \lceil 1/\varepsilon \rceil + 1$, it can be seen that $|I^*| \leq (1 + \varepsilon)|I(a^*)|$. Thus, [Algorithm 2](#) is a PTAS for the MIS problem.

4.2 The Second Technique: Expansion

Though the MDS problem on UBG satisfies the second observation, a transplantation of the analysis in [Sect. 3.3](#) to this problem does not produce the desired performance ratio. The difficulty here lies in the observation that the restriction of an optimal solution D^* to a cell Q_ℓ might not be a feasible solution to the local

Algorithm 3 PTAS for MDS

```

1: for each partition  $P(a)$  do
2:   for each cell  $Q_\ell(a)$  in  $P(a)$  whose expansion  $Q_\ell^{(e)}(a)$  contains at least one vertex do
3:     Compute a minimum dominating set  $D_\ell(a)$  of the vertices in  $Q_\ell^{(e)}(a)$ .
4:   end for
5:   Set  $D(a) = \bigcup_{Q_\ell^{(e)}(a)} D_\ell(a)$ .
6: end for
7: Choose  $a^*$  such that  $|D(a^*)| = \min\{|D(a)| : a = 0, 1, \dots, \ell - 1\}$ .
8: Output  $D(a^*)$ .

```

problem, since it is possible that some vertex in Q_ℓ has all its dominators outside of Q_ℓ . Hence, a modification has to be made to the algorithm.

For each cube Q_ℓ , suppose $Q_\ell = \{(x_1, x_2, x_3) \mid j_i\ell \leq x_i < (j_i + 1)\ell, i = 1, 2, 3\}$, let $Q_\ell^{(e)} = \{(x_1, x_2, x_3) \mid j_i\ell - 1 \leq x_i < (j_i + 1)\ell + 1, i = 1, 2, 3\}$ be the expansion of Q_ℓ , which expands the boundary of Q_ℓ by one unit on each of the six sides. The essential difference of [Algorithm 3](#) from [Algorithm 1](#) lies in Step 3, in which a minimum dominating set is computed for the *expanded* cell instead of the original cell. The output of [Algorithm 3](#) is clearly a dominating set of the unit ball graph.

Let D^* be a minimum dominating set of the unit ball graph. For a partition $P(a)$, let $D_\ell^*(a)$ be the restriction of D^* on $Q_\ell^{(e)}(a)$. Since every node in $Q_\ell(a)$ must have its dominators in $Q_\ell^{(e)}(a)$, it can be seen that $D_\ell^*(a)$ is a dominating set of the nodes in $Q_\ell(a)$. It follows that

$$|D_\ell(a)| \leq |D_\ell^*(a)|,$$

where $D_\ell(a)$ is the minimum dominating set computed in Step 3 of [Algorithm 3](#). Thus,

$$|D(a)| \leq \sum_{Q_\ell^{(e)}(a)} |D_\ell(a)| \leq \sum_{Q_\ell^{(e)}(a)} |D_\ell^*(a)|. \quad (3)$$

Notice that nodes in D^* might be repeatedly added in the right-hand side of inequality (3). Let $B(a) = \bigcup Q_\ell^{(e)}(a) \setminus Q_\ell(a)$, where the union is taken over all the expanded cubes which contain at least one node. Clearly, only those nodes which fall into $B(a)$ can be added more than once. Furthermore, a node in $B(a)$ can be repeatedly added at most eight times. Denote by $D_B^*(a)$ the set of nodes of D^* which fall in $B(a)$. By shifting the partitions, it can be seen that a node can fall into at most two of the $B(a)$'s. Thus, there exists a partition $P(\hat{a})$ such that

$$|D_B^*(\hat{a})| \leq \frac{2|D^*|}{\ell}.$$

Then by Step 7 and inequality (3), one has

$$|D(a^*)| \leq |D(\hat{a})| \leq |D^*| + 7|D_B^*(\hat{a})| \leq \left(1 + \frac{14}{\ell}\right) |D^*|.$$

Taking $\ell = \lceil 14/\varepsilon \rceil$, one has the desired $|D(a^*)| \leq (1 + \varepsilon)|D^*|$.

5 Connection

In many real-world applications, connection plays an important role. For example, in a wireless sensor network, establishing a virtual backbone can be modeled as finding a minimum connected dominating set of the UBG [19]. A vertex subset D of a graph G is said to be a *connected dominating set* (CDS) if D is a dominating set of G , and the subgraph of G induced by D is connected. Thus, in a wireless sensor network, all the sensors can communicate directly or indirectly with each other through nodes in D . For example, if a node u has a message to be transmitted to another node v . Suppose neither u nor v are in D . Then the message can be sent to the dominator of u in D , relayed to the dominator of v in D , and finally reaches node v . By restricting the major processing and transmission within the virtual backbone, a lot of energy is saved, and it is also saved a lot from suffering the broadcasting storm which is caused by too many nodes speaking at the same time. The MCDS problem asks for a connected dominating set with the minimum cardinality.

To devise a PTAS for the MCDS problem in a UBG needs a completely new idea for the connection part. Roughly speaking, in addition to computing local optimal solutions for all the inner regions, it computes a connected dominating set D^0 which is a constant approximation solution and uses the nodes of D^0 which fall into the boundary region to play the role of connection.

Two questions have to be answered. The first is how to compute a constant approximation solution. The second is how to harmonize D^0 with the local optimal solutions such that the output is indeed a connected dominating set with the desired performance ratio.

For the MCDS problem in UBG, Butenko and Ursulenko [13] gave a distributed 22-approximation. In [66], Zou et al. improved the performance ratio to $13 + \ln 10 \approx 15.303$. In [41], Kim et al. further improved the performance ratio to 14.937, using the solution for the Gregory–Newton problem concerning with the kissing number [65] and the Euler’s formula relating the number of edges, vertices, and faces of a surface in the geometric analysis.

The following introduces the PTAS given in [63] for the computation of an MCDS in UBG.

5.1 The Algorithm

For each cell Q_ℓ , the *boundary region* B_ℓ of Q_ℓ is the region contained in Q_ℓ such that each point in this region is at most distance 3 from the boundary of Q_ℓ .

Algorithm 4 PTAS for MCDS

Input: The geometric representation of a connected unit ball graph G and a positive real number $\varepsilon < 1$.

Output: A connected dominating set D of G .

- 1: Let $\ell = \lceil 300\rho/\varepsilon \rceil$.
 - 2: Use the ρ -approximation algorithm to compute a connected dominating set D_0 of G .
 - 3: For each $a \in \{0, 1, \dots, \ell - 1\}$, denote by $D_0(a)$ the set of vertices of D_0 lying in the boundary region of $P(a)$. Choose a^* with the minimum $|D_0(a)|$.
 - 4: For each cell Q_ℓ of $P(a^*)$, compute a local optimal solution D_ℓ satisfying the requirement in (4), using exhaust search.
 - 5: Let $D = D_0(a^*) \cup \bigcup_{Q_\ell \in P(a^*)} D_\ell$.
-

The *inner region* C_ℓ of Q_ℓ is the region of Q_ℓ such that each point is at least distance 2 away from the boundary of Q_ℓ . Note that B_ℓ and C_ℓ have an overlap.

The algorithm is described in [Algorithm 4](#). It first computes a connected dominating set D_0 which is a ρ -approximation solution. For example, $\rho = 22$ by the algorithm given by Butenko and Ursulenko [13], $\rho = 14.937$ by Kim et al. [41]. Then, for the partition $P(a^*)$ whose boundary region contains the minimum number of nodes in D_0 , and for the inner region of each cell, the algorithm computes a local optimal solution in the following sense. For each cell Q_ℓ of $P(a^*)$, denote by G_ℓ the subgraph of G induced by the vertices in the inner region C_ℓ . A vertex subset D_ℓ of vertices in Q_ℓ is said to be a *local optimal solution* if

$$\begin{aligned} \text{each connected component } H \text{ of } G_\ell \text{ is dominated by} \\ \text{only one connected component of } G[D_\ell], \end{aligned} \tag{4}$$

where $G[D_\ell]$ is the subgraph of G induced by the vertex set D_ℓ . Finally, the algorithm outputs the union of the local optimal solutions together with the nodes of D_0 which fall into the boundary region of $P(a^*)$.

5.2 Correctness

The following lemma shows the correctness of the algorithm.

Lemma 1 *The output D of [Algorithm 4](#) is a CDS of G .*

Proof First, it is shown that D is a dominating set. Let x be a vertex in $V(G)$. Suppose x is in cell Q_ℓ . If $x \in C_\ell$, then x is dominated by D_ℓ . If $x \in Q_\ell \setminus C_\ell$, then x is at distance less than two from the boundary of Q_ℓ . If $x \in D_0$, then $x \in D_0(a^*)$. If $x \notin D_0$, then the vertex $y \in D_0$ which dominates x is in $D_0(a^*)$ (notice that the overlapping of B_ℓ and C_ℓ plays an important role here). By the arbitrariness of x , D is a dominating set of G .

To show that $G[D]$ is connected, it is first shown that any components of $G[D_0(a^*)]$ are connected in $G[D]$. Let F_1, F_2 be two components of $G[D_0(a^*)]$. Since D_0 is a CDS of G , it can be seen that F_1 and F_2 can be connected by D_0 through the inner region of some cell Q_ℓ . Then there exist two vertices $x_1 \in V(F_1) \cap B_\ell \cap C_\ell$ and $x_2 \in V(F_2) \cap B_\ell \cap C_\ell$ such that x_1, x_2 are in a same component H of G_ℓ . By requirement (4), x_1 and x_2 are connected through D_ℓ , and thus F_1 and F_2 are also connected through $D_\ell \subseteq D$.

Let \tilde{G} be the component of $G[D]$ containing all the vertices of $D_0(a^*)$. It is to be shown that $\tilde{G} = G[D]$. Suppose this is not true, then there exists a cell Q_ℓ and a component R of $G[D_\ell]$ such that $V(R) \cap D_0(a^*) = \emptyset$ and R is not adjacent with any vertex in $D_0(a^*)$. Since D_0 is a CDS of G , there exists a vertex $x \in D_0$ which dominates some vertex $y \in V(R)$ (y may coincide with x). Since $x \notin D_0(a^*)$, one has $x \in Q_\ell \setminus B_\ell$. Hence, $y \in C_\ell$. Let H be the connected component of G_ℓ containing y . By requirement (4), it can be seen that R dominates H . Since $G[D_0]$ is connected, there is a path in $G[D_0]$ connecting x to the other parts of G outside of cell Q_ℓ . Such a path must contain a vertex $z \in D_0 \cap B_\ell \cap C_\ell \subseteq D_0(a^*)$. Note that z is also in H . Hence, there is a vertex w in $V(R)$ dominating z , contradicting that R is not adjacent with any vertex in $D_0(a^*)$. Hence, $\tilde{G} = G[D]$, and thus $G[D]$ is connected. \square

5.3 Time Complexity

It is easy to see that the most time-consuming step of [Algorithm 4](#) is the fourth step. In this section, it will be shown that exhaust search can be done in polynomial time. For this purpose, one has to show that the number of vertices chosen in Step 4 is upper bounded by a constant (depending on n and ε , where n is the number of vertices in G).

First study the relationship between the size of a dominating set and the size of a connected dominating set. For two subgraphs G_1, G_2 of G , let $dist_{\text{hop}}(G_1, G_2)$ be the hop distance between G_1 and G_2 , that is the number of edges of the shortest path connecting G_1 and G_2 in G . The next lemma is well known (see, e.g, [31]).

Lemma 2 *Let G be a connected graph and D be a dominating set of G . Then $G[D]$ has two connected components G_1 and G_2 such that $dist_{\text{hop}}(G_1, G_2) \leq 3$.*

Proof Let G_1, G_2 be two connected components of $G[D]$ such that they are the nearest to each other. Let $P = x_1x_2\dots x_k$ be a shortest path of G between G_1 and G_2 , where $x_1 \in V(G_1)$ and $x_k \in V(G_2)$. Suppose, to the contrary, that $dist_{\text{hop}}(G_1, G_2) > 3$, then $k \geq 5$. Since D is a dominating set of G , there is a vertex $y \in D$ which dominates x_3 . Since P is a shortest path between G_1 and G_2 , it can be seen that y is in a component G_3 of $G[D]$ which is different from G_1 and G_2 . But then G_3 and G_2 are nearer than G_1 and G_2 , a contradiction. \square

The following lemma is an easy consequence of [Lemma 2](#).

Lemma 3 *Let G be a connected graph and D be a dominating set of G . There exists a connected dominating set of G with at most $3|D| - 2$ vertices.*

Proof Suppose $G[D]$ has k components. By [Lemma 2](#), adding at most two vertices can reduce the number of components by one. Repeatedly merging the components like this, at most $2(k - 1)$ vertices are added to obtain a connected dominating set of G . Then the lemma follows from the observation that $k \leq |D|$. \square

Now, it is ready to show the time complexity of the algorithm.

Theorem 1 *Algorithm 4 runs in time $n^{O(1/\varepsilon^3)}$.*

Proof Clearly, the most time-consuming part is the fourth step. Since any vertex in a small cube with side length $\sqrt{3}/3$ dominates any other vertices in the same cube, it can be seen that a minimum dominating set of Q_ℓ uses at most $\lceil \sqrt{3}\ell \rceil^3$ vertices. By [Lemma 3](#), the local optimal solution $|D_\ell| \leq 3\lceil \sqrt{3}\ell \rceil^3$. Hence, the exhaust search takes time at most $\sum_{k=0}^{3\lceil \sqrt{3}\ell \rceil^3} \binom{n_\ell}{k} = n_\ell^{O(\ell^3)}$ to compute D_ℓ , where n_ℓ is the number of vertices in Q_ℓ . It follows that the total time complexity is bounded by $\sum_{Q_\ell \in P(a^*)} n_\ell^{O(\ell^3)} = n^{O(\ell^3)} = n^{O(1/\varepsilon^3)}$. \square

5.4 The Performance Ratio

To show that [Algorithm 4](#) is a PTAS for CDS in UBG, one has to compare the size of an optimal solution D^* with the size of the output D of the algorithm.

5.4.1 Estimates for the Boundary Nodes

Similarly to the previous problems, shifting strategy yields

$$|D_0(a^*)| \leq \frac{\varepsilon}{25} |D^*|. \quad (5)$$

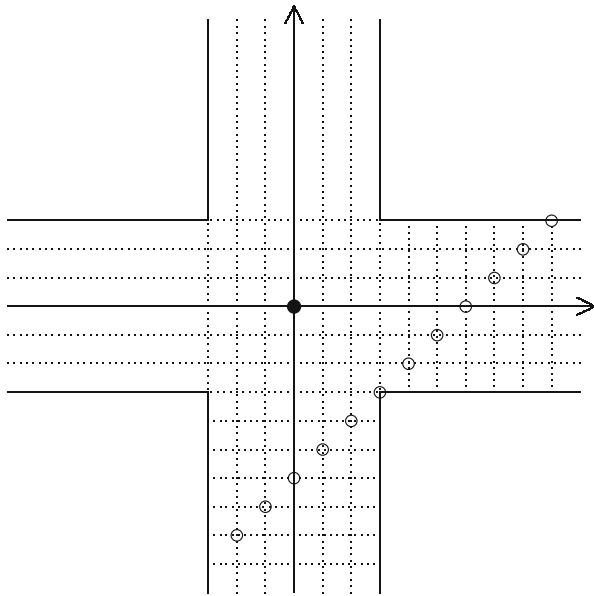

In fact, when a runs over $0, 1, \dots, \ell - 1$, each vertex belongs to at most 12 boundary regions of the $P(a)$'s (see [Fig. 1](#)). Hence,

$$|D_0(0)| + |D_0(1)| + \dots + |D_0(\ell - 1)| \leq 12|D_0|.$$

Since D_0 is a ρ -approximation for D^* , one has

$$|D_0(a^*)| \leq \frac{12}{\ell} |D_0| \leq \frac{12\rho}{\ell} |D^*| \leq \frac{\varepsilon}{25} |D^*|.$$

Fig. 1 When the partition shifts, each vertex falls into at most 12 boundary regions

5.4.2 Modification of Local Solution

Notice that the restriction of D^* to a cell Q_ℓ , denoted by D_ℓ^* , is a dominating set of G_ℓ . In fact, each vertex $x \in V(G_\ell) \setminus D^*$ is dominated by a vertex $z \in D^*$. Since x is in the inner region of Q_ℓ , it can be seen that vertex z is also in Q_ℓ and thus in D_ℓ^* .

However, D_ℓ^* is not necessarily a local feasible solution: a connected component of G_ℓ might be jointly dominated by several connected components of $G[D_\ell^*]$. Thus, to compare $|D_\ell^*|$ with $|D_\ell|$, where D_ℓ is the local optimal solution computed in Step 4 of the algorithm, one has to modify D_ℓ^* to another set \tilde{D}_ℓ such that \tilde{D}_ℓ is a local feasible solution (and thus $|D_\ell| \leq |\tilde{D}_\ell|$). To ensure the performance ratio $1 + \varepsilon$, the modification must be so slight that $|\tilde{D}_\ell|$ is larger than $|D_\ell^*|$ by only a very small amount.

If a connected component H of G_ℓ is jointly dominated by more than one connected components of $G[D_\ell^*]$, a natural way for the modification is to add some nodes to merge the components into one. The following lemma provides us an upper bound for the number of nodes that need to be added.

Let H be a subgraph of G . For two subgraphs R_1 and R_2 of G , the distance between R_1 and R_2 in H , denoted by $dist_H(R_1, R_2)$, is the length of the shortest path connecting R_1 and R_2 in H . In other words, if $dist_H(R_1, R_2) = d$, then R_1 and R_2 can be connected through at most $d - 1$ vertices of H .

Lemma 4 *Let H be a connected subgraph of G , and D be a subset of $V(G)$ dominating H . If H is not dominated by only one connected component of $G[D]$, then there exist two components R_1 and R_2 of $G[D]$ such that $dist_H(R_1, R_2) \leq 3$.*

Proof Let R_1, R_2, \dots, R_k ($k \geq 2$) be a minimum set of components of $G[D]$, the union of which dominates H . The *minimality* ensures that every R_i is adjacent with H . Since H is connected, it can be seen that $\bigcup_{i=1}^k R_i$ can be connected through vertices in H . Choose i and j such that $\text{dist}_H(R_i, R_j)$ is the minimum. Let $P = x_1 x_2 \dots x_t$ be the shortest path connecting R_i and R_j such that the inner vertices $x_2, \dots, x_{t-1} \in V(H) \setminus \bigcup_{i=1}^k V(R_i)$ and the end vertices $x_1 \in V(R_i), x_t \in V(R_j)$. Suppose $t \geq 5$. Let R_ℓ be a component dominating x_3 . Then, similarly to the proof of [Lemma 2](#), it can be seen that $\ell \neq i, j$ and $\text{dist}_H(R_\ell, R_j) < \text{dist}_H(R_i, R_j)$, contradicting the choice of i and j . \square

Suppose a component H of G_ℓ is jointly dominated by k components of $G[D_\ell^*]$. By [Lemma 4](#), it can be seen that at most $2k$ nodes are needed in order that requirement (4) is satisfied for H .

5.4.3 Compensation for The Added Nodes

Next, an upper bound is given for the number of added nodes in terms of ε . The idea is to use the nodes in $D_0(a^*) \cap Q_\ell$ to *compensate* for the nodes added for merging. By (5), the compensation can be expected to be small.

The compensation is *not one-to-one*, that is one node in $D_0(a^*) \cap Q_\ell$ might be used to compensate for more than one added nodes. However, the repetition is bounded by a constant which can be guaranteed by the result of the famous Gregory-Newton problem concerning about kissing number. The *kissing number* is the maximum number of unit balls that can simultaneously touch the surface of a unit ball (“touch” means two balls have exactly one point in common). It is known that the kissing number is 12 (see [[65](#)]).

Lemma 5 *For any vertex u in a unit ball graph G , the neighborhood $N_G(u)$ contains at most 12 independent vertices.*

Proof Let $S(u)$ be the unit ball with center u and $\{x_1, \dots, x_t\}$ be the maximum set of independent vertices in $S(u)$. For each $i = 1, \dots, t$, draw a radial r_i with origin u which goes through x_i . Suppose r_i intersects the surface of $S(u)$ at point \tilde{x}_i . Let S_i be a unit ball touching $S(u)$ at \tilde{x}_i . Since x_1, \dots, x_t are independent, the angle between any two radials is at least $\pi/3$. Hence, S_1, \dots, S_t are nonintersecting. It follows that t is at most the kissing number, which is 12. \square

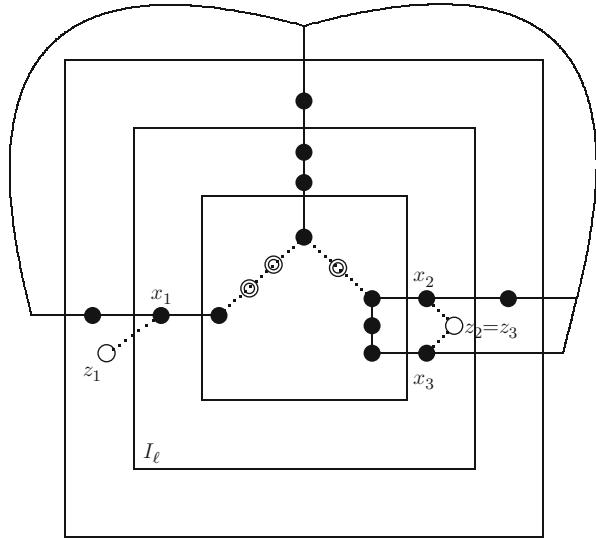

As a consequence of [Lemma 5](#), one has

Corollary 1 *Let G be a unit ball graph, D be a dominating set of G , and I be an independent set of G . Then $|I| \leq 12|D|$.*

Suppose a component H of G_ℓ is jointly dominated by k components of $G[D_\ell^*]$, say R_1, R_2, \dots, R_k . Then at most $2k$ nodes are added to merge them into one big component.

The following analysis is illustrated in [Fig. 2](#).

Fig. 2 An illustration for the compensation. The *solid nodes* are in D_ℓ^* , they are connected through D^* from the outside of the cell Q_ℓ . The *double-cycle nodes* are the ones added for merging. The *small circles* are the nodes used for compensation. Notice that x_2 and x_3 are compensated by a same node

Suppose that the components are merged in the order that R_1 is merged with R_2 , R_3 is merged with R_4, \dots, R_{2k-1} is merged with R_{2k} . To simplify the presentation of the idea, it is first assumed that the R_i 's are all distinct components of the original $G[D_\ell^*]$.

Denote by I_ℓ the region of Q_ℓ between distance 1 and 2 from the boundary of Q_ℓ . For each $i = 1, 2, \dots, k$, let x_i be a vertex in $V(R_{2i-1}) \cap I_\ell$. Notice that such x_i exists since R_{2i-1} dominates some vertex in H which is a component in the inner region of Q_ℓ (hence, R_{2i-1} is within distance 1 from the inner region), and $G[D^*]$ is connected (hence, R_{2i-1} is accessible from the outer side of Q_ℓ). Because D_0 is a dominating set of G , there is a vertex $z_i \in D_0$ dominating x_i . Since $x_i \in I_\ell$, one has $z_i \in B_\ell$, and thus $z_i \in D_0(a^*) \cap Q_\ell$. Note that for $i \neq j$, it is possible that $z_i = z_j$. However, in this case,

$$\begin{aligned} x_i \text{ and } x_j \text{ are independent} \\ \text{since they are in different components of } G[D_\ell^*]. \end{aligned} \tag{6}$$

Hence, by Lemma 5, a vertex serves at most 12 times as z_i 's. Thus, it has been shown that

$$k \leq 12|D_0(a^*) \cap Q_\ell|, \tag{7}$$

and thus the number of nodes added to merge R_1, R_2, \dots, R_k is at most $24|D_0(a^*) \cap Q_\ell|$.

Next, consider the case that there are some repetitions among the R_i 's. For example, suppose R_3 is the component of the new $G[\tilde{D}_\ell^*]$ obtained by merging R_1 and R_2 . Since x_1 is chosen to be in $V(R_1) \cap I_\ell$, one can choose $x_3 \in V(R_2) \cap I_\ell$.

In general, one is always able to choose x_i 's such that they are in different components of the original $G[D_\ell^*]$. Hence, (7) holds in any case.

Let H_1, H_2, \dots, H_t be the connected components of G_ℓ . Execute the above procedure for each H_j ($j = 1, 2, \dots, t$). Notice that a vertex z in $D_0(a^*) \cap Q_\ell$ might be used for compensation for different H_j 's. However, a similar observation as in (6) shows that the total number of times that z is used is still upper bounded by 12. Hence, one has the following:

Lemma 6 *One can modify D_ℓ^* into a local feasible solution \tilde{D}_ℓ satisfying (4) such that $|\tilde{D}_\ell| \leq |D_\ell^*| + 24|D_0(a^*) \cap Q_\ell|$.*

5.4.4 Analysis of the Performance Ratio

Now, it is ready to show that [Algorithm 4](#) is a PTAS.

Theorem 2 *[Algorithm 4](#) is a $(1 + \varepsilon)$ -approximation for CDS in UBG.*

Proof Let D^* be an optimal CDS of G , and let $\tilde{D} = \bigcup_{Q_\ell} \tilde{D}_\ell$, where \tilde{D}_ℓ is the modification of D_ℓ^* as in [Lemma 6](#). Since \tilde{D}_ℓ is a local feasible solution for Q_ℓ , one has

$$|D_\ell| \leq |\tilde{D}_\ell|,$$

where D_ℓ is the local optimal solution found in the fourth step. Then it follows from [Lemma 6](#) and inequality (5) that

$$\begin{aligned} \left| \bigcup_{Q_\ell \in P(a^*)} D_\ell \right| &= \sum_{Q_\ell \in P(a^*)} |D_\ell| \leq \sum_{Q_\ell \in P(a^*)} |\tilde{D}_\ell| \\ &\leq \sum_{Q_\ell \in P(a^*)} (|D_\ell^*| + 24|D_0(a^*) \cap Q_\ell|) \\ &= |D^*| + 24|D_0(a^*)| \leq \left(1 + \frac{24\varepsilon}{25}\right) |D^*. \end{aligned} \quad (8)$$

Combining inequalities (5) and (8), one has

$$|D| \leq \left| \bigcup_{Q_\ell \in P(a^*)} D_\ell \right| + |D_0(a^*)| \leq (1 + \varepsilon) |D^*|,$$

where D is the output of the algorithm. This proves the theorem. □

6 Multilayer Partition

The MIS problem in intersection graphs has interesting applications in map labeling and data mining [1, 9]. When the sizes of the objects do not differ too much, a slight modification of the above partition and shifting strategy will do, the only

difference is that the running time depends on D_{\max}/D_{\min} , where D_{\max} and D_{\min} are the sizes of the largest object and the smallest object, respectively. However, if D_{\max}/D_{\min} can be arbitrarily large, new ideas have to be implemented.

This section first illustrates the idea of multilayer partition by the MIS problem for the intersection ball graph, then introduces the idea used by Lev-Tov and Peleg in solving the MSRC problem.

6.1 Maximum Independent Set in Ball Graph

In an *intersection graph* G , every vertex corresponds to a geometric object in the space, and two vertices are adjacent in G if and only if the two objects corresponding to them intersect. If for an intersection graph, all the objects are balls, then it is an *intersection ball graph*, or one simply calls it a *ball graph* in this section.

6.1.1 The Partition

In the multilayer partition, both the region and the balls are partitioned into layers.

First, the balls are scaled such that the maximum one has diameter *a little less* than 1. Let d_{\min} be the minimum diameter after the scaling. For a fixed constant ℓ , set $j_0 = \lceil \log_{\ell+1}^{1/r_{\min}} \rceil - 1$. For each $0 \leq j \leq j_0$, the *layer j balls* (or simply, j -balls) are those with diameter $d \in \left[\frac{1}{(\ell+1)^{j+1}}, \frac{1}{(\ell+1)^j} \right)$. Then each ball belongs to exactly one layer.

Next, the region containing all the centers of the balls is partitioned as follows (refer to Fig. 3a for an illustration): similarly to Sect. 3.3, let Q be the region enclosing all the centers with side length L , and let \tilde{Q} be the enlarged region of

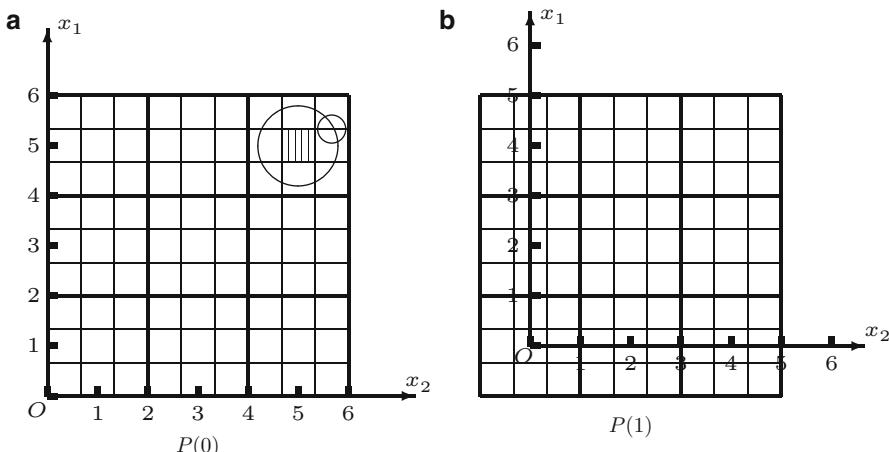

Fig. 3 Multilayer partition with $k = 2$ and $\ell = 1$. The *heavy lines* indicate the 0-planes and the *light lines* indicate the 1-planes

Q with side length $(q+1)\ell$, where $q = \lceil L/\ell \rceil$. For each $0 \leq j \leq j_0$, divide \tilde{Q} into $(q+1)(\ell+1)^j \times (q+1)(\ell+1)^j \times (q+1)(\ell+1)^j$ smaller cubes with side length $\ell/(\ell+1)^j$. Each smaller cube is called a j -cell, and the planes dividing j -cells are called j -planes. An important observation is that a j -plane is also a $(j+1)$ -plane. In fact, suppose a $(j+1)$ -plane has x_1 -coordinate $k \cdot \ell/(\ell+1)^{j+1}$, since $k \cdot \ell/(\ell+1)^{j+1} = k(\ell+1) \cdot \ell/(\ell+1)^j$, it is also a j -plane. This multilayered partition is denoted as $P(0)$. For $a = 0, 1, \dots, \ell-1$, the multilayer partition $P(a)$ is obtained from $P(0)$ by shifting it to the position such that the left-bottom-back corner is located at $(-a, -a, -a)$.

6.1.2 A Reduced Problem

A j -ball is called a *hitting ball* if it hits some j -planes (by hitting, the ball either intersects or touches the j -plane). It should be emphasized that one only considers those balls hitting the planes of their own levels. A j -ball which hits a j' -plane for $j' \neq j$ is not regarded as hitting the plane. It should also be noted that whether a ball is a hitting ball depends on the partition $P(a)$. When a shifts, since the maximum ball has diameter a little less than 1, it can be seen that every ball serves as a hitting ball at most three times (see Fig. 4).

Let $\mathcal{B}(a)$ be the set of balls obtained from \mathcal{B} by removing all the hitting balls with respect to the partition $P(a)$. The *reduced problem* is to find a maximum independent set for $\mathcal{B}(a)$. The idea is that the removal of hitting balls reduces the interlacing of balls at the boundaries, and thus the reduced problem can be solved polynomially by piecing up optimal local solutions. Simply piling them up does not do. Dynamic programming has to be used.

Lemma 7 *A maximum independent set of $\mathcal{B}(a)$ can be found in time $n^{O(\ell^6)}$ using dynamic programming.*

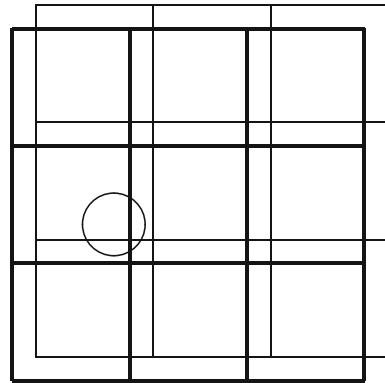

Proof A j -cell is said to be *relevant* if it contains a j -ball. For example, in Fig. 3a, the right-top 1-cell is a relevant 1-cell, but the shaded one is not. Though the shaded 1-cell contains a 0-ball, it does not contain any 1-ball.

Suppose $j' > j$ and a relevant j' -cell e' is contained in a relevant j -cell e . If for any j'' with $j < j'' < j'$, there is no relevant j'' -cell containing e' which is contained in e , then e' is called a *child* of e and e as a *parent* of e' . A *maximal relevant cell* is a relevant cell which has no parent.

For any index $j \in \{0, 1, \dots, j_0\}$ and any relevant j -cell e , let I be a set of independent balls hitting e whose levels are $< j$. Define $T(e, I)$ to be a *maximum* set of independent balls with levels $\geq j$ which are contained in e and independent with I . It should be noticed that since all the hitting balls are removed, every ball with level $\geq j$ which has nonempty intersection with e is completely contained in e . Clearly, the optimal solution to the reduced problem is

$$OPT = \bigcup_e T(e, \emptyset),$$

Fig. 4 In a d -dimensional space, every ball serves as a hitting ball at most d times. This figure is an illustration for $d = 2$

where the maximum is taken over all the maximal relevant cells e .

The element $T(e, I)$ can be calculated using the following recurrence relation:

$$T(e, I) = \arg \max_{I'} \left\{ \left| I' \cup \bigcup_{e'} T(e', (I \cup I')|_{e'}) \right|_{e'} \right\}, \quad (9)$$

where the set I' is taken over all the sets of independent balls with level j , the cell e' is taken over all the relevant children of e , and $(I \cup I')|_{e'}$ is the restriction of $I \cup I'$ to the cell e' , that is the set of independent balls in $I \cup I'$ which hit e' . The recurrence relation (11) is used bottom-up, that is, for $j = j_0, j_0 - 1, \dots, 0$. For a j_0 -cell, its children are empty.

Next it will be shown that the table $\{T(e, I)\}$ can be calculated in polynomial time depending on ℓ .

For each relevant j -cell e , using the assumption that a j -ball has radius at least $1/2(\ell + 1)^{j+1}$, one has

$$|I'| \leq \frac{\left(\frac{\ell}{(\ell+1)^j}\right)^3}{\frac{4}{3}\pi \left(\frac{1}{2(\ell+1)^{j+1}}\right)^3} = O(\ell^6).$$

Hence, for each fixed e , the number of choices for I' is at most $n^{O(\ell^6)}$.

To show that $|I|$ is upper bounded for each j -cell e , enlarge e on each of its six sides by $1/(\ell + 1)^j$. Denote the enlarged cube by e_e . Notice that for any $j' < j$, any j' -ball hitting e occupies at least $\frac{4}{3}\pi \left(\frac{1}{2(\ell+1)^{j'}}\right)^3$ volume of e_e . Since I is independent, one has

$$|I| \leq \frac{\left(\frac{\ell+2}{(\ell+1)^j}\right)^3}{\frac{4}{3}\pi \left(\frac{1}{2(\ell+1)^j}\right)^3} = O(\ell^3).$$

Hence, for each fixed e , there are at most $n^{O(\ell^3)}$ choices for I .

Then it follows that the size of the table $\{T(e, I)\}$ is bounded above by $n \cdot n^{O(\ell^3)} = n^{O(\ell^3)}$, and the total time for the dynamic programming is upper bounded by $n^{O(\ell^6)} \cdot n^{O(\ell^3)} = n^{O(\ell^6)}$. \square

6.1.3 The Algorithm and the Performance

Algorithm 5 uses the optimal solutions for the reduced problems to compute an independent set for the original ball graph G .

Clearly, the running time of **Algorithm 5** is $\ell n^{O(\ell^6)}$.

To show that the performance ratio is $(1 + \varepsilon)$, let I^* be a maximum independent set of G . For each $a = 0, 1, \dots, \ell - 1$, let $I_h^*(a)$ be the set of balls of I^* which are hitting balls with respect to $P(a)$. Since each ball serves as a hitting ball at most three times, one has

$$|I_h^*(0)| + |I_h^*(1)| + \dots + |I_h^*(\ell - 1)| \leq 3|I^*|,$$

and thus there is an index \tilde{a} such that

$$|I_h^*(\tilde{a})| \leq \frac{3}{\ell}|I^*|.$$

Since $I^* \setminus I_h^*(\tilde{a})$ is an independent set for $\mathcal{B}(\tilde{a})$, one has

$$|I| = |I(a^*)| \geq |I(\tilde{a})| \geq |I^*| - |I_h^*(\tilde{a})| \geq \left(1 - \frac{3}{\ell}\right)|I^*|,$$

and thus

$$|I^*| \leq \frac{\ell}{\ell - 3}|I| \leq \varepsilon|I|.$$

Algorithm 5 PTAS for MIS in Ball Graph

Input: A ball graph G and a positive real number $\varepsilon < 1$.

Output: An independent set I of G .

- 1: Set $\ell = \lceil \frac{3}{\varepsilon} + 3 \rceil$.
 - 2: **for** $a = 0, 1, \dots, \ell - 1$ **do**
 - 3: Find a maximum independent set $I(a)$ for $\mathcal{B}(a)$
 - 4: **end for**
 - 5: Let a^* be the index with $|I(a^*)| = \max\{|I(a)| : a = 0, 1, \dots, \ell - 1\}$.
 - 6: Output $I = I(a^*)$.
-

6.2 Minimum Sum Radii Cover

In an MSRC problem, one is given a set \mathcal{S} of servers and a set \mathcal{C} of clients. Each server $s \in \mathcal{S}$ is assigned a transmission range $r(s)$. A client $c \in \mathcal{C}$ can be served by $s \in \mathcal{S}$ if c falls into the transmission range of s . The goal is to find a subset $\mathcal{S}' \subseteq \mathcal{S}$ and an assignment of transmission ranges to the servers in \mathcal{S}' , such that every client is served and the total transmission ranges (which corresponds to the total energy consumed) are minimized. Although the transmission range can be chosen for a given server, in any optimal solution, for each chosen radius $r(s)$, there must be a client on the boundary of the ball with center s and radius $r(s)$. Hence, the problem is equivalent to the following: for each $s \in \mathcal{S}$ and each $c \in \mathcal{C}$, let B_s^c be the ball with center s and radius $dist(s, c)$, where $dist(s, c)$ is the Euclidean distance between s and c . A weight $w(B_s^c) = dist(s, c)$ is assigned to the ball B_s^c . Let $\mathcal{B} = \{B_s^c : s \in \mathcal{S}, c \in \mathcal{C}\}$. The goal is to select a subset $\mathcal{B}^* \subseteq \mathcal{B}$ such that \mathcal{B}^* covers all the clients in \mathcal{C} and the total weight $w(\mathcal{B}^*) = \sum_{B \in \mathcal{B}^*} w(B)$ is minimized.

The key idea of Lev-Tov and Peleg's method [44] is to cover the clients by fragments instead of whole balls. The key observation to the running time is that there exists an optimal solution owning some disjoint property.

6.2.1 Semi-disjointness

Two balls $B_{s_1}^{c_1}$ and $B_{s_2}^{c_2}$ are said to be *semi-disjoint* if neither $s_2 \in B_{s_1}^{c_1}$ nor $s_1 \in B_{s_2}^{c_2}$. A set of balls \mathcal{B}' is semi-disjoint if any two balls in \mathcal{B}' are semi-disjoint.

Lemma 8 *There exists an optimal solution to the MSRC problem which is semi-disjoint.*

Proof Let \mathcal{B}^* be an optimal solution to the MSRC problem and $B_{s_1}^{c_1}$ and $B_{s_2}^{c_2}$ be two balls in \mathcal{B}^* with $dist(s_1, c_1) \geq dist(s_2, c_2)$. Suppose they are not semi-disjoint, then $s_2 \in B_{s_1}^{c_1}$ (see Fig. 5). If $B_{s_2}^{c_2} \setminus B_{s_1}^{c_1}$ has no clients, then simply removing $B_{s_2}^{c_2}$ from \mathcal{B}^* will result in a cover with less weight, which is a contradiction. Hence, $B_{s_2}^{c_2} \setminus B_{s_1}^{c_1}$ contains a client. Choose c_0 to be such a client with $dist(s_1, c_0) = \max\{dist(s_1, c) : c \in B_{s_2}^{c_2}\}$. Then the ball $B_{s_1}^{c_0}$ contains all the clients in $B_{s_1}^{c_1} \cup B_{s_2}^{c_2}$. Notice that

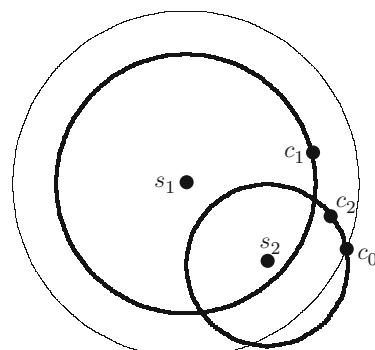

Fig. 5 An illustration for the semi-disjointness of the optimal solutions for the MSRC problem

$dist(s_1, c_0) \leq dist(s_1, c_1) + dist(s_2, c_2)$; thus, replacing $B_{s_1}^{c_1}$ and $B_{s_2}^{c_2}$ by $B_{s_1}^{c_0}$ will result in a cover whose weight is not larger than $w(\mathcal{B}^*)$. \square

The semi-disjointness is crucial in controlling the size of the table of the dynamic programming.

6.2.2 Fragment Covering

Unlike the MIS problem, to solve the MSRC problem, hitting balls cannot be removed. For example, the removal of a large hitting ball might greatly increase the number of balls in the solution. The key new idea is to use fragments instead of whole balls to cover all the clients.

The partition is the same as that in the above section. When a j -ball intersects some j -planes (by intersecting, the ball has more than one common points with the plane, touching is not regarded as intersecting), it is divided into *fragments*. It should be emphasized that one only considers those balls divided by the planes of their own levels. A j -ball which intersects a j' -plane for $j' \neq j$ is not regarded as being divided by the plane. Since the diameter of a j -ball is less than the spacing between j -planes, it can be seen that

$$\text{every ball corresponds to at most eight fragments.} \quad (10)$$

The idea is to cover the clients with these fragments together with those balls which fall completely in the cells of their own levels, such that the total weight is minimum. Such a problem is called a *fragment covering problem*. For simplicity of statement, a ball which falls completely into a cell of its own level is also referred to as a fragment. Clearly, those fragments which do not contain any client is useless in the covering; hence, in the following, when the term fragment is used, it is always referring to a fragment containing some clients. The advantage is that such a covering can be found in polynomial time using dynamic programming.

For a fragment F , denote by B_F the ball corresponding to F . For a set \mathcal{F} of fragments, let $\mathcal{B}_{\mathcal{F}} = \{B_F : F \in \mathcal{F}\}$ be the set of balls corresponding to the fragments in \mathcal{F} . A fragment F is said to be of level j if B_F is of level j , and a set \mathcal{F} of fragments is said to be semi-disjoint if $\mathcal{B}_{\mathcal{F}}$ is semi-disjoint.

Lemma 9 *The fragment covering problem can be solved in time $n^{O(\ell^6)}$ using dynamic programming.*

Proof For any index $j \in \{0, 1, \dots, j_0\}$ and any relevant j -cell e , denote by S_e the set of clients in e whose levels are $\geq j$. Let \mathcal{F} be a semi-disjoint set of fragments with levels $< j$ such that each fragment in \mathcal{F} contains some client in e . Denote by $S_{e,\mathcal{F}}$ the subset of clients of S_e which are not covered by the fragments in \mathcal{F} . Define $T(e, \mathcal{F})$ to be a set of semi-disjoint fragments with levels $\geq j$ which covers $S_{e,\mathcal{F}}$ such that the total weight is minimum. If such a covering does not exist, define $T(e, \mathcal{F})$ to be null and its value to be infinity. Clearly, every element of $T(e, \mathcal{F})$ is completely contained in e , $T(e, \mathcal{F}) \cup \mathcal{F}$ is a fragment covering of clients in e , and

the optimal fragment covering $OPT = \bigcup_e T(e, \emptyset)$, where the union is taken over all the maximal relevant cells e . The element $T(e, \mathcal{F})$ can be calculated using the following recurrence relation:

$$T(e, \mathcal{F}) = \arg \min_{\mathcal{F}'} \left\{ w \left(\mathcal{F}' \cup \bigcup_{e'} T(e', (\mathcal{F} \cup \mathcal{F}')|_{e'}) \right) \right\}, \quad (11)$$

where \mathcal{F}' is taken over all the set of semi-disjoint fragments with level j which is also semi-disjoint from \mathcal{F} , e' is taken over all the relevant children of e , and $(\mathcal{F} \cup \mathcal{F}')|_{e'}$ is the restriction of $\mathcal{F} \cup \mathcal{F}'$ to the cell e' , that is the fragments in $\mathcal{F} \cup \mathcal{F}'$ which contain some clients in e' .

Next, it will be shown that the table $T = \{T(e, \mathcal{F})\}$ can be calculated in polynomial time depending on ℓ . For this purpose, the following two claims are proved first. Let e be a relevant j -cell and $\mathcal{F}, \mathcal{F}'$ be the sets of semi-disjoint fragments as in the recurrence relation (11). Notice that no two fragments of \mathcal{F} and \mathcal{F}' can be induced by a same ball. Hence, to show the upper bounds for $|\mathcal{F}|$ and $|\mathcal{F}'|$, it suffices to show the upper bounds for $|\mathcal{B}_{\mathcal{F}}|$ and $|\mathcal{B}_{\mathcal{F}'}|$.

Claim 1 $|\mathcal{F}'| = |\mathcal{B}_{\mathcal{F}'}| \leq O(\ell^6)$.

Enlarge e on each of its six sides by $1/2(\ell+1)^j$. Denote the enlarged cube by e_e . Then e_e has side length $1/(\ell+1)^{j-1}$.

Recall that every ball $B \in \mathcal{B}_{\mathcal{F}'}$ has its diameter in $[\frac{1}{(\ell+1)^{j+1}}, \frac{1}{(\ell+1)^j}]$. Since B contains some client in e , its center is in e_e . Furthermore, for any two balls $B_1, B_2 \in \mathcal{B}_{\mathcal{F}'}$, by the semi-disjointness of \mathcal{F}' , the distance between the centers of B_1 and B_2 is larger than $1/2(\ell+1)^{j+1}$. Divide e_e into smaller cubes of side length $\frac{1}{2\sqrt{3}(\ell+1)^{j+1}}$ (with the exception of side strips whose side length might be smaller if the side length of e_e is not an integral multiplicity of $\frac{1}{2\sqrt{3}(\ell+1)^{j+1}}$). Then any point in a same small cube has distance at most $1/2(\ell+1)^{j+1}$, and thus each small cube contains at most one center of a ball in $\mathcal{B}_{\mathcal{F}'}$. It follows that

$$|\mathcal{B}_{\mathcal{F}'}| \leq \left(\frac{\frac{1}{(\ell+1)^{j-1}}}{\frac{1}{2\sqrt{3}(\ell+1)^{j+1}}} \right)^3 = O(\ell^6). \quad (12)$$

Claim 2 $|\mathcal{F}| = |\mathcal{B}_{\mathcal{F}}| \leq O(\ell^3)$.

Notice that for every ball $B \in \mathcal{B}_{\mathcal{F}}$, its diameter is at least $1/(\ell+1)^j$. Similarly to the above, it can be seen that the number of balls in $\mathcal{B}_{\mathcal{F}}$ whose centers belong to e_e is at most $O(\ell^3)$ (the difference is that the denominator of (12) is changed to $\frac{1}{2\sqrt{3}(\ell+1)^j}$).

Next, consider the balls of $\mathcal{B}_{\mathcal{F}}$ whose centers lie outside of e_e . In order that the idea can be understood easier, the analysis will first be illustrated on

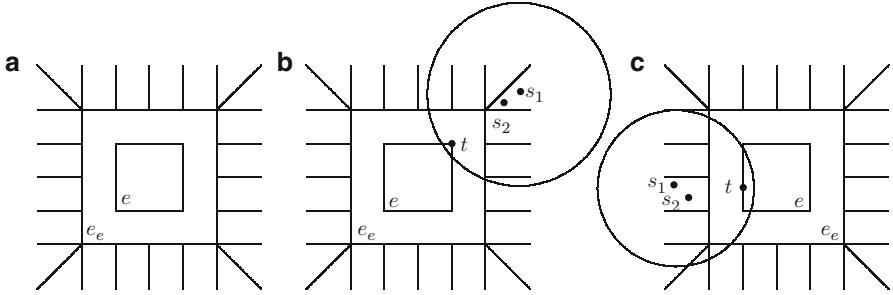

Fig. 6 An illustration for the division of the space outside of e_e

two-dimensional case. Divide the square outside of e_e into subregions as shown in Fig. 6a, where any two consecutive parallel lines have distance $1/2(\ell+1)^j$. It will be shown that each subregion R contains at most one center of a disk in \mathcal{B}_F . Suppose this is not true, let B_1, B_2 be two disks in \mathcal{B}_F whose centers s_1, s_2 are both in R . Suppose $dist(s_1, e) \geq dist(s_2, e)$, where $dist(s, e) = \min\{dist(s, s'): s' \in e\}$ is the distance between a point s and the square e . Since the ball B_{s_1} which corresponds to s_1 contains a client in e , its radius is at least as large as the length of s_1t in Fig. 6b, c. Then it can be seen that B_{s_1} contains s_2 , contradicting the assumption that B_{s_1} and B_{s_2} are semi-disjoint (the observation that B_{s_1} has radius $\geq 1/2(\ell+1)^j \geq$ the distance between any two consecutive parallel lines is used in considering the case of Fig. 6c).

For the three-dimensional case, the argument is almost the same except that the distance between any two consecutive parallel planes should be $1/2\sqrt{2}(\ell+1)^j$. Then, it can be seen that

$$|\mathcal{B}_F| \leq 6 \left(\frac{\frac{1}{(\ell+1)^{j-1}}}{\frac{1}{2\sqrt{2}(\ell+1)^j}} \right)^2 + 12 \left(\frac{\frac{1}{(\ell+1)^{j-1}}}{\frac{1}{2\sqrt{2}(\ell+1)^j}} \right) = O(\ell^2).$$

Then, Claim 2 follows by summing up the above analysis.

By Claim 1 and Claim 2, it can be seen that the running time for the dynamic programming is at most $n \cdot n^{O(\ell^3)} \cdot n^{O(\ell^6)} = n^{O(\ell^6)}$. \square

6.2.3 The Algorithm

Algorithm 6 uses the optimal solutions for the fragment coverings to obtain a solution to the MSRC problem.

6.2.4 The Performance Ratio

When a ball is used more than once, that is, when t fragments of a ball are used for covering, the ball is counted t times, which incurs some repetition. However, it can

Algorithm 6 PTAS for MSRC

Input: A set of servers \mathcal{S} , a set of clients \mathcal{C} , and a positive real number $\varepsilon < 1$.

Output: A solution \mathcal{B}' to the MSRC problem.

- 1: Determine the set $\mathcal{B} = \{B_s^c : s \in \mathcal{S}, c \in \mathcal{C}\}$ of possible balls.
 - 2: Set $\ell = \lceil 7/\varepsilon \rceil$.
 - 3: **for** $a = 0, 1, \dots, \ell - 1$ **do**
 - 4: Find a minimum weight fragment cover $\mathcal{F}(a)$ for the partition $P(a)$.
 - 5: **end for**
 - 6: Let a^* be the index with $w(\mathcal{F}(a^*)) = \min\{w(\mathcal{F}(a)) : a = 0, 1, \dots, \ell - 1\}$.
 - 7: Output $\mathcal{B}' = \mathcal{B}_{\mathcal{F}(a^*)}$.
-

be shown that by using the shifting strategy, the repetition can be controlled within a small portion of the optimal solution.

Let \mathcal{B}^* be a minimum ball cover. By the observation (10), the number of fragments resulted from \mathcal{B}^* is at most $8|\mathcal{B}^*|$ for all the partitions. Since there are ℓ partitions, there exists a partition $P(\tilde{a})$ such that the number of fragments resulted from \mathcal{B}^* for $P(\tilde{a})$ is at most $8|\mathcal{B}^*|/\ell$. To speak it more concretely, let \mathcal{B}_I^* be the set of the intersecting balls of \mathcal{B}^* with respect to $P(\tilde{a})$, and let $\mathcal{B}_B^* = \mathcal{B}^* \setminus \mathcal{B}_I^*$. Let \mathcal{F}^* be the set of fragments resulted from \mathcal{B}_I^* . Then $|\mathcal{F}^*| \leq 8|\mathcal{B}^*|/\ell$. It is clear that $\mathcal{F}^* \cup \mathcal{B}_B^*$ is a fragment covering for the partition $P(\tilde{a})$. Thus,

$$w(\mathcal{B}') \leq w(\mathcal{F}(a^*)) \leq w(\mathcal{F}(\tilde{a})) \leq w(\mathcal{F}^* \cup \mathcal{B}_B^*) \leq \left(1 + \frac{7}{\ell}\right) w(\mathcal{B}^*) \leq (1 + \varepsilon) w(\mathcal{B}^*).$$

7 Growing Partition

This section introduces the idea of growing partition which was first proposed by Nieberg et al. [51] to give a PTAS for the MIS problem in unit disk graphs. The method has the advantage that it does not require the geometric representation of the graph (recall that the recognition of a unit disk graph is NP-hard [12]). In fact, their algorithm is *robust* in the sense that it either gives a $(1 + \varepsilon)$ -approximation if the graph is a unit disk graph or gives a certificate that the given graph does not belong to the class of unit disk graphs.

Nieberg and Hurink [52] also implemented the method on the MDS problem in unit disk graphs. Gfeller and Vicari [29] generalized it to the MCDS problem for growth-bounded graphs. A graph G is *growth bounded* if there is a polynomial bounding function $f(r)$ such that for any integer $r \geq 0$, the size of any independent set in any r -closed neighborhood is upper bounded by $f(r)$. The implementation of the method on the d -hop CDS problem for growth-bounded graphs was made by Gao et al. [27].

This section illustrates the ideas of growing partition by MIS, MDS, and MCDS problems on unit ball graphs.

7.1 Maximum Independent Set

For a vertex $u \in V(G)$ and a nonnegative integer r , the closed r -neighborhood of u is $N^r[u] = \{v \in V(G) \mid \text{dist}_G(u, v) \leq r\}$. For a vertex subset $U \subseteq V(G)$, $N^r[U] = \bigcup_{u \in U} N^r[u]$ is the closed r -neighborhood of U . The subgraph of G induced by the vertex subset U is denoted by $G[U]$. The maximum independent set of $G[U]$ is denote by $\text{MIS}(U)$.

7.1.1 The Algorithm

The algorithm starts with an arbitrary vertex $u \in V(G)$, computes the minimum integer r such that $|\text{MIS}(N^{r+1}(u))| \leq (1 + \varepsilon)|\text{MIS}(N^r(u))|$. Remove $N^{r+1}[u]$ from the vertex set, and repeat this procedure in the remaining graph until there is no vertex left. The output is the union of $\text{MIS}(N^r[u])$ found in the iterations. The details are described in [Algorithm 7](#).

Suppose the algorithm iterates K times, and the vertex u and the integer r found in the i th iteration are u_i and r_i , respectively. Then $V(G)$ is partitioned into $N^{r_1+1}[u_1] \cup \dots \cup N^{r_K+1}[u_K]$. It should be noted that $N^{r_i+1}[u_i]$ refers to the $(r_i + 1)$ -closed neighborhood of u_i in the graph $G - \bigcup_{j=1}^{i-1} N^{r_j+1}[u_j]$ instead of G . Notice that the sets $\text{MIS}(N^{r_1}[u_1]), \dots, \text{MIS}(N^{r_K}[u_K])$ are mutually disjoint, since $N(N^{r_i}[u_i]) \subseteq N^{r_i+1}[u_i]$, which is disjoint from $N^{r_j+1}[u_j]$ for $i \neq j$. Hence, the output I is indeed an independent set.

The essence of the algorithm is still partitioning. The difference is that the partition is not predetermined as in the previous sections, it is obtained dynamically while the algorithm is being executed. The subgraphs resulted from the partition are $\{G[N^{r_i+1}[u_i]]\}_{i=1}^K$. Then each subgraph is shrink to $G[N^{r_i}[u_i]]$, and a local optimal solution is found for the shrink subgraph. This is in fact an application of vacancy technique introduced in [Sect. 4.1](#), the goal of which is to ensure that the union of the local optimal solutions is still independent.

7.1.2 The Performance Ratio

Let I^* be a maximum independent set of G . For $i = 1, 2, \dots, K$, denote $I_i^* = I^* \cap N^{r_i+1}[u_i]$. Then I_i^* is an independent set of $G[N^{r_i+1}[u_i]]$ and thus $|I_i^*| \leq |\text{MIS}(N^{r_i+1}[u_i])| \leq (1 + \varepsilon)|\text{MIS}(N^{r_i}[u_i])|$. It is clear that $I_i^* \cap I_j^* = \emptyset$ for $i \neq j$.

Algorithm 7 Growing PTAS for MIS

Input: A unit ball graph G and a positive real number $\varepsilon < 1$.

Output: An independent set I of G .

- 1: Set $U = V(G)$, $I = \emptyset$.
 - 2: **while** $U \neq \emptyset$ **do**
 - 3: Choose a vertex $u \in U$. Compute the minimum integer r such that $|\text{MIS}(N^{r+1}[u])| \leq (1 + \varepsilon)|\text{MIS}(N^r[u])|$.
 - 4: Set $I = I \cup \text{MIS}(N^r[u])$, $U = U \setminus N^{r+1}[u]$.
 - 5: **end while**
 - 6: Output I .
-

Thus, $|I^*| = \sum_{i=1}^K |I_i^*| \leq (1 + \varepsilon) \sum_{i=1}^K |MIS(N^{r_i}[u_i])| = (1 + \varepsilon)|I|$. Hence, [Algorithm 7](#) is a $(1 + \varepsilon)$ -approximation algorithm.

7.1.3 The Running Time

Notice that the most time-consuming step is to compute $MIS(N^r[u])$ and determine the minimum integer r satisfying the condition

$$|MIS(N^{r+1}[u])| \leq (1 + \varepsilon)|MIS(N^r[u])| \quad (13)$$

in Line 3 of [Algorithm 7](#).

Lemma 10 *In any unit ball graph G , the number of independent vertices in an r -closed neighborhood is upper bounded by $(2r + 1)^3$.*

Proof Let I^r be a maximum independent set in $N^r[u]$. Use $B_a(v)$ to denote the open ball with radius a and center v . For each vertex $v \in I^r$, draw an open ball $B_{1/2}(v)$. Notice that $N^r[u]$ is contained in the ball $B_r(u)$. Hence, all the balls $\{B_{1/2}(v)\}_{v \in I^r}$ are contained in the ball $B_{r+1/2}(u)$. Since I^r is independent, $B_{1/2}(v) \cap B_{1/2}(w) = \emptyset$ for $v, w \in I^r$ and $v \neq w$. It follows that $|I^r| \leq \frac{\frac{4}{3}\pi(r+\frac{1}{2})^3}{\frac{4}{3}\pi(\frac{1}{2})^3} = (2r + 1)^3$. \square

Lemma 11 *There is a constant $c_0 = O(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon})$ such that $r_i \leq c_0$ for all $i = 1, 2, \dots, K$.*

Proof By the choice of r_i and the observation $|MIS(N^0[u_i])| = 1$, one has $|MIS(N^{r_i}[u_i])| > (1 + \varepsilon)|MIS(N^{r_i-1}[u_i])| > (1 + \varepsilon)^2|MIS(N^{r_i-2}[u_i])| > \dots > (1 + \varepsilon)^{r_i}|MIS(N^0[u_i])| = (1 + \varepsilon)^{r_i}$. Combining this with [Lemma 10](#), one has

$$(2r_i + 1)^3 > (1 + \varepsilon)^{r_i}. \quad (14)$$

With the increase of r_i , since the increasing speed of $(1 + \varepsilon)^{r_i}$ is much higher than $(2r_i + 1)^3$, there must be a constant c_0 such that inequality (14) holds only for $r_i \leq c_0$.

The order of c_0 can be calculated from (14). \square

For $i = 1, 2, \dots, K$, denote by $n_i = |N^{r_i+1}[u_i]|$. As a consequence of [Lemma 10](#), the exhaust search for $MIS(N^r[u])$ runs in time at most $|N^r[u]|^{O(r^3)}$. It follows that the running time of [Algorithm 7](#) is upper bounded by $\sum_{i=1}^K r_i n_i^{O(r_i^3)} \leq c_0 \sum_{i=1}^K n_i^{O(c_0^3)} = c_0 n^{O(c_0^3)} = O(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon} \cdot n^{O((\frac{1}{\varepsilon} \log \frac{1}{\varepsilon})^3)})$.

7.2 Minimum Dominating Set

For a vertex subset $U \subseteq V(G)$, denote by $DS(U)$ the minimum vertex subset of $V(G)$ which dominates U , that is for each vertex $u \in U$, either $u \in DS(U)$ or u has a neighbor in $DS(U)$. Notice that $U \subseteq N_G[DS(U)]$ and $DS(U) \subseteq N_G[U]$. It should be emphasized that in this chapter, the symbol N refers to the neighbor set in the remaining graph, while N_G refers to the neighbor set in the original graph G . The algorithm is described in [Algorithm 8](#). As it has been emphasized, $N^r[u]$ is computed with respect to the remaining graph, while the dominating set $DS(\cdot)$ is computed with respect to the whole input graph G .

The partition resulted from [Algorithm 8](#) is $V(G) = N^{r_1+2}[u_1] \cup \dots \cup N^{r_K+2}[u_K]$, where K is the number of iterations and u_i and r_i are the vertex and the integer found in the i th iteration, respectively. Clearly, the output $D = \bigcup_{i=1}^K DS(N^{r_i+2}[u_i])$ is a dominating set of G .

Since $DS(N^{r_i+2}[u_i]) \subseteq N_G(N^{r_i+2}[u_i])$, it can be seen that vertices in $N_G(N^{r_i+2}[u_i]) \setminus N^{r_i+2}[u_i]$ might be used more than once as dominators. However, the repetition can be controlled to be small by the condition

$$|DS(N^{r+2}[u])| \leq (1 + \varepsilon)|DS(N^r[u])| \quad (15)$$

in Line 3 of [Algorithm 8](#).

Let D^* be a minimum dominating set of G , and let $D_i^* = D^* \cap N_G[N^{r_i}[u_i]]$. Since any vertex in $N^{r_i}[u_i]$ has its dominators in $N_G(N^{r_i}[u_i])$, it can be seen that D_i^* is a dominating set of $N^{r_i}[u_i]$, and thus

$$|DS(N^{r_i}[u_i])| \leq |D_i^*|.$$

Lemma 12 *The sets $N_G[N^{r_1}[u_1]], \dots, N_G[N^{r_K}[u_K]]$ are mutually disjoint.*

Proof Denote $U_0 = V(G)$ and $U_i = U_{i-1} \setminus N^{r_i+2}[u_i]$. By observing that $N_G[U_i] \cap N_G[N^{r_j}[u_j]] = \emptyset$ for $j < i$, the lemma follows by induction on i . \square

As a consequence of [Lemma 12](#),

$$|D^*| \geq \sum_{i=1}^K |D_i^*|.$$

Now, the performance ratio follows from

$$|D| = \sum_{i=1}^K |DS(N^{r_i+2}[u_i])| \leq (1 + \varepsilon) \sum_{i=1}^K |DS(N^{r_i}[u_i])|$$

Algorithm 8 Growing PTAS for MDS

Input: A unit ball graph G and a positive real number $\varepsilon < 1$.

Output: A dominating set D of G .

- 1: Set $U = V(G)$, $D = \emptyset$.
 - 2: **while** $U \neq \emptyset$ **do**
 - 3: Choose a vertex $u \in U$. Compute the minimum integer r such that $|DS(N^{r+2}[u])| \leq (1 + \varepsilon)|DS(N^r[u])|$.
 - 4: Set $D = D \cup DS(N^{r+2}[u])$, $U = U \setminus N^{r+2}[u]$.
 - 5: **end while**
 - 6: Output D .
-

$$\leq (1 + \varepsilon) \sum_{i=1}^K |D_i^*| \leq (1 + \varepsilon)|D^*|.$$

The analysis of time complexity is similar to the previous subsection and is omitted here.

7.3 Minimum Connected Dominating Set

To implement growing partition method on CDS problem, one first looks at condition (13) from another point of view and shows that it is essentially equivalent with

$$|MIS(N^{r+1}[u] \setminus N^r[u])| \leq \varepsilon|MIS(N^r[u])|. \quad (16)$$

To see the equivalence, first notice that the restriction of an independent set of $N^{r+1}[u]$ to $N^{r+1}[u] \setminus N^r[u]$ is still independent, so is the restriction of $N^{r+1}[u]$ to $N^r[u]$. Hence, $|MIS(N^{r+1}[u])| \leq |MIS(N^{r+1}[u] \setminus N^r[u])| + |MIS(N^r[u])|$, and thus condition (16) implies that $|MIS(N^{r+1}[u])| \leq (1 + \varepsilon)|MIS(N^r[u])|$.

However, condition (16) cannot be used directly to show that the running time is polynomial. The key is to find a constant c_0 such that the minimum integer r satisfying (16) can be found in at most c_0 steps (as in Lemma 11).

Lemma 13 *There is a constant $c_0 = O(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon})$ such that for any unit ball graph G and any vertex $u \in V(G)$, there is an integer $1 \leq r \leq c_0$ such that $|MIS(N^r[u] \setminus N^{r-1}[u])| \leq \varepsilon|MIS(N^{r-1}[u])|$.*

Proof Suppose this is not true. Then for any integer c , there exists a unit ball graph G and a vertex $u \in V(G)$ such that

$$|MIS(N^r[u] \setminus N^{r-1}[u])| > \varepsilon|MIS(N^{r-1}[u])| \quad (17)$$

holds for any integer $1 \leq r \leq c$. Since the union of an independent set of $N^r[u] \setminus N^{r-1}[u]$ and an independent set of $N^{r-2}[u]$ is an independent set of $N^r[u]$, one has $|MIS(N^r[u])| \geq |MIS(N^r[u] \setminus N^{r-1}[u])| + |MIS(N^{r-2}[u])|$. Combining this

with (17) and the observation $|MIS(N^{r-1}[u])| \geq |MIS(N^{r-2}[u])|$, one has

$$|MIS(N^r[u])| > (1 + \varepsilon)|MIS(N^{r-2}[u])|. \quad (18)$$

Recursively using inequality (18) and the observation $|MIS(N^0[u])| = 1$ and $|MIS(N^1[u])| \geq 1$, one has $|MIS(N^c[u])| > (1 + \varepsilon)^{\lfloor \frac{c}{2} \rfloor}$. By Lemma 10, one has

$$(2c + 1)^3 > (1 + \varepsilon)^{\lfloor \frac{c}{2} \rfloor}. \quad (19)$$

Since the left hand grows polynomially in c and the right hand grows exponentially in c , inequality (19) must be violated for some large c , a contradiction.

The order of c_0 can be calculated from inequality (19). \square

The implication of condition (16) is that in each iteration, the expansion of $N^r[u]$ halts when the boundary part is “thin” enough. This is why one does not lose too much at the boundary. This is especially important for the CDS problem, as suggested by the “compensation technique” in Sect. 5.4.

7.3.1 The Algorithm

For a connected vertex subset U , denote $CDS(U)$ the minimum connected subset of $V(G)$ which dominates U . Notice that such a *connected* set $CDS(U)$ exists since U is connected. Furthermore, $CDS(U) \subseteq N_G[U]$. As before, the symbol N refers to the neighbor set in the remaining graph, while the symbol N_G refers to the neighbor set in the original graph G . The algorithm is described in Algorithm 9.

7.3.2 Correctness

There are two major differences between Algorithm 9 and the previous ones. By Line 6, it can be seen that there is an overlap at the boundaries of the partition. By Line 4, it can be seen that except for the first vertex, the starting vertex u is not chosen arbitrarily, it is chosen to be “near” to the previous solutions. These two differences are made to ensure that the output is indeed a connected one.

Notice that $N^r[u]$ is always connected and $W \subseteq U$. In the following, u_i, r_i, U_i, W_i are used to denote the u, r, U, W obtained in the i^{th} iteration.

Algorithm 9 Growing PTAS for MCDS

Input: A connected unit ball graph G and a positive real number $\varepsilon < 1$.

Output: A connected dominating set D of G .

- 1: Set $U = V(G)$, $D = \emptyset$.
 - 2: Let u be an arbitrary vertex in U and set $W = \{u\}$.
 - 3: **while** $U \neq \emptyset$ **do**
 - 4: Choose $u \in W$.
 - 5: Compute the minimum integer r such that $|MIS(N_G[N^r[u]] \setminus N^r[u])| \leq \varepsilon |MIS(N^r[u])|$.
 - 6: Set $W = (W \cup N^{r+3}[u]) \setminus N^{r+2}[u]$, $D = D \cup CDS(N^{r+3}[u])$, $U = U \setminus N^{r+2}[u]$.
 - 7: **end while**
 - 8: Output D .
-

Lemma 14 *The output of Algorithm 9 is a connected dominating set of G .*

Proof Induction is used on i to show that the subset $C_i = \bigcup_{j=1}^i CDS(N^{r_j+3}[u_j])$ is connected. This is true for $i = 1$. Suppose C_i is connected. Since G is connected, it can be seen that as long as U_i is nonempty, the set W_i is nonempty. Hence, there exists a vertex $u_{i+1} \in W_i$. By the construction of W_i , the vertex $u_{i+1} \in N^{r_j+3}[u_j] \setminus N^{r_j+2}[u_j]$ for some $j < i$. Then u_{i+1} is dominated by a vertex $v \in CDS(N^{r_j+3}[u_j]) \subseteq C_i$. Thus, $C_{i+1} = C_i \cup CDS(N^{r_{i+1}+3}[u_{i+1}])$ is connected. \square

7.3.3 Performance

To analyze the performance ratio, it is first shown that the condition

$$|MIS(N_G[N^r[u]] \setminus N^r[u])| \leq \varepsilon |MIS(N^r[u])| \quad (20)$$

in Line 5 of Algorithm 9 guarantees a relationship which is similar to the condition (13) for the MIS problem and the condition (15) for the MDS problem.

Lemma 15 *There is a constant c_1 , such that $|CDS(N^{r_i+3}[u_i])| \leq (1 + c_1\varepsilon)|CDS(N^{r_i}[u_i])|$ holds for any $1 \leq i \leq K$.*

Proof The idea of the proof is to modify $CDS(N^{r_i}[u_i])$ to a connected dominating set of $N^{r_i+3}[u_i]$ by adding a controllable small number of vertices.

For convenience of statement, denote $C = CDS(N^{r_i}[u_i])$ and $M = MIS(N^{r_i+1}[u_i] \setminus N^{r_i}[u_i])$. Then $C \cup M$ is a dominating set of $N^{r_i+1}[u_i]$. Since each vertex $v \in M$ has a neighbor in $N^{r_i}[u_i]$, it can be seen that v can be connected to C by adding at most one vertex. For each vertex $v \in N^{r_i+3}[u_i] \setminus N^{r_i+1}[u_i]$, there is a vertex $w \in M$ which is at most 3 hops away from v . Thus, $N^{r_i+3}[u_i] \setminus N^{r_i+1}[u_i] \subseteq \bigcup_{w \in M} N^3[w]$. By further adding all the vertices in $\bigcup_{w \in M} CDS(N^3[w])$, one can obtain a connected dominating set of $N^{r_i+3}[u_i]$, denote it by \tilde{C} .

By Lemma 10 and Lemma 3, there is a constant c such that $|CDS(N^3[w])| \leq c$ holds for any w . Thus, $|\tilde{C}| \leq |C| + (2 + c)|M|$. By Corollary 1 and the condition (20), $|M| \leq |MIS(N_G[N^{r_i}[u_i]] \setminus N^{r_i}[u_i])| \leq \varepsilon |MIS(N^{r_i}[u_i])| \leq 12\varepsilon |CDS(N^{r_i}[u_i])| = 12\varepsilon |C|$. Taking $c_1 = 12(2 + c)$, one has $|CDS(N^{r_i+3}[u_i])| \leq |\tilde{C}| \leq (1 + c_1\varepsilon)|C|$. The lemma is proved. \square

Let D^* be a minimum connected dominating set of G . For $i = 1, 2, \dots, K$, let $D_i^* = D^* \cap N_G[N^{r_i}[u_i]]$. By Lemma 12, the sets $N_G[N^{r_1}[u_1]], \dots, N_G[N^{r_K}[u_K]]$ are mutually disjoint, and thus

$$|D^*| \geq \sum_{i=1}^K |D_i^*|.$$

Clearly, D_i^* is a dominating set of $N^{r_i}[u_i]$. However, D_i^* may be disconnected. Suppose $G[D_i^*]$ has k connected components. Similarly to the analysis in Sect. 5.4, adding at most two vertices reduces the number of components by one. Thus, one

can modify D_i^* into a connected dominating set of $N^{r_i}[u_i]$, denote it by \tilde{D}_i^* , such that

$$|\tilde{D}_i^*| \leq |D_i^*| + 2(k - 1).$$

Since D^* is connected, every connected component of $G[D_i^*]$ contains a vertex in $N_G[N^{r_i}[u_i]] \setminus N^{r_i}[u_i]$. These vertices must be independent since they belong to different connected components. Hence, $k \leq |\text{MIS}(N_G[N^{r_i}[u_i]] \setminus N^{r_i}[u_i])| \leq \varepsilon |\text{MIS}(N^{r_i}[u_i])| \leq 12\varepsilon |\text{DS}(N^{r_i}[u_i])| \leq 12\varepsilon |D_i^*|$. It follows that

$$|\tilde{D}_i^*| \leq (1 + 24\varepsilon) |D_i^*|.$$

Then the output D satisfies

$$\begin{aligned} |D| &\leq \sum_{i=1}^K |\text{CDS}(N^{r_i+3}[u_i])| \leq (1 + c_1\varepsilon) \sum_{i=1}^K |\text{CDS}(N^{r_i}[u_i])| \\ &\leq (1 + c_1\varepsilon) \sum_{i=1}^K |\tilde{D}_i^*| \leq (1 + c_1\varepsilon)(1 + 24\varepsilon) \sum_{i=1}^K |D_i^*| \leq (1 + \tilde{\varepsilon}) |D^*|. \end{aligned}$$

Similarly to the proof of [Lemma 13](#), it can be shown that there is a constant $c_0 = O(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon})$ such that the condition (20) is met by some integer $r \leq c_0$, and thus the algorithm is polynomial.

7.3.4 A Remark

Observe that the key to achieving the above performance is the uniform upper bound for the MIS in a closed neighborhood. Hence all above algorithms apply to growth,-bounded graphs. For d -hop CDS problem, more vertices have to be added for connection. The main idea is that the added vertices can be compensated by those vertices in boundary region, which is thin enough to produce an ε .

8 Conclusion

This chapter focuses on partition method and its variations which are used to produce PTASs for geometric problems, including ball cover, maximum independent set, minimum dominating set, minimum connected dominating set, and minimum sum radii cover. Some techniques are introduced, including small compensation technique, multilayer partition technique, and growing partition technique. These methods are of methodological value and are applicable in an Euclidean space of any dimension. Whether there exists a constant approximation algorithm for minimum connected dominating set in disk graph is still an open problem.

Abstract

This chapter describes some of the highlights of the theory of Probabilistically Checkable Proofs, from the milestone discovery of Feige et. al. through Dinur’s proof of the PCP theorem to the lately discovered consequences of the Unique Games Conjecture.

Our goal is to illuminate the major themes that run through the entire theory: probabilistic verification, proof recursion, gap enlarging reductions, code checking, constraint satisfaction problems. We have also discussed specific problems: set cover, independent set, graph coloring, etc. Since a completely comprehensive picture of this vast subject is not possible, we give pointers to a generous amount of literature.

1 Introduction

In 1991, Feige, Goldwasser, Lovász, Safra, and Szegedy [38] showed that results about multi-prover systems or equivalently PCPs imply the relative hardness of approximating the maximum clique number of a graph. Their discovery has joined the subjects of probabilistic verification and the theory of NP optimization, and a new subject emerged, called PCP theory. The goal of this chapter is to give an introduction and an overview of this theory. Since the key results alone would span several hundred pages, we have restricted ourselves to a representative selection.

Undoubtedly, the most fundamental part of the theory, with its numerous consequences, is the PCP theorem, which asserts that MAX3SAT is NP hard to approximate within a factor of $1 + \epsilon$ (for some $\epsilon > 0$). In Sect. 3 we sketch the short proof of it by Irit Dinur [33].

Reductions play a key part in proving hardness of approximation. They fall roughly into two types. Originally and traditionally relative hardness of approximating optimal values of NP optimization problems (NPO) was proven by gap-preserving reductions. In the more modern theory, we almost exclusively use Karp reduction between gap problems. We explain both types, as well as various amplification techniques, such as the parallel repetition.

We introduce the reader to probabilistic verification. The prover-verifier intuition has been the powerful force that exponentially accelerated the theory’s development and even today, when alternative interpretations are available, still proves to be indispensable when trying to obtain stronger results.

We shall talk about the non-approximability of classic NPO such as Max Clique, graph coloring, and set cover.

We shall explain the long code of Bellare, Goldreich, and Sudan, as it receives multiple applications throughout the theory.

A well-studied class of optimization problems is the class of Constraint Satisfaction Problems (CSP), which also happens to be the class, for which our non-approximability theory is the most successful. We devote a lot of attention to this class and sketch optimal non-approximability for its members.

Many of the optimal non-approximability results come from unique games, in particular, a beautiful and general result due to Raghavendra [83]. Unique

games-based hardness assumptions, initiated by Khot [61], might transform our views on complexity, by providing an alternative to the P versus NP paradigm. We devote two sections to unique games.

As we have indicated, we have made several omissions. We do not discuss several known non-approximability results. We do not mention efforts and techniques to optimize parameters of PCPs, such as proof size. Our chapter is concerned only with NPO. Probabilistic debate systems [26] and non-approximability of #P problems are out of the scope of this survey.

1.1 Probabilistically Checkable Proofs

The idea of probabilistic verification builds on the idea of deterministic verification. Recall that every language $L \in NP$ is deterministically verifiable in polynomial time, meaning that for every $L \in NP$, there is a polynomial-time machine V such that if $x \in L$ then there exists a polynomial size membership such that $V(x, P) = 1$ and if $x \notin L$ then for every P , $V(x, P) = 0$ (Fig. 1). The concept of probabilistic verification is analogous.

Definition 1 (Probabilistic Verification) For functions $f, g : \mathbf{N} \rightarrow \mathbf{N}$, a probabilistic polynomial-time verifier $V(x, P, r)$ is (f, g) -restricted if, for every input x of size n , it uses at most $f(n)$ random bits and examines at most $g(n)$ bits in the membership proof while checking it. Let Σ be an alphabet and $L \subseteq \Sigma^*$. V is an (f, g) -restricted polynomial-time probabilistic verifier for L with completeness q and soundness p if for every input x :

- If $x \in L$, then there exists a membership proof P such that

$$\text{Prob}_r(V(x, P, r) = 1) \geq q$$

- If $x \notin L$, then for any membership proof P ,

$$\text{Prob}_r(V(x, P, r) = 1) \leq p$$

If q and p are not stated explicitly, then, by definition, $q = 1$, and $p = 1 - \epsilon$ for some fixed $\epsilon > 0$.

Here we have to make some comments. First, it is best to think of V as a random access machine. Since Turing machines and random access machines are polynomial-time equivalent, we may also view V as a Turing machine, but even in the latter case, we need to assume that V has random access to the bits of P . Another issue is the *adaptivity* of V . Are the bits of P which V accesses determined in advance from x and r , or the location of the second bit read from P may depend on value of the first bit read from P , etc.? In the first case, we call the verifier *nonadaptive*, and in the second case, we call the verifier *adaptive*. Most verifier constructions in the PCP theory are nonadaptive.

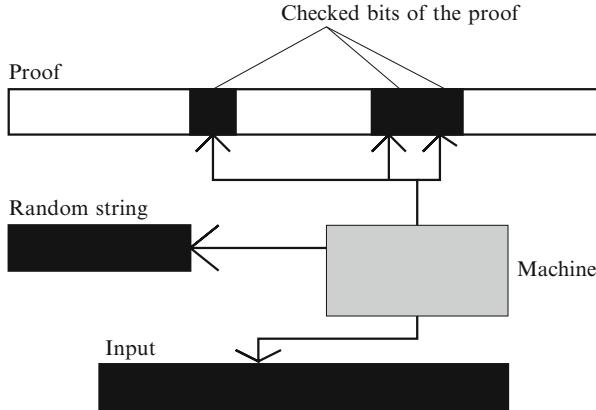

Fig. 1 A schematic picture of a probabilistic verifier. Only the black bits are read for a fixed random choice r

Definition 2 (PCP Classes[5]) A language L is in the class $PCP(f, g)$ iff there exists a constant $C > 0$ and an $(f(|x|^C), g(|x|^C))$ -restricted polynomial-time probabilistic verifier for L . For completeness and soundness values other than 1 and $1 - \epsilon$, we denote the corresponding PCP class by $PCP_{q,p}(f, g)$.

Clearly, $NP = PCP(0, |x|)$.

Lemma 1 If $L \in PCP_{q,p}(f, g)$ and L_1 polynomial time many-one reduces to L , then $L_1 \in PCP_{q,p}(f, g)$.

Proof Since L_1 many-one reduces to L , there is a polynomially computable T such that for every $x \in \Sigma^*$, $T(x) \in L$ iff $x \in L_1$. Let $V(x, P, r)$ be a probabilistic verifier for L . Then $V(T(x), P, r)$ is a probabilistic verifier for L_1 with the required parameters. \square

The PCP notation allows for a compact description of many known results:

Arora=A, Babai=B, Feige=Fe, Fortnow=F, Goldwasser=G, Levin=Le, Lovasz=Lo, Lund=Lu, Motwani=M, Safra=Safra, Sudan=Sudan, Szegedy=Sz	
$NEXP = PCP(n, n)$	BFLu [11]
$NP \subseteq PCP(\log n \log \log n, \log n \log \log n)$	BFLeSz [12]
$NP \subseteq PCP(\log n \log \log n, \log n \log \log n)$	FeGLoSaSz [38]
$NP = PCP(\log n, \sqrt{\log n})$	ASa [5]
$NP = PCP(\log n, 3)$	ALuMSuSz [4]

In Sect. 1.4 we are going to prove the last one [4] which we also call the basic PCP theorem because it is the basis of many further improvements. To describe these improvements we need to introduce new parameters such as free bit complexity,

amortized complexity, and their combinations. The various parameters will be discussed in details in Sect. 2.4.

1.1.1 Alphabet Size

Besides the four parameters of a probabilistic verifier (randomness, query size, completeness, soundness), sometimes its alphabet size may be an issue. Actually, for a machine $V(x, P, r)$, we have two different alphabets we may care about: that of input x and that of proof y . We will see cases, when the alphabet size of P is particularly important. We assume that alphabet of the input is either binary or it is understood from the context.

Definition 3 A language L is in the class $[\Sigma]PCP(f, g)$ iff there exists a constant $C > 0$ and an $(f(|x|^C), g(|x|^C))$ -restricted polynomial-time probabilistic verifier $V(x, P, r)$ for L , where $P \in \Sigma^*$.

Perhaps interestingly, $[\{0, 1\}]PCP_{1,p}(\log n, 2) = P$ for any $p < 1$.

1.2 A Brief History of Probabilistic Verification

The usual definition of NP uses the notion of a deterministic verifier that checks membership proofs of languages in polynomial time. Goldwasser, Micali, and Rackoff [49] and Babai [9, 13] were the first who allowed the verifier to be a probabilistic polynomial-time Turing machine that interacts with a “prover,” which is an infinitely powerful Turing machine trying to convince the verifier that the input x is in the language. A surprising result due to Lund, Fortnow, Karloff, and Nisan [10, 73] and Shamir [90] has shown that every language in PSPACE—which is suspected to be a much larger class than NP—admits such “interactive” membership proofs. Another variant of proof verification, due to Ben-Or, Goldwasser, Kilian, and Wigderson [17], involves a probabilistic polynomial-time verifier interacting with more than one mutually noninteracting provers. The class of languages with such interactive proofs is called MIP (for multi-prover interactive proofs). Fortnow, Rompel, and Sipser [43] gave an equivalent definition of MIP as languages that have a probabilistic polynomial-time oracle verifier that checks membership proofs (possibly of exponential length) using *oracle access* to the proof.

Babai, Fortnow, and Lund [11] showed that MIP is exactly NEXP, the class of languages for which membership proofs can be checked deterministically in exponential time. This result is surprising because NEXP is just the exponential analogue of NP, and its usual definition involves no notion of randomness or interaction. Therefore, researchers tried to discover if the MIP = NEXP result can be “scaled down” to say something interesting about NP. Babai, Fortnow, Levin, and Szegedy [12] introduced the notion of *transparent* membership proofs, namely, membership proofs that can be checked in polylogarithmic time, provided the input is encoded with some error-correcting code. They showed that NP languages have such proofs. Feige et al. [38] showed a similar result, but with a somewhat more efficient verifier. Arora and Safra [5] further improved the efficiency of checking

membership proofs for NP languages up to the point that they were able to give a new definition for NP this way.

They define a parameterized hierarchy of complexity classes called PCP (for probabilistically checkable proofs). This definition uses the notion of a “probabilistic oracle verifier” of Fortnow et al. [43] and classifies languages based on how efficiently such a verifier can check membership proofs for them. The notion of “efficiency” refers to the number of random bits used by the verifier as well as the number of bits it reads in the membership proof. Note that we count only the bits of the *proof* that are read—not the bits of the *input* which the verifier is allowed to read fully. The definition of a class very similar to PCP was implicit in the work of Feige et al. [38].

The paper of Arora, Lund, Motwani, Sudan, and Szegedy [4] in 1992 building on [5] was the first to decrease the number of check bits to constant. It is not just philosophically important that every transparently written proof can be checked with high accuracy by looking only at a constant number of places in the proof, but the construct of ALMSS also serves as a building block for nearly every construct that comes after it.

1.3 The Language of Cryptography

Articles in cryptography often describe mathematical objects such as information, knowledge, and secret through interactions between human characters. While the framework originally was used almost exclusively by cryptographers, it has become an integral part of the entire computer science culture.

In the remaining part of the text, we are going to need expressions such as “true prover,” “verifier,” and “cheating prover.” But what do they mean exactly? When we prove that a probabilistic verifier V recognizes a language L , our argument consists of two parts. In the first part we show that if $x \in L$, the verifier accepts some proof P with probability 1. In the second part we show that if $x \notin L$ then the verifier rejects every proof with probability at least ϵ .

The first part of the argument features the *true prover* who is responsible to provide a string P which is accepted by the verifier with probability one. In this formula, $\text{Prob}_r(V(x, P, r) = 1) = 1$. The presumed structure of P is expressed in terms of the actions of the true prover. For instance, when we say that “the good prover encodes string a using an encoding E ,” it means that the presumed structure of the proof is a code word $E(a)$.

When we investigate the $x \notin L$ case, the main character of the story is the *cheating prover*. By assumption he is an ultimately devious creature whose proof does not adhere to the structure of the true prover. He has to cheat somewhere, since no correct proof exists when $x \notin L$. This property is required by the axioms of a proof system for L . The goal of the cheating prover is to maximize the probability with which the verifier accepts P , the “proof” he presents. It is important to emphasize that the proof of the cheating prover is an arbitrary string formed from the letters of the given alphabet, typically $\Sigma = \{0, 1\}$. When we argue about the $x \in L$ case, we never need to talk about the cheating prover.

Like in the case of other formal proof systems in the case of PCPs, the proof itself is just a vehicle to indicate that a statement holds and itself is not interesting for the verifier at all. Only the mere existence or non-existence of its corrected version matters. The verifier does not want to learn the entire proof or to verify that the proof adheres to the structure of the good prover *everywhere*. It is sufficient for us to show that if $x \notin L$, no matter what string the cheating prover may write down, it is so far from being consistent either with the structure of the true prover or with other constraints defined by input x that the verifier is able to catch the error with probability ϵ .

1.4 The PCP Theorem

Theorem 1 (PCP Theorem) $NP \subseteq PCP(\log n, 3)$. Moreover, we can also assume that the verifier is nonadaptive and his accepting criterion is a disjunct (i.e., “OR”) of the literals made from the three bits he looks at.

Notice that by [Definition 2](#), the factor $\log n$ scales by a constant, but not the second argument. The following seemingly weaker variant of the above theorem is also often called the PCP theorem:

Theorem 2 $NP \subseteq [\Sigma]PCP(\log n, c)$ for some fixed constant c and for some fixed alphabet Σ .

This statement was first proven by Arora, Lund, Motwani, Sudan, and Szegedy [4], based on several previous works [11, 12, 38], in particular on a simultaneous work of Arora and Safra [5]. The original proof was based on several algebraic and combinatorial techniques. The proof had several variations, but they all had the basic design. We call this the classic PCP proof design. A new type of proof was given by Irit Dinur in 2005 [33]. She has proved the following:

Theorem 3 $NP \subseteq [\{0, 1\}^3]PCP(\log n, 2)$.

We give a sketch of her proof in [Sect. 3](#). In the rest of this section, we show that [Theorem 2](#) implies [Theorem 1](#) (the converse is straightforward).

Lemma 2 Let $\ell > 3$ be a constant and $f(n)$ be an arbitrary function from the positive integers to the positive integers. If there is a nonadaptive $(f(n), \ell)$ -restricted verifier V that checks a proof P with alphabet Σ and recognizes a language L with completeness 1 and soundness $1 - \epsilon$, then there is a non-adaptive $(f(n) + O(1), 3)$ -restricted verifier V' that checks a proof P' with alphabet $\{0, 1\}$ and recognizes L such that its checking criterion is always a disjunct of three literals made from the three bits it reads. Furthermore, V' has completeness 1 and soundness ϵ/K , where $K > 0$ is some constant dependent only on ℓ and Σ .

Proof We prove this lemma with a technique called *proof composition*. Proof composition is a very general principle stating that if we prove the existence of a proof for $x \in L$, then $x \in L$ follows (thus, instead of a proof, it suffices to have a proof that a proof exists). A proof composition technique in the PCP context was developed in [5]. Here we need a very simple version of it.

Let us fix x . For every fixed random choice r , the accepting criterion of V is a Boolean-valued function φ_r of the ℓ places of P examined by V . The composed proof contains the original proof and some extra information that helps the verifier. Since we want the composed proof to have a binary alphabet, we also encode the alphabet of the original proof in binary via some (arbitrary) injection $\Sigma \rightarrow \{0, 1\}^{\lceil \log |\Sigma| \rceil}$. The part of the new proof that is identical to P , with its letters encoded in binary is called the *core*. For every $r \in \{0, 1\}^{f(n)}$, we then create a constant size proof β_r that helps to convince the verifier that φ_r holds. The entire new proof is now the union of the core and $\bigcup_r \beta_r$. The details are as follows:

First recall from logic that every Boolean function $\varphi(\alpha)$ on v variables can be written in the form $(\exists \beta) \psi(\alpha, \beta)$, where ψ is a 3CNF formula. β is a sequence of at most $(v - 1)2^v$ auxiliary variables, and ψ has at most $2^v + (v - 1)2^{v+1}$ clauses, but for our purposes, we only care that these quantities are constants in terms of v .

Let $(\exists \beta_r) \psi_r(\alpha_r, \beta_r)$ be the 3CNF-equivalent of φ_r . Here α_r is the $\ell \lceil \log |\Sigma| \rceil$ bits of information that machine V reads from P under random bit r . The help β_r (of the true prover) is any evaluation of the auxiliary variables for which $\psi_r(\alpha_r, \beta_r) = 1$.

The new verifier, V' , picks a random r and a random clause of ψ_r and accepts if the selected clause evaluates to 1 under α_r and β_r of the composed proof (α_r is part of the core, β_r is the sequence of auxiliary bits that the prover provides for query r). Since ψ_r has constant number of clauses, the composed verifier needs at most constant number of additional random bits to perform its query.

If V accepts a proof P with probability 1, then for every r there exists a β_r such that $g_r(\alpha_r, \beta_r) = 1$, so there exists a composed proof which V' accepts with probability 1.

Assume now that $x \notin L$. We claim that no composed proof will be accepted with probability greater than $1 - \frac{\epsilon}{K}$ by V' , where K is the uniform upper bound on the number of clauses in $\psi_r(\alpha_r, \beta_r) = 1$ for all r s.

To see this, assume that a composed proof with core P is accepted with probability greater than $1 - \frac{\epsilon}{K}$. Then the fraction of r s for which the predicate $(\exists \beta_r) \psi_r(\alpha_r, \beta_r)$ is false is less than $K \times \frac{\epsilon}{K} = \epsilon$. Then V accepts P with probability greater than $1 - \epsilon$, a contradiction. \square

2 Non-approximability Results

NPO (see [29, 30, 56]) have one of the following forms:

- Find $\max_{|y| \leq q(|x|)} P(x, y)$ given input x . [maximization]
- Find $\min_{|y| \leq q(|x|)} P(x, y)$ given input x . [minimization]

Here $P(x, y)$ is a polynomially computable function that assigns non-negative rationals to pairs of strings, and q is a polynomial. (In the literature witness y is selected from an arbitrary polynomial-time computable set of strings not necessarily only of the form $\{y \mid |y| \leq q(|x|)\}$. Our definition is sufficient to describe all relevant problems and enables us to avoid anomalies that arise from the more general definition.)

While one can construct optimization problems that are not in NPO, the class plays a primary role in optimization theory with such well-known problems as coloring, allocation, scheduling, Steiner tree problems, TSP, linear and quadratic programming, knapsack, and vertex cover. The consequences of the PCP theory almost solely concern NPO problems. There are exceptions [26, 27], but we do not discuss them here.

Most NPO problems are NP-hard to compute exactly. A polynomial-time algorithm A is said to *approximate* an NP maximization problem P to within a factor $r(x) \geq 1$, if A outputs a witness y such that the optimal solution for input x lies within $\max_{|y| \leq q(|x|)} P(x, y)/r(x)$ and $\max_{|y| \leq q(|x|)} P(x, y)$. Here $r(x)$ is called *approximation ratio* and can be generalized also to minimization problems in an obvious way.

Below we give three examples to NPO problems:

MAX3SAT: Let x represent a 3CNF formula, y represent an assignment, and $P(x, y)$ be the number of clauses in x satisfied by y . [Maximization]

Set cover: Let x represent a polynomial size set system, y represent a selection of sets, and $P(x, y)$ be the function, which equals to the number of selected sets if the selected sets cover the universe, otherwise, the size of the entire set system. [Minimization]

PCP: Let V be an $(\log n, g(n))$ -restricted probabilistic verifier for a language L . x represents an input, y represents a proof, and $P(x, y)$ is the acceptance probability of proof y for input x . Since the verifier uses $\log n$ randomness, we can run V on all random strings and compute this probability in polynomial time. [Maximization]

If in the latest example, we take L to be an NP-complete language and V to be the verifier of [Theorem 1](#), then it is easy to see that if we could efficiently approximate the acceptance probability of V to within a factor better than $1 - \epsilon$ (for the ϵ of the theorem), then we could also solve the membership problem for L . This is an example to an argument about non-approximability. What is special about the optimization problem coming from [Theorem 1](#) is that the value of $P(x, y)$ is proportional to a number of very simple predicates that y satisfies, namely, each predicate depends only on three bits of y . This makes this NPO problem a *CSP*. Before the PCP theorem there were no non-approximability results for any CSP. The theory of PCP exploits the fact that probabilistic verifiers for NP-complete languages translate to provably hard approximation problems.

2.1 A Brief History of Approximating NPO Problems

The NP-completeness theory of Cook [28] and Levin [70] puts NPO problems into two categories: NP-hard or not NP-hard. The first alarm that this characterization is too coarse was sent off in an early paper of D. Johnson [56] entitled “Approximation Algorithms for Combinatorial Problems.”

Motivated by exact bounds on the performance of various bin packing heuristics of [45], Johnson gave algorithms for the subset sum, the set cover, and the MAX k -SAT problems with guarantees on their performances ($1 + o(1)$, $O(\log |S|)$, $2^k/(2^k - 1)$, respectively). He also gave non-approximability results, but unfortunately they referred only to specific algorithms. Nevertheless, he has brought up the issue of classifying NPO problems by the best approximation ratio achievable for them in polynomial time.

For years advances were very slow. Sahni and Gonzales [88] proved the non-approximability of the nonmetric traveling salesman and other problems, but their proofs were very similar to standard NP-completeness proofs, and they effected only problems where approximation algorithms were not explicitly sought for. A more promising approach was found by Garey and Johnson [46] who used graph products to show that the chromatic number of a graph cannot be approximated to within a factor of $2 - \epsilon$ unless $P = NP$ and an approximation algorithm for the Max Clique within *some* constant factor could be turned into an algorithm which approximates Max Clique within *any* constant factor.

The old landscape of approximation theory of NPO radically changed when in 1991 Feige, Goldvasser, Lovász, Safra, and Szegedy [38] for the first time used Babai, Fortnow, and Lund’s characterization of NEXP in terms of multi-prover interactive proof systems [11] to show that approximating the clique within any constant factor is hard to $\text{NTIME}(n^{1/\log \log n})$. Simultaneously Papadimitriou and Yannakakis defined a subclass of NPO what they called MAXSNP, in which problems have an elegant logical description and can be approximated within a constant factor. They also showed that if MAX3SAT, vertex cover, Max Cut, and some other problems in the class could be approximated with an arbitrary precision, then the same would hold for all problems in MAXSNP. They established this fact by reducing MAXSNP to these problems in an *approximation preserving* manner. Their original intention was most likely to build a theory of non-approximability via defining suitable reductions, analogous to those in the theory of NP, but new non-approximability results in [4] let them achieve much more. The theory of NP and the theory of non-approximability met, and research developed rapidly in three directions:

1. Non-approximability results for NPO problems
2. Construction of approximation algorithms achieving optimal or near-optimal ratios
3. Development of approximation preserving reductions and discovery of new (non)-approximability classes

Today, we have a precise idea about the non-approximability status of many NPO problems. The on-line compendium of Pierluigi Crescenzi and Viggo Kann [29] keeps track of the growing number of results and continuously updates data about most known NPO problems.

2.2 The FGLSS Graph

The first paper to construct a combinatorial object from a PCP was that of Feige et al. [38]. For deterministic verifiers an analogous construction cannot be meaningfully made (Fig. 2). The combinatorial object was simply a graph G , and the construction implied hardness of approximating the optimization problem

$$\text{MaxClique}(G) = \max_{S \subseteq V(G)} \{|S| \mid \text{for all } v, w \in S \text{ we have } (v, w) \in E(G)\}$$

Let V be an (f, g) -restricted verifier. The evaluation of the entries of the proof the verifier sees is called a *view*. An *accepting view* is a view the verifier accepts for some input x and random coin flip r .

By definition, an accepting view contains stars at positions where the verifier never looks at (for a particular random run) and exactly at these positions. Thus, an accepting view can be thought of as a partial proof that causes the verifier to accept. When the verifier is adaptive, the first bit read by him determines the location of the second bit, etc., so even for a fixed r , the locations of the non-stars may vary from view to view. Since the query size is upper bounded by $g(n)$, every accepting view contains at most $g(n)$ entries which are not stars. We call two accepting views consistent if they agree in locations where both are non-stars.

Let $ACC_V(x, r)$ be the set of all accepting views for a verifier V for input x and random string r , and let

$$ACC_V(x) = \{(r, W) \mid |r| = f(n), W \in ACC_V(x, r)\}.$$

Definition 4 (FGLSS Graph $G_V(x)$) Feige et al. [38] define a graph $G_V(x)$ on vertex set $ACC_V(x)$ such that (r, W) and (r', W') are connected if and only if $r \neq r'$ and W and W' are consistent.

Lemma 3 *Let V be an (f, g) -restricted verifier. Then:*

1. $G_V(x)$ has at most $2^{f(n)+g(n)}$ vertices.
2. $G_V(x)$ can be constructed in time polynomial in $\max\{n, 2^{f(n)+g(n)}\}$.
3. $\text{MaxClique}(G_V(x))$ is equal to $\max_P |\{r \mid V(r, P, x) = 1\}|$.

Proof One can easily check that even for an adaptive V , there are at most $2^{g(n)}$ different accepting views for a fixed r . Thus, the total number of accepting views is at most $2^{f(n)}2^{g(n)}$. In order to check whether a pair (r, W) is an accepting view or not, we can run V , which is by definition a polynomial-time machine. By comparing two views bit-wise, we can check in linear time if they form an edge in $G_V(x)$. As a result $G_V(x)$ can be constructed in time polynomial in $\max\{n, 2^{f(n)+g(n)}\}$.

The main observation of FGLSS is that there is a natural many-one map from the set of proofs (or proof candidates) to the set of cliques of $G_V(x)$ such that all maximal clique has at least one inverse image. Indeed, if we map a proof P to the set of all (r, W) pairs, with the property that $V(x, P, r) = 1$ and W is the verifier's view of P when reads r , then these pairs form a clique in $G_V(x)$, since their view

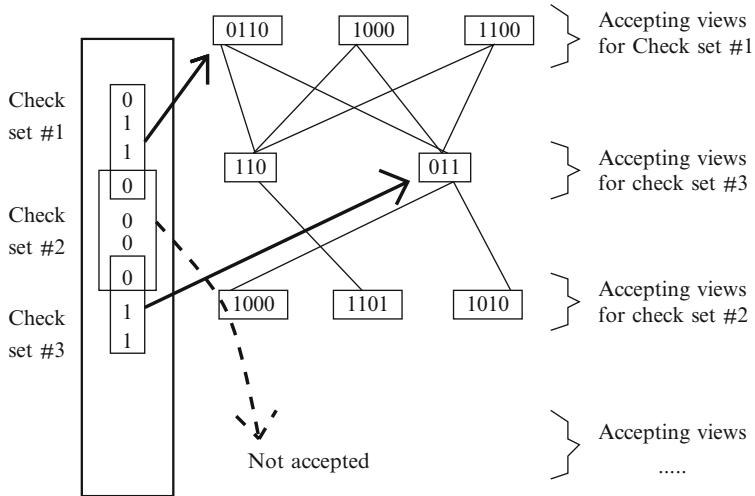

Fig. 2 Construction of the FGLSS graph. The set of all accepted views of a proof map to the set of vertices of a clique (the map is represented by the arrows). The reverse also holds as follows: every maximal clique of the graph corresponds to some proof

components are consistent with each other. Conversely, let C be a maximal clique of $G_V(x)$. There is a string (i.e., a proof) which is consistent with all elements of C . This can be easily seen, since a location is either star in all elements of C or uniquely defined by some elements of C . This string cannot be consistent with any view that is not in C , since C was maximal. Notice that in this correspondence, the size of C is exactly the number of those r s for which there is a W such that $(r, W) \in C$, since W , if exists, is unique for a fixed r . This number further equals to the number of different coin flips for which the verifier accepts any proof that maps to C . Point 3 of the lemma follows. \square

We shall apply Lemma 3 in Sect. 2.8.

2.3 The Gap-3SAT Instance

The gap-3SAT instance is a 3SAT formula, which is either satisfiable or at most $1 - \epsilon$ of its clauses are satisfiable.

Theorem 4 ([4]) *There exists an $\epsilon > 0$ such that for every $L \in NP$, there is polynomial-time computable map from Σ^* to 3SAT instances (mapping $x \in \Sigma^*$ to ϕ_x) such that:*

1. *If $x \in L$, then ϕ_x is satisfiable.*
2. *If $x \notin L$, then every assignment leaves at least ϵ clauses of ϕ_x unsatisfied.*

Indeed, build a PCP for L as in Theorem 1, and define

$$\phi_x = \wedge_r c_r,$$

where c_r is the verifier's accepting criterion for random string r and which by the assumption of [Theorem 1](#) is a disjunct of three literals. The variables are the bits of the proof. If $x \in L$ then all c_i 's evaluate to 1, but if $x \notin L$ then ϵ fraction of the clauses must remain unsatisfied for every assignment, i.e., for every proof of the prover.

The theorem has the immediate consequence that $MAX3SAT$ cannot be approximated in polynomial time to within a factor better than $1/(1-\epsilon)$; otherwise, we could use this algorithm to efficiently compute if $x \in L$. Since $MAX3SAT$ is in $MAXSNP$ (Papadimitriou and Yannakakis [80]), we get

Theorem 5 ([4]) *No $MAXSNP$ -complete problem can be efficiently approximated to within a factor arbitrarily close to 1 unless $P=NP$.*

[Theorem 5](#) does not give explicit non-approximability gaps. For explicit gaps see [Sect. 2.7](#).

2.4 Refined Parameters of PCPs

In [Sect. 1.1](#) we parameterized probabilistic verifiers with the number of random bits, $f(n)$, and the number of check bits $g(n)$ (see [Definition 1](#)). When we make a reduction from a PCP to an NPO problem, the exact non-approximability gap of the latter may depend on several other parameters of the PCP. Here we list some, starting with the most important ones:

1. The *completeness probability*, $q(n)$, which is the least probability of acceptance, when $x \in L$. Originally $q(n) = 1$, but Håstad [53, 54] proved that we can improve on other parameters if we allow $q(n)$ to be slightly less than 1.
2. The *soundness probability*, $p(n)$, which is the greatest probability of acceptance, when $x \notin L$.
3. The *free bit complexity*. In [Sect. 2.2](#) we defined $ACC_V(x, r)$. Using this notation,

$$free(n) = \max_{|x|=n} \log_2 \max_r |ACC_V(x, r)|.$$

4. The *average free bit complexity*:

$$free_{av}(n) = \max_{|x|=n} \log_2 \left(\frac{1}{2^{f(n)}} \sum_r |ACC_V(x, r)| \right).$$

Note that $\sum_r |ACC_V(x, r)|$ is the size of the FGLSS graph.

5. The alphabet size $|\Sigma|$. In most cases we assume that the witness \mathbf{w} is a string over the binary alphabet $\{0, 1\}$. Raz and Safra [87] showed the relevance of using alphabets which may contain up to n symbols.

The parameters we have discussed so far were defined from the model of PCP. We also consider *derived parameters* that can be expressed in terms of the parameters we have defined so far:

1. The *gap* function $gap(n) = q(n)/p(n)$.
2. The *amortized query bit complexity* defined as $\frac{g(n)}{\log_2 gap(n)}$.
3. The *amortized free bit complexity* defined as $\frac{free(n)}{\log_2 gap(n)}$, sometimes as $\frac{free_{av}(n)}{\log_2 gap(n)} = \max_{|x|=n} \log_{q/p} \left(\frac{1}{2^{f(n)}} \sum_r |ACC_V(x, r)| \right)$ [40].

The following notations for PCP classes with refined parameters are more or less standard in the literature:

$FPCP_{q,p}(f, free)$ denotes the class, where the query complexity is replaced with the free bit complexity. $\overline{FPCP}(f, \overline{free})$ is $\cup FPCP_{q,p}(f, free)$, where the union runs through for all choices of $q(n)$, $p(n)$, and $free(n)$ such that the amortized free bit complexity is at most $\overline{free}(n)$.

2.5 Amplification Techniques

Amplification techniques are transformations on probabilistically checkable proofs or on the FGLSS graph that improve on their parameters. An ancestor of these techniques was used in [46] to prove that the chromatic number cannot be approximated to within a factor of $2 - \epsilon$. In this section we review the naive repetition, the parallel repetition, the proof composition, and the randomized graph product (see also in Fig. 3). All of them are playing important roles in the theory of non-approximability.

2.5.1 Naive Repetition

In the case of naive repetition, the new verifier's query is the conjunct of k independently chosen queries of the original verifier. It increases the gap in between the completeness and the soundness probabilities as shown in the table below:

<i>Naive repetition</i>	Original verifier	Repeated verifier
Number of random bits	$f(n)$	$k f(n)$
Number of check-bits	$g(n)$	$k g(n)$
Completeness probability	$q(n)$	$q(n)^k$
Soundness probability	$p(n)$	$p(n)^k$

Perhaps the most troublesome aspect of the naive repetition is that it increases the number of random bits the verifier needs to use. Zuckerman [98] suggests a “less naive” repetition, where the verifier chooses its k -tuple from a set S of polynomially

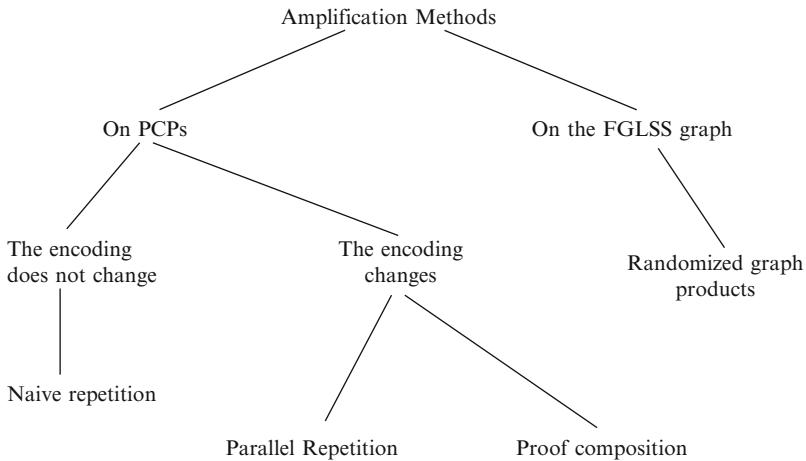

Fig. 3 Various types of amplifications

many k -tuples. Unfortunately, Zuckerman constructs S randomly. A PCP^S verifier is a PCP verifier that works with a (random) advise S . With high probability over a random S with $|S| = 2^{F(n)}$, the following holds for Zuckerman's verifier:

	Original verifier	Zuckerman's verifier
Number of random bits	$f(n)$	$F(n)$
Number of check bits	$g(n)$	$g(n)(F(n) + 2)$
Completeness probability	1	1
Soundness probability	$1/2$	$2^{f(n)-F(n)}$

Lars Engebretsen and Jonas Holmerin [36, Lemma 14] have computed the performance of the Zuckerman's verifier for all values of the completeness and soundness probabilities. This is what they got:

	Original verifier	EH-verifier
Number of random bits	$f(n)$	$F(n)$
Number of check bits	$g(n)$	$g(n)\frac{F(n)+2}{-\log p(n)} = g(n)D$
Completeness probability	$q(n)$	$q^D(n)/2$
Soundness probability	$p(n)$	$2^{f(n)-F(n)}$

In the case of perfect completeness, the EH verifier also has perfect completeness.

2.5.2 Parallel Repetition

Parallel repetition of PCPs, as opposed to naive repetition, requires to change not only the verifier's behavior but also the encoding. It increases the alphabet size in order to keep the query size only two and works as follows.

Assume that an (f, g) -restricted verifier V expects P to be segmented, i.e., P consists of blocks (usually of some fixed block size). Note that the segmentation is something that is only in the verifier's mind, so a cheating prover has no influence on this: segmented proof simply refers to the verifier's reading behavior. Assume that the verifier always accesses data only from two different blocks of the proof. A further restriction is that P consists of two sets of blocks, P_1 and P_2 , such that for every random string, V accesses one block from each set. A PCP with this structural restriction is called a *two-prover system*, since P is being thought to be provided by two different provers whose answers the verifier compares one with another.

Any naive repetition with $k > 1$ would alter the two-prover nature of the system, but parallel repetition keeps it. We shall denote a verifier V repeated k times in parallel by V^k . The true prover for V^k writes down all possible ordered k -tuples of segments from P_1 and all possible ordered k -tuples of segments from P_2 , and these k -tuples are the segments of the repeated provers. The verifier uses $kf(n)$ randomness to simulate k independent checks $(c_{1,1}, c_{2,1}), \dots (c_{1,k}, c_{2,k})$ of V by querying segments $(c_{1,1}, \dots, c_{1,k}) \in P_1^k$ and $(c_{2,1}, \dots, c_{2,k}) \in P_2^k$. V^k accepts iff V would accept all pairs $(c_{1,i}, c_{2,i})$ for $1 \leq i \leq k$.

It is easy to compute the acceptance probabilities if the proof has the P_1^k, P_2^k structure, but there is no guarantee that cheating provers adhere to this structure. Surprisingly we can still say something about the maximum acceptance probability for V^k .

Theorem 6 (Raz's Parallel Repetition Theorem [86]) *For every verifier V of a 2-prover PCP, there is a constant $0 \leq c \leq 1$:*

$$\max_{P'} \text{Prob}_{r_1, \dots, r_k}(V^k(x, P', r_1, \dots, r_k) = 1) \leq c^k, \quad (1)$$

where c depends only on $p(V, x) = \max_P \text{Prob}_r(V(x, P, r) = 1)$ and the maximum segment size for V and is strictly less than 1 if $p(V, x) < 1$. (In Eq. (1) P' ranges through all (possibly cheating) proofs for V^k .)

The properties of the repeated proof are summarized in the table below:

	Original verifier	With k repetitions
Number of random bits	$f(n)$	$kf(n)$
Number of check bits	$g(n)$	$kg(n)$
Completeness probability	$q(n)$	$q(n)^k$
Soundness probability	$p(n)$	c^k (see Theorem 6)

The price we pay for keeping the two-prover structure is a weaker bound on the soundness probability than in the case of naive repetition.

Two-prover systems were introduced by Ben-Or, Goldwasser, Kilian, and Wigderson [17] and have been studied by Rompel and Sipser [43], Feige and Lovász [41], and by many others.

In many PCP constructions, we use a certain folklore two-prover protocol. The verifier of this protocol, which we call $V_{3\text{SAT}}$, comes from the gap-3SAT instance of Sect. 2.3 and works as below.

Let ϕ_x (associated with $x \in \Sigma^*$) be a 3SAT instance, which is either completely satisfiable or at most $1 - \epsilon$ fraction of its clauses are satisfiable for some $\epsilon > 0$. By Theorem 4 we can assume that the language $L = \{x \mid \phi_x \text{ is satisfiable}\}$ is NP-complete and that ϕ_x is polynomial-time computable from x . The verifier $V_{3\text{SAT}}$ computes ϕ_x , picks a random clause in it, and asks the first prover to evaluate the three literals in the clause. If all the three literals evaluate to false, $V_{3\text{SAT}}$ rejects outright. Otherwise, he picks a random variable in the clause and asks the second prover to evaluate this variable (the two provers do not hear each other's answers, but they can agree in a strategy in advance, and they also know x). If the two provers evaluate the variable differently, the verifier rejects, otherwise accepts.

In order to see that the above informal description indeed defines a two-prover system in our former sense, identify P_i with the concatenation of all answers to all possible questions of the verifier to prover i . Each answer is one segment, and the number of segments in P_i equals to the number of different questions the verifier may ask from prover i . The segment size of P_1 is three bits, and the segment size of P_2 is one bit.

Next we show that the above protocol has a gap at least $\epsilon/3$. Clearly, when $x \in L$, i.e., when ϕ_x is satisfiable, both provers play consistently with the lexicographically first satisfying assignment of ϕ_x , and $V_{3\text{SAT}}$ accepts with probability 1. If $x \notin L$, every assignment fails to satisfy at least ϵ fraction of the clauses of ϕ_x . Observe that the strategy of P_2 corresponds to an assignment to the variables of ϕ_x . For the sake of simplicity, we call this assignment P_2 . This assignment must fail to satisfy at least ϵ fraction of the clauses of ϕ_x , and the verifier has probability ϵ that he finds one of these clauses. The first prover of course will lie and will not give the same evaluation to one of the variables in that clause as P_2 (to avoid sure rejection), but then, conditioned on the event that P_2 gets the clause in question, the verifier notices this inconsistency with probability at least $1/3$. Thus, in case $x \notin L$, $V_{3\text{SAT}}$ accepts with probability at most $1 - \epsilon/3$.

Feige [37] shows that we may also assume that in ϕ_x each variable appears exactly in 5 clauses and that each clause contains exactly 3 variables. By Feige's restriction, we may assume that $V_{3\text{SAT}}$ first selects a random variable and then chooses a clause randomly out of the five that contains this variable. Observe that the sequence in which the verifier asks the provers does not matter, and in the sequel we call the prover who provides the clauses the "second prover." We may also assume that the verifier decides at his output after he has heard both provers.

In all applications $V_{3\text{SAT}}$ is going to be repeated in parallel ℓ times, where ℓ depends on the application and ranges from a large constant to $\log n$. The lemma

below, which is a consequence of the PCP theorem and the parallel repetition theorem, summarizes the properties of $V_{3\text{SAT}}^\ell$.

Lemma 4 *Let $\ell = \ell(|x|)$ be an arbitrary function of $|x|$ (but most often a constant), and let $b = \{b_1, \dots, b_N\}$ be the set of variables of Feige's ϕ_x and $c = \{c_1, \dots, c_{5N/3}\}$ be the clauses of ϕ_x . (We say $b_i \in c_j$ if b_i or \bar{b}_i appears in c_j). Then $V_{3\text{SAT}}^\ell$ works as follows:*

1. *It randomly picks an ℓ tuple $U = (b_{i_1}, \dots, b_{i_\ell})$ and checks it against an ℓ tuple $W = (c_{j_1}, \dots, c_{j_\ell})$ such that $b_{i_v} \in c_{j_v}$ for $1 \leq v \leq \ell$. W is called a companion of U , and it is randomly picked from the set of all companions of U . The provers provide evaluations of all variables involved in the queries to them (in particular, the second prover gives the values of all variables in all clauses occurring in W) without listening to each other. The verifier accepts if $V_{3\text{SAT}}$ would accept (b_{i_v}, c_{j_v}) for every $1 \leq v \leq \ell$, i.e., all c_{j_v} are satisfied, and the assignments of the variables in U and W are consistent.*
2. *It has perfect completeness.*
3. *It has soundness at most c^ℓ for some fixed constant $c < 1$.*
4. *It uses $O(\ell \log n)$ random bits and $\ell + 3\ell$ check bits. (Here parameter n is the length of x , and it is in polynomial relation with N .) More importantly, the verifier reads only two segments of the proof. With segment sizes ℓ (bits) for prover one and 3ℓ (bits) for prover two, this is a two-query PCP.*

The above lemma amplifies the PCP theorem and implies approximation hardness of the *label cover* problem:

Label Cover Problem: An instance of the *label cover* problem is a tuple, $\mathcal{P} = (G, \Sigma_1, \Sigma_2, \Pi)$, where:

1. $G = (X, Y, E)$ is a bipartite graph with $V(G) = X \cup Y$ and $E = E(G) = E(X, Y)$.
2. Nodes in X, Y are assigned labels from Σ_1, Σ_2 , respectively.
3. $\Pi = \{\pi_{xy} \mid (x, y) \in E\}$ is a set of functions, $\pi_{xy} : \Sigma_1 \rightarrow \Sigma_2$.

The variables of \mathcal{P} , by definition, are the labels assigned to nodes in $X \cup Y$. For each edge $(x, y) \in E$, $\pi_{xy}(l(x)) = l(y)$ defines a binary “projection” constraint. Here, $l(x), l(y)$, are the labels assigned to x, y , respectively. The value of a label assignment is the fraction of constraints that are satisfied.

A $V_{3\text{SAT}}^\ell$ instance is a special label cover problem \mathcal{P} , where the vertices of X are the ℓ -tuples of clauses of a $V_{3\text{SAT}}$ instance Φ_x and the vertices right partition are the ℓ -tuples of the variables of Φ_x . Therefore, $\Sigma_1 = \{0, 1\}^{3\ell}$ and $\Sigma_2 = \{0, 1\}^\ell$.

Lemma 4 implies:

Theorem 7 *For any positive $\epsilon < 1$, there exist sufficiently large, but constant size alphabets $\Sigma_1 = \Sigma_1(\epsilon), \Sigma_2 = \Sigma_2(\epsilon)$, such that it is NP-hard to approximate label cover instances $\mathcal{P}(G, \Sigma_1, \Sigma_2, \Pi)$ within a factor smaller than $1/\epsilon$.*

Proof Choosing $\ell \in O(\log \frac{1}{\epsilon})$, the soundness of V_{3SAT}^ℓ can be made smaller than ϵ , giving the required hardness. \square

2.5.3 Proof Composition

The idea of composing probabilistic verifiers first appears in the paper of Arora and Safra [5] and is aimed at reducing the number of check bits of a probabilistic proof system.

To describe proof composition, consider a proof system with an (f, g) -restricted verifier V that recognizes a language L . From now on we call V the *outer verifier*. We would like to construct a new verifier V' which recognizes the exact same language as V but uses less check bits. Let $x \in L$, $|x| = n$. The composed proof for x consists of the old proof P , which we call the *core*, and a proof P_r for every choice of the random string r with $|r| = f(n)$ which we describe later. We shall compose proof systems only if their verifiers are non-adaptive. Let Q_r be the set of bits that V reads from P when we run it with random string r . The set of accepting views $ACC_V(x, r)$ can be viewed as a language L_r consisting of words only of length $|Q_r| = g(n)$. Let V_r be an (f', g') -restricted probabilistic verifier that recognizes L_r , where $f'(g(n))$ and $g'(g(n))$ are the number of random bits and check bits V_r needs for its verification. The f' and g' bounds must uniformly hold for each L_r (a more elegant formalism for composition was worked out in [92]). V_r is called the *inner verifier*, and it verifies that the view of the original verifier is accepting, with the help of some extra advise string φ_r , provided separately for every r in addition to the view.

The compound verifier works as follows: it picks a random r with $|r| = g(n)$ and a random string r' with $|r'| = f'(|Q_r|)$. It then runs V_r with random string r' on input Q_r , proof φ_r (reading $g'(|Q_r|)$ bits from the latter), and outputs $V_r(Q_r, \varphi_r, r')$.

Let us compute the parameters of the composed proof system. Assume that V has completeness probability $q(n)$ and soundness probability $p(n)$ and that each V_r has completeness probability $p'(n)$ and soundness probability $q'(n)$. Here is what we get:

	Original proof	Composed proof
Completeness probability	$q(n)$	$q(n)q'(n)$
Soundness probability	$p(n)$	$(1 - p(n))p'(n) + p(n)$
Number of check-bits	$g(n)$	$g(n) + g'(g(n))$

As we see, all parameters are getting worse. Why? The composed verifier uses $g(n) + g'(g(n))$ check bits. The second term is small, but the first term, $g(n)$, is

there, because although Q_r is input from the inner verifier's view point, it is in fact part of the composed proof. The situation would be different if V_r checked its input Q_r together with the associated proof φ_r instead of reading its entire input.

Babai, Fortnow, Levin, and Szegedy [12] have introduced a probabilistic verifier, which reads only a few bits from its input. The price of this efficiency is that the BFLS verifier can recognize a language only if it receives its input encoded. If now the outer verifier is *segmented*, i.e., the outer verifier reads k chunks of the proof, each of length $g(n)/k$, where k is a constant, we may use the BFLS verifier as the inner verifier if we replace the proof of the outer verifier with a one where each segment is encoded. (See Sect. 2.5.2 for an example to a segmented outer verifier.) In [12] it is shown:

Theorem 8 *For every language $L \in NP$ and every polynomial-time encoding function $E_n : \{0, 1\}^n \rightarrow \{0, 1\}^{\text{poly}(n)}$ that defines a code with relative distance ϵ , and associated decoding function D , there is a verifier V^{BFLS} that uses at most $f'(n) = O_\epsilon(\log n)$ random bits, reads at most $e(n) = (\log n)^{O_\epsilon(1)}$ bits of the input and $g'(n) = (\log n)^{O_\epsilon(1)}$ bits of the proof, and has the following properties:*

1. *If the input of the verifier is of the form $z = E(x)$ for some $x \in L$, then the verifier accepts with probability at least 1.*
2. *If V^{BFLS} accepts an input z with probability at most $\frac{1}{2}$, then z decodes to some $x \in L$.*

Assume now that the outer verifier's proof is segmented and that the verifier reads at most k segments for every r , where k is a constant. The composed prover encodes the segments (each individually) with an efficient error-correcting code E' . This will be the core of the composed proof. If we now apply the BFLS verifier of Theorem 8 as the inner verifier, then the last line of our earlier table will change to

	Original proof	Composed proof
Number of check bits	$g(n)$	$e(g(n)) + g'(g(n))$

The above composition technique was employed in [5] and in [4]. A serious effort in these articles had to be made to create segmented outer verifiers. Dinur's proof of the PCP theorem does not use the above exact composition technique, although it also uses proof composition.

2.5.4 Randomized Graph Products

Graph products amplify gaps in sizes of independent sets [47] and chromatic numbers [71]. There are many different types of graph products, but the one that will work for us here is the *inclusive graph product*.

Definition 5 (Inclusive Graph Product) Let G_1 and G_2 be graphs with vertex sets V_1 , resp., V_2 , and edge sets E_1 , resp. E_2 . We define the inclusive graph product of $G_1 \times G_2$ on the vertex set $V_1 \times V_2$ such that (x_1, x_2) is connected with (y_1, y_2) if and only if x_1 is connected with y_1 in G_1 or x_2 is connected with y_2 in G_2 .

Let $\alpha(G)$ be the maximum independent set size of G and $\omega(G)$ be the maximum clique size of G . Independent set sizes are multiplicative with respect to the inclusive graph product. For G^k , the k -wise inclusive graph product of G with itself, means

$$\begin{aligned}\alpha(G^k) &= \alpha(G)^k \\ \omega\left(\overline{G}^k\right) &= \omega(G)^k.\end{aligned}$$

To obtain the behavior of powers of G with respect to the chromatic number, we first define the fractional chromatic number of a graph:

Definition 6 (Fractional Chromatic Number) Let G be an undirected graph and I be a set of G . The indicator function X_I of I is map from $V(G)$ to the reals which assigns 1 to the elements of I and 0 to the elements of $V(G) \setminus I$. Let $Ind(G)$ be the collection of all independent sets of G . We define the fractional chromatic number of G by

$$\chi_f(G) = \min \sum_{I \in Ind(G)} \lambda_I$$

subject to

$$\lambda_I \geq 0 \text{ for all } I \in Ind(G)$$

$$\sum_{I \in Ind(G)} \lambda_I X_I \geq X_{V(G)} \text{ coordinate-wise.}$$

Clearly,

$$\chi(G) \geq \chi_f(G) \geq \max\left(\frac{V(G)}{\alpha(G)}, \omega(G)\right). \quad (2)$$

With respect to powering we have

$$\chi(G^k) \leq \chi(G)^k \quad (3)$$

$$\chi_f(G^k) = \chi_f(G)^k. \quad (4)$$

Equation (4) is observed by Lovász [72]. We wish to amplify constant gaps in the independence number and the fractional chromatic number to polynomial gaps by setting $k = c \log n$, but the size of the resulting graph becomes super-polynomial. In order to overcome this problem, Berman and Schnitger [18] developed a randomized

version of this graph product. Instead of taking G^k , they randomly, select an induced subgraph of it. Feige and Kilian [40] give the following lemma:

Lemma 5 *Vertex-induced subgraphs G' of G^k have the following properties:*

1. $\chi_f(G') \leq \chi_f^k(G)$.
2. *If $\alpha(G) \leq C$, then $\alpha(G') \leq k|V(G)|$ for nearly all subgraphs G' with $\frac{|V(G)|^k}{C^k}$ vertices.*
3. $\chi_f(G') \geq \frac{|V(G')|}{k|V(G)|}$, for all G' satisfying $\alpha(G') \leq k|V(G)|$.
4. $\alpha(G') \geq \frac{|V(G')|}{c^k}$ with high probability over a fixed sized subgraph G' , where $c = |V(G)|/\alpha(G)$.

The lemma lets us amplify the PCP theorem in a simple way to prove polynomial (n^ϵ) gap for the clique approximation problem. The reduction is randomized, however.

2.6 The Long Code

The long code was invented by Bellare, Goldreich, and Sudan [14], and it has become a standard tool to prove exact non-approximability bounds for various CSP. It is also used to prove the non-approximability of Max Clique to within a factor of $|V(G)|^{1-\epsilon}$ in [55].

Let U be an fixed finite set of so-called “labels.” The coordinates of the long code correspond to all possible functions $f : U \rightarrow \{0, 1\}$. When we encode an $\mathbf{x} \in U$, the coordinate corresponding to f takes the value $f(\mathbf{x})$:

$$\text{long}_U(\mathbf{x})_f = f(\mathbf{x}).$$

Since there are $2^{|U|}$ Boolean-valued functions on n inputs, the long code is a string of length $2^{|U|}$. Let A be a function that every $f : U \rightarrow \{0, 1\}$ associates an element $A_f \in \{0, 1\}$. Then A is a word of the long code if and only if there is an \mathbf{x} such that for every f : $A_f = f(\mathbf{x})$.

Alternatively, we can think of the long code as the composition of two encodings: first we encode $\mathbf{x} \in U$ to $\text{unary}(\mathbf{x}) \in \{0, 1\}^{|U|}$, where $\text{unary}(\mathbf{x})$ is one only at a single position, indexed with \mathbf{x} , and zero everywhere else. Then we encode $\text{unary}(\mathbf{x})$ with the *Hadamard encoding*. The latter contains all subset sums of the binary string it encodes, modulo two.

\mathbf{x}	$\text{unary}(\mathbf{x})$	Hadamard
1	0001	\rightarrow 000000011111111
2	0010	\rightarrow 0000111100001111
3	0100	\rightarrow 0011001100110011
4	1000	\rightarrow 0101010101010101

Sometimes we need a technique that is due to Bellare et. al. [14] called *folding*. If $A = \text{long}_U(\mathbf{x})$, then for every f , we have $A_{\neg f} = (\neg f)(\mathbf{x}) = \neg(f(\mathbf{x})) = \neg A_f$. Let $\mathbf{x}_0 \in U$ be a fixed (but otherwise arbitrarily chosen) element of U . For every f exactly one of $f(\mathbf{x}_0)$, $\neg f(\mathbf{x}_0)$ is zero. The folded long code long'_U is obtained by puncturing long_U , keeping only those entries of every word that belong to index f with $f(\mathbf{x}_0) = 0$. This is exactly half of all entries. We, however, think of the omitted entries that they are implicitly present, and for any f with $f(\mathbf{x}_0) = 1$, we define

$$A_f = \neg A_{\neg f}. \quad (5)$$

Unfolding of A makes sense even when A is not in long'_A , but rather an arbitrary 0–1 vector over the index set $\{f : U \rightarrow \{0, 1\} \mid f(\mathbf{x}_0) = 0\}$, if we “read” the entries that are not explicitly present by an application of Eq. (5). PCP constructs sometimes (or oftentimes) contain the folded variation.

2.6.1 Long Code Tests

Long code tests try to find out if in a prospective long code word A , there exists an \mathbf{x} such that A is close to $\text{long}_U(\mathbf{x})$, by the means of checking only a few randomly chosen entries of A . The checking procedure should have the following properties:

1. If $A = \text{long}_U(\mathbf{x})$ for some \mathbf{x} , then the test accepts with probability q ($q = 1$ or it is close to one, depending on the setting).
2. If no such \mathbf{x} is decodable from A and not even a short list of candidates, then the test accepts with probability at most p (in general, $p < q$, typically p is close to zero).

Perhaps the following arguments explain why we want to use such a wasteful encoding in our constructions:

- The long code is very efficiently testable, giving rise to efficient inner verifiers.
- From a long code word or from any word that is close to a long code word, we can efficiently decode the value that *any* Boolean-valued function takes over the encoded label.

Long code tests have either 1. perfect completeness or 2. imperfect completeness. Below we describe important examples to both ones. Our first example is a test with perfect completeness that checks long'_U and is due to Dinur [33]. In the test we

Dinur’s Folded Long Code Check [33].

1. Randomly select f_1, f_2, f_3 , conditioned on $f_1 \vee f_2 \vee f_3 = 1$. Retrieve $b_1 = A_{f_1}$, $b_2 = A_{f_2}$, $b_3 = A_{f_3}$.
2. Accept if $b_1 \vee b_2 \vee b_3 = 1$.

Remark 1 Note that for any word A of the long code, if $f_1 \vee f_2 \vee f_3 = 1$, then $A_{f_1} \vee A_{f_2} \vee A_{f_3} = 1$.

Lemma 6 *For the above checking procedure, the following holds:*

1. *If $A = \text{long}'_U(\mathbf{x})$, then A is accepted with probability 1.*
2. *If $\text{dist}(A, \text{long}'_U) > \delta$, then A is rejected with probability $\Omega(\delta)$.*

The other test is a test with imperfect completeness, and it is due to Håstad [54]. It has historical significance too: the first exact non-approximability results were obtained using this code. We also assume that the input is folded, i.e., Eq. (5) holds. Below \mathcal{F} denotes all functions of the form $f: U \rightarrow \{0, 1\}$.

Hastad's Folded Long Code Check [54]

1. Choose f_0 and f_1 from \mathcal{F} with uniform probability.
2. Choose a function $\mu \in \mathcal{F}$ by setting $\mu(\mathbf{x}) = 1$ with probability $1 - \epsilon$ and $\mu(\mathbf{x}) = 0$ otherwise, independently for every $\mathbf{x} \in U$.
3. Set $f_2 = f_0 \oplus f_1 \oplus \mu$, i.e., define f_2 for each $\mathbf{x} \in U$ by $f_2(\mathbf{x}) = f_0(\mathbf{x}) \oplus f_1(\mathbf{x}) \oplus \mu(\mathbf{x})$.
4. Accept if $A_{f_0} \oplus A_{f_1} \oplus A_{f_2} = 0$.

Lemma 7 *If A is the table of a word in the folded long code, the verifier accepts with probability at least $1 - \epsilon$. If a folded string A passes the test with probability at least $\frac{1+p}{2}$, then there is a B which is the modulo two sum of at most $\epsilon^{-1} \log 1/p$ words of the long code, and A and B agree in at least $\frac{1+p}{2}$ fraction of the $2^{|U|}$ bit positions.*

Remark 2 Notice the difference between the soundness conditions of Dinur's test and Hastad's test. If Dinur's test succeeds with high probability, \mathbf{x} is decodable from the code. In the case of Håstad, it is only list-decodable. Of course, in the case of Håstad "high probability" means $\frac{1+\text{tiny}}{2}$, while in the case of Dinur, it means $1 - \text{tiny}$. Dinur's objective was not to prove sharp results, but to prove the PCP theorem. Her long code test is part of her alphabet reduction step.

When we prove sharp results, the outer verifier plays a role too. Some generic outer verifiers, like the label cover instance of Sect. 2.5.2, lead to a variety of optimal non-approximability results, but the inner verifier is slightly more involved than the verifier of the long code alone. The inner verifier for the label cover problem needs to check two long codes at the same time together with a relation between them. We do not describe the test here, which is very similar to Håstad's long code test, and also appears in [54]. If we replace the label cover problem with the so-called unique game problem (Sect. 4), we get sharper results, but this outer verifier is not proven to be NP-hard.

2.7 Constraint Satisfaction Problems

A general CSP instance is a set

$$\Phi = \{f_i(x_{i,1}, \dots, x_{i,k})\}_{1 \leq i \leq m}$$

of k -variate functions acting on k -tuples of n variables, x_1, \dots, x_n , each ranging in a domain D . Often $D = \{0, 1\}$, but in general it can be any fixed finite set. The goal is to find an assignment to the variables such that all or in the maximization version the maximum number of f_i s is satisfied. Specific CSP have restrictions on the f_i s, namely, they have to come from a constraint family Γ , which is a subset of k -variate functions on D (in the most general setting, “ k -variate” has to be replaced with “at most k -variate”), where k is a fixed constant. CSP problems are in MAXSNP and therefore approximable within some constant factor. Here we discuss MAX k LIN, MAX k SAT and MAX k CSP. All of these problems are over the Boolean domain, i.e., $|D| = 2$.

Problem Name: MAX k LIN:

Instance: A set of linear equations over \mathbf{F}_2 , $L = \{x_{i,1} \oplus x_{i,2} \oplus x_{i,3} = c_i \mid 1 \leq i \leq m\}$ such that for $1 \leq i \leq m$, $1 \leq j \leq 3$: $x_{i,j} \in \{x_i\}_{1 \leq i \leq n}$, where x_i are variables in \mathbf{F}_2 and c_i ($1 \leq m$) are constants in \mathbf{F}_2 .

Witness: An assignment to the variables x_i ($1 \leq i \leq n$).

Objective: Maximize the number of equations set true in L .

Obviously, a random replacement on expectation satisfies half of the constraints. On the other hand, Håstad constructs a PCP reduction [55] which shows as follows:

Theorem 9 ([55]) *For any $\epsilon > 0$, $k \geq 3$ it is hard to approximate MAX k LIN to within a factor of $2 - \epsilon$.*

Håstad’s reduction [54] briefly works as follows: The label cover problem from Sect. 2.5.2 is the outer verifier (one may view it as a starting point of the reduction). A random string of the outer verifier leads to checking an edge (x, y) of the label cover instance for the relation $\pi_{xy}(l(x)) = l(y)$, where $l(x)$ and $l(y)$ are the labels assigned to these nodes. The compound prover encodes each label with the folded long code (with $long'_{\Sigma_1}$ or with $long'_{\Sigma_2}$ depending on the node), and upon the outer verifier picking edge (x, y) , the inner verifier checks the long codes associated with *both* nodes and *also* if the desired relation holds between the labels that these long codes encode. This seems like a lot of checking, but Håstad does the checking very economically, only with three query bits. It becomes important that π_{xy} is a projection. The verification process is very similar to the long code test of Håstad in Sect. 2.6, with a little extra twist, which we do not describe here. The composed verifier accepts with probability $1 - p$ for positive inputs and with probability at least $\frac{1-p}{2}$ for negative inputs, where p can be made arbitrarily small. Moreover, each checking criterion is a linear equation over \mathbf{F}_2 involving three variables. Theorem 9 follows.

Problem Name: MAX k SAT:

Instance: A set of disjuncts $\Phi = \{(t_{i,1} \vee t_{i,2} \vee t_{i,3}) \mid 1 \leq i \leq m\}$ such that for $1 \leq i \leq m$, $1 \leq j \leq 3$ $t_{i,j} \in \{x_1, \bar{x}_1, \dots, x_n, \bar{x}_n\}$, where x_i ($1 \leq i \leq n$) are Boolean variables.

Witness: A Boolean assignment to the variables x_i ($1 \leq i \leq n$).

Objective: Maximize the number of disjuncts set true in Φ .

Johnson [56] in 1974 showed that the MAX k SAT is approximable to within a factor of $\frac{1}{1-2^{-k}}$ in polynomial time as long as each clause contains exactly k literals. Trevisan, Sorkin, Sudan, and Williamson [95] show that MAX3SAT is approximable within 1.249 without any restriction, and Karloff and Zwick [57] show that it is approximable within a factor of 8/7 for satisfiable instances. Here we prove the non-approximability of MAX3SAT.

Theorem 10 ([55]) *For any $\epsilon > 0$, it is hard to approximate MAX3SAT to within a factor of $8/7 - \epsilon$.*

Proof We reduce the problem to the non-approximability of MAX3LIN. Let L be an instance of MAX3LIN such that either at least $1 - \epsilon_1$ fraction of its equations are satisfied or at most $1/2 + \epsilon_2/2$ fraction of its equations are satisfied. We replace every equation $x \oplus y \oplus z$ of L with a set of four clauses $(x \wedge y \wedge \bar{z})$, $(x \wedge \bar{y} \wedge z)$, $(\bar{x} \wedge y \wedge z)$, and $(\bar{x} \wedge \bar{y} \wedge \bar{z})$. An assignment that satisfies the linear equation satisfies all the clauses, while an assignment that does not satisfies the linear equation satisfies three of the four clauses. The MAX3SAT instance Φ we construct for L is the multiset union of these replacements. It is easy to see that either $1 - \epsilon_1$ fraction of the clauses of Φ are satisfied or at most $7/8(1 + \epsilon_2)$ fraction. \square

Håstad has proven the more general statement that MAX k SAT is not approximable within $\frac{1}{1-2^{-k}} - \epsilon$ for any k and $\epsilon > 0$, even if every clause consists of exactly k literals.

Theorem 10 is proven via a specific *gadget reduction*, i.e., where each constraint of a CSP is replaced with a set of constraints from another CSP, called *gadget*. These in general may contain auxiliary variables. Trevisan, Sorkin, Sudan, and Williamson [97] use linear programs to systematically construct gadgets that give optimal gap-CSPs starting from gap-E3LIN2. For a large class of CSPs, they prove that optimal gadgets exist. They arrive at these gadgets via linear programming.

Problem Name: MAX k CSP:

Instance: A set $S = \{f_i \mid 1 \leq i \leq n\}$ of Boolean expressions (constraints), each depending on at most k of the Boolean variables x_i $1 \leq i \leq k$.

Witness: A Boolean assignment to the variables x_i ($1 \leq i \leq n$).

Objective: Maximize the number of expressions set true in S .

The best known algorithm for the MAX k CSP problem has an approximation ratio 2^{k-1} [94]. Samorodnitsky and Trevisan [89] showed that for any $\delta > 0$ and any NP-complete language L , there is a PCP with amortized query complexity $1 + \delta$ (!). Their proof leads to the following:

Theorem 11 ([89]) *For every k the MAX k CSP problem is NP-hard to approximate to within $2^{k-O(\sqrt{k})}$.*

2.8 The Max Clique

Instance: Undirected graph $G = (V, E)$.

Witness: A clique $C \subseteq V$ in G : $(x, y \in C) \wedge (x \neq y) \rightarrow (x, y) \in E(G)$

Objective: $\omega(G) = \max\{|C| : C \text{ is a clique in } G\}$.

Boppana and Halldórsson [20] in 1992 proved that the maximum clique problem can be approximated within a factor of $O(|V|/(\log |V|)^2)$. The hope for a big improvement faded away as non-approximability results arose. Feige, Goldwasser, Lovász, Safra and Szegedy [38] in 1991 made the following connection between clique approximation and proof checking:

Theorem 12 (FGLSS) *Let $NP \subseteq PCP_{q,p}(f, g)$. Then if MaxClique of a graph of size $h(n) = 2^{f(n)+g(n)}$ can be approximated within a factor better than $q(n)/p(n)$ in time polynomial in $h(n)$, then $NP \subseteq DTIME(poly(h(n)))$.*

Proof Let L be an NP -complete language. Let $V(r, P, x)$ be a probabilistic verifier that recognizes L using $f(n)$ query bits, and $g(n)$ random bits, and which accepts for at least $q(n)2^{f(n)}$ choices of r for some P , if $x \in L$ and accepts for at most $p(n)2^{f(n)}$ choices of r for every P , if $x \notin L$.

Consider the FGLSS graph $G_V(x)$ defined in Sect. 2.2. Conditions 1–3 of Lemma 3 imply the theorem, since if we could approximate the Max Clique of $G_V(x)$ within a factor better than $q(n)/p(n)$ in time $poly(h(n))$, then we would be able to use this algorithm to tell whether $x \in L$ or not. \square

Let $f(n) = \log n \log \log n$. Feige et al. show that $NP \subseteq PCP_{1,1/2}(f, f)$. This argument used the scaled-down version of the two-prover interactive protocol by Babai Fortnow and Lund [11] and provided the first rudimentary PCP construction. If we apply $\log^k n$ independent naive repetitions on the above verifier (see Sect. 2.5.1) we obtain

$$NP \subseteq PCP_{1,1/2^{\log^k n}}(f(n) \log^k n, f(n) \log^k n).$$

By Theorem 12 this implies that for every fixed $\epsilon > 0$, Max Clique cannot be approximated within a factor of $2^{\log^{1-\epsilon}|V|}$ unless NP has quasi-polynomial-time algorithms.

The next important step was made by Arora and Safra [5] who showed the NP -hardness of Max Clique up to an approximation factor $2^{\sqrt{\log|V|}}$. This result was the first to show the non-approximability of Max Clique under the natural $P \neq NP$ assumption and provided the first PCP that characterized NP .

Arora, Lund, Motwani, Sudan, and Szegedy [4] proved that $NP = PCP_{1,1/2}(\log n, O(1))$ (see Theorem 1). An amplification method [25] based on the “expander walk” technique of Ajtai, Komlós, and Szemerédi [1] yields that $NP = PCP_{1,1/n}(\log n, \log n)$. Then Theorem 12 gives that there is an ϵ that it is NP -hard to approximate MaxClique up to a factor of $|V|^\epsilon$. Alon, Feige,

Wigderson, and Zuckerman [3] showed how to obtain the same result starting with FGLSS graph constructed from [Theorem 1](#) by derandomizing the graph product of Berman and Schnitger [18].

The constant ϵ was made explicit by Bellare, Goldwasser, Lund, and Russel [15]. They also slightly improved on the proof methods of [4] and coupled it with a new amplification technique of [18, 98] to show that Max Clique is hard to approximate within a factor of $|V|^{1/25}$ unless NP is contained in $co-R\tilde{P}$. Here \tilde{P} stands for the quasi-polynomial time.

Notice that in the last result the hardness condition is different than before, because it involves the randomized class, $co-R\tilde{P}$. BGLR replace the condition $NP \subseteq PCP_{q(n), p(n)}(f(n), g(n))$ of [Theorem 12](#) with $NP \leq_R PCP_{q(n), p(n)}(f(n), g(n))$, where \leq_R stands for “randomly reducible.” Although this weakens the hardness condition, it allows better amplification methods and thus better parameters.

Feige and Kilian [39] have observed that [Theorem 12](#) can be replaced with the following lemma (for the definitions see [Sect. 2.4](#)):

Lemma 8 [39] *Let $NP \subseteq FPCP_{q,p}(f, \text{free})$. Then if Max Clique of a graph of size $h(n) = 2^{f(n)+\text{free}(n)}$ can be approximated within a factor better than $q(n)/p(n)$ in time polynomial in $h(n)$, then $NP \subseteq \text{DTIME}(\text{poly}(h(n)))$.*

From the above lemma they showed that Max Clique cannot be approximated to within a factor of $|V|^{1/15-\epsilon}$ unless $NP = coRP$. Bellare and Sudan in [16] introduced the amortized free bit complexity, $\overline{\text{free}}$ (see [Sect. 2.4](#)), and notice that the best available amplification techniques give that

Lemma 9 *If there is a PCP which uses $O(\log n)$ randomness and has amortized free bit complexity $\overline{\text{free}}$, then Max Clique cannot be approximated within a factor better than $n^{\frac{1}{1+\overline{\text{free}}}}$ unless $NP \subseteq coR\tilde{P}$.*

They prove that Max Clique cannot be approximated to within a factor better than $|V|^{1/4}$ unless $NP \subseteq coR\tilde{P}$. The next major step was made by Bellare, Goldreich, and Sudan [14], who discovered the long code (see [Sect. 2.6](#)), and building it into their PCP immediately could reduce the free bit complexity. They prove the non-approximability of Max Clique to within a factor better than $|V|^{1/3}$ unless $NP \subseteq coRP$.

Although the constant in the exponent gradually improved, it seemed that theoretical limitations bar the improvement of the non-approximability exponent beyond $1/2$. It has turned out that the limitations could be overcome by dropping the perfect completeness property of the PCP. Relying on a new test for the long code of Bellare et. al., Håstad was able to show the following:

Theorem 13 [54] *Max Clique cannot be approximated to within a factor of $|V|^{1-\epsilon}$ for any $\epsilon > 0$ unless $NP \subseteq ZPP$.*

Fig. 4 A summary table on the history of clique non-approximability

In the proof of this theorem, Håstad uses the same probabilistically checkable proof construction as he does for CSP, but the verifier works differently, and the analysis is different. He is able to achieve amortized free bit complexity ϵ for any $\epsilon > 0$.

Sudan and Trevisan [91] and Samorodnitsky and Trevisan [89] simplified the involved analysis of Håstad and constructed a PCP which has the additional benefit of having amortized query bit complexity $1 + \epsilon$. Building on [91] and [89] Lars Engebretsen and Jonas Holmerin [36] showed that unless $NP \subseteq ZPTIME(2^{O(\log n(\log \log n)^{3/2})})$, Max Clique cannot be approximated to within a factor of $|V|^{1-O(\sqrt{\log \log n})}$. Under the same assumption, Khot [60] was able to increase the non-approximability ratio to $|V|/2^{\log^{1-\epsilon}|V|}$. Using new construction of dispersers, Zuckerman de-randomized the PCP constructions of Håstad and Khot [99]. Fig. 4 summarizes developments on the Clique non-approximation problem.

2.9 The Chromatic Number

Instance: Undirected graph $G = (V, E)$.

Witness: An integer k and a k -coloring F of $V(G)$ with the property that $F : V(G) \rightarrow [1, k]$ and for every $(a, b) \in E(G) : F(a) \neq F(b)$.

Objective: $\chi(G) = \min k$ such that a k -coloring F of $V(G)$ exists.

The best-known lower bound for approximating the chromatic number was obtained by Halldórsson in 1993 [52]. Given a graph G on n nodes, he finds a coloring of G in polynomial time with at most

$$\chi(G) \times O\left(n \frac{(\log \log n)^2}{\log^3 n}\right)$$

colors. From the other direction, an early result of Garey and Johnson [46] shows that $\chi(G)$ is NP-hard to approximate to within any constant less than 2. In 1992 Lund and Yannakakis found a reduction from approximating the Max Clique of the FGLSS graph of the ALMSS verifier to the problem of approximating the chromatic number.

Theorem 14 (Lund and Yannakakis [74]) *There is an ϵ such that it is NP-hard to approximate $\chi(G)$ within a factor of $|V(G)|^\epsilon$.*

The proof of Lund and Yannakakis works in three steps:

1. Construct the FGLSS graph $G_V(x)$ for the ALMSS verifier V of an NP-complete language L . Observe that $\overline{G}_V(x)$ has bounded degree and:
 - a. If $x \in L$ then $\alpha(\overline{G}_V(x)) = R$ (for some $R = n^\epsilon$).
 - b. If $x \notin L$ then $\alpha(\overline{G}_V(x)) \leq R(1 - \epsilon)$.
2. Use the randomized graph products of Berman and Schnitger [18] and Blum [19] to obtain a graph G_1 from $\overline{G}_V(x)$, which has maximum independence number n^{ϵ_1} for positive instances and maximum independence number n^{ϵ_2} for negative instances, for some $\epsilon_1 > \epsilon_2 > 0$.
3. Apply another transformation which turns G_1 into a graph G_2 such that $\chi(G_2) \geq n^{\epsilon_3}$ for positive instances and $\chi(G_2) \leq n^{\epsilon_4}$ for negative instances, for some $\epsilon_3 > \epsilon_4 > 0$.

Improving upon this result and its subsequent sharpening [16, 58], Fürer [44] gives a randomized reduction which shows that if $\omega(G)$ cannot be approximated to within $|V(G)|^{\frac{1}{free+1}}$, then $\chi(G)$ cannot be approximated to within $|V(G)|^\delta$, where $\delta = \min\left(\frac{1}{2}, \frac{1}{2free+1}\right) - o(1)$. His reduction assumes the FGLSS graph structure. Feige and Kilian [40] have taken a different route and building on the Max Clique result of Håstad [54] show:

Theorem 15 [40] *Unless $NP \subseteq ZPP$, it is hard to approximate $\chi(G)$ to within $|V(G)|^{1-\epsilon}$ for any constant $\epsilon > 0$. Here ZPP denotes the class of languages that are*

solvable with a randomized algorithm that makes no error and on expectation runs in polynomial time.

The proof of this theorem gives more, namely, that it is NP-hard (under randomized reductions) to distinguish between graphs with $\alpha(G) \leq |V(G)|^\epsilon$ and graphs with $\chi(G) \leq |V(G)|^\epsilon$. To understand their proof scheme, we need to introduce a new parameter for a PCP which requires the notion of fractional chromatic number of Sect. 2.5.4 (Definition 6).

Definition 7 (Covering Parameter) The covering parameter of a PCP with verifier V is

$$\rho = \min_{x \in L} \frac{1}{\chi_f(\overline{G}_V(x))}. \quad (6)$$

Here $G_V(x)$ is the FGLSS graph for V and x (see Definition 4).

Since for every graph G we have $\chi_f(G) \geq \omega(G)$, the covering parameter of a PCP for input x is at most $2^{-\text{free}(|x|)}$. The notion of covering parameter first appears in [40] in the context of RPCPs. RPCPs are PCPs such that for every $x \in L$, there is a probability distribution (possibly different for different inputs) on all the proofs. For a fixed $x \in L$, this distribution gives rise to a probability distribution on $\text{Ind}(\overline{G}_V(x))$, which in turn can be used to give a lower bound on the covering parameter of the PCP. This lower bound is what Feige and Kilian call the covering parameter of the RPCP. Whether we talk about RPCPs or immediately define the covering parameter of a PCP is a matter of taste. RPCPs were introduced because their definition suggests an elegant connection to zero knowledge proof systems.

Feige and Kilian do their crucial transformation directly on the FGLSS graph of the PCP theorem, and *then* they amplify it with the randomized graph product. This is the reverse of how Lund and Yannakakis do it. Here is what Feige and Kilian rely on.

Assume that for an NP-complete language L , there is a polynomial-time transformation that sends a word x into a graph $G(x)$ such that for some constants $0 < c_2 < c_1 < 1$:

$$\text{If } x \in L \text{ then } \chi_f(G(x)) \leq 1/c_1. \quad (7)$$

$$\text{If } x \notin L \text{ then } \alpha(G(x)) \leq c_2|V(G(x))|. \quad (8)$$

Then, if we apply the randomized graph product construction of [18] on $G(x)$ with $k = c_3 \log_{c_2^{-1}} |V(G(x))|$, where $c_3 > 1$ is a constant, and select a random subgraph G' of G^k with size c_2^{-k} , then from Lemma 5 of Sect. 2.5.4,

$$\chi_f(G') \leq |V(G')|^{\frac{\log c_1}{\log c_2}} \quad \text{if } x \in L, \quad (9)$$

$$\alpha(G') \leq |V(G')|^\epsilon \quad \text{if } x \notin L, \quad (10)$$

where ϵ can be made arbitrarily small if c_3 is large enough. We immediately obtain the following:

Lemma 10 *Assume that for an NP-complete language L there is a polynomial-time transformation that sends a word x into a graph $G(x)$ such that for some constants $0 < c_2 < c_1 < 1$ conditions (7) and (8) hold. Then for every $\epsilon > 0$, we can construct a graph G' in randomized polynomial time such that*

$$\chi(G') \leq |V(G')|^{\frac{\log c_1}{\log c_2} + \epsilon} \text{ if } x \in L, \quad (11)$$

$$\chi(G') \geq |V(G')|^{1-\epsilon} \text{ if } x \notin L. \quad (12)$$

Indeed the Inequality (11) follows from Inequality (10) and Inequality (12) is implied by Inequality (9) and by the following result of Lovász [72]:

$$\chi(G) \leq \chi_f(G) \log(1 + \alpha(G)). \quad (13)$$

If we combine Lemma 10 with Definition 7 of the covering parameter, we obtain the following:

Lemma 11 *Suppose that one can generate a PCP for NP with $f(n)$ random bits, soundness probability $p = p(n)$, average free bit complexity $f_{av} = free_{av}(n)$, and $\rho = \rho(n)$. Assume that p , f_{av} , and ρ are constants and that the size of the FGSSS graph, $2^{f(n)+f_{av}}$, is polynomially bounded as n grows to infinity. Then it is hard to approximate $\chi(G)$ to within $|V(G)|^{\frac{f_{av}-\log \rho + \log \rho}{f_{av}-\log p} - \epsilon}$, where ϵ is an arbitrarily small positive constant, assuming $NP \not\subseteq ZPP$.*

Starting from the construction of Håstad [55], Feige and Kilian show the existence of PCPs for an NP-complete problem such that $\log \rho/(f_{av} - \log p)$ is arbitrarily small. Theorem 15 is implied now by Lemma 11.

We can also use Lemma 10 to derive the Lund Yannakakis result from the non-approximability result from the MAXSNP-hardness of the MAX-3-coloring problem proved by Petrank [82]. This example was given by Feige and Kilian, and it is so easy that we can give their entire proof here:

Proof (Theorem 14) Let H be the graph of Petrank's construction such that it has m edges and either it has a valid three-coloring or every three-coloring of its vertices miscolor at least qm edges, where $q > 0$ is some fixed constant. From H we construct a graph G , which has $6m$ vertices of the form (e, c) , where e ranges over the m edges of H and c ranges over the 6 valid 3-colorings of the two endpoints of an edge. Two vertices (e_1, c_1) and (e_2, c_2) are connected by an edge if e_1 and e_2 intersect at a vertex of H and c_1 and c_2 disagree on the coloring of this vertex. A valid 3-coloring C of H induces an independent set of size m in G . Let π be a permutation of the three colors. As π ranges over its 6 possibilities,

the composition of C with π induces 6 independent sets in G of size m . Furthermore, these independent sets are disjoint and cover $V(G)$. Hence, G has a chromatic number of 6. If H is not 3-colorable (and hence qm of its edges are miscolored) then the largest independent set of G is of size at most $m(1 - q)$. If we apply Lemma 10 for G with $c_1 = 1/6$, $c_2 = (1 - q)/6$, we get Theorem 14. \square

The above non-approximability of $\chi(G)$ was derandomized by Zuckerman [99] to get the same non-approximability ratio conditioned on $P \neq NP$.

Finally we mention another type of non-approximability result for $\chi(G)$. S. Khanna, N. Linial, and S. Safra [58] have shown that it is NP-hard to tell apart 3-chromatic graphs from 5 chromatic graphs. But the following question is open and would be very interesting to resolve:

Problem 1 Prove that for any fixed $k > 5$, it is NP -hard to tell apart a k -chromatic graph from a three-chromatic graph.

Remark 3 Recently, Dinur, Mossel, and Regev have shown [35]: For any two fixed integers $Q > q > 2$, it is hard to decide whether for an input graph G we have $\chi(G) \leq q$ or $\chi(G) \geq Q$. The hardness is under the 2-1 conjecture, if $q \geq 4$, and under a similar, but slightly more complicated “fish shaped” variant of this conjecture, if $q = 3$ (see the definition of 2-1 conjecture in Sect. 4).

2.10 Set Cover

Instance: A collection $F = \{S_1, \dots, S_s\}$ of subsets of $S = \{1, \dots, n\}$.

Witness: A subcollection F' of F such that $\cup_{S_i \in F'} S_i = S$.

Objective: $v(F) = \min |F'|$.

In 1974 D. Johnson [56] showed that the greedy algorithm finds a collection F' for the problem such that $|F'|$ is to within $\log n$ factor optimal (here the \log is based on $e = 2.71\dots$). Chvatal [24] extended this algorithm to the weighted version, and Lovász [72] has studied a linear programming relaxation with logarithmic (in terms of the hypergraph degree) integrality gap.

The first hardness result is that of Lund and Yannakakis [74]. They show using a construction coming from the PCP theory that set cover cannot be approximated to within a factor of $\frac{\log n}{4}$ unless $NP \subseteq TIME(n^{\text{polylog} n})$ and within a factor of $\frac{\log n}{2}$ unless $NP \subseteq ZTIME(n^{\text{polylog} n})$. Here $ZTIME(t)$ denotes the class of problems for which there is a probabilistic algorithm that makes no error and runs in expected time t .

Subsequent works went in two different directions. The best results up to date that represent these directions are that of Feige [37] which proves that set cover cannot be approximated efficiently to within a factor of $(1 - o(1)) \log n$ unless $NP \subseteq TIME(n^{O(\log \log n)})$ and that of Raz and Safra [87] which proves that set cover is NP-hard to approximate within a factor of $\epsilon \log n$ for some fixed $\epsilon > 0$. Until now

there is no result which would achieve both optimal non-approximability ratio and hardness condition $P \neq NP$.

A predecessor of [37] was the result of Bellare et.al. [15], which proved that the set cover cannot be approximated within any constant ratio unless $P = NP$ and that it cannot be approximated within a factor of $\frac{\log n}{4}$ unless $NP \subseteq \text{TIME}(n^{O(\log \log n)})$. Arora and Sudan [6] followup on [87] and achieve the same bound using elegant and difficult algebraic techniques such as Hilbert's Nullstellensatz.

We cannot give here the technically very involved result of Raz and Safra, but we present a complete proof of Feige's result. The proof is a modification of a simplified argument due to Håstad (A Rewriting of Feige's Proof for the Setcover, Unpublished). At many places we use his original wording. We ought to remark that simplification is formal to a large extent: the key components of the proof are the same as those in [37].

Theorem 16 [37] *The set cover cannot be approximated efficiently to within a factor of $(1 - o(1)) \log n$ unless $NP \subseteq \text{TIME}(n^{O(\log \log n)})$. The logarithm is $e = 2.71\dots$ based.*

Proof A partition system $B(m, p, k, d)$ [37] is a system of p partitions, $(p_i)_{i=1}^p$, on a basis set B with $|B| = m$ such that:

1. Each p_i ($1 \leq i \leq p$) consists of k parts. The parts of p_i are denoted $p_{i,j}$ ($1 \leq j \leq k$).
2. No collection $(p_{i_l, j_l})_{l=1}^d$ of d partition segments with all i_l distinct covers the universe.

In other words if we only use sets from different partitions to cover, we need at least d sets, while a small cover is given by the k sets of one p_i . \square

Lemma 12 (Feige [37]) *For any $c > 0$, there exists a $B(m, p, k, d)$ partition system with $p \leq (\log m)^c$, k an arbitrary constant, and $d = (1 - f(k))k \ln m$, where $f(k)$ tends to 0 when k tends to infinity and m is large enough compared to k and c .*

Feige shows that a random partition system satisfies Properties 1–2 with high probability. Since $d = O(\log m)$, we can quickly check if the Properties 1–2 hold. Deterministic constructions are also known. Next we describe the PCP reduction to the set-cover problem.

Our starting point is the probabilistic verifier V_{3SAT}^ℓ of Lemma 4 in Sect. 2.5.2 for an NP-complete language L with the choice of $\ell = c_0 \log \log n$, where we shall choose $c_0 > 0$ to be large enough. Recall that this verifier is associated with a gap-3SAT instance ϕ_x with N Boolean variables. Note that $|x| = n$ is in polynomial relationship with N . On the other hand, the instance of set cover we construct will have slightly super-polynomial size in n .

The verifier sends a subset U of variables with $|U| = \ell$ to the first prover who answers with an assignment σ_U to these variables. Independently, he sends a W companion of U to the second prover, i.e., a set of ℓ clauses containing these

variables. The second prover answers with the evaluation of the 3ℓ variables in W . The verifier rejects if not all clauses are satisfied in W or if σ_U is not equal to the projection $\pi_U(\sigma_W)$, i.e., the assignment that σ_W gives to U . What is important for our purposes is that if $x \notin L$, the verifier accepts with probability at most c_1^ℓ for some fixed $0 < c_1 < 1$. The structure of ϕ_x determines all companion pairs U, W and all the projections π_U , and we can compute these in $DTIME(n^{O(\ell)})$ from x . From now on, when we talk about a U, W pair, we always mean a pair, where W is a companion of U .

Let $k > 0$ be a constant such that $f(k)$ of Lemma 12 is less than ϵ . For each U and each k -tuple $W_1, W_2 \dots W_k = \vec{W}$ of possible W companions of this U , we construct a separate partition system on a new set of m points. We have N^ℓ different U and, given the choice of U , each W_i can be chosen in 5^ℓ ways. We thus have $R = N^\ell 5^{k\ell}$ partition systems, and with the choice of $m = R^{\frac{1}{\epsilon}}$, the total size of the universe is $R^{1+\frac{1}{\epsilon}} = m^{1+\epsilon}$. We set the further parameters of the partition systems as $p = 2^\ell, k$, and $d = (1-f(k))k \ln m$. Since $p = 2^{c_0 \log \log n} = (\log n)^{c_0}$ and $\log m > \log n$, the conditions of Feige's lemma hold, and the existence of such partition systems is guaranteed. Notice that $m = n^{O(\log \log n)}$ for a fixed ϵ . A particular set in one of the partition systems has an index given by $U, \vec{W}, \alpha \in \{0, 1\}^\ell$ and $i \in [k]$, and we denote it by $S_{U, \vec{W}, \alpha, i}$.

The sets in our set-cover instance are indexed by W and β where $\beta \in \{0, 1\}^W$ should be thought of as an answer from the second prover on the question W . We denote it by $T_{W, \beta}$ and it is a union of $S_{U, \vec{W}, \alpha, i}$ which satisfy

$$(W_i = W) \wedge (\pi_U(\beta) = \alpha),$$

where we of course assume that β satisfies the clauses used to construct W .

Let $Q = (5N/3)^\ell$ be the number of different W . We first have the simple lemma telling us what happens when $x \in L$.

Lemma 13 *If $x \in L$, the associated set system has a cover of size Q .*

Proof We cover the universe with $\{T_{W, \sigma_W}\}_W$, where σ_W is the answer of the second prover to question W . Since the answers are consistent with those of the first prover, for each U and \vec{W} , there is some σ_U so that the chosen sets contain $S_{U, \vec{W}, \sigma_U, i}$ for all i . This σ_U is simply the answer of the first prover to question U . By definition, the system $\{S_{U, \vec{W}, \sigma_U, i}\}_{1 \leq i \leq k}$ covers the m points of the associated U, \vec{W} pair. \square

Thus, we just need to prove the lemma below (and choose c_0).

Lemma 14 *If $x \notin L$, the associated set system has a no cover of size $dQ / (k(1 + \epsilon))$.*

Proof Suppose we have a cover of size rQ . For each W there is a set A_W of assignments β on W such that $T_{W, \beta}$ belong to the cover. By assumption

$$\sum_W |A_W| = rQ. \quad (14)$$

We note that none of the A_W is empty since we need to cover the partition systems with $W_i = W$ for all i . Let us call a W *good* if $|A_W| \leq r(1 + \epsilon)$. We claim that for appropriate choice of c_0 either $r > \log m$ or there is U, \vec{W} such that

1. $\pi_U(A_{W_i})$ ($1 \leq i \leq k$) are pairwise disjoint.
2. W_i ($1 \leq i \leq k$) are good.

Let us recall a simple lemma in set theory:

Lemma 15 *Let A_1, \dots, A_q be sets of size at most s with the property that no k of them are pairwise disjoint. Then there is an element which is contained in at least $\frac{1}{(k-1)s}$ fraction of the sets.*

Proof Without loss of generality we may assume that A_1, \dots, A_l are pairwise disjoint, but for all $j > l$, the set A_j intersects $A = \cup_{i=1}^l A_i$. Note that by our assumption $l \leq k - 1$; hence, $|A| \leq (k - 1)s$. Since every A_i intersects A , there must be an element of A which is contained at least $\frac{1}{(k-1)s} \leq \frac{1}{|A|}$ of the sets. \square

Let

$$S_U = \{\pi_U(A_W) \mid W \text{ is a companion of } U, \text{ and } W \text{ is good}\}$$

be a set system on the assignments for U , and let σ_U be an assignment which is contained in as large fraction of elements of S_U as possible (If S_U is empty then σ_U is arbitrary). Consider the strategy of the two provers when to question U the first prover answers σ_U , and to question W the second prover answers with a random $\sigma_W \in A_W$. (So the strategy of the second prover is randomized. An averaging argument shows that there is an equally good deterministic strategy.)

If for a fixed U , there is no \vec{W} such that both Conditions 1 and 2 hold, then among the good companions of U , there are no W_1, \dots, W_k such that $\pi_U(A_{W_i})$ ($1 \leq i \leq k$) are pairwise disjoint. By applying Lemma 15 to S_U , we obtain that there is an assignment to U which occurs in at least $\frac{1}{(k-1)r(1+\epsilon)}$ fraction of the sets in S_U , and if fact σ_U is such. In what follows we assume that Conditions 1 and 2 do not hold for any U, \vec{W} .

By Eq. (14) the expected value of $|A_W|$ for a random W is r , so for at least $1 - (1 + \epsilon)^{-1}$ fraction of W s, we have $|A_W| \leq r(1 + \epsilon)$. The verifier chooses such a W with probability at least $1 - (1 + \epsilon)^{-1}$. Conditioned on the intersection of this event (i.e., that W is good) and the event that the verifier picks some fixed U , by our earlier remark, the verifier chooses a W such that $\pi_U(A_W)$ contains σ_U with probability at least $\frac{1}{(k-1)r(1+\epsilon)}$. Hence, the probability of the event that the verifier picks a U, W pair such that W is good and $\sigma_U \in \pi_U(A_W)$ is at least

$$\frac{1 - (1 + \epsilon)^{-1}}{(k - 1)r(1 + \epsilon)}. \quad (15)$$

In the case of this event, there is a $\frac{1}{|A_W|} \geq \frac{1}{r(1+\epsilon)}$ chance over $\sigma_W \in A_W$ that $\pi_U(\sigma_W) = \sigma_U$. Combining this with (15), we get that V_{3SAT}^ℓ accepts the described strategy of the two provers with probability at least

$$\frac{1 - (1 + \epsilon)^{-1}}{(k - 1)r(1 + \epsilon)} \frac{1}{r(1 + \epsilon)} = \Omega(r^{-2}). \quad (16)$$

Either $r > \log m$ or since $\log m = O(c_0 \log n \log \log n)$, we can choose a large enough c_0 that depends on ϵ, k, c_1 , and $\log_n N = O(1)$, such that $2^{-c_1 \ell} = 2^{-c_1 c_0 \log \log n}$ becomes smaller than Expression (16), and we arrive at a contradiction.

It follows from the contradiction that there exist an U and \vec{W} such that Conditions 1 and 2 hold. Fix this choice of U and \vec{W} and consider how the elements from the corresponding partition system are covered. Since $|W_i| \leq r(1 + \epsilon)$ for $1 \leq i \leq k$, the cover system has at most $kr(1 + \epsilon)$ sets. By the disjointness of $\pi_U(A_{W_i})$ s, these sets all come from distinct partitions. Using the property of the cover system, we conclude that $kr(1 + \epsilon) > d$.

In the case $r > \log m$, since we have $d \leq (1 - f(k))kr$, we conclude the same. We are done, since the cover size $|rQ| > dQ/k(1 + \epsilon)$, as claimed. \square

Since the universe for the set-cover instance has total size $t = m^{1+\frac{1}{\epsilon}}$, we get that the quotient of the minimum cover sizes when $x \notin L$ versus when $x \in L$ is

$$\frac{1 - f(k)}{1 + \epsilon} \log m = \frac{1 - f(k)}{(1 + \epsilon)^2} \log t,$$

which tends to $\log t$ when $k \rightarrow \infty$ and $\epsilon \rightarrow 0$.

2.11 Some More Non-approximability Results

The label cover problem from Sect. 2.5.2 and its variants have served as the starting point for several known optimal non-approximability results assuming $P \neq NP$. The table below describes some further known approximation hardness results based on the NP -hardness of the label cover. Let γ_p be the p^{th} moment of the Gaussian random variable with expectation 0 and variance 1.

Problem	Known approx.	Inapprox.	Ref.
Max Cut	≈ 1.1389 .	$\frac{17}{16} - \epsilon$	[48, 55]
L_p Groth. Problem	γ_p^2	$\gamma_p^2 - \epsilon$	[51, 67]
L_p Subspace approx.	γ_p	$\gamma_p - \epsilon$	[32, 51]

The L_p Grothendieck problem is a maximization problem where the input is a symmetric $n \times n$ matrix $A = (a_{ij})$ with zero diagonal entries. The objective

is to maximize the quadratic multilinear function $\sum_{i,j \in [n]} a_{ij} x_i x_j$ subject to $\sum_{i=1}^n |x_i|^p \leq 1$ for $x_i \in \mathbb{R}$. The L_p subspace approximation problem is a generalization of the well-known *least squares regression* problem. The input to the problem is a set of m points a_1, \dots, a_m in \mathbb{R}^n . The objective of the problem is to find a k -dimensional subspace H such that $\sum_{i=1}^m dist(H, a_i)^p$ is minimized. Here $dist(H, a_i)$ is the ℓ_2 distance from a_i to H . The non-approximability results for the L_p Grothendieck problem and subspace approximation problem are from a recent manuscript by Guruvanam, Raghavendra, Saket, and Wu [51] who use a stronger, *smooth* variant of the label cover from [42].

3 A Short Proof of the PCP Theorem

Before [33] and [34], several different proofs have been made for the PCP theorem, but their rough structure did not differ much. In 2005, Dinur published a combinatorial proof for the PCP theorem. One feature of Dinur's proof is that it can be fully explained without mentioning PCPs and talking only about gap-CSPs. The only hint to the old PCP ideas is the use of the long code.

Definition 8 An instance of a $[k, \Sigma]$ CSP problem, where Σ is a constant size alphabet, consists of a set x_1, \dots, x_n of variables that take their values from Σ and a set of m constraints, where each constraint is a k -ary relation for a subset of k variables. The instance is satisfiable if there is an assignment to the variables which satisfies all constraints. We identify $[k, \Sigma]$ CSP with the language of satisfiable instances.

The gap version of the problem is analogous to the gap- k -SAT problem:

Definition 9 $Gap([k, \Sigma]CSP, p, q)$ for $0 \leq p < q \leq 1$ is the problem, where we output 1 on $[k, \Sigma]$ CSP instances, that have an assignment satisfying at least q fraction of the constraints and 0 on those instances with no assignment satisfying more than p fraction of the constraints. On any other instances the output is arbitrary.

Fact 1 Every PCP for a language L , with completeness q , soundness p , query size $k = O(1)$, and witness-alphabet Σ can be interpreted as a Karp reduction from L to $Gap([k, \Sigma]CSP, p, q)$ and vice-versa.

Proof Recall that a Karp reduction from a language $L \subseteq \Sigma^*$ to the gap version of a maximization problem OPT , with lower and upper thresholds p, q , respectively, is a polynomial-time computable function f from Σ^* to instances of OPT such that:

1. If $x \in L$, then $OPT(f(x)) \geq q$
2. If $x \notin L$, then $OPT(f(x)) \leq p$.

Let now $V(x, P, r)$ be the verifier of a PCP for L , which queries at most k bits nonadaptively. For fixed x and r , there is a k -ary relation $\varphi_{x,r}$ expressing if the verifier accepts or rejects the entries of the proof P it views. We have

$$\max_y \text{Prob}(V(x, P, r) = 1) = \max_P |\{r | \varphi_{x,r}(P) = 1\}| / 2^{|r|}. \quad (17)$$

The problem on the right-hand side of (17) is a gap $[k, \Sigma]$ CSP problem, and the completeness and soundness conditions of the PCP translate to the gap requirements. The converse is also straightforward: Let Φ_x be a $[k, \Sigma]$ CSP instance that we get from x by the Karp reduction for L that we have assumed to exist. This is a PCP when we treat the assignment to the variables of Φ_x as proof P . The verifier of this PCP checks if P satisfies a random clause of Φ_x . The completeness of this system is q and the soundness is p . \square

Till the end of the section we are going to focus only on gap-CSP instances.

Theorem 17 (Dinur's Theorem) *Let $\Sigma = \{0, 1\}^3$. Then there exists $\epsilon > 0$ such that $[2, \Sigma]$ CSP Karp reduces to Gap ($[2, \Sigma]$ CSP, $1 - \epsilon$, 1).*

Remark 4 Let $\Sigma = \{0, 1\}^3$. Then the $[2, \Sigma]$ CSP is NP-complete, and the PCP theorem follows.

For the rest of the section, we fix $\Sigma = \{0, 1\}^3$.

Instance Size and Satisfiability Gap

For a $[2, \Sigma]$ CSP instance $\Phi = \bigwedge_{i=1}^m \Phi_i$ (in Sect. 2.7 Φ_i was denoted by f_i), we define the *instance size* as $|\Phi| = m$. The *satisfiability gap* of Φ is $\overline{\text{sat}}(\Phi) = \min_P |\{i | \Phi_i(P) = 0\}| / m$ (one minus the maximal fraction of the simultaneously satisfiable constraints by any assignment P).

Let Φ be a $[2, \Sigma]$ CSP instance. Either $\overline{\text{sat}}(\Phi) = 0$ (the formula is satisfiable) or $\overline{\text{sat}}(\Phi) \geq 1/|\Phi|$ (the formula is not satisfiable). For unsatisfiable instances, the satisfiability gap cannot be smaller than $1/|\Phi|$, since if the formula is not satisfiable, then at least one component of Φ is not satisfied under any assignment. Dinur constructs a reduction that enlarges this tiny gap to a constant. The same reduction, if applied to a satisfiable instance, leaves the resulting instance satisfiable. The latter property will be straightforward, so we shall focus on unsatisfiable instances. The reduction proceeds in $O(\log_2 m)$ steps, making small progresses at a time.

It is sufficient to show that there exists a (sufficiently large) constant $C > 0$ and an $\epsilon > 0$ such that any $[2, \Sigma]$ CSP instance Φ can be reduced in polynomial time to a $[2, \Sigma]$ CSP instance Φ' that has the following properties:

1. If Φ is satisfiable, then Φ' is satisfiable.
2. $|\Phi'| \leq C|\Phi|$.
3. $\overline{\text{sat}}(\Phi') \geq \min\{2 \overline{\text{sat}}(\Phi), \epsilon\}$.

To get [Theorem 17](#), we start from the original instance and apply the above reduction on it $\log_2 m$ times. The size of the final instance is polynomially bounded by that of the original instance (i.e., by m). To construct the reduction sequence takes polynomial time.

3.1 The Three Sub-Steps of Dinur's Basic Reduction Step

We obtain Φ' from Φ of the previous section in three steps: (1) structural Improvement, (2) gap amplification, (3) alphabet reduction. We say that a $[2, \Sigma]$ CSP instance is d -regular, expanding, if the graph we obtain by replacing each constraint with the corresponding pair of variables is a d -regular expander. Let Φ be an arbitrary $[2, \Sigma]$ CSP. Let $d = 11$ and t be a large enough constant to be determined later. The steps are as follows:

$$\begin{aligned} \Phi &\in [2, \Sigma]\text{CSP} & \rightarrow & \text{(Structural improvement)} \\ \Phi_{\text{reg}} &\in d\text{-regular, expanding } [2, \Sigma]\text{CSP} & \rightarrow & \text{(Gap amplification)} \\ \Phi_{\text{big}} &\in [2, \Sigma^{(d+1)^{\lceil \frac{t}{2} \rceil}}]\text{CSP} & \rightarrow & \text{(Alphabet reduction)} \\ \Phi' &\in [2, \Sigma]\text{CSP} \end{aligned}$$

Furthermore:

- If Φ is satisfiable, then so are Φ_{reg} , Φ_{big} and Φ' .
- There are constants C' and C'' such that

$$|\Phi_{\text{reg}}| \leq C' |\Phi|, \quad |\Phi_{\text{big}}| = (d + 1)^{\lceil \frac{t}{2} \rceil - 1} |\Phi_{\text{reg}}|, \quad |\Phi'| \leq C'' |\Phi_{\text{big}}|.$$

- There are $\epsilon > 0$, $D > 1$, and $\delta > 0$ with $D\delta \geq 20$ such that the satisfiability gaps change as follows:

$$\begin{aligned} \overline{\text{sat}}(\Phi_{\text{reg}}) &\geq 0.1 \overline{\text{sat}}(\Phi) \\ \overline{\text{sat}}(\Phi_{\text{big}}) &\geq \min\{D \overline{\text{sat}}(\Phi_{\text{reg}}), \epsilon/\delta\} \\ \overline{\text{sat}}(\Phi') &\geq \delta \overline{\text{sat}}(\Phi_{\text{big}}). \end{aligned}$$

Notice that from Φ to Φ' the satisfiability gap increases by a factor of at least $0.1D\delta \geq 2$, unless it is already ϵ . Only the $\Phi_{\text{big}} \rightarrow \Phi'$ reduction requires classic PCP ideas, namely, the long code.

3.1.1 Structural Improvement

The $\Phi \rightarrow \Phi_{\text{reg}}$ reduction is a fairly standard transformation, which starts with creating $\deg v$ clones of every node v of the constraint graph of Φ . We distribute the outgoing edges among the clones, making every clone an end-point of exactly one outgoing edge. Then for every clone group (associated with the same original node),

we place a degree 5 expander on the members of the clone group (each member is one node of the expander), and we put equality constraints on the new edges. This way the entire graph will be a 6-regular graph, and it may not be an expander itself, since we assume nothing about the structure of Φ . To ensure the expanding property, we now add new edges with empty constraints on them in such a way that the new edges form a degree 5 expander on all nodes. The final graph is $d = 11$ -regular, and it is an expander (since expander + any graph = expander). Throughout the whole construction, we preserve multiple edges (possibly with different constraints). The parameter changes are easy to calculate.

3.1.2 Gap Amplification

The second reduction ($\Phi_{\text{reg}} \rightarrow \Phi_{\text{big}}$) is a wonderful new addition to *PCP* theory, and this is the one that gains us the gap. We define an operation on binary constraint systems called *powering*. Let G be a constraint graph and $t > 1$ be an integer. First we add a loop to each node (with an empty constraint). We denote the resulting graph with $G + I$. Then we construct $(G + I)^t$ in such a way that:

- The vertices of $(G + I)^t$ are the same as the vertices of G .
- Edges: u and v are connected by k edges in $(G + I)^t$ iff the number of paths of length t from u to v in $G + I$ (if the path includes a loop, it also counts towards the length) is exactly k .
- Alphabet: The alphabet of $(G + I)^t$ is $\Sigma^{(d+1)^{\lceil t/2 \rceil}}$, where every vertex (when the prover is honest) specifies values for all of its neighbors reachable in $\lceil t/2 \rceil$ steps.
- Constraints: The constraint associated with an edge (u, v) of $(G + I)^t$ is satisfied iff the assignments for u and v are consistent with an assignment that satisfies all of the constraints induced by the union of the $\lceil t/2 \rceil$ neighborhoods of u and v .

If G is satisfiable, then $(G + I)^t$ is satisfiable as well. To see what happens with the negative instances, Dinur shows that powering has the following gap-enlarging property:

Lemma 16 (Amplification Lemma [33]) *Let Σ be an arbitrary constant size alphabet. There exists a constant $\gamma = \gamma(d, |\Sigma|) > 0$ such that for any $t > 0$ and for any d -regular expanding constraint graph G ,*

$$\overline{\text{sat}}((G + I)^t) \geq \gamma \sqrt{t} \min \left\{ \overline{\text{sat}}(G), \frac{1}{t} \right\}.$$

We define $\Phi_{\text{big}} = (\Phi_{\text{reg}} + I)^t$. Parameter t has to be chosen so that we get a large enough $\overline{\text{sat}}(\Phi_{\text{big}})/\overline{\text{sat}}(\Phi_{\text{reg}})$ ratio to compensate for the loss in the satisfiability gap in the first and third transformations and even gaining a factor of two over that. In other words, **Lemma 16** ensures that we can choose D to be sufficiently large.

3.1.3 Alphabet Size Reduction

$(\Phi_{\text{big}} \rightarrow \Phi')$: The gap amplification step has increased the alphabet size from Σ to Σ_{big} , and now we have to reduce the alphabet to Σ without losing much of the gap we have gained.

Since $\Sigma = \{0, 1\}^3$, we can identify $\Sigma_{\text{big}} \stackrel{\text{def}}{=} \Sigma^{(d+1)^{\lceil \frac{l}{2} \rceil}}$ with $\{0, 1\}^{3(d+1)^{\lceil \frac{l}{2} \rceil}}$. If Φ_{big} is satisfiable, the true prover encodes each variable of the satisfying assignment (i.e., element of Σ_{big}) with some encoding function $E : \{0, 1\}^{3(d+1)^{\lceil \frac{l}{2} \rceil}} \rightarrow \{0, 1\}^{10 \times 3(d+1)^{\lceil \frac{l}{2} \rceil}}$ that corrects constant fraction of errors (from coding theory we know that such encoding exists). To represent the bits of the code word, we shall use Σ -valued variables, somewhat wastefully $10 \times 3(d+1)^{\lceil \frac{l}{2} \rceil}$ of them. The necessity of the error-correcting encoding will be explained later.

These are, however, not all the variables the true prover provides. If v_i and v_j are two variables on which Φ_{big} has a constraint, we install a Dinur assignment tester for the (v_i, v_j) pair. This means an additional constant number of Σ -valued variables per every constraint of Φ_{big} . For a constraint on (v_i, v_j) Dinur's tester checks, using the additional information given by the prover, if the desired relation holds between the (encoded) labels of v_i and v_j . The details are as follows:

Lemma 17 (Assignment Tester of Dinur) *Let h be an arbitrary positive integer, $\mathcal{T} \subseteq \{0, 1\}^h$. Then there are positive integers l and f , and a 2-query verifier V , that uses a random string $r \in \{0, 1\}^f$ accesses a pair of oracles (theorem, $P \in \{0, 1\}^h \times \Sigma^l$) and satisfies:*

1. *If $\text{theorem} \in \mathcal{T}$, then there is $P \in \Sigma^l$ such that $\text{Prob}_r(V(\text{theorem}, P, r) = 1) = 1$.*
2. *If $z \in \{0, 1\}^h$ is η -far from all words in \mathcal{T} , then for every $P \in \Sigma^l$, we have $\text{Prob}_r(V(z, P, r) = 0) \geq \eta/100$.*

It is crucial, that the verifier does not read theorem that it verifies.

We do not prove Lemma 17 here, only mention, that to construct P of the true prover, Dinur employs the folded long code together with her test described in Sect. 2.6 and standard techniques.

For every constraint (v_i, v_j) of Φ_{big} , Dinur installs an assignment tester to verify the property:

$$\mathcal{T}_{i,j} = \{(E(\sigma_i), E(\sigma_j)) | (\sigma_i, \sigma_j) \in \Sigma_{\text{big}}^2 \text{ satisfy all constraints of } \Phi_{\text{big}} \text{ on } v_i, v_j\}.$$

Why is error-correcting encoding E necessary at all, when Dinur's assignment tester in Lemma 17 does not require encoded input? Notice that the success of the test depends on the distance of the assignment from \mathcal{T} . The tester should not accept its input with high probability, unless there is an underlying assignment for Φ_{big} that satisfies the constraint that the tester tests. If $\mathcal{T}_{i,j}$ was simply defined as the collection of all (σ_i, σ_j) laid out in binary (without any encoding) that satisfy all constraints of Φ_{big} on v_i, v_j , then if Σ_{big} is large, changing a single bit in the pair

could make the constraint of Φ_{big} fail on (σ_i, σ_j) , yet the assignment tester would still accept it with high probability.

In contrast, if we change one bit of $E(\sigma_i) \cup E(\sigma_j)$, σ_i is still decodable from $E(\sigma_i)$ and σ_j from $E(\sigma_j)$, using the closest code-word decoding. (It is crucial that the decoding procedure depends on the members of the pair individually and not on the entire pair globally.) In fact, one has to change a constant fraction of the bits of $E(\sigma_i) \cup E(\sigma_j)$ to make either σ_i or σ_j un-decodable. Thus, when the constraints of Φ_{big} are replaced with assignment testers and the average acceptance probability of all assignment testers is $1 - \epsilon'$, the closest distance decoding decodes to an assignment for Φ_{big} that has satisfiability gap at most ϵ'/δ , where δ is some fixed constant.

Summarizing the above, the true prover transforms the proof $\sigma_1 \dots \sigma_n$ of Φ_{big} as follows:

$$\begin{array}{ll} \sigma_1 \dots \sigma_n & \rightarrow \quad (\text{Encodes the alphabet}) \\ E(\sigma_1) \dots E(\sigma_n) & \rightarrow \quad (\text{Adds assignment testers}) \\ E(\sigma_1)' \dots E(\sigma_n)' P_{i_1, j_1} \dots P_{i_{m'}, j_{m'}}. & \end{array}$$

Here $m' = |\Psi_{\text{big}}|$, and $P_{i,j}$ is the proof of the assignment tester for constraint (i, j) . The apostrophes in $E()$ ' refer to the embedding of every bit of $E()$ into an element of Σ : $0 \rightarrow 000$ and $1 \rightarrow 100$. The new tests are those of the assignment testers, combined, appropriately weighted.

It is easy to see that when Φ_{big} is satisfied and the prover is faithful to the protocol, all tests are accepting. Assume now that Φ_{big} is a negative instance. As was sketched a little earlier, in this case the satisfiability gap of Φ' is at least $\delta_{\text{sat}}(\Phi)_{\text{big}}$ for some fixed δ , *independently of* $|\Sigma_{\text{big}}|$ (independence of $|\Sigma_{\text{big}}|$ is crucial, since we need the freedom to set t in the $\Phi_{\text{reg}} \rightarrow \Phi_{\text{big}}$ step to achieve a gap enlargement that more than compensates us for the cumulative loss in the $\Phi_{\text{big}} \rightarrow \Phi'$ and the $\Phi \rightarrow \Phi_{\text{reg}}$ steps). The transformation blows up the instance size by only a constant factor (the constant depends on $|\Sigma_{\text{big}}|$, but it is all right). Since the tester looks at binary constraints over the alphabet $\Sigma = \{0, 1\}^3$, by Fact 1 it corresponds to a $[2, \{0, 1\}^3]CSP$.

4 The Unique Games Conjecture

Amplification of the PCP theorem via parallel repetition results in the non-approximability of the label cover problem. When the label cover is composed with the long code inner verifier, Hastad's Fourier analytic technique yields optimal non-approximability bounds for problems like MAX3SAT [55], MAX3LIN [55], and Max Clique [54]. It is not known, however, how to prove such results for 2CSPs like vertex cover, MAX2LIN, MIN2SAT Deletion. The primary barrier is that it is not possible to efficiently perform both the code-word and consistency tests for projection constraints with just two queries. The barrier gets larger, when the image of the projection becomes much smaller than the domain. This state of affairs compelled Subhash Khot [61] to investigate what happens if we substitute the

$P \neq NP$ assumption with the assumption that label cover with bijective constraints are hard to approximate for large label size. Optimally, this could be NP-hard too, but as of now no one can prove this.

An instance of the *unique games* (\mathcal{UG}) problem (*bipartite unique games problem*) is a tuple $\mathcal{U} = (G, \Sigma, \Pi)$, where:

1. $G = (V, E)$ is a graph ($G = (V, W, E)$ is a bipartite graph with bipartition V, W) with edge set E .
2. Nodes in V (in both V and W) are assigned labels from Σ .
3. $\Pi = \{\pi_{vw} \mid (v, w) \in E\}$, is a set of bijections (permutations), $\pi_{vw} : \Sigma \rightarrow \Sigma$.

An assignment $l : V \rightarrow \Sigma$ ($l : V \cup W \rightarrow \Sigma$) is a labeling of the nodes with the elements of Σ . An edge (v, w) is satisfied iff $\pi_{vw}(l(v)) = l(w)$. Notice that unique games are special label cover instances, where projections are bijections.

Conjecture 1 (Unique Games Conjecture (UGC) [61]) *For every $\epsilon, \delta > 0$, there exists a fixed alphabet Σ , such that $\text{Gap}([2, \Sigma]\mathcal{UG}, \delta, 1 - \epsilon)$ is NP-hard.*

A weaker version of the conjecture is that $\text{Gap}([2, \Sigma]\mathcal{UG}, \delta, 1 - \epsilon)$ is not in polynomial time.

Remark 5 Khot, Kindler, Mossel, and O'Donnell [63] proved that the UGC is equivalent to the special case where each projection constraint is a linear constraint modulo q , i.e., $\Sigma = [q]$ and π_{uv} is defined via $l(u) = l(v) + c_{uv} \pmod q$. Khot and Regev [65] proved that it is enough to consider constraint graphs that are *left regular*.

Conditioned on the conjectured hardness of unique games, [61] was able to prove optimal bounds for problems including MIN2SAT Deletion and MAX2LIN.

4.1 Algorithms for Unique Games

Before discussing further remarkable consequences of the UGC, let us investigate in what sense the unique games problem is different from (easier than) the general label cover problem. Several algorithms solve the unique games in polynomial time for special cases, but none is strong enough to disprove the conjecture. In general, these algorithms impose relations between the parameters ϵ, δ , and $|\Sigma|$ or constraints on the underlying graph, and their existence tells us that one has to be careful with the parameters and the structure of the instance, when trying to prove the conjecture.

It is in P to tell if a unique games instance is perfectly satisfiable. It is also easy to see that a random assignment of labels to the nodes satisfies at least $\frac{1}{|\Sigma|}$ fraction of edges on expectation, implying $\delta > \frac{1}{|\Sigma|}$.

From the result of Charikar, Makarychev, and Makarychev [22], it follows, that if $\epsilon \in O\left(\frac{1}{\log |\Sigma|}\right)$, the UGC is in polynomial time (regardless of δ).

In order to disprove the UGC, it is enough to have a polynomial-time algorithm that finds an assignment that satisfies $\delta(\epsilon)$ fraction of the constraints, given a $1 - \epsilon$

satisfiable unique games instance and $\delta \rightarrow c$ as $\epsilon \rightarrow 0$, where $c > 0$ is some universal constant. Importantly, δ should not depend on $|\Sigma|$.

Motivated by sparsest cut, researchers have considered the special case, where the unique games graph, G , is a good *spectral expander*. If $\lambda = \lambda_2(G)$ is the second smallest eigenvalue of the Laplacian of G , Arora, Khot, Kolla, Steurer, Tulsiani, and Vishnoi [8] (improved by Makarychev and Makarychev [75]) give a polynomial-time algorithm with $\delta(\epsilon) = 1 - \frac{\epsilon}{\lambda} \log \frac{\lambda}{\epsilon}$.

In a recent result Arora, Barak, and Steurer [7] give an algorithm with $\delta(\epsilon) = 1 - \epsilon^\alpha$ that runs in $\exp(n^{\epsilon^\alpha})$ time for a fixed constant $\alpha > 0$. Underlying their analysis is a graph decomposition theorem, stating that the vertex set of a graph can be partitioned in such a way that each resulting subgraph has few large eigenvalues ($\leq n^{O(\epsilon)}$) and there are at most a constant fraction (dependent on ϵ) of edges that go across the parts. The result involves applying this decomposition to the unique games graph and then solving the unique games problem for the induced subgraphs in the partition, using similar methods to the one used by Kolla [68].

We refer the reader to Khot's survey [62], which has an excellent discussion of many of the details.

4.2 Variants of the Unique Games Conjecture

There are several non-approximability results that have been proved starting from variants of Unique Games. Here we mention some of the variants.

A $d \rightarrow 1$ game is a special case of the label cover problem, and it is a generalization of unique games, where $|\Sigma_1| = d|\Sigma_2|$ and each projection constraint π is a $d \rightarrow 1$ map, i.e., $|\pi^{-1}(x)| \leq d$ for every $x \in \Sigma_2$. When $\Sigma_1 = [dq]$ and $\Sigma_2 = [q]$, we denote such a game by $[2, q]\mathcal{PG}_{d \rightarrow 1}$. For every positive integer $d \geq 2$, Khot [61] makes the following conjecture:

Conjecture 2 ($d \rightarrow 1$ -conjecture [61]) *For every $\epsilon > 0$, there exists a $q = q(\epsilon)$ such that $\text{Gap}([2, q]\mathcal{PG}_{d \rightarrow 1}, \epsilon, 1)$ is NP-hard.*

The $d \rightarrow 1$ -conjecture has the perfect completeness property which is useful in some situations. It is shown by O'Donnell and Wu [78] that given a satisfiable instance of a Boolean 3CSP, it is $2 \rightarrow 1$ -hard to find an assignment that satisfies more than $\frac{5}{8}$ fraction of the constraints.

Although the unique games is easy if the underlying graph is a good expander, it may be still hard if the graph is mildly expanding. A variant of the UGC states exactly this:

Conjecture 3 (UGC with expansion, [8]) *There exists a universal constant $1/2 < t < 1$ with the following properties: For every $\epsilon, \delta > 0$, there exists a $\Sigma(\epsilon, \delta)$ such that given a unique games instance $\mathcal{U} = (G, \Sigma, \Pi)$, it is NP-hard to distinguish between the following cases:*

- \mathcal{U} is at least $1 - \epsilon$ -satisfiable.
- \mathcal{U} is at most δ -satisfiable and for every partition $A \dot{\cup} B \dot{\cup} C$ of the vertex set of \mathcal{U} , where $|A| \leq 0.001|V|$ and $|B|$ and $|C| \geq 0.1|V|$, the (B, C) cut has at least ϵ^t fraction of the edges across.

Among the consequences of the above conjecture is that the balanced separator problem, and therefore the sparsest cut problem, is hard to approximate within any constant factor.

4.3 Optimal Bounds Under the Unique Games Conjecture

Assuming the unique games conjecture, exact non-approximability bounds can be proved for several classes of problems. These include max-CSPs [83], strict CSPs [69], ordering problems [50], and clustering problems [64]. There are also problems for which the UGC does not give optimal bounds but still better ones than the $P \neq NP$ assumption alone. These include graph partitioning [2, 23, 66] and graph coloring [35, 60]. Some of the results, like those for graph coloring, are based on variants of the UGC. There are several excellent surveys that have details regarding these problems and the UGC [62, 96]. In this section, we discuss some outstanding consequences of the UGC, including Raghavendra's general hardness result for CSPs.

4.3.1 Optimal Non-approximability for Max Cut

Given a graph G , the Max Cut problem is to find a bipartition of $V(G)$ such that the fraction of edges crossing between the parts is maximized. In [55] an $\frac{17}{16} - \epsilon$ non-approximability bound was shown under $P \neq NP$. The best polynomial-time algorithm, due to Goemans and Williamson [48] approximates Max Cut within a factor of ≈ 1.1389 and employs breakthrough *semidefinite programming (SDP)* techniques.

The celebrated Goemans–Williamson (GW) approximation bound, which is precisely $\frac{\pi}{2} \max_{0 < \theta \leq \pi} \frac{1 - \cos \theta}{\theta}$, at first was not conjectured to be optimal. In a surprise move, however, Khot, Kindler, Mossel, and O'Donnell [63] proved that assuming UGC, the GW ratio is essentially the best possible. Their result was later beautifully extended by Raghavendra [83], who showed that a natural class of semidefinite programs solves all CSP optimally under UGC. We shall sketch the ideas in KKMO in this section and its generalization in Sect. 4.3.3.

For proving the non-approximability of Max Cut, we build our PCP from a bipartite unique games instance $\mathcal{U} = (G, \Sigma, \Pi)$ with $G = (V, W, E)$ as the outer verifier. By Remark 5 we will assume that the instance is left regular, i.e., that all $v \in V$ have the same degree. Depending on how closely we want to get to the GW bound, we choose the alphabet size, $|\Sigma| = R$, of \mathcal{U} to be an appropriately large constant. Next, we need to set a parameter $-1 < \rho < 0$ optimally. For any ρ in this range, we get that to tell instances apart that are $\frac{1-\rho}{2}$ satisfiable (positive instances) from instances that are slightly more than $\frac{\arccos \rho}{\pi}$ satisfiable (negative instances) is unique games hard. The choice for ρ that gives the largest relative gap leads to

the GW bound. The inner verifier is designed a little differently from the usual reductions, where the outer verifier is the label cover problem:

- The (true) prover encodes the labels, $l(w)$, of every $w \in W$ with the long code long_R . (But it does not use the labels of $v \in V$ anyhow!)
- The verifier picks a vertex $v \in V$ at random and two of its neighbors $w, w' \in W$ at random. Let $\pi = \pi_{vw}$ and $\pi' = \pi_{vw'}$ be the respective bijections for edges (v, w) and (v, w') .

At this point we apply the following inner verifier:

1. Let y^w and $y^{w'}$ be the supposed long codes of the labels of w and w' , respectively.
2. Pick $f : R \rightarrow \{0, 1\}$ uniformly and randomly.
3. Pick $\mu : R \rightarrow \{0, 1\}$ by choosing each function value independently to be 0 with probability $\frac{1}{2} + \frac{1}{2}\rho$ and 1 with probability $\frac{1}{2} - \frac{1}{2}\rho$.
4. Accept iff $y_g^w \neq y_{g'}^{w'}$, where $g = f \circ \pi$ and $g' = (f \circ \pi') \oplus \mu$. Here operation \oplus means the exclusive or of two Boolean-valued function.

It is easy to see that the completeness of the above test is almost (where the “almost” comes from the imperfect completeness of the outer verifier) at least $\frac{1}{2} - \frac{1}{2}\rho$. Analyzing the soundness requires Fourier analytic techniques and the brilliant majority is stablest theorem of Mossel, O’ Donnell, and Oleszkiewicz [77]. If the soundness of the above PCP is slightly bigger than $(\arccos \rho)/\pi$, then a solution for \mathcal{U} exists satisfying a small, but constant fraction of the constraints (independently of M), which is a contradiction, if M was chosen large enough (which makes the soundness of the outer verifier small enough). Without giving the details of the calculation, we just hint that reason for this is that for those $v \in V$, whose average “neighbor-pair” inner verifiers have average success rate at least $(\arccos \rho)/\pi + \text{small constant}$, a “probabilistic” (supposed) long code word exists, namely, $\frac{1}{\deg v} \sum_{w \sim v} \pi_{v,w} y^w$ (notice, we needed to shuffle the coordinates of y^w), from which a label l for v can be decoded, which correlates with the (supposed) long codes for v ’s neighbors as follows: The individual (supposed) long codes, y^w , of a constant fraction of the neighbors w of v have the property that from them we can decode a constant length list of labels such that at least one from the list is $\pi_{v,w}(l)$. A standard random assignment technique (which picks a random label from each list) now gives a labeling for \mathcal{U} , which satisfies a constant fraction of the constraints. Important was that the list for each w was recovered only from the supposed long code of w , without looking at v .

4.3.2 Semidefinite Programming and Integrality Gap

Semidefinite programming has resulted in the best known approximation ratios for various classes of optimization problems. For the performance analysis of semidefinite programs, it is crucial to understand the notion of *integrality gap*.

Fix instance Φ of a maximization problem Λ (think of Λ as Max Cut). The first step in designing an SDP-based algorithm for Φ is to translate it to a quadratic program QP_Φ , such that the optimal solutions for Φ and QP_Φ are the same. Then we *relax* the variables, allowing them to take any real vector values. Multiplications between the variables of QP_Φ become scalar products ($xy \rightarrow (\vec{x}, \vec{y})$) in the corresponding semidefinite programming instance, SDP_Φ .

An optimal solution, $SDOPT_\Phi$, to SDP_Φ is then computed, which is *rounded* to a solution of QP_Φ . Let OPT_Φ be the optimal value for Φ (and QP_Φ). Suppose the value of the rounded solution for SDP_Φ is $ROUND_\Phi$. To prove an approximation ratio of r_Φ , it is sufficient to have $r_\Phi ROUND_\Phi \geq SDOPT_\Phi$. The approximation ratio follows because

$$SDOPT_\Phi \geq OPT_\Phi \geq ROUND_\Phi \geq \frac{1}{r_\Phi} SDOPT_\Phi. \quad (18)$$

A barrier to this rounding technique is the *integrality gap* of the relaxation, $IGap_\Lambda = \max_\Phi \frac{SDOPT_\Phi}{OPT_\Phi}$. A lower bound on the integrality gap is usually proved by exhibiting a suitable sequence of instances Φ with integrality gap arbitrarily close to $IGap_\Lambda$.

4.3.3 Exact Non-approximability for All CSPs

In a remarkable recent result, Raghavendra [83] proved that assuming the UGC, SDP rounding algorithms yield essentially the best possible approximation ratios achievable in polynomial time. This result has confirmed former beliefs about the extraordinary strength of semidefinite programming. For every CSP Λ , Raghavendra explicitly constructs semidefinite programs whose maximal integrality gap is the optimal non-approximability bound for Λ .

We will describe the SDP for any 2-variable CSP maximization problem. Let Λ be a 2-variable CSP over the alphabet $\Sigma = [q]$. We can think of each instance Φ of Λ as a directed graph $G = (V, E)$ with nodes denoting variables and edges denoting constraints. Each edge (u, v) has a corresponding *pay-off* function $P_{uv} : \Sigma^2 \rightarrow [0, 1]$ (generalized from $\{0, 1\}$). Without loss of generality, we can assume that the constraints have nonnegative weights w_{uv} summing up to one, which is a probability distribution over E . Our goal is to find an assignment $l : V \rightarrow \Sigma$ such that

$$\sum_{(u,v) \in E} w_{uv} P_{uv}(l(u), l(v))$$

is maximized. When we turn this into a quadratic program, for every node u of G and for every element $i \in \Sigma$, we introduce a variable u_i that takes value one, if u gets label i in the optimal solution, and zero otherwise. The quadratic program is the same in appearance as the analogous semidefinite relaxation, where the u_i 's are now vectors and the “dot” means scalar product:

SDP_Λ

$$\text{Maximize } \sum_{(u,v) \in E} w_{uv} \left(\sum_{i,j \in [q]} P_{uv}(i, j) u_i \cdot v_j \right)$$

Subject to,

$$\forall u, v \in V, i, j \in [q] : u_i \cdot u_j = 0, u_i \cdot v_j \geq 0$$

$$\forall u \in V : \sum_{i \in [q]} |u_i|^2 = 1$$

$$\forall u, v \in V : \sum_{i,j \in [q]} u_i \cdot v_j = 1$$

Raghavendra [83] creates a long code test $Test_A(\Phi)$ from instance Φ , whose completeness and soundness ratio is the integrality gap of Φ . The long code test is a generalization of the folded long code, where $\{0, 1\}$ valued functions are replaced with $[q]$ valued functions. The key idea is that to define the query distribution of $Test_A(\Phi)$, Raghavendra uses an optimal solution of the above SDP. For each edge $(u, v) \in E$ and for each node $u \in V$, we define distributions $D_{uv} : Prob[i, j] = u_i \cdot v_j$ and $D_u : Prob[i] = |u_i|^2$, respectively. The following is the long code test for $z \in [q]^{q^R}$:

$Test_A(\Phi, \epsilon)$ for $z \in [q]^{q^R}$

Choose an edge $(u, v) \in E$ according to w_{uv}

Pick R independent copies from D_{uv} to obtain $x, y \in [q]^R$

Form \hat{x} from x by replacing each x_i independently, with probability ϵ , from the distribution D_u

Form \hat{y} from y by replacing each y_i independently, with probability ϵ , from the distribution D_v

Return “yes” with probability $P_{uv}(z_{\hat{x}}, z_{\hat{y}})$

From the definition of the test it is fairly straightforward that the completeness of the test $Test_A(\Phi)$ is $SDOPT_\Phi - o_\epsilon(1)$. Recall that completeness means the probability with which a word of the long code is accepted, minimized over all long code words.

To talk about soundness, Raghavendra first defines what it means that a word is far away from all words of the long code. In his definition, this happens when the word to be checked is pseudorandom, which he expresses in terms of the Fourier coefficients of the word. The soundness analysis is nontrivial and crucially depends on Mossel’s invariance principle of [76]. It turns out that the soundness cannot be much larger than OPT_Φ . More precisely Raghavendra shows that any word w that is sufficiently pseudo-random gives a randomized rounding procedure round_w to round the optimal solution of the semidefinite program $SDP_A(\Phi)$, yielding an integral solution (i.e. a solution to the original Φ), whose value is close to the success probability of $Test_A(\Phi)$ on w . Here “close” means in terms of ϵ and the pseudorandomness parameters. To understand this beautiful duality better we refer the reader to [83].

Using the unique games outer verifier of [63] in the manner as described in Sect. 4.3.1 for the special case of Max Cut, we obtain the following result:

Theorem 18 *Let Φ be an instance of the CSP A . Then for every $\gamma > 0$, there exist $\epsilon, \delta > 0$ such that there is a polynomial-time reduction from $\text{Gap}(\mathcal{UG}, \delta, 1 - \epsilon)$ to $\text{Gap}(A, SDOPT_\Phi - \gamma, OPT_\Phi + \gamma)$.*

4.3.4 Small Set Expansion and Unique Games

The unique games conjecture has contributed to the great progress in understanding optimal non-approximability bounds. Since unique games conjecture is so central,

it is natural to look for equivalent ways of stating it. Finding natural approximation-equivalent problems to unique games, however, have eluded us for a long time. To remedy this situation, Raghavendra and Steurer [84] consider the *small set expansion (SSE)* problem, a natural and widely applicable graph partitioning problem. They observe that the current techniques do not seem to be able to solve the problem and hence propose the *small set expansion conjecture (SSEC)*; that SSE is NP-hard. They proved that the small set expansion conjecture implies the unique games conjecture. In the rest of the section, we will state the small set expansion conjecture and briefly discuss the recent results related to this conjecture.

Let $G = (V, E)$ be a d -regular undirected graph, $E(A, B)$ for $A, B \subseteq V$, $A \cap B = \emptyset$ be the set of edges between A and B , and μ be the uniform measure on V . The *edge expansion* of a subset of vertices S is defined as $\Phi_G(S) = \frac{|E(S, V \setminus S)|}{d|S|}$ and $\Phi_G(\delta) = \min_{\mu(S) \approx \delta} \Phi_G(S)$, where $0 \leq \delta \leq 1$, and $a \approx b$ means $1/2 \leq a/b \leq 2$. (We have opted to use Φ , which is a standard notation for conductance, and has nothing to do with the Φ of earlier sections, where it denotes two-query PCP instances.) Then $\text{Gap}(SSE, \eta, \delta)$ problem is distinguish between the cases $\Phi_G(\delta) \geq 1 - \eta$ and $\Phi_G(\delta) \leq \eta$. Raghavendra and Steurer make the following conjecture:

Conjecture 4 (SSE Conjecture) *For every $\eta > 0$, there exists a $\delta > 0$ such that $\text{Gap}(SSE, \eta, \delta)$ is NP-hard.*

Small set expansion comes up in several contexts in relation to unique games. If a unique games instance \mathcal{U} with alphabet Σ satisfies at least $1 - \epsilon$ fraction of the edges, then the *label extended* graph has a less-than- ϵ -expanding set of measure $\frac{1}{|\Sigma|}$. In the first step of their sub-exponential algorithm for unique games, [7] use a graph decomposition scheme that partitions the unique games graph into almost-non-expanding small sets. Also, all known integrality gap instances for unique games and various other CSPs have very good small set expansion properties.

The small set expansion conjecture is interesting for several reasons. As is the case with the unique games conjecture, it is in a way a “win–win” situation; a positive resolution would of course prove the unique games conjecture and a negative resolution would solve a very important natural problem, likely with powerful new techniques. Since it is a stronger conjecture, it could potentially lead to optimal non-approximability results for problems like sparsest cut which have so far been out of the reach of the unique games conjecture. In fact, in a recent result, Raghavendra, Steurer, and Tulsiani [85] prove better non-approximability bounds for problems including balanced separator and min linear rearrangement, than those that are known via UGC. Another interesting line of research is to have a unifying conjecture by reducing SSEC to the variants of UGC [62].

5 Structural Consequences of the PCP Theory

What makes some NPO problems hard to approximate, while others easy? This natural question had already been raised by Johnson in [56] long before the PCP theory was developed: “Is there some stronger kind of reducibility than the simple

polynomial reducibility that will explain [approximation] results, or are they due to some structural similarity between the problems as we define them?" In this section we present two completeness results that are consequences of the basic PCP theorem. These results give an evidence that different problems in the same non-approximability classes have the same reason for their hardness of approximation.

5.1 Polynomial-Time Approximation Schemes

Not all natural NP-hard optimization problems are hard to approximate. Easy classes include PTAS and FPTAS. For the definition of these classes and for that of the class APX, see the table below.

	FPTAS	PTAS	APX
Quantifiers	$\exists c \forall \epsilon > 0 \exists A_\epsilon$	$\exists c(\epsilon) \forall \epsilon \exists A_\epsilon$	$\exists c \exists C > 1 \exists A$
Algorithm	A_ϵ	A_ϵ	A
Running Time	$(x + 1/\epsilon)^c$	$ x ^{c(\epsilon)}$	$ x ^c$
Approximability Factor	$1 + \epsilon$	$1 + \epsilon$	C

Clearly, the following inclusions hold as follows:

$$FPTAS \subseteq PTAS \subseteq APX \subseteq NPO.$$

These inclusions are strict if $P \neq NP$. Cesati and Trevisan [21] also introduce the class *EPTAS* which differs from *FPTAS* in that the bound on the running time is $f(\epsilon)n^c$, where $f(\epsilon)$ is an arbitrary function of ϵ and $c > 0$ is an arbitrary constant.

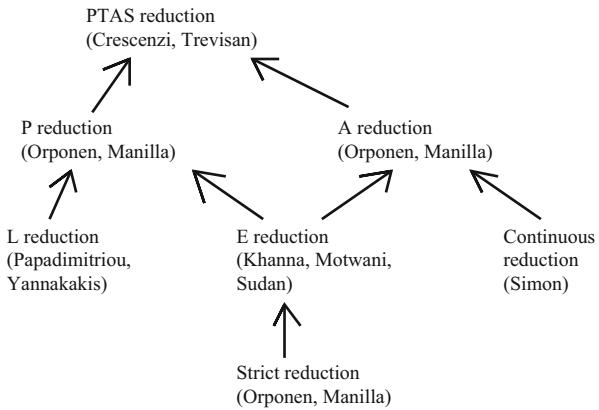

An optimization problem is practically tractable if it has a fully polynomial-time approximation scheme or somewhat weaker, an EPTAS. If a problem has a PTAS, but not EPTAS, then there is ϵ such that the $|x|^{c(\epsilon)}$ running time practically prohibits approximating it within a factor better than $1 + \epsilon$.

5.2 Approximation Preserving Reductions

Approximation preserving reductions in between NPO problems are used to show that if a problem P_1 is easy to approximate, then any problem P_2 is also easy to approximate which reduces to P_1 . Since the easiness of an approximation problem is associated with its membership in *PTAS*, almost all approximation preserving reductions preserve membership in *PTAS* (Fig. 5).

The first paper which defines an *approximation preserving reduction* was that of Orponen and Mannila [79]. Up to the present time, there are at least eight notions

Fig. 5 The taxonomy of approximation preserving reducibilities (Courtesy of Crescenzi et. al. [30])

of approximation preserving reductions in use with a similar overall scheme. This scheme is the following:

Let $P_1(x, y)$ and $P_2(x', y')$ be two polynomial-time functions that are to be optimized for y and y' (maximized or minimized in an arbitrary combination). Let $OPT_1(x)$ and $OPT_2(x')$ be the optimum of these problems. A *reduction* assumes two maps:

1. A map f to transform instances x of P_1 into instances $x' = f(x)$ of P_2 [instance transformation]
2. A map g to transform (input, witness) pairs (x', y') of P_2 into witnesses y of P_1 [witness transformation]

Let $OPT_1 = OPT_1(x)$, $OPT_2 = OPT_2(h(x))$, $APPR_1 = P_1(x, g(h(x), y'))$, and $APPR_2 = P_2(h(x), y')$. The centerpiece of any approximation scheme is a relation which is required to hold between these four quantities. This relation must roughly say: “If $APPR_2$ well approximates OPT_2 , then $APPR_1$ well approximates OPT_1 .” To see that indeed this is what we need, assume that we have a PTAS for OPT_2 and that P_1 reduces to P_2 . In order to get a good approximate solution for $OPT_1(x)$, where x is an arbitrary input instance of P_1 , first we construct $h(x)$ and find a witness y' such that $P_2(h(x), y')$ approximates $OPT_2(h(x))$ well. By the central assumption of the reduction, $P_1(x, y)$ well approximates $OPT_1(x)$ for $y = g(h(x), y')$. For the above argument to hold, f and g must be computable in polynomial time.

Different reductions differ in the relation required in between the four quantities. The L -reduction of Papadimitriou and Yannakakis [81] requires that OPT_2 is upper bounded by $c_1 OPT_1$ and that $|APPR_1 - OPT_1|$ is upper bounded by $c_2 |APPR_2 - OPT_2|$ for some constants c_1 and c_2 . It follows from the next lemma that L -reduction preserves PTAS.

Lemma 18 *A reduction scheme preserves PTAS iff it enforces that $|APPR_1 - OPT_1|/OPT_1 \rightarrow 0$ whenever $|APPR_2 - OPT_2|/OPT_2 \rightarrow 0$.*

5.3 APX Complete Problems

APX is the class of constant factor approximable NPO problems, and APX-PB is its subclass with problems that have a polynomial bound on their objective function. Our goal in this section is to give complete problems for *APX* and *APX – PB*.

Completeness proofs assume an underlying reduction. Even though in the theory of *APX*, the *L*-reduction is the most widely used reduction, in [31] it has been shown that it does not allow to reduce some problems which are known to be easy to approximate to problems which are known to be hard to approximate. Another flaw of the *L*-reduction is that it is too weak in another sense, namely, it is not always approximation preserving unless $P = NP \cap co-NP$ [30]. Therefore, we cannot hope for completeness results for *APX* or *APX – PB* with respect to the *L*-reduction. Instead, S. Khanna, R. Motwani, M. Sudan, and U. Vazirani [59] define the *E* reduction which, using the notation of the previous section, requires that

$$\max \left\{ \frac{APPR_1}{OPT_1}, \frac{OPT_1}{APPR_1} \right\} \leq 1 + c \left(\max \left\{ \frac{APPR_2}{OPT_2}, \frac{OPT_2}{APPR_2} \right\} - 1 \right)$$

for some $c > 0$. It can be easily shown that the *E* reduction preserves PTAS. Using the basic PCP theorem, Khanna et al. show the following:

Theorem 19 [59] *The MAX SAT problem is complete for APX – PB with respect to the E reduction. Also,*

$$APX - PB = \overline{\text{MAX SNP}} = \overline{\text{MAX NP}},$$

where the closure means closure under the *E* reduction.

The *E* reducibility is still somewhat too strict. In [31] it has been shown that natural PTAS problem exists, such as *MAX KNAPSACK*, which are not *E* reducible to polynomially bounded *APX* problems such as *MAX3SAT*. This drawback is mainly due to the fact that an *E* reduction preserves optimum values (see [31]). Crescenzi, Kann, Silvestri, and Trevisan [30] develop a reduction where functions f and g (see previous section) are allowed to depend on the *performance ratio*, where the performance ratio of an *NPO* problem A is defined as the function

$$R_A(x, y) = \max \left\{ \frac{A(x, y)}{OPT_A(x)}, \frac{OPT_A(x)}{A(x, y)} \right\}.$$

Definition 10 (AP Reduction [30]) Let A and B be two *NPO* problems. A is said to be *AP reducible* to B , if two functions f and g and a positive constant α exist such that:

1. For any x and for any $r > 1$, $f(x, r)$ is computable in time $t_f(|x|, r)$.
2. For any x and for any $r > 1$ and for any y , $g(x, y, r)$ is computable in time $t_g(|x|, |y|, r)$.

-
3. For any fixed r , both $t_f(., r)$ and $t_g(., ., r)$ are bounded by a polynomial.
 4. For any fixed n , both $t_f(n, .)$ and $t_g(n, n, .)$ are nonincreasing functions.
 5. For any x and any $r > 1$ and for any y , $R_B(f(x, r), y) \leq r$ implies

$$R_A(x, g(x, y, r)) \leq 1 + \alpha(r - 1).$$

The triple (f, g, α) is said to be an LP reduction from A to B .

In [30] the following is claimed:

Theorem 20 *MAX SAT is APX complete with respect to the AP reduction.*

6 Conclusion

The major challenge of PCP theory is to build PCP reductions. The intuition to these reductions came from Arthur–Merlin games and zero knowledge proofs. From a combinatorial point of view, PCP reductions correspond to isoperimetric inequalities. From a complexity theoretical standpoint, they are pseudorandom constructs. We cannot, however, identify a single tool for building them. PCP theory takes its tools from many different branches of mathematics and computer science: complexity theory, polynomials, coding theory, combinatorics, pseudorandomness, probability theory, and geometry (for semidefinite programming). PCP reductions serve as the atoms of the theory, from which its proofs are composed.

The theory of PCP consists of the PCP theorem and its consequences. The PCP theorem states that every proof has a “transparent” version that admits a quick Monte Carlo verification algorithm with a constant number of check bits. Its current shortest proof, due to Irit Dinur, differs structurally from the previous proofs. The transformation of an ordinary proof into a transparent one is a PCP reduction itself.

The greatest consequence of PCP theory is the conditional hardness of approximating NPO. The theory of NP had cast serious doubt that for many important problems in NP we will ever find a polynomial-time solution, but hope still existed that algorithms will be available that output increasingly good approximate solutions. This hope has been shattered by the PCP theory: we know now that our long-term inability to design approximation algorithms for classical optimization problems such as *MAX CLIQUE*, *SET COVER*, *COLORING*, and *METRIC TSP* is due to the NP-hardness of the associated gap problems. PCP theory had a very major effect on the theory of CSP. Not only that the PCP theorem itself is an inapproximability statement of a CSP problem but due to the search for sharper inapproximability bounds, our understanding of CSPs has gone through an exponential acceleration. Much of this investigation has been centered around the so-called long code.

The most important spin-off of PCP theory is hardness studies based on the unique game conjecture (UGC). The UGC allows us to fully characterize the approximation bounds of all CSPs.

PCP theory has also provided a wealth of new algebraic and combinatorial ideas, like the notion of checkable codes and Raz's parallel repetition theorem for two-prover games.

Although PCP reductions have mostly replaced the approximation preserving reductions of the pre-PCP era, the latter still may be interesting when we study syntactically defined classes of optimization problems.

In spite of the tremendous advances, many questions remain open, like the NP-hardness of the unique games problem itself, the behavior of chromatic number under approximation for small chromatic graphs, and whether asymmetric TSP is constant factor approximable. These problems will give exciting projects for future generations of complexity theorists.

Abstract

The completion of the Human Genome Project has launched the post-sequencing phase of genome research. Once a genome information is identified, protein structures become most important in life sciences. Drug design is one immediate example, and docking, a computational method to understand molecular binding between protein and compound, is one of its fundamental implementation methods.

This chapter presents a docking problem between a receptor and a ligand in the framework of combinatorial optimization and is an effort to formalize the problem into a mathematically and computationally rigorous theory so that follow-up studies can safely rely on the concepts presented in this chapter. Docking problem is a mathematical and computational problem and a highly complicated, intractable problem. In addition, this problem is very much interdisciplinary encompassing biology, biochemistry, biophysics, medicinal chemistry, and computational disciplines such as optimization, mathematics, and geometric computations. Therefore, it is desirable to develop a common language. To accomplish this objective, this chapter is based on geometric constructs called the beta-complex and beta-shape of molecules.

This chapter has three parts. The first part introduces basic concepts and theory of molecular binding/recognition process and tries to formalize the transformation of the docking problem to a combinatorial optimization problem. This part will be particularly useful for people from mathematical and computational disciplines who wants to learn about the fundamentals of docking problem in a nutshell. The second part introduces the topology representation of molecules and the fundamental building blocks for the computational process with a slightly mathematical rigor. The Voronoi diagram, the spatial tessellations (triangulations), and the beta-complex and beta-shape are primary geometric objects introduced. The third part shows how to formulate and solve a protein-ligand docking problem as combinatorial optimization problems using the beta-complex and beta-shape, as it is done in BetaDock – the docking software developed by author's group.

1 Introduction

An interaction between a protein and another molecule is important for understanding the biological function of the protein and is essential for *structure-based drug design* because it helps to identify lead compounds. For example, *imatinib mesylate* (also called Gleevec® or STI571¹) binds to a tyrosine kinase, the protein related

¹STI stands for *signal transduction inhibitor*.

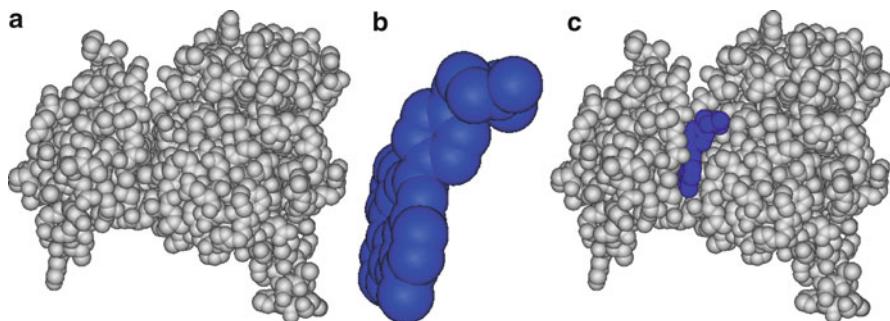

Fig. 1 Tyrosine kinase and imatinib. (a) Tyrosine kinase, (b) Imatinib, and (c) Tyrosine kinase with imatinib

to leukemia, at an *active site*² so that the drug effectively inhibits or inactivates the function of the tyrosine kinase [6, 160].³ Figure 1a, b show tyrosine kinase and imatinib, respectively. Figure 1c shows the result of the binding between these two molecules. Here, the tyrosine kinase is called a *receptor* and the imatinib is called a *ligand*. Tyrosine kinase is also called a *target protein* in that it is responsible for disease. The binding between receptor and ligand occurs due to the physicochemical interaction between the two molecules such as van der Waals forces among all atoms, electrostatic forces among charged or polar atoms, and hydrogen bonds between hydrogen donors and acceptors [114, 140]. Binding phenomenon is frequently formulated as an energy minimization process because a ligand is believed to bind to a receptor at its lowest potential energy. Gleevec® indeed opened a new medication model called *target therapy* which blocks the growth of cancer cells by interfering with specific target protein.

Protein-ligand docking is a computational method that attempts to find the *best binding* or the *best match* between a receptor and a ligand, given chemical bonding constraints of the molecules. There are other kinds of docking: protein-protein docking, protein-DNA docking, protein-RNA docking, etc. In this chapter, “docking” refers to the protein-ligand docking, unless otherwise stated.

Docking assumes that the structure of both receptor and ligand is known where the molecular structure implies its atomic coordinates and biochemical properties. The objective of docking is to predict the *ligand pose* with respect to a receptor as precisely and as quickly as possible through a computational method. “Ligand pose” is the position and orientation of ligand with respect to receptor and its conformation

²A substrate binds at (usually one or at most a few) specific (not random) sites of an enzymatic protein. Such binding sites are called an *active site*.

³Gleevec® was developed by rational drug design at Novartis in the late 1990s. With high-throughput screening, researchers identified 2-phenylaminopyrimidine which was then modified introducing methyl and benzamide groups to add enhanced binding properties. Receiving FDA approval in May 2001, it made the cover of TIME magazine as the *magic bullet* to cure cancer.

determined by the prescribed dihedral angle of rotatable bonds. In general, the best binding occurs when the potential energy of a ligand minimizes with respect to a receptor where the potential energy is usually formulated as a nonlinear function in a high-dimensional space. The potential energy function contains many local minima where each corresponds to a locally stable ligand pose. Therefore, finding the best binding becomes solving a nonlinear optimization problem to find the global minimum of the energy function. Receptor is usually a protein, and thus the problem is often called a protein-docking problem. Ligand is usually a compound of small molecular weight or sometimes another protein.

Computational method is useful only when it is accurate, robust, and sufficiently efficient. This statement applies to any application area. In docking, the number of local minima grows exponentially with respect to the size of the molecules (i.e., the number of atoms of both receptor and ligand) leading the problem to NP-hard [33, 119, 188]. Small proteins usually have hundreds of atoms, and some larger ones have hundreds of thousands of atoms. Hence, classical nonlinear optimization techniques such as the conjugate gradient method suffer [67]. For example, Gehlhaar et al. presented a docking example having more than 10^{30} local minima [70]. Therefore, docking is computationally challenging and usually deemed to be intractable [145, 189] which inevitably invites heuristic approaches to solution process. If conformational flexibility is also allowed for molecules, the docking problem becomes even harder.

It is generally agreed that binding usually occurs at molecular boundaries in spite that there are important exceptional cases due to significant conformational flexibility of molecules. Hence, there is no doubt that effectively recognizing molecular boundary contributes to the efficient docking simulation. In this respect, the recent theory of the beta-complex and beta-shape defined for sphere set contributes to docking problem and others [101, 103, 105, 182].

A docking simulation is usually done between a particular protein related to a disease of interest and many compounds in chemical databases. Hence, the computational speed and the solution quality are critical in *virtual screening* (VS) [10, 207] which is to identify new drug candidates, called *lead compounds*, from compound database through protein vs. compound docking simulation. For example, the Cambridge Structural Database (CSD) has 541,748 compound structures (as of Jan. 2011) [4, 27], the Available Chemicals Directory (ACD) has over 3,870,000 non drug-like compounds [9], and MACCS-II Drug Data Report (MDDR) has over 150,000 drug-like compounds [139]. *High-throughput screening* (HTS) is a method based on scientific experimentation in drug discovery using robotics, sensors, miniaturization technologies, etc., to quickly perform millions of biochemical or pharmacological tests. HTS quickly processes to identify active compounds or antibodies which modulate a particular biomolecular pathway, and the results provide starting points for drug design. Starting with 96-well plates in mid-1990s [24], current HTS technology supports 1,536-well microplate format for compound handling [113, 142]. VS and HTS are two very important components of modern drug discovery research. VS and HTS have been traditionally considered

distinct approaches in that VS is theoretical, computational whereas HTS is experimental. However, they are now being considered very much complementary to each other and beginning to be merged [11]. The success of the fusion of VS and HTS will largely lie in the representation of the three-dimensional molecular structure.

It is not the intention of this chapter to try to provide a comprehensive review about protein docking. The objective of this chapter is two-fold at the cost of sacrificing other aspects of docking:

- Understanding the rationale behind docking problem and its mathematical/computational formulation
- Understanding the combinatorial optimization aspect of docking problem

Significant emphasis is focused on the formalization of docking problem because many previous studies from communities of biology, chemistry, medicine, etc., tend to ignore or lack mathematical rigor, computational efficiency, and sufficient level of reproducibility. Good review papers on different aspects of docking problem are already available [19, 39, 151, 154, 170, 189, 190, 194].

This chapter consists of three parts:

Part (1) the fundamentals of molecular binding process and the mathematical/computational formulation of docking problem ([Sects. 2–5](#))

Part (2) the theory of topology representation for biomolecules based on the Voronoi diagram, the quasi-triangulation, and the beta-complex ([Sect. 6](#))

Part (3) the combinatorial optimization formulation for the new, powerful docking method based on the beta-complex and its implementation in BetaDock⁴ ([Sects. 7–9](#))

[Section 2](#) briefly introduces the basic biophysics about the force field theory and is important for correctly understanding the molecular binding and docking process. [Section 3](#) defines what the docking problem is and how the problem is modeled for computation. This chapter is important in that the theoretical justification of the combinatorial optimization formulation of docking problem is presented. [Section 4](#) discusses the flexibility issue related with the conformation changes of molecules during docking process. [Section 5](#) presents a literature survey related to docking with a particular emphasis on the historical development of docking concept. Important docking softwares are also briefly described. [Section 6](#) presents the formalization of the topology representation of geometric constructors related to docking problem and provides a rigorous theoretical, mathematical, and computational basis for not only docking but also many other molecular modeling and analysis problems. In particular, the important geometric constructs called the beta-complex and beta-shape are introduced. [Section 7](#) presents the algorithm, including a short survey of related previous works, for extracting pockets on the boundary of receptors using the beta-shape of the receptor. [Section 8](#) presents

⁴BetaDock and BetaMol are freely available at Voronoi Diagram Research Center (VDRC, <http://voronoi.hanyang.ac.kr>).

an algorithm generating initial conformations of ligands to launch the genetic algorithm to find the global optima on the energy surface. [Section 9](#) presents the genetic algorithm used in BetaDock. [Section 10](#) concludes the paper. All three-dimensional figures are generated from BetaMol, the molecular modeling software based on the beta-complex theory and available at VDRC [204].

2 Brief on Molecular Binding Process

To correctly understand the receptor-ligand binding process and to formulate the computational problem of docking, it is necessary to have a good understanding about the physicochemical aspect of the binding process, in particular the forces involved.

2.1 Force Field

The free energy of a molecular system is the amount of work that the system can perform. It can be estimated most precisely by solving quantum mechanics that explicitly represents the electron distribution to derive the properties of the molecular system. However, most problems in quantum mechanics are too large to be correctly solved by current computing technology. *Molecular mechanics* (also known as *force field method*), ignoring the contribution of electrons, calculates the free energy as a function of the nuclear coordinates in the molecular system. The function is often a convenient form of a rational polynomial. Being computationally much less expensive than quantum mechanics, molecular mechanics can handle molecules with a significant number of atoms.

In molecular biology, force field refers to the mathematical function of nuclear coordinate of atoms in the molecular system and the parameters describing the function. The function and its parameters are derived from both experimentation and quantum mechanical calculations. It is called the “force field” because forces on individual atoms are related to the gradient of this function. Force field is empirical. This implies that it is not appropriate to question about the correctness of a particular force field. One force field function may perform better for a given molecular system than another depending on the condition of the problem of interest. The mathematical form of force field is usually devised considering the trade-off between accuracy and computational efficiency. Studies on protein force field began in early 1980s. Even if the force field approach is empirical, NP-hardness is still a challenge for efficiently solving a docking problem using the force field method. Another class of *semiempirical* approach called the ab initio [80, 167] is also computationally prohibitive in many practical problems [217].

A simple, popular example of force field that can be used for a single or a set of molecules is as follows:

$$\begin{aligned}
E = & \sum_{\text{bonds}} \frac{1}{2} k_b (l_b - l_b^*)^2 + \sum_{\text{angles}} \frac{1}{2} k_a (\theta_a - \theta_a^*)^2 + \sum_{\text{torsions}} \frac{1}{2} k_t (1 + \cos(t\omega - \gamma_t))^2 \\
& + \sum_{i < j} \left\{ \frac{A_{ij}}{d_{ij}^{12}} - \frac{B_{ij}}{d_{ij}^6} \right\} + \sum_{i < j} \frac{q_i q_j}{\varepsilon(d_{ij}) \cdot d_{ij}} + \sum_{i < j} \cos^4 \theta \left\{ \frac{C_{ij}}{d_{ij}^{12}} - \frac{D_{ij}}{d_{ij}^{10}} \right\}. \quad (1)
\end{aligned}$$

In the first term, l_b and l_b^* are the *instance length* and the *ideal length* of the b -th bond, respectively. The “instance length” denotes the bond length observed in the protein structure file such as those in PDB, and the “ideal length” denotes the bond length that the two atoms in the bond are theoretically most stable. The values of ideal length for bonds between different atom types are available [17]. k_b is the force constant of the b -th bond. The first term models the interaction between pairs of bonded atoms and is approximated by Hooke’s law to measure the deformation of each bond due to either stretch or compression. In the second term, θ_a and θ_a^* are the instance angle and the ideal angle, respectively, and k_a is a force constant of the a -th angle. The second term models the interaction among triplets of bonded atoms and measures the angular deformation among pairs of bonds incident to each atom. In the third term, γ_t is the phase angle and k_t is a force constant of the t -th torsion, respectively. The third term models a torsional potential and measures the twist of two planes intersecting at each bond. Hence, these three terms altogether model the internal energy of a molecular system due to chemical bond and thus denoted by E_{bonded} [114]. E_{bonded} measures intramolecular interactions. The fourth term is the well-known (12,6)-Lennard-Jones potential function which models the van der Waals interaction between pairs of atoms. The van der Waals interaction consists of two forces: an attractive force and a repulsive force which are represented by d^{-6} term and d^{-12} term, respectively. The fifth term is the Coulomb’s law between two point charges which models the electrostatic interaction between pairs of atoms. The last term models the hydrogen-bonding interaction between pairs of atoms lying on the boundary of molecules. Note that, in the binding environment around proteins, only three atom pairs, OH, NH, and SH, can define hydrogen bonding. A_{ij} , B_{ij} , C_{ij} , and D_{ij} are all constants depending on the type of two atoms i and j ; d_{ij} is the distance between the centers of two atoms. q_i and q_j are two point charges; $\varepsilon(d_{ij})$ is the dielectric permittivity of the medium where the two charges are placed and is given as a function of distance; θ is the angle defined at the hydrogen atom with two nearby atoms (where one is the hydrogen donor and the other is the hydrogen acceptor) when the hydrogen bonding may be defined and is frequently taken as 180°. The last three terms are all defined between nonbonded atoms and thus altogether denoted as $E_{\text{nonbonded}}$. $E_{\text{nonbonded}}$ models intermolecular interactions. In fact, Eq.(1) is very close to the one actually used in AutoDock, one of the most popular docking software. Then, Eq.(1) can be rewritten in a simple form as

$$E = E_{\text{bonded}} + E_{\text{nonbonded}}. \quad (2)$$

AMBER (Assisted Model Building and Energy Refinement) [114, 212, 213] and CHARMM (Chemistry at HARvard using Molecular Mechanics) [20] are the two most popular molecular mechanics force fields. In certain situations, extremely simplified representations of force field can be used from computational efficiency point of view. For example, Gehlhaar et al. used a piecewise linear approximation with five line segments for the van der Waals forces [70]. For the review of various force fields, see [110, 174].

2.2 Funnel in Energy Landscape

Levinthal observed the following paradox, called the *Levinthal paradox* in 1968 [132]: “Proteins fold into native state extremely quickly in spite that there exist exponential number of local minima in the energy surface with respect to the number of rotatable bonds in proteins.” As a possible resolution of Levinthal paradox, in 1992, Leopold et al. proposed the concept of *protein-folding funnel* as a kinetic mechanism for understanding protein folding [22, 131]. A protein-folding funnel is a set of downhill kinetic pathways that converge to a single minimum on the energy surface leading to a unique, stable, and native conformation. In the world of proteins, it has long been agreed that the potential energy surface of protein is biased toward the global minimum so that a single deep funnel leads proteins to fold to their native state, despite very large configurational spaces [53, 205].

As the physicochemical principle of protein binding is similar to that of protein folding, it is natural to extend the concept of funnel to intermolecular phenomenon such as binding. Frauenfelder et al. presented the idea for connecting ligand binding to the funnel of energy landscapes by showing that the energy surface for small molecule binding to myoglobins could be viewed as the energy landscape for the protein-folding theory [68]. Others also used the funnel concept in molecular binding or recognition [196, 198, 200, 205].

3 Definition of Docking Problem: Search + Scoring

Having modeled the free energy E of a molecular system as Eq. (2), solving docking problem is then equivalent to solving the optimization problem given as

$$\text{Minimize } E. \quad (3)$$

In formulating docking problem, there are usually four assumptions in the model of binding as stated by Miller and Dill [150]:

- *Steric fit*: a binding is determined mainly by a shape complementarity.
- *Native binding*: ligands mainly bind to native state of receptors.
- *Locality*: ligands perturb protein structures mainly at the binding site.
- *Continuity*: small changes in ligand or protein structure lead to small changes in binding affinity.

Note that three out of the four assumptions (i.e., the steric fit, the locality, and the continuity) are related with “geometry.” However, be aware that there are cases that these assumptions are not preserved. For example, some ligands bind to highly denatured states more tightly than native states. The function E is frequently replaced by $E_{\text{nonbonded}}$, ignoring the E_{bonded} terms, yielding the following formula:

$$\begin{aligned} \text{Min } E_{\text{nonbonded}} = & \sum_{l \in L} \sum_{r \in R} \left\{ \frac{A_{lr}}{d_{lr}^{12}} - \frac{B_{lr}}{d_{lr}^6} \right\} + \sum_{l \in L} \sum_{r \in R} \frac{q_l q_r}{\varepsilon(d_{lr}) \cdot d_{lr}} \\ & + \sum_{l \in L} \sum_{r \in R} \cos^4 \theta \left\{ \frac{C_{lr}}{d_{lr}^{12}} - \frac{D_{lr}}{d_{lr}^{10}} \right\} \end{aligned} \quad (4)$$

where L and R are ligand and receptor, respectively. This formulation is mainly due to the assumption that the conformational flexibility of molecules in the binding process can be separately reflected.

Equation (4) is an unconstrained nonlinear minimization problem, still in a high-dimensional space even when both receptor and ligand have a moderate number of atoms. For example, the PDB model 1t46 contains both a tyrosine kinase (2,381 heavy atoms) and an imatinib (37 heavy atoms). Therefore, the van der Waals force between the tyrosine kinase and the imatinib consists of 157,176 terms and the electrostatic force consists of 78,588 terms. There may be up to 37 hydrogen bonds between tyrosine kinase and imatinib because the number of ligand atoms is the upper bound of the number of hydrogen bonds between the receptor and the ligand. Hence, there may be between 0 and 74 terms for hydrogen bond. Therefore, there are altogether more than 235,764 nonlinear terms in this minimization problem. Hence, efficiently finding the global minimum of Eq.(4) is still a challenge.

In addition, in solving a docking problem, Eq.(4) needs to be solved several times. After solving Eq.(4) once, the ligand is transformed in the space with respect to a fixed receptor to result in a new pose with respect to the receptor. Then, a new instance of Eq.(4) is formulated to be solved again so that the ligand is to be transformed again. This process repeats until the termination condition, which may be defined differently depending on the employed docking method, is encountered. Hence, the efficiency of the algorithm searching for the global minimum of an entire docking problem is very important.

It is known that the energy function in Eq.(4) usually has an exponential number of minima with respect to the number of atoms in the system. This leads the docking problem to NP-hard and therefore, in search of the global minimum, it is inevitable and a common practice to employ a heuristic method. Based on this observation, docking is usually viewed as a problem consisting of two major subproblems of search and scoring. To emphasize,

$$\text{Docking} = \text{Search} + \text{Scoring}. \quad (5)$$

The search subproblem is to align a ligand to the receptor boundary, and the scoring subproblem is to estimate their binding affinity represented by a mathematical function such as Eq.(4). However, the two subproblems are not completely independent but they are closely related in the following sense: If a scoring function is not sufficiently accurate, the computational effort required in the search for a good ligand pose may be wasted or a bad pose may be selected as a solution. Hence, devising good scoring functions is critical for the success of good docking method. This chapter will mainly focus on efficiently exploring the search space based on the scoring function in Eq.(4) is employed.

Exploring the search space is inherently based on the combinatorics among the atoms in the system. Therefore, this chapter discusses the “combinatorial optimization” of Eq.(4) whose combinatorial space is from the all atoms in both receptor and ligand.

3.1 Search Subproblem

Consider a pair of atoms. For example, consider an oxygen O and a hydrogen H where O is from a receptor and H is from a ligand. Assume that both molecules are rigid. Depending on condition, O and H may or may not define a hydrogen bond (See Sect. 3.5). Let E_{vdW}^{OH} , E_{es}^{OH} , and E_{hb}^{OH} be the forces of van der Waals, electrostatic, and hydrogen bonding, respectively. Then, from Eq.(4), E_{vdW}^{OH} and E_{hb}^{OH} are given as

$$E_{vdW}^{OH} = \frac{38,919.64}{d^{12}} - \frac{124.0492}{d^6} \quad (6)$$

$$E_{hb}^{OH} = \cos^4 \theta \left\{ \frac{75,570}{d_{lr}^{12}} - \frac{23,850}{d_{lr}^{10}} \right\}. \quad (7)$$

The coefficients for E_{vdW}^{OH} and E_{hb}^{OH} are borrowed from AutoDock 1.0 which adopted these parameters from AMBER. θ is considered to be 180° here because the hydrogen bonding is most strong at this angle. Figure 2a–c shows the graphs of E_{vdW}^{OH} , E_{es}^{OH} , and E_{hb}^{OH} , respectively, where the horizontal axis denotes the *interatomic distance* between the centers of two atoms and the vertical axis denotes the function value.

E_{es}^{OH} needs a little bit of explanation. Cornell et al. published an important paper which contained the point-charges of atoms in residues (i.e., amino acids) [43]. According to that paper, the charge of a particular atom type is not fixed but varies depending on the amino acid type and the location of the atom in the amino acid. The minimum and maximum values of the charges for the five popular atom types are given as follows [43]: C: [-0.4121 (LEU), 0.076 (ARG)]; N: [-0.0407 (GLN), -0.2548 (PRO)]; O: [-0.8188 (GLU), -0.5579 (TYR)]; S: [-0.3199 (CYS), -0.2731 (MET)]; H: [-0.0425 (GLU), 0.4478 (ARG)]. The three-letter words in parentheses denote the amino acid type from which the charges are defined.

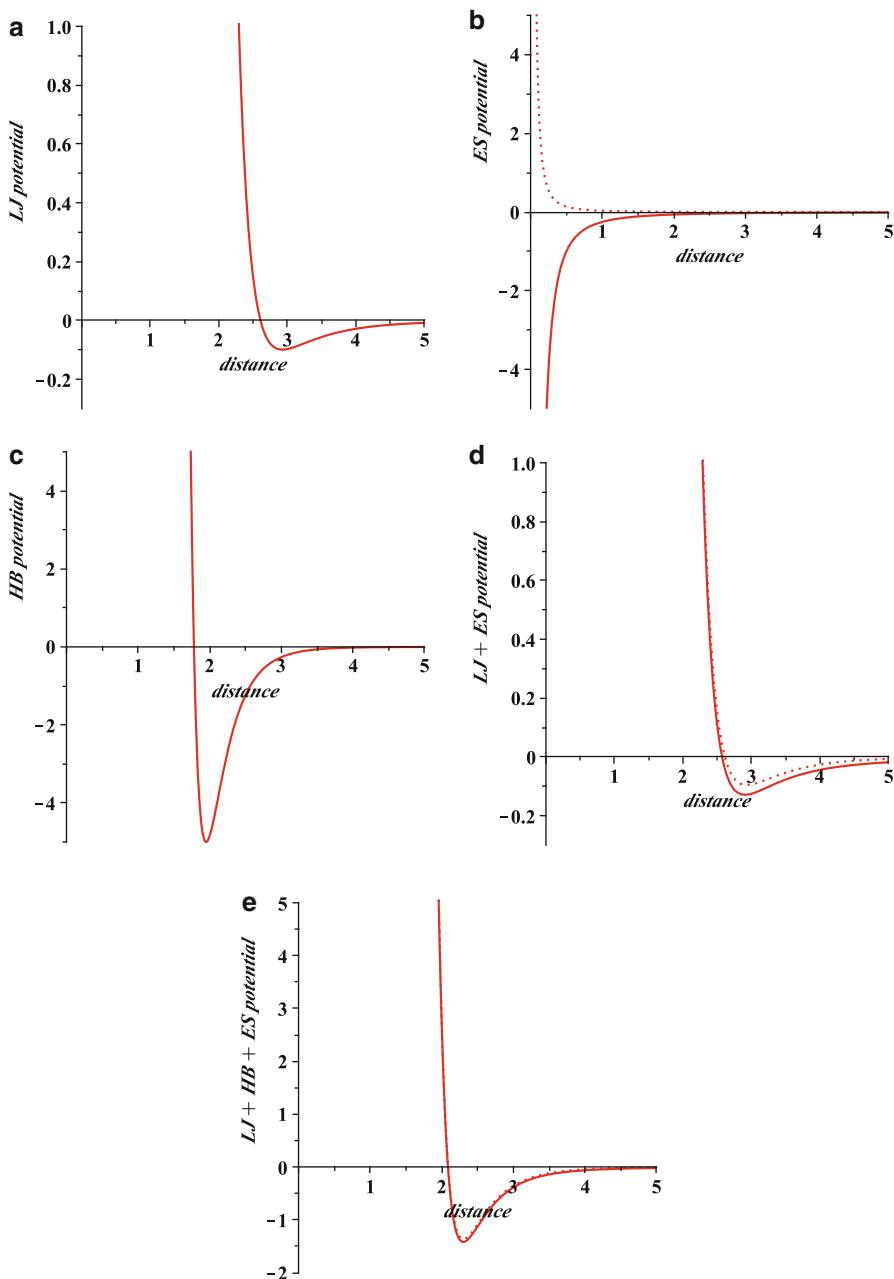

Fig. 2 Nonbonded force terms between O and H using AMBER force field (where the hydrogen bonding may exist). (a) The (12,6)-Lennard-Jones potential term (E_{vdW}^{OH}), (b) the electrostatic term (E_{es}^{OH}), (c) the hydrogen bonding term (E_{hb}^{OH}), (d) (a)+(b), and (e) (a)+(b)+(c)

For example, “LEU” denotes leucine, “ARG” denotes arginine, etc. Let \underline{E}_{es}^{OH} be the curve of the electrostatic force between O and H where their charges are both defined by the minimum values. Similarly, let \overline{E}_{es}^{OH} be defined by the maximum values of both O and H. Then, they define the lower and upper bound of the electrostatic force given as follows:

$$\underline{E}_{es}^{OH} = \frac{(-0.5579) \cdot (0.4478)}{d_{lr}^2}. \quad (8)$$

$$\overline{E}_{es}^{OH} = \frac{(-0.8188) \cdot (-0.0425)}{d_{lr}^2} \quad (9)$$

In Fig. 2b, the solid curve denotes \underline{E}_{es}^{OH} and the broken curve denotes \overline{E}_{es}^{OH} .

An example of the interpretation of these graphs is as follows: In the van der Waals force point of view (Fig. 2a), the two atoms O and H will be located and stable at the interatomic distance where E_{vdW}^{OH} minimizes, unless another force affects the system. Similar explanation can be made for the hydrogen bond (Fig. 2c). Therefore, the minimum of each curve is of interest. In Fig. 2a, the minimum is at (2.926, -0.099). In Fig. 2c, the minimum is at (1.950, -5.002). In the case of Fig. 2b, both curves for the upper and lower bound of the electrostatic force are monotonic.

Figure 2d shows $E_{vdW}^{OH} + E_{es}^{OH}$ and Fig. 2e shows $E_{vdW}^{OH} + E_{es}^{OH} + E_{hb}^{OH}$. Each of both figures has two curves because E_{es}^{OH} has two curve instances. In Fig. 2d, the minimum of the upper-bound curve is at (2.929, -0.095) and one of the lower-bound curves is at (2.903, -0.128). In Fig. 2e, the minimum of the upper-bound curve is at (2.302, -1.364) and one of the lower-bound curves is at (2.300, -1.418).

The claim to be made is as follows. Consider the interatomic distance in the example. The most commonly used van der Waals radii of atoms in proteins are those reported by Bondi as follows (unit: Å) [17]: C(1.70), H(1.20), O(1.52), N(1.55), and S(1.80). Without the consideration of hydrogen bonding, Fig. 2d says that the two atoms O and H are most stable where the inter-atomic distance is between 2.903 and 2.929, and this forms an interval of length 0.026 Å where the minimum of the curve in Fig. 2d exists. Because the van der Waals radii of O and H are 1.52 and 1.20, respectively, this interval is in the free space (i.e., O and H do not intersect). The boundaries of O and H are apart from each other: at least 0.183 (= 2.903 - (1.52 + 1.20)) Å and at most 0.209 (= 2.929 - (1.52 + 1.20)) Å away from each other. With hydrogen bonding, however, Fig. 2e says that O and H are most stable where the interatomic distance is between 2.300 and 2.302. In this case, the interatomic distance is between -0.420 and -0.418. This implies that two atoms slightly overlap when they are stable. Recall that the hydrogen bonding can be defined on the boundaries of two molecules only when certain conditions are satisfied and does not occur very often. This observation, therefore, strongly asserts that O and H, in general, stay stable together around their contact distance.

Consider another pair of atoms, O and N, that cannot define a hydrogen bonding. Let E_{vdW}^{ON} and E_{es}^{ON} be the van der Waals potential and electrostatic force between

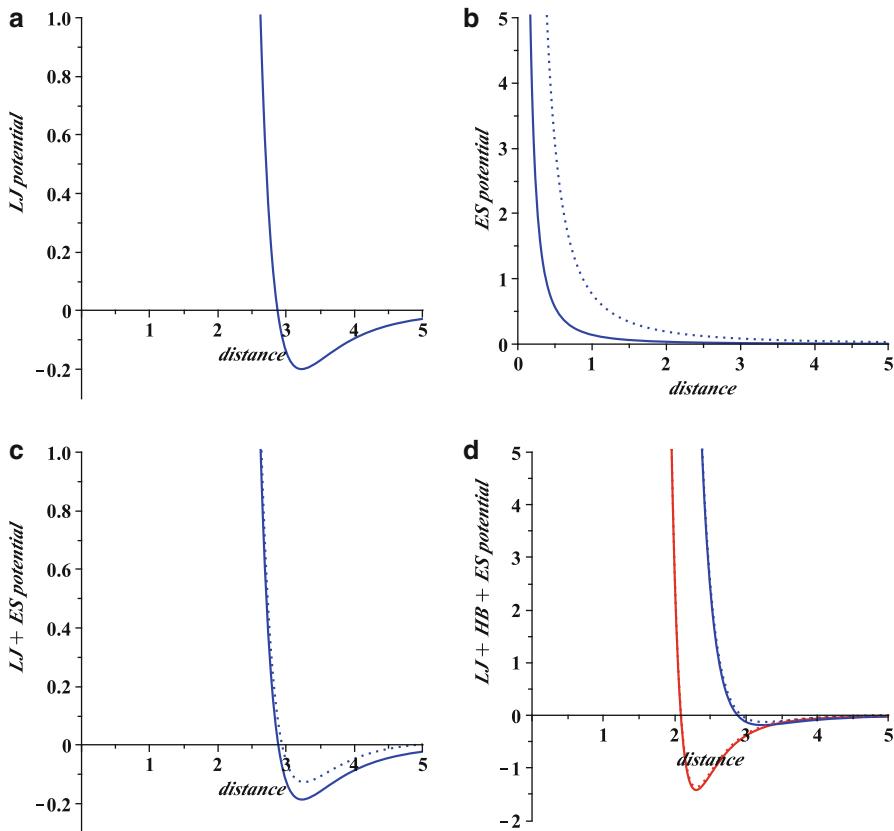

Fig. 3 Nonbonded force terms between O and N using AMBER force field (where the hydrogen bonding does not exist). (a) The (12,6)-Lennard-Jones potential term (E_{vdW}^{ON}), (b) the electrostatic term (E_{es}^{ON}), (c) (a) + (b), and (d) (c) and Fig. 2e together

O and N. Formulae similar to Eqs. (6) and (7) can be defined for this pair, and Fig. 3a, b shows E_{vdW}^{ON} and E_{es}^{ON} , respectively. Figure 3c shows $E_{vdW}^{ON} + E_{es}^{ON}$. The analysis similar to above shows the following: O and N are most stable where their interatomic distance is between 3.229 and 3.259. Subtracting the radii of O and N, the distance is 0.157 and 0.189. This observation also states that there is a slight free space between the two atoms when they are stable. Investigation of other pairs of atoms frequently found in proteins (i.e., C, H, O, N, and S) shows similar phenomena. Therefore, it can be safely said that the binding between two molecules are very stable around their boundaries. In addition, note that there are very few terms in E_{hb} because the hydrogen bonding is only defined on the boundary of receptor. This observation therefore asserts the important consensus that binding usually occurs at the boundary of molecules. However, there are two reservations in this explanation: (i) In a live body, the molecular binding actually occurs in

solvent, and therefore the condition of the above discussion may differ slightly; (ii) the rest atoms in the system may push the atoms on the boundary so that the free space may shrink. **Figure 3d** shows the curves for both OH and ON: For OH, $E_{vdW}^{OH} + E_{es}^{OH} + E_{hb}^{OH}$ is shown in red; for ON, $E_{vdW}^{ON} + E_{es}^{ON}$ is shown in blue.

Therefore, it is very useful to have an effective and efficient way to recognize and manipulate the “molecular boundary.” Then, the search space of the combinatorial optimization problem of [Eq. \(4\)](#) significantly reduces as its combinatorial space is from the boundary atoms in receptor and ligand. As stated earlier, the unavoidable combinatorial explosion nature of docking problem necessarily requires to adopt a heuristic method into the solution process. Frequently used heuristics are genetic algorithm, Monte Carlo (the simulated annealing) method, tabu search, or some combination of these heuristics. Local search method, such as the conjugate gradient method, is also sometimes combined with heuristic method [156]. The generation of some initial solutions is usually the precondition to launch the solution process.

3.2 Scoring Subproblem

Binding affinity between receptor and ligand is measured by the scoring functions whose role is to estimate the binding free energy that estimates the fitness between the molecules. The accuracy of the scoring function has a major impact on the quality of docking results because the final docked pose is usually selected according to their scores. There are three categories of scoring functions [19, 186]:

- *First-principle method* [62, 90, 156]

This method is also called the *force field method* because binding affinity is estimated by the mathematical function of the force field used in molecular mechanics. For instance, [Eq. \(4\)](#) itself is an example of the scoring function of this type. Compared to other two methods below, this approach is usually computationally expensive while the solution quality is better.

- Empirical (or statistical) scoring functions [13–15, 60, 70, 177, 177, 180, 193, 209]

This method estimates binding affinity by a weighted sum of statistically uncorrelated, additive terms where the formula is devised through a multivariate regression analysis based on a set of carefully chosen learning set of structure files from PDB. For instance, the scoring function used by LUDI takes into account hydrogen bonds, ionic interaction, the lipophilic protein-ligand contact surface, and the number of rotatable bonds in the ligand [14]. Hence, taking other types of molecular features into consideration introduces different empirical scoring functions. While the computational speed is very fast, the main disadvantage of this approach is its dependence on the data set used in the regression analysis and the regression model used in the parameter estimation. To improve the precision of estimation, the solvent accessible surface is sometimes taken into consideration [13, 14].

- Knowledge-based scoring functions [49, 50, 73, 85, 159, 201]

This method estimates binding affinity by primarily observing the frequencies of the contacts between protein-ligand atom pairs in the database of

three-dimensional structures of protein-ligand complexes via a procedure based on statistical mechanics [85]. This type is built from statistical analysis of experimentally determined structures in PDB assuming that interatomic distances occurring more often than some average value should represent favorable contacts. Usually this method uses very simple potential function and allows very efficient screening of large compound databases.

Combination of more than one type of scoring functions is sometimes used in the name of *consensus scoring* to reduce a false positive [30, 37, 210]. Depending on the problem at hand, different scoring function needs to be used by compromising accuracy and computational requirement. For example, virtual screening requires to use a computationally efficient scoring function because it has to scan a large compound database to quickly locate a set of lead compounds. Examples of well-known chemical databases are as follows: Available Chemicals Directory [9], Cambridge Structural Database [4, 27], and MACCS-II Drug Data Report [139]. The performance of a scoring function can be evaluated by checking how closely the predicted conformation resembles the one observed in the experimentally determined structure by X-ray crystallography or NMR. Devising a good scoring function still remains an important problem of future study. It is important to note that the “empirical scoring function” is a misnomer in that all scoring functions are indeed empirical in principle. Instead, the *statistical (regression) scoring function* may be more appropriate to denote this type of scoring functions. A comparative evaluation of 11 scoring functions is given in [210]. Other reviews on the scoring function are also available [72, 110, 152, 190, 195, 210].

3.3 Two Primary Uses of Heuristics in Docking

There are two main locations in docking simulation where heuristics are used:

- In the search of the global minimum of the energy function of Eq. (4), and
- the conformation change by assigning a new dihedral angle for each rotatable bond.

The heuristics used in docking software for finding the global minima should also be discussed. In much software, the classical concept of GA is sometimes modified to fit special requirements. For example, Lamarckian GA used in AutoDock or the tabu search-enhanced GA in PSI-DOCK have been reported as exploring the conformational space of ligand efficiently [156, 169]. Most heuristics in docking algorithms require some initial ligand conformations in the vicinity of receptor at the early phase of the algorithm execution. Recent studies suggested locating the initial positions of the ligand around the predicted binding site [42, 158]. Good reviews on the heuristics in docking are available as follows: Westhead et al. reported a comparison of four heuristic algorithms for molecular docking: the simulated annealing, the genetic algorithm, the evolutionary programming, and the tabu search [215]. Baxter et al. reported a docking algorithm using tabu search as the meta-heuristic [12]. In these works, the starting position and orientation of the ligand were randomized around the bounding box containing a pocket, without

explaining how the pocket was computed. Diller and Verlinde reported a comparison of four heuristic algorithms for molecular docking: the random walk, the simulated annealing, the stochastic approximation with smoothing, and the terminal repeller unconstrained subenergy tunneling [52]. In this work, the authors also distributed the initial ligand uniformly around the bounding box. In [110], the use of GA for the docking problem was described in detail.

3.4 Grid: Computational Acceleration

Because of heavy computational requirement in docking simulation, acceleration techniques are important. To reduce computation time, various types of preprocessing are usually performed before main computational process launches for docking. One of the most common and effective techniques is to use a grid system as proposed by Eyck to approximate the force field around the Euclidean space where docking simulation is conducted [63].

Usually a rectangular bounding box containing receptor is first created and the space within the box is transformed into a grid system with a prescribed granularity. Then, the potential energy of ligand is computed and assigned at each grid point so that the grid system is to be used as a lookup table for the rapid evaluation of potential energy via interpolation. Suppose that the ligand is placed at an arbitrary location within the bounding box during docking simulation. Then, the values at the nearby grid points are retrieved and appropriately interpolated to estimate the energy of the ligand at the location. Since the evaluation of the potential energy can be expensive, this interpolation-based technique can save a significant amount of computation. Particularly when a complicated force function is used, this type of preprocessing is effective and therefore most programs like DOCK and AutoDock use variations of such a grid system. For example, see [75, 76]. Without such a supplementary device, the computation time ordinarily increases rather quickly with respect to the product of the numbers of atoms in receptor and ligand.

3.5 Input Data to Docking Simulation

For docking simulation, it is a prerequisite to have the three-dimensional structure (i.e., the atomic coordinates) of molecules. Usually X-ray diffraction, NMR, or homology modeling are used to determine the three-dimensional structure of proteins. Once the structure is solved⁵, the structure data are usually uploaded in a public database called Protein Data Bank (PDB) [179] from which they can be freely

⁵In the structural biology community, the term *solved* or *determined* means that the atomic coordinates of molecules are determined by interpreting data obtained from X-ray crystallography, NMR, or other means such as computational homology modeling.

downloaded. Each PDB file is a text file containing geometric data, physicochemical data, and biological data of a protein.

A PDB file usually contains a protein. However, a PDB file may contain other molecules bound to protein. Water molecules are frequently found. There are also many PDB files containing a protein bound by chemical compounds, DNA, and/or RNA. Depending on application that use PDB file, it is usually necessary to preprocess the file. For example, water molecules, ligands, or other molecules like DNA or RNA may have been removed from the file before the protein is processed. Each PDB file is associated with a resolution which denotes the precision level of the file. A PDB file may not have a complete information about the corresponding protein. Depending on the condition that the protein structure is determined, a subset of the protein structure may be missing from the PDB file.

Each distinct protein has a unique sequence defining its primal structure. Once a protein sequence is identified, it is usually uploaded to UniPROT [199], a public website maintaining protein sequence database. On the other hand, PDB catalogues the structure data of proteins (possibly with other molecules). A distinct protein in UniPROT may correspond to several files (i.e., structures) in PDB because different researcher may solve the structure of the identical protein and upload to the PDB site. For example, the famous P53 (also known as *protein 53* or *tumor protein 53*) corresponds to more than 40 PDB files. Therefore, it is important to choose a good PDB file for the study of particular protein because different PDB files have different file characteristics.

PDB files mostly contain only heavy atoms and ignore most hydrogen atoms because of the limitation of current technology to determine structure. Hence, it may be necessary to generate those missing hydrogen atoms before using in an application. There are rules to generate hydrogen atoms and the following is an example. Suppose that x , y , and z denote the center of atoms. Let $d(x, y)$ be the Euclidean distance between x and y and $\angle xyz$ be the smaller angle at y . Let H be the hydrogen atom, D be the hydrogen donor, and A be the hydrogen acceptor. It is generally agreed that a hydrogen-bond is defined between H and A if all of the following conditions are simultaneously satisfied [143]: (i) $d(H, A) \leq 2.5 \text{ \AA}$, (ii) $d(A, D) \leq 3.9 \text{ \AA}$, and (iii) $\angle AHD > 90^\circ$ (A , H , and D denote their centers). HBPLUS [143] implements this rule for identifying hydrogen bonds between molecules [86, 149, 218]. There are only three cases of atom pairs that hydrogen bonding can be defined: OH, NH, and SH.

4 Flexibility of Molecules

In 1958, Koshland proposed the *induced fit* theory which states that live proteins change their conformation within solvent and ligands also change their conformation when they bind to proteins [115]. Koshland indeed emphasized the notion of “shape.” Hence, an induced fit denotes the change of molecular shape during binding. This idea adds the flexibility of both receptor and ligand where the flexibility comes from rotatable bonds of both molecules. If the flexibility is to

be considered during docking simulation, the computational requirement increases rather quickly. If both molecules are rigid and do not change their conformations during the process of docking simulation, the docking method is called the *rigid body docking*. If one of both parties (usually the ligand) is flexible, it is called the *semi-flexible docking*. If both parties are flexible, it is called the *flexible docking*.

It can easily be verified that the number of possible conformation of flexible ligand increases exponentially in the number of rotatable bonds. A compound with m rotatable bonds has c^m distinct conformations if there are c local minima for each bond. It can be easily verified that $m = O(n)$ in the worst case where n represents the number of atoms in a ligand (or a receptor). This is because protein is a linear sequence of amino acids and each amino acid has a side chain consisting of atoms. Note that there is an upper bound in the number of atoms in side chains. Recall that rigid-body docking problem is already NP-hard. Let $T(\text{RigidDock})$ be the time complexity of an algorithm solving a rigid-body docking. Let $C(\text{FlexLigand})$ and $C(\text{FlexReceptor})$ be the combinatorial complexity of the flexible ligand and flexible receptor, respectively. Then, the time complexity $T(\text{FlexDock})$ of an algorithm solving the flexible docking problem can be given as

$$T(\text{FlexDock}) = C(\text{FlexLigand}) \cdot C(\text{FlexReceptor}) \cdot T(\text{RigidDock}). \quad (10)$$

This implies that the flexible docking problem is much harder than its rigid-body counterpart. Both the computational difficulty and the computational requirement increase in the order of rigid-body docking, semi-flexible docking, and flexible docking.

4.1 Ligand Flexibility

There are three major methods to incorporate ligand flexibility in docking: *stochastic*, *incremental construction*, and *multi-conformer*. The stochastic method is to use randomness in finding new ligand conformations, and the genetic algorithm or the Monte Carlo algorithm is usually used. Suppose that a ligand has a set of m rotatable bonds where the corresponding dihedral angles are represented as $\Theta = \{\theta_1, \theta_2, \dots, \theta_m\}$. Then, Monte Carlo algorithm assigns each $\theta_i \in \Theta$ at random. As usual convention, the Monte Carlo algorithm adopts the annealing concept in that the first cycle is run at high temperature and the later cycles are done at lower temperatures [26, 75, 76, 191, 211]. ICM and the earlier version of AutoDock use the Monte Carlo method for ligand flexibility. Genetic algorithm is also popular for this purpose. In the genetic algorithm, a new conformation is created by the mutation and crossover of the dihedral angles among the population of ligand conformations [70, 90, 156, 168]. DOCK, GOLD, and the later version of AutoDock use the genetic algorithm.

The multi-conformer method is to create multiple instances of ligand conformations of low energy. Then, the rigid-body docking is tried for each ligand

conformation. In other words, this approach uses rigid-body docking several times [36, 125]. This approach tends to produce an exponential number of ligand conformations with respect to rotatable bonds in the ligand. To avoid the combinatorial explosion, the incremental construction method was devised.

The incremental construction method first divides a ligand into a set of fragments at each rotatable bond and each fragment is independently docked within the binding pocket. Then, fragments are incrementally assembled back to form the entire ligand [13, 14, 45, 126, 185, 214]. The idea was first introduced by Goodford [74] and is now very popular for incorporating ligand flexibility. Hammerhead [214], DOCK4.0, and FlexX use this approach. This method is also used for de novo design of ligand [153]. In the process of fragment assembly, the dynamic programming is frequently used [79]. Minimization using a quasi-Newton method is used to avoid unfavorable steric contacts between adjacent atoms in a molecule as much as possible [111]. The comparison among these approaches are discussed in [25].

4.2 Receptor Flexibility

During the induced fit, conformational change also occurs for receptors. In the reflection of receptor flexibility, it is usual to distinguish two locations of receptor from which the flexibility is induced: the side chain and the backbone. While receptor conformational change usually occurs around the side chains, large backbone movements are also sometimes observed. For example, there is a report for seven test cases that caused significant conformational change for more than half of the interface backbone residues [32]. To cope with the receptor flexibility, the approaches above for ligand can also be used. However, care should be exercised because the blind use of these approaches may find the computational requirement prohibitive.

The most significant approach for receptor flexibility is to use *rotamer library* which is a set of rotamers (meaning *rotational isomer*) where each is a side chain of amino acid found in the crystal structure of proteins [125, 183] or may exist in the native state of may-be-found proteins. Hence, a rotamer library can be considered as a discretization of the large, continuous conformation space of side chains into a finite, small number of probable instances.

A rotamer library can be backbone-independent or backbone-dependent depending on whether the dihedral angles of the rotamers (and their frequencies) depend on the backbone conformation or not [91]. The backbone-independent rotamer library is calculated from the structures of side chains without the reference to the backbone conformation, whereas the backbone-dependent rotamer library presents the side-chain conformations (and frequencies) that are dependent on the backbone conformation. If the information about secondary structure such as helix or sheet is used in calculating a rotamer library, it is called secondary-structure dependent. The first rotamer library was reported by Ponder and Richards [175]. The most widely

used are the backbone-dependent one developed by Dunbrack's group [181] and the backbone-independent one developed by Lovell's group [138].⁶

Given a rotamer library, algorithms are designed to find the most favorable receptor conformation by exploring the entire combinatorial space of all rotamer instances for all amino acids of the receptor. Computing the most favorable protein conformation is also another combinatorial optimization problem and is known to be NP-hard [172]. There are two categories of algorithms for this problem: stochastic and deterministic. Stochastic algorithm obvious includes approaches using the genetic algorithm and Monte Carlo simulation with the randomness incorporated. An important stochastic algorithm is FASTER (Fast and Accurate Side-chain Topology and Energy Refinement) developed by Desmet [48]. FASTER is a greedy algorithm iteratively optimizing single protein conformation given that the rotamers of the other positions are fixed. Deterministic algorithm includes those based on the optimization techniques such as the linear programming, the semi-definite programming, or the mixed-integer programming [5, 31, 69, 77, 109, 202, 219]. An important deterministic algorithm is DEE (Dead-End Elimination) developed by Desmet [47, 123]. DEE is one of the most effective algorithms for pruning the search space of rotamers by attempting to eliminate as many rotamers as possible that are guaranteed incompatible with the global minima of energy function. Originally developed as a method for side-chain optimization problem, DEE is now the most popular method for various other problems as well, such as protein design problem.

However, fully incorporating the receptor flexibility into docking problem is still far beyond current technology. It is interesting to find that the concept of side-chain optimization was already used early in 1975 by Levinthal et al. when they initially proposed the computational approach to understand molecular interaction [133]. There were a few reported cases of employing receptor flexibility (even at a limited sense) [21, 184]. Carlson and McCammon presented a good review of approaches to receptor flexibility [28]. Note: It may seem possible and be even better to create a set of random rotamers because a random library may enable to explore a larger search space. However, it turns out that most members of randomly constructed libraries do not fold into stable protein-like structures.

5 Previous Studies on Docking

In 1890, Emil Fischer, the Nobel Laureate for chemistry in 1902, proposed the theory of *lock-and-key* [64, 65] that became the initial proposition of both the molecular binding and the *shape complementarity*. In 1953, Francis Crick, the Nobel Laureate in physiology or medicine in 1962, suggested the idea of a computational approach to the binding between two small molecules through their surfaces in 1953 (the same year that the double-helix structure of DNA was published in

⁶Both rotamer libraries are freely available at: <http://dunbrack.fccc.edu/bbdep/bbdebformat.php> and <http://kinemage.biochem.duke.edu/databases/rotamer.php>.

Nature by Watson and Crick) and called *knob-and-hole* [44]. Crick suggested that shape complementarity in the helical coiled coil could be modeled as knobs fitting into holes. In 1958, Koshland proposed the *induced-fit* theory explaining the mutual adaptation of both molecules in a certain degree during binding [115–117]. Therefore, the induced-fit theory is a generalization of the initial proposition of the lock-and-key concept by adding the concept of flexibility. Both theories of lock-and-key and induced fit assert that molecular binding is largely shape-determined. In 1963, Koshland reported the strong correlation of the function of an enzyme with its structure and proposed that the geometry of enzyme surface must be a critical feature of the enzymatic process [116].

In 1931, Lennard-Jones explained the possibility of modeling the attractive and repulsive forces between two atoms in the van der Waals fields using the inverse powers of the distance between the centers of atoms [130] among other kinds of empirical functions [23,88]. The original form was the form of (13,7)-powers of the distance, and it was later modified to the currently popular function of (12,6)-powers (as shown in Eq.(1)) to accelerate the function evaluation. This change was because the major portion of the computation in the docking (and the molecular dynamics simulation) was spent in the evaluation of the energy function.⁷

The report [173] by Platzer et al., in 1972, from Scheraga's group, Cornell University, seems to be one of the earliest works of computational docking which was applied to an enzyme against substrates. The study already discussed the two distinct aspects of docking: (i) the prediction of location and orientation of a substrate and (ii) the minimization of the estimated free energy. In 1975, Levinthal et al. used computerized molecular modeling to study the arrangement of hemoglobin molecules within a sickling cell by analyzing the geometric contacts between molecules after geometric transformations are made [133]. This study employed a purely geometric approach in analyzing the relation between molecules by using fully determined structures and attempted to maximize the “size” of the contact region in terms of the number of interacting atomic groups.

In 1978, Wodak and Janin first presented an algorithm for docking that solely used the empirical potential energy function for the nonbonded interaction between proteins [216]. In this very first work, they used the simplified (8,6)-Lennard-Jones potential function to refine the relative configuration to allow more interpenetrations (i.e., more intersections) between receptor atoms and ligand atoms.⁸ In the same

⁷ Note that r^{-12} can be computed as $(r^{-6}) * (r^{-6})$ where r^{-6} can be computed by $r^{-2} * r^{-2} * r^{-2}$. Hence, for one function evaluation, r^{-12} (used in the (12,6)-form) requires four multiplications whereas r^{-13} (used in the (13,7)-form) requires five multiplications, both in floating-point arithmetic. Therefore, one multiplication is saved in each function evaluation by the modification. Recall that this function evaluation is performed many times in docking simulation.

⁸ In (8,6)-Lennard-Jones form, r^{-8} term represents the repulsive force. Note that r^{-8} grows slower than r^{-12} as r , the interatomic distance, decreases. Hence, (8,6)-Lennard-Jones form allows more intersections between receptor atoms and ligand atoms than (12,6)-Lennard-Jones form does.

year, Greer and Bush discussed an algorithm for computing the boundary⁹ [78] and proposed the possibility of applying the algorithm for detecting the “shape complementarity” between receptor and ligand. The study by Wodak and Janin in [216] was based on the force function whereas the one by Greer and Bush in [78] was purely geometric.

In 1982, Kuntz’s group, University of California San Francisco, observed the possibility of better using the shape complementarity between a receptor and a ligand [121]. They first extracted a pocket on the receptor boundary and primarily used the geometric fit or shape matching between the pocket and the ligand. They first generated a set of artificial spheres on the surface of the receptor and collected the spheres in each presumptive binding site that corresponded to a pocket. Then, they tried the shape matching between the sphere set in the pocket and the atoms in the ligand by comparing the distribution of intersphere distances for the pocket and the distribution of the interatomic distances for the ligand. They continued the study to speed up and explore more search space [46, 61, 187, 188]. Later in 1993, they also included the minimization of the (12,6)-Lennard-Jones potential energy function [146] and incorporated the flexibility of the ligand [62, 158]. Hence, the approach by Kuntz’s group eventually evolved to a hybrid approach starting from a purely geometric approach. For the shape matching, they used bipartite graph matching, etc. The effort by Kuntz’s group has resulted in the software DOCK whose core part is still being actively used in some softwares. Connolly also suggested using the shape complementarity for docking [41]. There have also been many other studies following the idea of using the shape complementarity in docking [33, 34, 41, 66, 81, 87, 93, 129, 149, 161–164, 187, 206, 208].

An approach solely based on the energy minimization immediately follows. In 1985, Goodford reported an approach using the energy function including the (12,6)-Lennard-Jones potential function, the electrostatic function, and the hydrogen bond function [74]. In 1990, Olson’s group, Scripps in California, extended Goodford’s approach adapting the Monte Carlo method [147, 148] in the search of the global minimum of the energy function [75] based on the AMBER force field. Later, Olson’s group generalized their study to cope with ligand flexibility [76, 155]. In 1998, they adopted the genetic algorithm to replace the Monte Carlo method in the search of the global minimum [156]. The continuing research of this group has resulted in the popular software AutoDock [84, 157]. It is interesting to note that this group is solely based on the energy function minimization and does not take advantage of shape complementarity at all. AutoDock produces initial ligand conformations by placing ligands on the boundary of a bounding box around a receptor. AutoDock is reported to be the most frequently cited docking software in publications [190]. Scheraga’s group is another example of solely using the

⁹Specifically speaking, the boundary was the Lee-Richards (accessible) surface in structural molecular biology term or the offset surface in geometer’s term. For the clear-cut explanation about these terms, see [106].

energy minimization [71, 127, 128, 135, 137, 165] which led to the docking software PRODOCK in 1999 [197].

Starting with the concept of “shape complementarity” by Fischer, there were many studies emphasizing either one of the shape or potential energy. In 1991, S. Kim’s group verified that both geometric and energetic complementarity on molecular boundary are important in docking and proposed *soft docking* concept [87]. In the soft docking, they used both shape and energy: They first used geometric complementarity to effectively and efficiently reduce the solution space and then used the minimization of energy function. Since then, there were many studies and softwares which follows the idea of soft docking. In 1995, the group of Jones and Glen, University of Sheffield and Wellcome Research Lab, respectively, reported GOLD (Genetic Optimization for Ligand Docking) which is a hybrid approach using both shape complementarity and energy function minimization [89, 90]. After extracting a protein pocket (without an explanation), they placed ligand within the pocket using a least-square fitting technique. Then, they applied the minimization of the energy function consisting of (12,6)-Lennard-Jones potential and the hydrogen bonding. They used a genetic algorithm in the search of the global minima of the energy function.

In 1994, Abagyan’s group, European Molecular Biology Laboratory at Heidelberg, reported ICM¹⁰ which is based on the internal coordinate system [1, 3]. In ICM, both the search of global minimum and the ligand flexibility are found by Monte Carlo simulation.

In 1995, Rarey’s group, German National Research Center (GMD) for Computer Science, reported FlexX which emphasizes the explicit exploitation of ligand flexibility in docking. They used the incremental construction algorithm to handle the ligand flexibility [118, 176–178]. They reported FlexE as the derivative of FlexX to add the receptor flexibility using a pre-created, superimposed ensemble of receptor structures [38]. FlexE uses the same scoring function as FlexX.

Sousa et al. reported a good review about the docking software currently used [190]. According to the statistics reported in [190], the five most popular docking softwares are AutoDock, GOLD, FlexX, DOCK, and ICM in the given order.

In the context of this chapter, it may be necessary to mention about the research and development effort for molecular docking simulation from author’s group. Author’s group has developed the theory of beta-complex based on the Voronoi diagram of atoms in molecules (which is briefly explained in the section). Based on the beta-complex theory, a new, powerful docking method has recently been developed [108]. Later sections explain docking problem formulated as the combinatorial optimization problem based on the beta-complex theory. The presented theory was entirely implemented into a software BetaDock and is freely available from the Voronoi Diagram Research Center (VDRC), Hanyang University [204].

¹⁰Initially, ICM was short for Internal Coordinate Modeling [3] and it is now for Internal Coordinate Mechanics [2].

6 Formalization of Topology Structures

As explained earlier, the recognition of molecular boundary is very helpful for facilitating the effective and efficient combinatorial search of ligand location and orientation with respect to receptor. Recognized molecular boundary is in general two-dimensional manifold, and therefore it is useful to have its own two-dimensional topology representation. This is because applications frequently require topology information for efficient query processing. There are different definitions of molecular boundary depending on context [106]. Regardless its definition, it is necessary to have the representation of proximity among molecular atoms for the effective and efficient recognition of molecular boundary. Earlier studies on the molecular shape, however, rarely used the concept of topology.

This section introduces the theory about topology among (spherical) particles, including molecular atoms, in \mathbb{R}^3 from three different perspectives: *primal structures*, *dual structures*, and *molecular structures*. Despite that the primary interest is spherical atoms with different radii in \mathbb{R}^3 , points are also discussed as they may represent atoms with equal radii. The combinatorial complexity of all structures in this section are $O(n^2)$ in the worst case and $O(n)$ on average in \mathbb{R}^3 for n generating particles [7, 8, 166]. For convenience of discussion, all particles are assumed to be in general position so as to avoid computational degeneracy.

6.1 Primal Structures

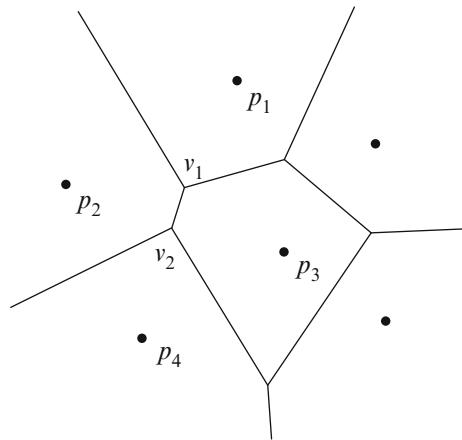

6.1.1 Ordinary Voronoi Diagram of Points

Let $P = \{p_1, p_2, \dots, p_n\}$ be a finite set of point sites in \mathbb{R}^d , $d = 1, 2, \dots$. An *ordinary Voronoi diagram* $VD(P)$ of P tessellates the space \mathbb{R}^d such that each cell in the tessellation corresponds to one of the sites and all the locations in the cell are closer to the corresponding point site than to any other site. Formally, a *Voronoi cell* $VC(p_i)$ of a site p_i is defined as

$$VC(p_i) = \{x \in \mathbb{R}^d \mid d(x, p_i) \leq d(x, p_j) \text{ for } i \neq j\} \quad (11)$$

where $d(x, p)$ is the Euclidean distance between two points $x, p \in \mathbb{R}^d$. Voronoi cell $VC(p)$ is always a convex polyhedron. The ordinary Voronoi diagram $VD(P)$ can be defined as $VD(P) = \{VC(p_1), VC(p_2), \dots, VC(p_n)\}$ where the connectivity among the topological entities (such as vertices, edges, faces, and higher-dimensional cells) of the ordinary Voronoi diagram is appropriately represented. $VD(P)$ is a cell complex and the most compact, concise proximity representation for points in Euclidean space. For the review on the theory, algorithms, and applications of the ordinary Voronoi diagram, see [8, 166]. Efficient and robust codes for computing $VD(P)$ in \mathbb{R}^2 and \mathbb{R}^3 are available [29, 144, 192]. Figure 4 shows an example of the ordinary Voronoi diagram of six points in the plane. Note that the

Fig. 4 An example of the ordinary Voronoi diagram of six points in the plane

circle passing through the three points p_1 , p_2 , and p_3 is centered at the Voronoi vertex v_1 and never contains p_4 inside.

6.1.2 Power Diagram of Weighted Points

Suppose that each point site $p_i \in P$ is assigned with a real number $w_i \geq 0$, where w_i denotes the weight of p_i . The weighted points $p_i^w = (p_i, w_i)$ form a set $P^w = \{p_1^w, p_2^w, \dots, p_n^w\}$. Let $\text{pow}(x, p_i^w) = d(x, p_i)^2 - w_i$ be the power distance. Then, a *power cell* $\text{PC}(p^w)$ is defined as

$$\text{PC}(p_i^w) = \{x \in \mathbb{R}^d \mid \text{pow}(x, p_i^w) \leq \text{pow}(x, q_j^w) \text{ for } i \neq j\}. \quad (12)$$

The power diagram $\text{PD}(P^w)$ can be defined as $\text{PD}(P^w) = \{\text{PC}(p_1^w), \text{PC}(p_2^w), \dots, \text{PC}(p_n^w)\}$ where the connectivity among the topological entities is appropriately represented [7]. $\text{PD}(P^w)$ is also sometimes called the Laguerre diagram or the Dirichlet cell complex. Bisectors in the power diagram are planar. Hence, the power cells in the power diagram are bounded by planar facets and form a cell complex. The power distance corresponding to a point $p \in \mathbb{R}^d$ and the related weight w has a nice geometric interpretation as follows. A weighted point $p^w = (p, w)$ can be viewed as a sphere $s = (p, \sqrt{w})$ where p and \sqrt{w} are the center and radius of s , respectively. Then, $\text{pow}(x, p^w)$ can be interpreted as a tangential distance from point x to sphere s . Hence, the topology of the power diagram $\text{PD}(P^w)$ is not necessarily identical to the topology of the ordinary Voronoi diagram $\text{VD}(P)$. Figure 6 shows an example of the power diagram for six circles in the plane where the circle centers are at the points in Fig. 4. Note that the empty tangent circle defined by the three circles a_1 , a_2 , and a_3 is not centered at v_3 in general and may intersect the other circle a_4 .

Power diagram reflects the size of spheres in the tessellation at a certain level, while the ordinary Voronoi diagram of points does not. Its computation is based on the solution of a linear system like the ordinary Voronoi diagram of points. A power bisector between two spheres s_i and s_j always passes through the intersection of the boundaries of the spheres, if s_i and s_j do intersect. Hence, power diagram correctly represents the intersection events among the intersecting spheres. However, it should be emphasized that power diagram has a few shortcomings for Euclidean space applications: (i) the Euclidean proximity among nonintersecting spheres may not be correctly represented in the topology of the power diagram, and (ii) a power cell $\text{PC}(p^w)$ may not contain the center p of its generating sphere. Aurenhammer [7] gives an excellent review on the power diagram.

6.1.3 Voronoi Diagram of Spheres

Consider a d -dimensional sphere set $S = \{s_1, s_2, \dots, s_n\}$ where $s_i = (p_i, r_i)$ is a sphere (or an atom) with the center p_i and radius r_i . Hence, $s_i = \{q \in \mathbb{R}^d \mid \|q - p_i\| \leq r_i\}$. Assume that $s_i \not\subseteq s_j$ for all $i \neq j$, but $s_i \cap s_j \neq \emptyset$ for some $i \neq j$. Let $\text{VC}(s_i)$ denote a *Voronoi cell* for s_i defined as follows:

$$\text{VC}(s_i) = \{x \in \mathbb{R}^d \mid d(x, p_i) - r_i \leq d(x, p_j) - r_j \quad \text{for } i \neq j\}. \quad (13)$$

Then, the Voronoi diagram $\text{VD}(S)$ for the sphere set S is defined as $\text{VD}(S) = \{\text{VC}(s_1), \text{VC}(s_2), \dots, \text{VC}(s_n)\}$ where the connectivity among the topological entities are appropriately represented. In \mathbb{R}^3 , the topological entities are vertices (V-vertices), edges (V-edges), faces (V-faces), and cells (V-cells) whose sets are denoted as $V^V = \{v_1^V, v_2^V, \dots\}$, $E^V = \{e_1^V, e_2^V, \dots\}$, $F^V = \{f_1^V, f_2^V, \dots\}$, and $C^V = \{c_1^V, c_2^V, \dots, c_n^V\}$, respectively. By definition, a V-vertex v^V is the center of an empty sphere tangent to the boundaries of four nearby atoms, and a V-edge e^V is a locus of points equidistant from the boundaries of three nearby atoms. A V-face f^V is the mid-surface between the boundaries of two nearby atoms. While both $\text{VD}(P)$ and $\text{PD}(P^w)$ are cell complexes, $\text{VD}(S)$ may not be a cell complex because a Voronoi face in $\text{VD}(S)$ may contain holes. The Voronoi diagram of spheres in \mathbb{R}^3 can be computed in $O(n^3)$ time in the worst case [98] and in $O(n)$ time on average [35], where n is the number of spheres in S . Figure 5 shows an example of the Voronoi diagram for the six circles in Fig. 6. Verify the topology difference in the two figures. Note that the empty tangent circle defined by the three circles a_1, a_2 , and a_4 is centered at the Voronoi vertex v_5 and does not intersect the other circle a_3 .

The Voronoi diagram of spheres is also known as an additively weighted Voronoi diagram in computational geometry [166]. However, from the application point of view (particularly for structural molecular biology point of view), the name of “Voronoi diagram of spheres (or spherical atoms)” is preferred because the interpretation of the weights associated with point sites are more intuitive when they are considered as the radii of spheres or atoms in the Euclidean space. For the details of the Voronoi diagram of spheres, see [95, 98].

Fig. 5 An example of the ordinary Voronoi diagram of six points in the plane

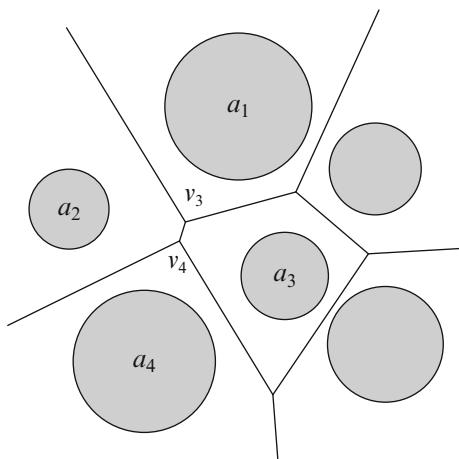

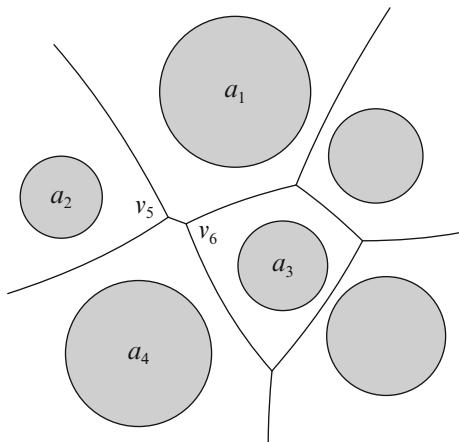

Fig. 6 An example of the power diagram of six circles in the plane

6.2 Dual Structures

Dual structure is usually more convenient than the corresponding primal structure for reasoning the spatial proximity among particles. If a dual structure is a simplicial complex, it can be usually more compactly stored in the memory than its primal structure while the query performance is maintained at the same level of efficiency. In addition, algorithms for topology traversal in a simplicial complex are much simpler.

6.2.1 Dual Mapping

The topological dual mapping between the primal and the dual structures has been recently reported in [100, 104]. Let \mathbb{D} be a *dual operator* which transforms \mathcal{VD} to \mathcal{QT} which is defined as follows:

- $\mathbb{D} : c^{\mathcal{V}} \Rightarrow v^{\mathcal{Q}}$ is a mapping from a V-cell $c^{\mathcal{V}} \in C^{\mathcal{V}}$ to a q-vertex $v^{\mathcal{Q}} \in V^{\mathcal{Q}}$. The coordinate of the q-vertex $v^{\mathcal{Q}}$ is the center p of the atom a corresponding to the V-cell $c^{\mathcal{V}}$.
- $\mathbb{D} : f^{\mathcal{V}} \Rightarrow e^{\mathcal{Q}}$ is a mapping from a V-face $f^{\mathcal{V}} \in F^{\mathcal{V}}$ to a q-edge $e^{\mathcal{Q}} \in E^{\mathcal{Q}}$. The q-edge $e^{\mathcal{Q}}$ is a line segment bounded by $v_i^{\mathcal{Q}}$ and $v_j^{\mathcal{Q}}$, for distinct i and j , where the atoms a_i and a_j define the V-face $f^{\mathcal{V}}$. The orientation of $e^{\mathcal{Q}}$ can be arbitrary.
- $\mathbb{D} : e^{\mathcal{V}} \Rightarrow f^{\mathcal{Q}}$ is a mapping from a V-edge $e^{\mathcal{V}} \in E^{\mathcal{V}}$ to a q-face $f^{\mathcal{Q}} \in F^{\mathcal{Q}}$. The q-face $f^{\mathcal{Q}}$ is a triangle whose vertices are $v_i^{\mathcal{Q}}$, $v_j^{\mathcal{Q}}$, and $v_k^{\mathcal{Q}}$, for distinct i , j , and k , where the atoms a_i , a_j , and a_k define the V-edge $e^{\mathcal{V}}$. The orientation of $f^{\mathcal{Q}}$ should be consistent with the orientation of $e^{\mathcal{V}}$.
- $\mathbb{D} : v^{\mathcal{V}} \Rightarrow c^{\mathcal{Q}}$ is a mapping from a V-vertex $v^{\mathcal{V}} \in V^{\mathcal{V}}$ to a q-cell $c^{\mathcal{Q}} \in C^{\mathcal{Q}}$. The q-cell $c^{\mathcal{Q}}$ is a topological tetrahedron bounded by four vertices $v_i^{\mathcal{Q}}$, $v_j^{\mathcal{Q}}$, $v_k^{\mathcal{Q}}$, and $v_l^{\mathcal{Q}}$, for distinct i , j , k , and l , which correspond to the four atoms defining the V-vertex $v^{\mathcal{V}}$. The orientation among the four q-vertices is identical to the orientation of the four tangent points between the four atoms and the empty tangent sphere corresponding to the V-vertex. Each pair of q-vertices defines a q-edge $e^{\mathcal{Q}}$ of $c^{\mathcal{Q}}$, and each triplet of $v^{\mathcal{Q}}$'s defines a q-face $f^{\mathcal{Q}}$ of $c^{\mathcal{Q}}$, where the orientation of $e^{\mathcal{Q}}$ and $f^{\mathcal{Q}}$ are maintained as stated above.

6.2.2 Delaunay Triangulation

Given a set P of d -dimensional points, the Delaunay triangulation $\text{DT}(P)$ is the set of simplexes $d\text{-}\sigma$ such that the $(d + 1)$ vertices of $d\text{-}\sigma$ are in P and the interior of $d\text{-}\sigma$ does not contain any point of P . It is well-known that $\text{DT}(P)$ is the topological dual of the Voronoi diagram $\text{VD}(P)$ of P obtained by applying the dual operator \mathbb{D} to $\text{VD}(P)$. Due to several convenient properties, $\text{DT}(P)$ has been extensively studied and used. Robust and efficient algorithms and codes for $\text{DT}(P)$ in \mathbb{R}^2 and \mathbb{R}^3 are available [29, 144, 192]. The transformation between $\text{VD}(P)$ and $\text{DT}(P)$ takes linear time with respect to the number of topological entities involved. $\text{VD}(P)$ is a cell complex and $\text{DT}(P)$ is a simplicial complex¹¹ if the points are in general position [7, 8, 16].

6.2.3 Regular Triangulation

The process for obtaining regular triangulation is similar to the process for Delaunay triangulation. The regular triangulation can be obtained by applying the dual operator \mathbb{D} to the power diagram [141]. The regular triangulation is also a simplicial complex and the transformation between the power diagram and the regular triangulation can be done in linear time with respect to the number of topological entities involved [166].

¹¹A *simplicial complex* \mathcal{C} is a finite set of simplexes such that (1) any face of a simplex in \mathcal{C} is also a simplex in \mathcal{C} and (2) if two simplexes in \mathcal{C} intersect, they intersect at a lower-dimensional simplex which is a face of both simplexes [16].

6.2.4 Quasi-triangulation

While the Voronoi diagrams of circles in \mathbb{R}^2 and spheres in \mathbb{R}^3 have been discussed since the eighties, the topological dual of the Voronoi diagram has never been discussed until the notion of the quasi-triangulation was proposed by author's group in 2006 [100]. Recall that the Voronoi diagram of spheres may not be a cellcomplex. It turns out that the dual structure of the Voronoi diagram of spheres is not necessarily a simplicial complex. In fact, the dual structure may not even satisfy the conditions for being a complex.

Suppose that the dual operator \mathbb{D} is applied to the Voronoi diagram $VD(S)$ of a sphere set S . Then, a Voronoi diagram $VD(S)$ is mapped to a dual structure called the *quasi-triangulation* $QT(S)$ where $QT(S) = \{\tau_1, \tau_2, \dots, \Delta_1, \Delta_2, \dots\}$, where τ and Δ denote a tetrahedron and a triangle, respectively, which are the dual cells in the quasi-triangulation $QT(S)$. Its topology is assumed to be appropriately represented. Let $V^Q = \{v_1^Q, v_2^Q, \dots, v_n^Q\}$, $E^Q = \{e_1^Q, e_2^Q, \dots\}$, $F^Q = \{f_1^Q, f_2^Q, \dots\}$, and $C^Q = \{c_1^Q, c_2^Q, \dots\}$ denote the sets of vertex simplexes, edge simplexes, face simplexes, and cell simplexes in $QT(S)$ in \mathbb{R}^3 , respectively. There are n vertices in V^Q since a vertex v_i^Q corresponds to a generator sphere s_i . For the details of the quasi-triangulation, see [96, 97, 100].

Even though a quasi-triangulation is not a valid triangulation, its topological entities are still vertices, edges, triangles, and tetrahedra. $QT(S)$ is called a quasi-“triangulation” since “most” of the tetrahedra in the dual structure of the Voronoi diagram of spheres satisfy the “local” condition for a simplicial complex. It is called a “quasi”-triangulation since there may be some, “mostly very few,” tetrahedra which altogether do not form a complex and their influences are local in the dual structure. The quasi-triangulation of most protein models reveals this characteristics.

The concept of quasi-ness has been devised due to the following two important reasons:

- The proximity among particles which is stored in the topology of the Voronoi diagram can be most compactly stored in the dual structure.
- To solve application problems more effectively and efficiently using the proximity information, it is necessary to have a well-defined dual structure stored in an appropriate data structure. The computation of the beta-complex and beta-shape is such an example.

6.3 Molecular Structure

6.3.1 Alpha-Shape and Weighted Alpha-Shape

The theory of the alpha-shape is very powerful for the spatial reasoning among point clouds. The initial concept of the alpha-shape was proposed for \mathbb{R}^2 in 1983 [56], and its development for \mathbb{R}^3 was published in 1994 [55] by Edelsbrunner's group. The following intuitive description is adopted from [55]. Suppose that α is a real number such that $0 \leq \alpha \leq \infty$.

Consider a three-dimensional space filled with a soft matter with a set P of solid points scattered within the matter. Carving out the matter with an omnipresent spherical eraser with the radius α will result in a shape called an *alpha-hull*. Since the eraser is omnipresent, there can be interior voids as well. The spherical eraser is called a probe. If the alpha-hull is straightened by substituting straight edges for the circular ones and triangles for the spherical caps, the resulting object bounded by the edges and triangles is called the *alpha-shape* of P .

If $\alpha = \infty$, the alpha-shape is identical to the convex hull of P . For $\alpha = 0$, the alpha-shape reduces to the point set P itself. In general, alpha-shapes can be concave and disconnected. Alpha-shapes can contain two-dimensional patches of triangles and one-dimensional strings of edges. An alpha-shape may have handles and interior voids. Each instance of an alpha-shape for a given value of α can be efficiently computed by checking if each simplex in the Delaunay triangulation should remain in the alpha-shape. The theory of alpha-shape is based on the Delaunay triangulation of points and therefore does not account for the size variations among atoms centered at the points in P at all. The subset of the Delaunay triangulation contained within or on the boundary of an alpha-shape is called the alpha-complex.

To reflect the size variation among atoms, the alpha-shape was extended to the weighted alpha-shape using the regular triangulation [54]. Concepts and algorithms for the weighted alpha-shape are very close to the ordinary alpha-shape except that the distance measure used is now the power distance. Hence, a regular triangulation for the weighted points is first computed, and the edges and faces which are considered to be larger than a spherical eraser, in the power distance sense, are removed from the regular triangulation. Hence, the weighted alpha-shape reflects the size variations among spheres into consideration at a certain level. The weighted alpha-shapes have been used in biology to recognize the shapes of proteins since the atoms in the proteins usually have different sizes. However, the distance metric, the power distance, is not very convenient in many aspects. While the power diagram has correct information about the intersection event between atoms, the spatial proximity between nonintersecting atoms cannot be made correctly unless a global search is performed in the worst case. The weighted alpha-complex inherits this shortcoming. Therefore, for many spatial reasoning problems among nonintersecting atoms, the weighted alpha-shape algorithm requires to recompute the power diagram after an input atom set is modified based on the problem formulation in terms of intersecting atoms. Difficulty to comprehend the behavior of the weighted alpha-shape is another significant drawback. It is not easy to intuitively visualize and anticipate how the theory may operate in the Euclidean space. The discussions of the theoretical aspects of the weighted alpha-shapes are not widely available, very few [54].

6.3.2 Beta-Complex and Beta-Shape

To fully incorporate the size differences of spheres in the Euclidean space, the concept of the beta-complex and beta-shape has been proposed by author's group [101, 105]. The beta-complex is very powerful in reasoning the spatial

properties of a sphere set S in the ordinary, intuitive Euclidean distance sense. The beta-complex is an “abstraction” of the set S as a set of vertices, edges, faces, and cells with an appropriate representation of its topology among the simplexes. On the other hand, the beta-complex is also an “exact representation” of the set S itself. Hence, the beta-complex is not an ordinary approximation of S . Due to these properties, the beta-complex can be used for efficient processing of both the global reasoning about the shape of S and the local computation such as mass properties like the volume and area of the union of spheres in S . The beta-shape defines the topology among atoms on the boundary and facilitates the efficient computation of the Connolly surface [182], the extraction of pockets [99], etc.

Intuitive explanation of the beta-shape follows. Consider a soft matter filled \mathbb{R}^3 with some spherical, metallic balls of varying radii scattered within the matter. Carving out the soft matter with an omnipresent spherical eraser with the radius β will result in a shape called the *beta-hull*. Hence, the boundary of the resulting beta-hull contains the *blending surface* created by the spherical eraser as the blending ball in addition to the subset of ball boundaries. There can be interior voids as well. The spherical eraser is called a β -probe.

Given a beta-hull, suppose that the beta-hull is straightened as follows. Replace each spherical cap on the boundary of the beta-hull by a triangle whose vertices are the centers of balls touching the cap. Then, the resulting shape consists of those triangular faces, the edges shared by the faces, and the vertices corresponding to the centers of balls touching the spherical caps. The straightened object bounded by the triangular, planar facets is the *beta-shape* of A . It is called a beta-shape because the shape is defined by adopting the concept of β -lending in geometric modeling. No explicit computation for blending operation is performed during the computation but the existence of such blending patches on the boundary of beta-hull is only checked by referring to the appropriate simplexes in the quasi-triangulation. The computations of the beta-complex and the beta-shape are well-defined and very efficient algorithms are available.

Explanation for the beta-complex follows. Consider again the spherical rocks, or atoms, $A = \{a_1, a_2, \dots, a_n\}$ inside the soft matter filled \mathbb{R}^3 where $a_i \cap a_j = \emptyset, i \neq j$. Let a spherical eraser b of size 0 be located at a point $x \in \mathbb{R}^3$ where $x \notin \forall a \in A$. Increase the radius of the eraser b from zero until it touches one rock a_i . While keeping its tangency with a_i , increase the radius of b until it touches another rock $a_j, i \neq j$. In some cases, b may not touch a_j even though its radius increases to ∞ . If it touches two rocks a_i and a_j , increase the radius until it touches $a_k, i \neq j \neq k$, while the tangent contact is maintained. Increase the radius of b until it reaches β . When a_i is touched, a vertex simplex is defined at the center of a_i . When a_i , and a_j are touched, an edge simplex is also defined, in addition to another new vertex simplex corresponding to a_j , between the centers of two rocks. When a_i, a_j , and a_k are touched, a face simplex is defined by the three centers in addition to one more vertex and two more edge simplexes. If a_i, a_j, a_k and a_l are touched, a tetrahedral cell simplex is similarly defined. Hence, during this process starting from a location x , four vertex simplexes, six edge simplexes, four face simplexes, and one tetrahedral cell simplex are created. By repeating this

process for all possible locations in \mathbb{R}^3 , we get the beta-complex of A . Hence, a beta-complex, once computed, can represent the interior topology of the atom set very nicely, while a beta-shape is very convenient for representing the topology among the boundary atoms. The beta-complex is the subset of the quasi-triangulation that is topologically contained within or on the boundary of the beta-shape.

It is important to mention the following. The beta-complex can be computed very efficiently from the quasi-triangulation of a given molecule. The computation is done simply by checking each simplex in the quasi-triangulation if it should remain in the beta-complex for a given value of β . Because the Voronoi diagram of a given molecule is unique, the quasi-triangulation is also unique. This property implies that only one Voronoi diagram (and therefore only one quasi-triangulation) needs to be computed for the beta-complex for any value of β . Therefore, any kind of problems in Euclidean distance can be solved by one Voronoi diagram and therefore one quasi-triangulation. Almost all application problems are Euclidean. The beta-shape can also be computed efficiently from the beta-complex because the boundary of the beta-shape is the boundary of the beta-complex.

[Figure 7](#) illustrates the concept of the Voronoi diagram, the quasi-triangulation, the beta-complex, and beta-shape in the plane. [Figure 7a](#) shows a two-dimensional molecule S consisting of two-dimensional atoms, and [Fig. 7b](#) shows the boundary of S . Note that the boundary contains two internal voids, a few shallow depressions, and a deep depression on the exterior boundary. [Figure 7c](#) is the beta-hull of S corresponding to a small β -probe (shown in the black circle). Note that only one interior void is left in [Fig. 7c](#), which corresponds to the larger void in [Fig. 7b](#). The void corresponding to the smaller one has disappeared. [Figure 7d](#) shows the beta-shape corresponding to the beta-hull of [Fig. 7c](#) where the shaded region is the interior of the beta-shape. The beta-shape in [Fig. 7d](#) has an interior void corresponding to the void of the beta-hull and a dangling edge corresponding to a pair of atoms that are exposed to or touched by the probe. The dangling edge corresponds to the deep depression in the external boundary of the beta-hull. [Figure 7e](#) shows the beta-complex corresponding to the beta-shape in [Fig. 7d](#). Note that each vertex of the beta-shape and beta-complex corresponds to an atom. [Figure 7f, g](#) shows the beta-shape and beta-complex corresponding to a larger probe, respectively. Note that both the dangling edge and the internal void in the beta-shape of [Fig. 7d](#) have now disappeared. The dotted line segments in [Fig. 7g](#) form the quasi-triangulation of the molecule S together with the beta-complex. [Figure 7h](#) shows a three-dimensional protein model, and [Fig. 7i](#) shows its beta-shape corresponding to a probe of the radius 1.4 Å. The white spot in the middle of the beta-shape in [Fig. 7i](#) in fact denotes a tunnel passing through the beta-hull of the protein.

[Figure 8a](#) shows an atomic complex of HIV(PDB accession code: 5hvp). [Figure 8b](#) shows the beta-hull (also frequently called the Connolly surface) of the molecule corresponding to a probe with a radius of 1.4 Å which approximates a water molecule. [Figure 8c-f](#) is the (boundary of) beta-shapes corresponding to the probes of sizes 0, 1.4, 5, and ∞ Å, respectively.

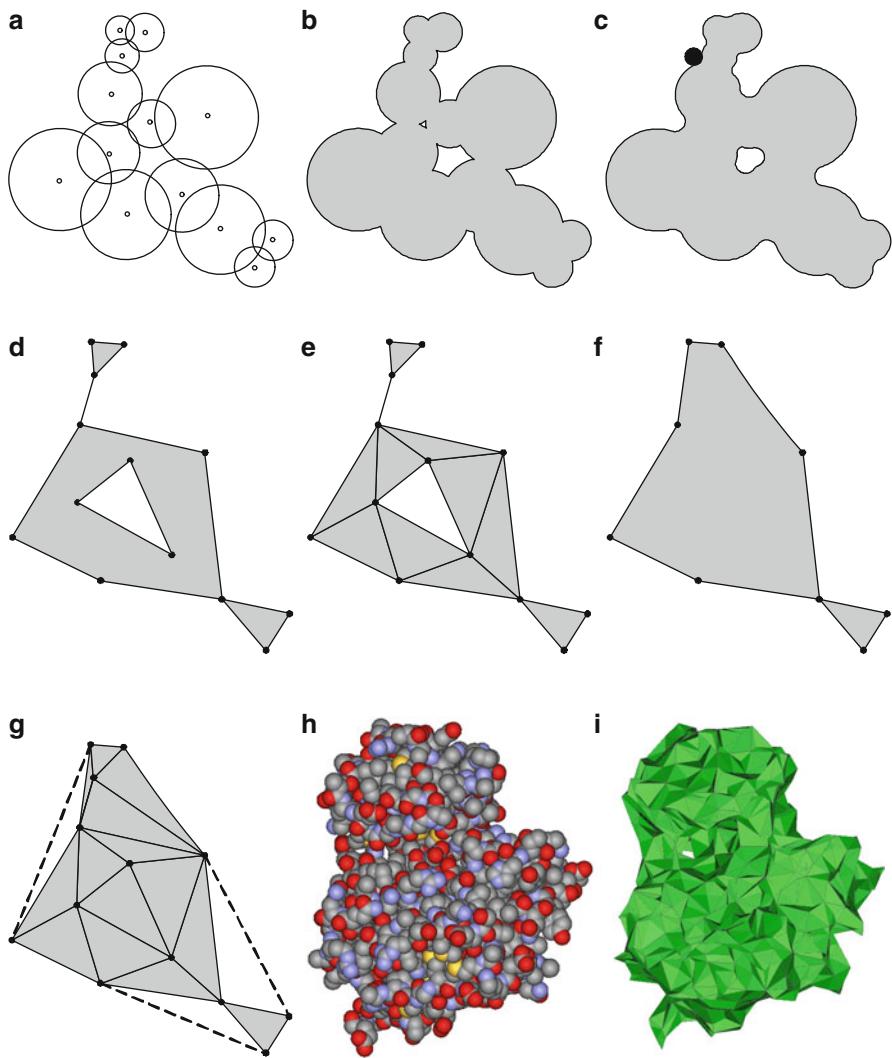

Fig. 7 Protein, the boundaries of the protein, the beta-shape, and the beta-complex. (a) A set of 13 atoms in \mathbb{R}^2 , (b) the vdw-boundary, (c) the molecular surface corresponding to a small probe, (d) the corresponding beta-shape, (e) the corresponding beta-complex, (f) a beta-shape corresponding to a larger probe, (g) the corresponding beta-complex with simplexes removed from the quasi-triangulation, (h) the protein tyrosine kinase (1xba, 2,068 atoms), (i) the beta-shape of 1xba corresponding to $\beta = 1.42 \text{ \AA}$

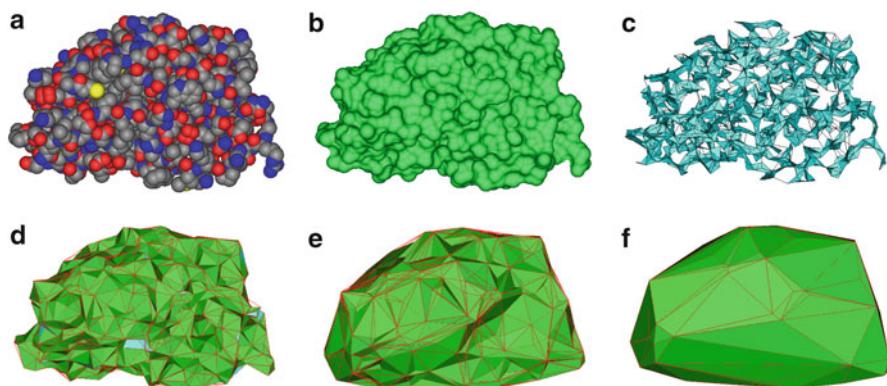

Fig. 8 The beta-hull and different beta-shapes defined by different probes from an atom set. (a) An atomic complex of HIV (PDB accession code: 5hvp), (b) the beta-hull (or the Connolly surface) obtained by a probe with the radius 1.4 Å. (i.e., a water molecule), (c)–(f) the beta-shape corresponding to different values of β : (c) $\beta = 0 \text{ \AA}$, (d) $\beta = 1.4 \text{ \AA}$, (e) $\beta = 5 \text{ \AA}$, (f) $\beta = \infty \text{ \AA}$. Note that (b) and (d) corresponds to the same probe

7 Pocket Extraction Using Beta-Shape

As previously explained, the interaction between receptor and ligand occurs at their boundaries. Assuming the rigidity of molecules (i.e., ignoring flexibility of their conformations), this is obviously true. More importantly, the concept of funnel in the binding energy landscape naturally leads to the concept of geometric and physicochemical complementarity between receptor and ligand. It is generally believed that the bottom of a funnel in the energy landscape corresponds to the depressed shape, called *pocket*, on receptor boundary. The shape complementarity is indeed the fundamental concept of lock-and-key proposed by Fischer in 1890 [64]. Since then, many studies repeatedly have shown that the shape complementarity is of primary importance in docking. In fact, the solution obtained from direct formulation of docking problem as a single, global energy minimization problem is usually very close to the solution obtained by the approach using pocket. Hence, it is not a surprise to find that there were several studies on docking purely based on geometry only [40, 46, 121].

The concept of the shape complementarity naturally leads to the concept of locating a probable docking site, pocket, on the boundary of receptor that a ligand may bind with a high probability. Shape complementarity has long been used in docking. In the past, however, there was no framework of formal theory for properly defining and representing molecular boundary but some ad hoc approaches. Having the powerful theory of the beta-complex and beta-shape to detect molecular boundary, the docking problem can be transformed to a matching problem for sets of points, sets of edges, sets of faces, or their combination. This transformation

naturally leads the docking problem to a combinatorial optimization problem among these discrete entities representing the continuous molecular boundaries. Sections 7–9 present this transformation as used in the docking method and software, called BetaDock, developed by author's group [107, 108].

7.1 Previous Works

There are three approaches for recognizing pockets on molecular boundary: a grid-based approach, a sphere-coating approach, and an approach based on the proximity among atoms on the receptor boundary. Being both conceptually and computationally straightforward, the grid-based approach was the first method of choice that used a three-dimensional spatial lattice of the space occupied by the receptor to reason the relations among the grid points in the lattice [83, 134, 203]. The grid points, associated with some attributes, were then used to extract the exterior boundary of receptor and to recognize the depressed regions on the surface. The sphere-coating approach was to place a set of artificial spherical balls not intersecting the receptor in the space and reasons about the spatial property of the spheres [18, 121, 122]. After making some efforts to use the concept of filling small spheres around a receptor and separating some meaningful chunks of spheres, the mainstream of this approach proceeded to use the mathematically rigorous, computationally efficient, and robust representation of the atomic complex.

Compared to the approaches above, the Voronoi diagrams and their derivative structures provided a formal, theoretical framework to the pocket extraction problem. The alpha-shape was the first generation of this effort and it was used to reason about the proximity among atoms on the boundary of molecules, assuming that all atoms were identically sized. Liang et al. presented a discrete-flow algorithm for extracting pockets [136] based on the definition of a pocket using a alpha-shape [57]. The pocket recognized in this approach was equivalent to the invagination in [112]. Peters et al. reported an algorithm using the alpha-shape to construct the topology among atoms on the surface of a protein [171]. There was an effort to extend the idea of the ordinary alpha-shape to the weighted alpha-shape to cope with the size variation among atoms in proteins.

Kim et al. reported an algorithm to extract pockets of protein based on the theory of the beta-shape. The idea was to use two instances of beta-shapes where one was defined by a small probe (corresponding to water molecule) and the other was defined by a large probe (corresponding to a ligand) [99]. The beta-shape defined by a small β value was called an *inner beta-shape*, and one defined by a large β was called an *outer beta-shape*. Then, the difference between the outer beta-shape and the inner beta-shape defined pockets on the protein boundary. To facilitate the computational efficiency, the boundary of the beta-shape was represented by the winged-edge data structure so that the traversal among simplexes could be done very efficiently. To overcome the non-manifoldness of the beta-shape, manifoldization technique was used [102].

7.2 Extraction of Pocket Using Beta-Shape

Let \mathcal{S} be the beta-shape where $\beta = 1.4$ which corresponds to the probe (1.4-probe) with the radius 1.4 \AA representing water molecule. Proteins usually exist in a cell which is mostly filled with water. Hence, the smallest molecular unit interacting with proteins is usually water. It is well-known that the shape of water molecule is nonsymmetric. However, the interaction of a real water molecule with a biomolecule is too complex to analytically, precisely analyze. Furthermore, the interaction is stochastic rather than deterministic. Hence, it is usual practice to approximate the water molecule with a spherical probe with the radius 1.4 \AA .

Let Σ be the set of all simplexes (i.e., vertices, edges, and triangular faces) of the boundary $\partial\mathcal{S}$ of \mathcal{S} . Let \mathcal{S}^* be the beta-shape corresponding to a threshold β -value $\beta^* > 1.4$. Consider a vertex simplex $\sigma \in \Sigma$ such that σ is exposed to 1.4-probe but not exposed to β^* -probe. This implies that σ , which is a vertex exposed to air in \mathcal{S} , is now internal to $\partial\mathcal{S}^*$. Such a vertex σ on the boundary of \mathcal{S} is called a *potential pocket vertex* and denoted as the *pp-vertex*. The atom corresponding to a pp-vertex is called the *potential pocket atom* and denoted as the *pp-atom*. Let V^{pp} be the set of pp-vertices and A^{pp} be the set of pp-atoms. Suppose that $f \subset \partial\mathcal{S}$ be a face such that all three vertices of f are pp-vertices. Then, f is called the *potential pocket face*, denoted as the *pp-face*. Let F^{pp} be the set of all pp-faces. If $f_i \in F^{pp}$ and $f_j \in F^{pp}$ share an edge in common, they are said to be *edge-connected*.

Let \mathcal{F}^{\max} be a maximal set of edge-connected pp-faces in F^{pp} that is the set of edge-connected faces with the largest number of faces. Hence, for a given F^{pp} , \mathcal{F}^{\max} can be easily found. Let $F^{pp} = F^{pp} - \mathcal{F}^{\max}$. Repeating this operation until F^{pp} is empty, F^{pp} can be decomposed into a set of edge-connected components $\mathcal{F}^{\text{MAX}} = \{\mathcal{F}_1^{\max}, \mathcal{F}_2^{\max}, \dots\}$. Suppose that the elements in \mathcal{F}^{MAX} are in a sorted order such that $|\mathcal{F}_i^{\max}| \geq |\mathcal{F}_j^{\max}|$ if $i < j$, where $|\mathcal{F}_i^{\max}|$ denotes the number of faces in \mathcal{F}_i^{\max} . Hence, \mathcal{F}_i^{\max} does not have fewer atoms than \mathcal{F}_j^{\max} , and \mathcal{F}_i^{\max} is said bigger than \mathcal{F}_j^{\max} , $i < j$. Each component $\mathcal{F}_i^{\max} \in \mathcal{F}^{\text{MAX}}$ is called a *raw pocket*. Let \mathcal{V}_i^{\max} and \mathcal{A}_i^{\max} be the sets of all distinct pp-vertices and the corresponding pp-atoms collected from the faces in the raw pocket \mathcal{F}_i^{\max} , respectively. The computation of the raw pockets is very fast.

[Figure 9a](#) illustrates the PDB model 1t46 which is a combined complex consisting of tyrosine kinase (in gray) with imatinib (in blue) which was found via X-ray crystallography. This type of model, the protein structure with bound compounds, is called a *bound* model. The compound in a bound model is usually regarded as the optimal solution of the computational docking simulation. Note that the most part of the imatinib boundary is buried in the receptor. [Figure 9b](#) shows the tyrosine kinase with a partial transparency. [Figure 9c](#) shows the beta-shape \mathcal{S} of the tyrosine kinase which corresponds to the probe of radius 1.4 \AA . [Figure 9d](#) shows the imatinib. The minimum sphere S_{\min} enclosing the imatinib is computed with the radius 8.13 \AA .

[Figure 10](#) illustrates some examples of the atom set \mathcal{A}_1^{\max} , the biggest raw pocket of the model 1t46 for the various values of β . The blue set is the bound ligand, the imatinib. In all figures of [Fig. 10a–f](#), the imatinib is positioned at the identical location in the receptor. The red set in [Fig. 10](#) is the largest raw pocket \mathcal{A}_1^{\max}

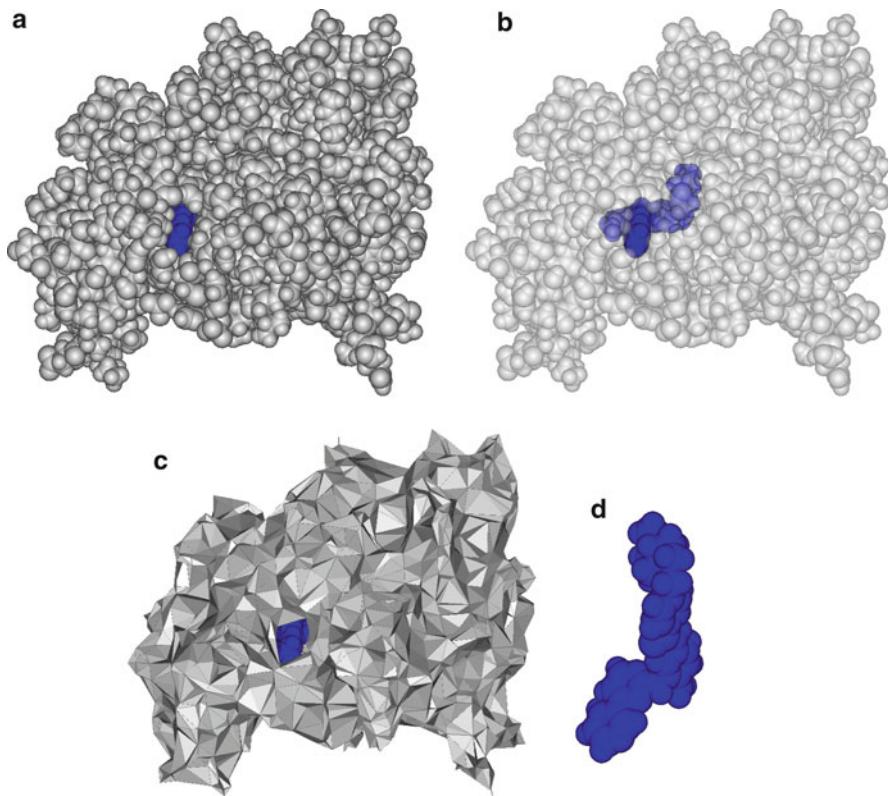

Fig. 9 The protein 1t46 (tyrosine kinase) with a bound ligand (imatinib): (a) space-filling model, (b) transparency applied model, (c) beta-shape for tyrosine kinase corresponding to the probe of water molecule, and (d) imatinib

corresponding to various threshold values of β^* . Figure 10a shows A_1^{\max} where $\beta^*=1.5 \text{ \AA}$. Obviously, 1.5 \AA is significantly smaller than 8.13 \AA , the radius of the minimum sphere of the ligand, and therefore this pocket surely cannot contain the ligand. Therefore, A_1^{\max} corresponding to 1.5 \AA is either located far away from the ligand or interacts with the ligand at a relatively small portion of the interface between the ligand and the receptor. Figure 10b–f shows A_1^{\max} where β^* is 2.0, 3.0, 4.0, 5.0, and 5.71 \AA , respectively. Note that the size of A_1^{\max} increases as β^* increases. When $\beta^* \geq 3.0 \text{ \AA}$, it seems that A_1^{\max} almost completely contains the ligand. Deciding the optimal value of β^* is a challenge and left for future study.

A raw pocket extracted by the procedure above may have noise and therefore the raw pocket goes through a refining process called the pocket refinement. Figure 11 shows the largest pocket of tyrosine kinase extracted by the explained algorithm viewed from three different orientations. In this figure, the raw pocket is visualized as a set of faces on the beta-shape boundary. There are red faces and blue faces in

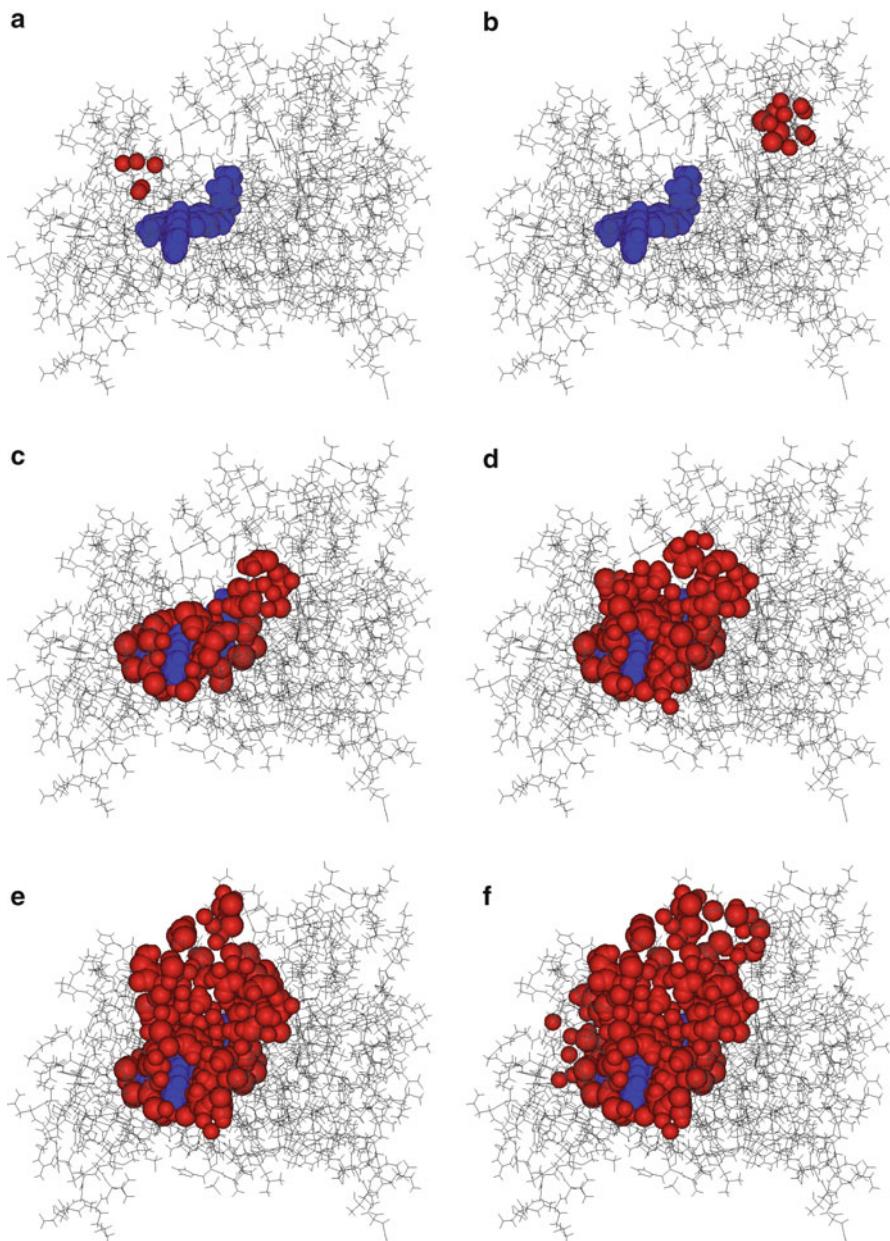

Fig. 10 Atoms in the largest raw pocket \mathcal{F}_l^{\max} of 1t46 corresponding to a particular threshold value. The blue is the ligand (imatinib), and the red are the pockets corresponding to β^* as follows: (a) $\beta^* = 1.5 \text{ \AA}$, (b) $\beta^* = 2.0 \text{ \AA}$, (c) $\beta^* = 3.0 \text{ \AA}$, (d) $\beta^* = 4.0 \text{ \AA}$, (e) $\beta^* = 5.0 \text{ \AA}$, and (f) $\beta^* = 5.71 \text{ \AA}$

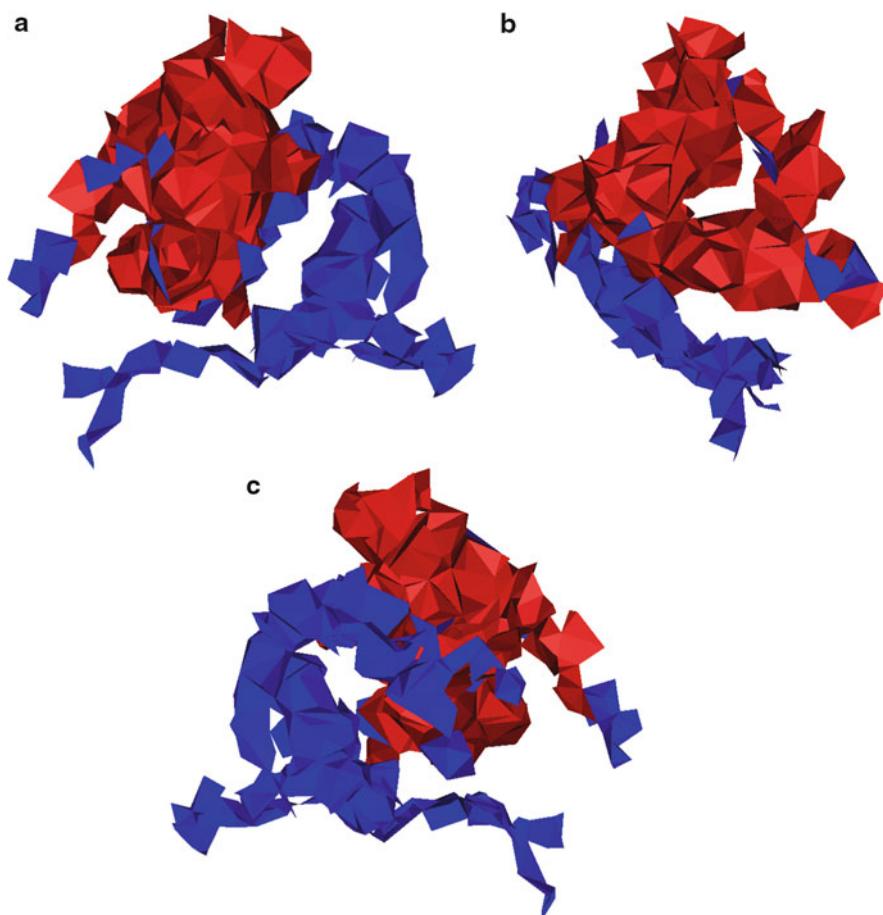

Fig. 11 The largest raw pocket of tyrosine kinase viewed from three different orientations. (a), (b), and (c) 1t46 where $\beta_\theta = 5.71 \text{ \AA}$

the figure. The blue faces are considered as noise and have to be removed from the raw pocket. Therefore, the red face set is the eventually recognized, largest pocket.

There may be other raw pockets: the second largest \mathcal{F}_2^{\max} , the third largest \mathcal{F}_3^{\max} , etc. Figure 12a shows the top three largest potential pockets \mathcal{F}_1^{\max} , \mathcal{F}_2^{\max} , and \mathcal{F}_3^{\max} (to be more precise, \mathcal{A}_1^{\max} , \mathcal{A}_2^{\max} , and \mathcal{A}_3^{\max} , respectively) for the threshold β^* -value 2.0 Å. The red set, the green set, and the brown set denote the largest, the second largest, and the third largest pocket, respectively. Figure 12b, c shows the equivalent pockets corresponding to the threshold β^* -values of 4.0 and 5.71 Å, respectively.

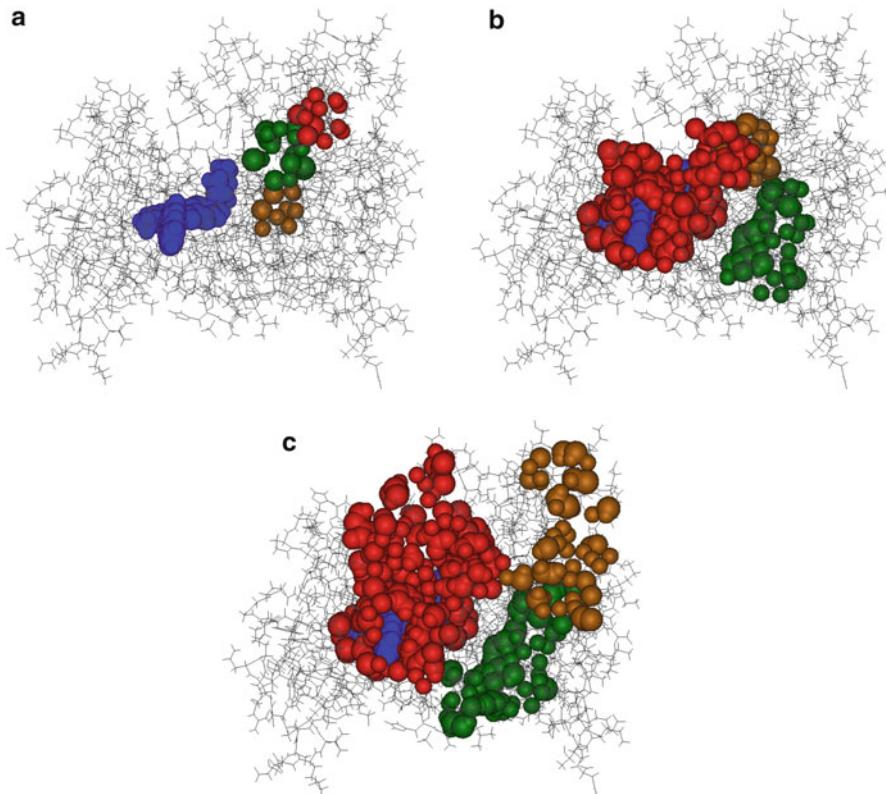

Fig. 12 Three largest raw pockets of 1t46 corresponding to three threshold values. Blue atoms constitute the ligand (imatinib). The red, green, and brown atoms constitute \mathcal{F}_1^{\max} , \mathcal{F}_2^{\max} , and \mathcal{F}_3^{\max} . The values of β^* are as follows: (a) $\beta^* = 2.0 \text{ \AA}$, (b) $\beta^* = 4.0 \text{ \AA}$, and (c) $\beta^* = 5.71 \text{ \AA}$

8 Generation of Initial Ligand Conformations

Finding an optimal pose of ligand in a docking problem is NP-hard and a heuristic is inevitable. Before launching the search of the global optimum via the genetic algorithm, it is necessary to compute an initial population $\Xi^0 = \{\xi_1^0, \xi_2^0, \dots, \xi_q^0\}$ of chromosomes where each chromosome represents an initial ligand conformation with respect to a receptor. Because the best position of the ligand is most probably in the vicinity of a pocket on the boundary of a receptor, the generation of Ξ^0 uses the shape complementarity between the recognized pocket and the ligand L . For this purpose, we use the beta-shapes of the receptor R corresponding to $\beta = 1.4 \text{ \AA}$, which corresponds to water molecule.

Each chromosome consists of six *genes*: three for the location and another three for the orientation of the ligand with respect to the pocket of R , assuming that R is fixed and centered at the origin. The set of chromosomes is called the *population*.

Fig. 13 Placement of ligand into a pocket

Hence, the initial ligand conformations constitute an initial population Ξ^0 where $\xi \in \Xi^0$ is represented as $\xi^0 = (\theta_x, \theta_y, \theta_z, x, y, z)$. For the notational convenience, $\xi = (g_1, g_2, \dots, g_6)$ is also used when it is convenient. This representation of the chromosome was used by many previous studies in docking.

Figure 13 shows a two-dimensional analogy of the process. The cluster of shaded circles denote the atoms constituting a pocket on the receptor, and the cluster of white circles denote the atoms of a ligand. First, some offset points (shown as black dots) are computed from the shaded circles toward the outside of the receptor, as shown in Fig. 13a. An offset point is computed as the center of a sphere, shown as the broken circle, tangent to the shaded atoms where the tangent sphere represents a typical atom in the ligand. The offset amount can be determined in various ways by reflecting the radius of atoms. Suppose that O is the set of offset points. Second, a subset $O' \subset O$ of consecutive offset points is computed where $|O'| = |L|$ for the ligand L . In this example, $|O'| = 3$ and Fig. 13b shows the leftmost three offset points selected. Then, the ligand L is transformed by optimally superposing the centers of atoms in L to O' , where the distance between L and O' is minimized. Then, the transformed ligand is considered as an initial chromosome. Figure 13c shows another chromosome produced from the set of the rightmost three offset points.

8.1 Superposition of Two Point Sets with Identical Cardinalities

The superposition between the centers of atoms in L with O' is formulated as the following optimization problem. Let L' be the superposed conformation of the ligand after the rigid body transformation and considered as an initial chromosome $\xi^0 \in \Xi^0$. Assume that the pocket has m faces. Then, the offsetting operation produces m offset points. Let $O = \{o_1, o_2, \dots, o_m\}$ be the set of the offset points. The following computation is repeated as many times as the number of the required initial chromosomes.

Let $\Lambda = \{c_1, c_2, \dots, c_m\}$ be the set of points where c_i represents the center of an atom $l_i \in L$. Note that $|\Lambda| = |O|$. Then, an optimal superposition of Λ onto O is attempted as follows. Suppose that O is fixed. Then, Λ is moved via a rigid-body

transformation to superpose onto O . Then, the optimal superposition of Λ onto O is formulated as the following integer linear programming problem:

Problem 1 Find the transformation T between Λ and O such that

$$\text{Minimize } \mathcal{D} = \sum_{o_i \in O, c_j \in \Lambda} ||o_i - T * c_j|| x_{ij} \quad (14)$$

$$\text{Subject to } \sum_i x_{ij} = 1, \text{ for all } j, 1 \leq j \leq m$$

$$\sum_j x_{ij} = 1, \text{ for all } i, 1 \leq i \leq m$$

$$x_{ij} = 0 \text{ or } 1$$

In other words, the transformation T is such that the distance \mathcal{D} between O and the transformed Λ is minimized, where \mathcal{D} is the sum of the Euclidean distances in all pairwise assignments (satisfying the constraints) between points $o_i \in O$ and $c_j \in \Lambda$, $1 \leq i, j \leq |\Lambda|$. Finding such an optimal transformation is hard even though $|O| = |\Lambda| = m$ [124]. Hence, iterative heuristic algorithms are usually employed based on an approach frequently used in the structure superposition problem as follows [51, 82, 92, 94].

First, an association between O and Λ is defined as follows. Select one point $o_i \in O$ and one point $c_j \in \Lambda$. After associating o_i and c_j , they are removed from O and Λ , respectively. If there is any remaining element in O and Λ , this procedure is repeated. Then, this procedure yields a set of associations $E(O, \Lambda) = \{(o_1, c_1), (o_2, c_2), \dots, (o_m, c_m)\}$ which is called the *equivalence* between O and Λ . Secondly, the following problem is solved.

Problem 2 Find the transformation T such that

$$\text{Minimize } \mathcal{D}' = \sum_{i=1}^m (o_i - T * c_i)^2 \quad (15)$$

Hence, Eq. (15) finds the optimal transformation so that the distance \mathcal{D}' between O and Λ is minimized with the equivalence constraint $E(O, \Lambda)$. Based on the observation in [59], the singular value decomposition (SVD) solves Eq. (15) $O(1)$ time in the worst case. The details of SVD for the superposition of two sets with an identical number of points is skipped. However, the solution to Eq. (15) does not guarantee the global minimum of Eq. (14). Hence, the procedure iterates as follows. Let $\Lambda' = \{c'_1, c'_2, \dots, c'_m\}$ be the set of transformed points by T computed from Eq. (15). Then, the new equivalence $E(O, \Lambda')$ is computed after the transformation.

Let $E(O, \Lambda') = \{(o_{i1}, c_{j1}), (o_{i2}, c_{j2}), \dots, (o_{ir}, c_{jr})\}$ be a new equivalence between O and Λ' so that $\sum_{k=1}^m |o_{ik} - c_{jk}|$ is minimized. Then, finding the new

equivalence $E(O, \Lambda')$ can be formulated as an assignment problem, a special case of an integer linear programming problem. Let $d_{ij} = dist(o_i, c_j)$ which denotes the Euclidean distance between o_i and c_j . Note that all d_{ij} for $1 \leq i \leq m$ and $1 \leq j \leq m$ are known after the transformation via T . Then, the assignment problem is defined as follows:

Problem 3 Solve the following problem.

$$\begin{aligned} & \text{Minimize} \quad \sum_i \sum_j d_{ij} x_{ij} \\ & \text{Subject to} \quad \sum_i x_{ij} = 1, \text{ for all } j, 1 \leq j \leq m \\ & \quad \sum_j x_{ij} = 1, \text{ for all } i, 1 \leq i \leq m \\ & \quad x_{ij} = 0 \text{ or } 1 \end{aligned} \tag{16}$$

Then, the new equivalence $E(O, \Lambda')$ is optimal between O and Λ' . The assignment problem can be efficiently solved by the Hungarian method initially proposed by Kuhn [120] and can be solved by the Edmond and Karp algorithm in $O(n^3)$ time in the worst case where n represents $|O| = |\Lambda'|$ [58]. Therefore, iterating the solution process of [Problems 2](#) and [3](#) a few times yields a solution of [Problem 1](#) (which may not be optimal) that gives one of the chromosomes in Ξ .

9 Search of Global Minima

Given an initial population (i.e., a set of initial chromosomes), the genetic algorithm is applied in the search of the optimal solution. While there may be variations, this chapter presents an approach employed by authors group. The fitness function used is a slight variation of [Eq.\(4\)](#) where $\varepsilon(d_{lr}) = d_{lr}$ and $\cos \theta = 1$ (implying $\theta = 180^\circ$). Therefore, the fitness function of BetaDock is as follows:

$$F = \sum_{l \in L} \sum_{r \in R} \left\{ \frac{A_{lr}}{d_{lr}^{12}} - \frac{B_{lr}}{d_{lr}^6} \right\} + \sum_{l \in L} \sum_{r \in R} \frac{q_l q_r}{d_{lr}^2} + \sum_{l \in L} \sum_{r \in R} \left\{ \frac{C_{lr}}{d_{lr}^{12}} - \frac{D_{lr}}{d_{lr}^{10}} \right\} \tag{17}$$

where L and R are ligand and receptor, respectively. BetaDock uses AMBER parameters [43] for the van der Waals force and the electrostatic force and AutoDock parameters for the hydrogen-bond interaction [84, 157].

9.1 Genetic Operators

Suppose that the k -th generation $\Xi^k = \{\xi_1^k, \xi_2^k, \dots, \xi_q^k\}$ of q chromosomes is available and each chromosome $\xi_i^k \in \Xi^k$ is associated with a fitness function value F_i^k from Eq.(17). The process proceeds to the $(k+1)$ -th generation Ξ^{k+1} by applying the three standard operators of genetic algorithm: selection, crossover, and mutation.

9.1.1 Selection

Suppose that the q chromosomes in Ξ^k are ordered so that $F_i^k \leq F_j^k$, $0 < i < j \leq q$. First, π_{select} percent of chromosomes is selected from the front of Ξ^k and copied into Ξ^{k+1} . Hence, these chromosomes have lower energy level than the others. Recall that the lower the value of F_i^k is, the better the chromosome is in docking simulation. These chromosomes are stored in another temporary storage Q_{temp} for later use after the crossover and the mutation operations are also completed. Let $|\Xi^{k+1}|$ be the number of current chromosomes in Ξ^{k+1} . Then, $q - |\Xi^{k+1}|$ chromosomes are selected from Ξ^k so that one with lower energy has a higher chance to be selected, and thus selected chromosomes are copied into Ξ^{k+1} . Hence, a new chromosome set Ξ^{k+1} is eventually created completely when $|\Xi^{k+1}| = |\Xi^k|$. Note that some chromosomes in Ξ^{k+1} can be redundant. The redundancy in Ξ^{k+1} has two important implications. A chromosomes with a better fitness function value has a higher probability to have redundancy. This implies that the neighbors of a good chromosome get a higher probability to be explored. On the other hand, by allowing redundancy, the search space itself is actually reduced by the reduction of the gene variety in the chromosome set Ξ^{k+1} , thus reducing the probability of finding a better solution.

9.1.2 Crossover

The crossover operator produces new chromosomes in Ξ^{k+1} by interchanging and/or mixing genes between chromosomes in the same population. Recall that all chromosomes are already located in a relatively narrow region in a pocket. From Ξ^{k+1} , a subset $\widehat{\Xi} \subset \Xi^{k+1}$ is selected with the crossover probability π_{cross} . If $|\widehat{\Xi}|$ is an odd number, we select one more chromosome at random to make $|\widehat{\Xi}|$ even. From $\widehat{\Xi}$, $\frac{1}{2}|\widehat{\Xi}|$ pairs of chromosomes are created in the order of selection. Then, each pair of chromosomes in $\widehat{\Xi}$ produces a pair of new chromosomes in Ξ^{k+1} . Three variants of crossover operators are studied as follows.

Two-Point Crossover: Consider a chromosome pair $\phi = (\xi_i, \xi_j) \in \widehat{\Xi}$. Recall that a chromosome ξ has six genes represented as $\xi_i = (\theta_x^i, \theta_y^i, \theta_z^i, x^i, y^i, z^i) = (g_1^i, g_2^i, \dots, g_6^i)$. First, two genes g_{left}^i and g_{right}^i are located at random from the six genes in ξ_i , where $\text{left} < \text{right}$. This is equivalent to selecting two elements from the array of ξ_i (which consists of six elements). Let Δ_i be the subset of ξ_i consisting of g_i^1 and g_i^2 and those other genes located between g_i^1 and g_i^2 on ξ_i . For example, suppose that $g_{\text{left}}^i = g_2^i$ and $g_{\text{right}}^i = g_5^i$. Then, $\Delta_i = \{g_2^i, g_3^i, g_4^i, g_5^i\}$. Let Δ_j be the set of genes on ξ_j corresponding to Δ_i . In the example, $\Delta_j = \{g_2^j, g_3^j, g_4^j, g_5^j\}$.

Then, Δ_i and Δ_j are switched between ξ_i and ξ_j to complete the crossover operation for the pair ϕ . This rule is called the standard *two-point rule* for crossover in the genetic algorithm.

Interpolated Crossover: Given a pair of chromosomes ξ_i and ξ_j , both in $\widehat{\Xi}$, each pair of corresponding genes from both chromosomes is interpolated. Suppose that $i < j$. Then, $F_i \leq F_j$. The interpolation is defined between two chromosomes as follows:

$$g'_k = (0.75 * g_k^i) + (0.25 * g_k^j), \quad 1 \leq k \leq 6 \quad (18)$$

$$g''_k = (0.25 * g_k^i) + (0.75 * g_k^j), \quad 1 \leq k \leq 6 \quad (19)$$

Then, $\{g'_1, g'_2, g'_3, g'_4, g'_5, g'_6\}$ and $\{g''_1, g''_2, g''_3, g''_4, g''_5, g''_6\}$ are the new chromosomes in Ξ^{k+1} . The motivation for this interpolated crossover is to increase the number of distinct genes in the entire chromosomes in Ξ^{k+1} .

Annealed Interpolated Crossover: Adding a simple simulated annealing concept to Eqs. (18) and (19) yields the following:

$$g'_k = (0.75 * u_1 * g_k^i) + (0.25 * u_2 * g_k^j), \quad 1 \leq k \leq 6 \quad (20)$$

$$g''_k = (0.25 * u_3 * g_k^i) + (0.75 * u_4 * g_k^j), \quad 1 \leq k \leq 6 \quad (21)$$

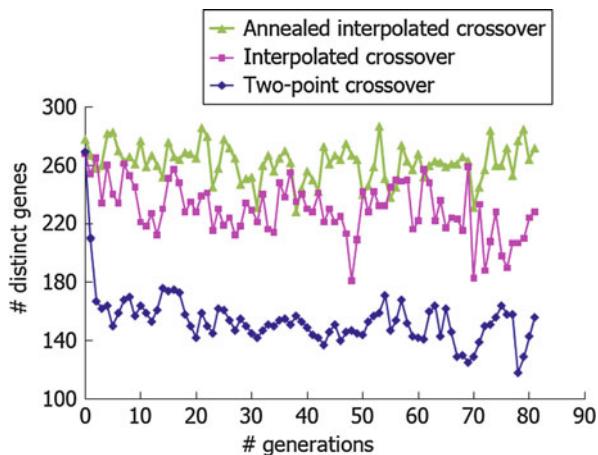

where u_1, u_2, u_3 , and u_4 are random numbers between 0 and 1. The rationale behind Eqs. (20) and (21) is the following: It is preferred to have a larger search space than that could be provided by the standard two-point crossover scheme which simply switches some genes in two chromosomes without changing any gene value. The motivation of the annealed interpolated crossover is to attempt to maximize gene diversity in Ξ^{k+1} .

To verify the behavior of the three crossover operators, an experiment was conducted as follows. Initially, the genetic algorithm was launched with 50 distinct initial chromosomes. Therefore, there were initially a little less than 300 distinct genes because there existed some redundancy in the initial gene set. Figure 14 shows the distribution of the number of distinct genes in Ξ^k with respect to the generation number k . The lowest curve with blue diamonds corresponds to the traditional, standard two-point crossover. Note that the curve decays quite rapidly. The middle curve with red rectangles corresponds to the interpolated crossover. The topmost curve with green triangles corresponds to the annealed interpolated crossover. Note that the gene diversity is maximally maintained in the annealed interpolated crossover.

9.1.3 Mutation

For each chromosome in Ξ^{k+1} , each gene is mutated with the mutation probability π_{mutate} . Suppose that a gene g is selected to be mutated where $g \in \{g_1, g_2, g_3\}$. Then, g is a rotation gene and a random number is produced between 0 and 360 to be added to the current value of g . Suppose that g is a translation gene

Fig. 14 Distribution of the number of distinct genes in each generation. The *blue diamond* at the bottom is the standard two-point crossover. The *red rectangle* in the middle is the interpolated crossover. The *green triangle* at the top is the annealed interpolated crossover

(i.e., $g \in \{g_4, g_5, g_6\}$). Then, the value of g is changed by the amount selected from the radius of the minimum enclosing sphere of the ligand. The direction of the move is also determined at random.

9.2 Genetic Iteration

Given a new set of chromosomes $\Xi^{k+1} = \{\xi_1^{k+1}, \xi_2^{k+1}, \dots, \xi_q^{k+1}\}$, its fitness is measured by evaluating the fitness function values F_i^{k+1} for all chromosomes in Ξ^{k+1} . Then, Q_{temp} is concatenated to Ξ^{k+1} and sorted according to the fitness function value. This is the restoration of the chromosomes with good fitness function values because they may disappear during the crossover and the mutation operation. Taking the first q chromosomes from the sorted set as the set Ξ^{k+1} , one iteration of the genetic algorithm is completed. This process repeats until a termination condition is encountered.

The genetic iteration process terminates when one of the following two conditions is encountered. First, the iteration terminates when the a priori defined maximum number of generations N_{maxgen} is encountered. Second, there is the maximum number of consecutive iterations N_{stable} where the best energy function value is stable and does not improve. Hence, if the genetic iteration does not improve the currently best solution during N_{stable} consecutive generations, the algorithm terminates.

The presented docking method was implemented into the software BetaDock and tested using a standard benchmark data set. It turned out that the performance of BetaDock is very powerful despite that the current version is an intermediate result of an ongoing research. For the details of the benchmark result, please refer to [107, 108].

10 Conclusion

There has long been a general consensus that protein structure is the most important in determining protein function. In particular, it is generally agreed that structural genomics, the discipline to study protein structure in relation with the entire genome, will be one of the main foci of research in life science after the complete identification of genome. Designing new drugs is an immediate example because information about protein structure is critically important in designing drugs. Docking is one of the most important technologies in the drug design process.

This chapter presented docking problem in the framework of combinatorial optimization with a slight level of mathematical and computational rigor. Because docking problem is a mathematical problem and is highly complicated, and highly interdisciplinary, the effort given in this chapter will be worth if it has succeeded to develop a common language that future scientists and engineers from different disciplines can rely on. It is expected that the optimization theory along with the powerful geometric constructs, the Voronoi diagram, the quasi-triangulation, and the beta-complex and beta-shape, will be the basis of future advancement of the structural molecular biology.

Abstract

This chapter introduces quadratic assignment problems (QAP) as models for finding an optimal assignment among two sets of interrelated objects. References to many applications of QAPs, like in location theory, are given. Moreover, several classical combinatorial optimization problems are identified as special cases of the QAP, like the traveling salesman problem, graph partitioning, max clique problem, minimum-weight feedback arc set problem, (FASP) and packing problems in graphs. These subproblems show that the QAP is \mathcal{NP} -hard.

Several different formulations of the QAP are presented in detail as being basic for different solution approaches. Special emphasis is laid to the different possibilities for describing QAPs as (mixed-)integer linear programs. Moreover, QAP polyhedra are discussed.

Crucial for exact solution approaches are lower bounding procedures. The paradigm of admissible transformations is introduced for describing several variants of Gilmore–Lawler type bounds. Moreover, bounds based on eigenvalues and bounds found by semidefinite programming are discussed in detail. Among exact solution methods, special emphasis is laid on branch-and-bound approaches. With respect to heuristics, not only simple construction heuristics and improvement heuristics are described, but also several metaheuristics like simulated annealing, tabu search, greedy randomized search, genetic algorithms, and ant systems are discussed. Links to available computer programs are delivered.

As QAPs are \mathcal{NP} -hard problems, there is a special interest in polynomially solvable special cases. A comprehensive survey of results in this direction is given. Moreover, QAPs show an interesting asymptotic behavior, as the ratio of best and worst solution value tends to one in probability. This phenomenon is thoroughly discussed and implications of this strange behavior are shown.

Finally, related problems are shortly treated. So, the quadratic bottleneck assignment problem is introduced and lower bounds, efficiently solvable special cases, as well as asymptotic results are reported. Moreover, cubic assignment problems, biquadratic assignment problems, and the quadratic semi-assignment problem are surveyed. An extensive bibliography provides the most important links to the literature in this field.

1 Introduction

The quadratic assignment problem (QAP) was introduced by Koopmans and Beckmann in 1957 as a mathematical model for the location of indivisible economical activities [146]. Consider the problem of allocating n facilities to n locations, with the cost being a function of the distance and flow between the facilities plus costs associated with placing a facility at a certain location. The objective is to assign each facility to a location such that the total cost is minimized. Specifically, let n be the number of facilities and locations and denote by N the set $N = \{1, 2, \dots, n\}$. We are given three $n \times n$ input matrices with real elements $F = (f_{ij})$, $D = (d_{kl})$, and $B = (b_{ik})$, where f_{ij} is the flow between the facility i and facility j , d_{kl} is the distance between the location k and location l , and b_{ik} is the cost of placing facility i at location k . The Koopmans–Beckmann version of the QAP can be formulated as follows:

$$\min_{\varphi \in \mathcal{S}_n} \sum_{i=1}^n \sum_{j=1}^n f_{ij} d_{\varphi(i)\varphi(j)} + \sum_{i=1}^n b_{i\varphi(i)}, \quad (1)$$

where \mathcal{S}_n is the set of all permutations $\varphi : N \rightarrow N$. Each individual product $f_{ij} d_{\varphi(i)\varphi(j)}$ is the cost of assigning facility i to location $\varphi(i)$ and facility j to location $\varphi(j)$. In the context of facility location, the matrices F and D are symmetric with zeros in the diagonal, and all matrices are nonnegative. An instance of a QAP with input matrices F , D , and B will be denoted by $\text{QAP}(F, D, B)$, while we will denote an instance by $\text{QAP}(F, D)$, if there is no linear term, that is, $B = 0$.

A more general version of the QAP was introduced by Lawler [152]. In this version, we are given a four-dimensional array $C = (c_{ijkl})$ of coefficients instead of the two matrices F and D and the problem can be stated as

$$\min_{\varphi \in \mathcal{S}_n} \sum_{i=1}^n \sum_{j=1}^n c_{ij\varphi(i)\varphi(j)}. \quad (2)$$

By adding a constant c to all cost coefficients, the objective function values change by the constant n^2c . Therefore, all cost coefficients can be assumed to be nonnegative. Clearly, a Koopmans–Beckmann problem QAP(F, D, B) can be formulated as a Lawler QAP by setting $c_{ijkl} := f_{ij}d_{kl}$ for all i, j, k, l with $i \neq j$ or $k \neq l$ and $c_{iikk} := f_{ii}d_{kk} + b_{ik}$, otherwise.

Although extensive research has been done for more than four decades, the QAP remains one of the hardest optimization problems, in contrast to its linear counterpart, the *linear assignment problem* (LAP). No exact algorithm can solve problems of size $n > 35$ in reasonable computational time nowadays. In fact, Sahni and Gonzalez [208] have shown that the QAP is NP-hard and that even finding an approximate solution within some constant factor from the optimal solution cannot be done in polynomial time unless $P = NP$. These results hold even for the Koopmans–Beckmann QAP with coefficient matrices fulfilling the triangle inequality (see Queyranne [194]). So far a polynomial-time approximation scheme has been found only for a very special case of the Koopmans–Beckmann QAP, the *dense linear arrangement problem*; see Arora et al. [16]. Complexity aspects of the QAP will be discussed in more detail in Sect. 3.4.

The QAP is widely known due to its many applications. In addition to facility layout problems, the QAP appears in applications such as chip design (cf. Hanan and Kurtzberg [128]), scheduling, process communications, turbine balancing, and many others. In the context of location theory, Dickey and Hopkins [83] discuss a *campus planning* problem with the objective to minimize the total walking distance between the buildings. A related hospital lay-out model was considered by Elshafei [92].

In the field of ergonomics, Burkard and Offermann [54] have shown that QAPs can be applied to the design of typewriter keyboards. The problem is to arrange the keys on a keyboard such as to minimize the time needed to write some text. Let $N = \{1, 2, \dots, n\}$ denote the set of symbols to be arranged. Moreover, let f_{ij} denote the frequency of the appearance of the pair of symbols i and j . The entries of the distance matrix $D = d_{kl}$ are the times needed to press the key in position l after pressing the key in position k . An assignment of symbols to keys is modeled as a permutation $\varphi \in S_n$. An optimal solution φ^* for the QAP minimizes the average time for writing a text. A similar application related to ergonomic design is the development of control boards in order to minimize eye fatigue by McCormick [162]. Other applications concern the arrangement of probes on a microarray chip [77], data analysis [131], coding theory [225], ranking of archeological data [147], ranking of a team in a relay race [129], scheduling parallel production lines [109], shunting of trams in a storage yard [224], and analyzing chemical reactions for organic compounds [220].

Literature

This survey is based on the previous article *The Quadratic Assignment Problem* by Burkard, Çela, Pardalos, and Pitsoulis in the first edition of the *Handbook of*

Combinatorial Optimization. A recent treatment on QAPs appeared in the monograph on assignment problems by Burkard et al. [46]. Quadratic assignment problems are also comprehensively treated in the monograph by Çela [60]. For further more recent surveys, see Anstreicher [12], Loiola et al. [160], the encyclopedia article of Pitsoulis and Pardalos [192], as well as Bayat and Sedghi [22] in the book *Facility Location* by Farahani and Hekmatfar.

2 Combinatorial Optimization Problems Formulated as QAPs

A number of well-known combinatorial optimization problems can be formulated as Koopmans–Beckmann QAPs with specific coefficient matrices. These problems allow an additional insight in structure and complexity of QAPs. QAP algorithms are in general, however, far inferior in comparison to specialized algorithms for these problems.

2.1 The Traveling Salesman Problem

In the *traveling salesman problem* (TSP), we are given n cities and the pairwise distances between them. The task is to find a tour which visits each city exactly once and has minimal length. Let the set of integers $N = \{1, 2, \dots, n\}$ represent the n cities and let the symmetric $n \times n$ matrix $D = (d_{ij})$ represent the distances between the cities, where d_{ij} is the distance between city i and city j ($d_{ii} = 0 \forall i = 1, 2, \dots, n$). The TSP can be formulated as

$$\begin{aligned} \min \quad & \sum_{i=1}^{n-1} d_{\varphi(i)\varphi(i+1)} + d_{\varphi(n)\varphi(1)} \\ \text{s.t. } & \varphi \in \mathcal{S}_n. \end{aligned} \tag{3}$$

The TSP can be formulated as a QAP with the given distance matrix D and a flow matrix F which is the adjacency matrix of a cycle on n vertices.

The TSP is a strongly NP-hard combinatorial optimization problem; see the monograph edited by Lawler et al. [153] as a comprehensive reference.

2.2 The Linear Arrangement Problem

In the *linear arrangement problem*, the vertices of a graph G have to be placed at the points $1, 2, \dots, n$ on a line so as to minimize the sum of pairwise distances on the line between vertices which are joined by an edge in G . The linear arrangement problem is an NP-hard problem; see Garey and Johnson [106]. It can be formulated

as a QAP where the distance matrix D is the (weighted) adjacency matrix of the given graph and the flow matrix $F = (f_{ij})$ given by $f_{ij} = |i - j|$, for all i, j .

2.3 Graph Partitioning and Maximum Clique Problem

The *graph partitioning problem* (GPP) and the *maximum clique problem* (MCP) are two well-studied NP-hard combinatorial optimization problems which are special cases of the QAP. In the GPP, we are given an (edge) weighted graph $G = (V, E)$ with n vertices and a number k which divides n . We want to partition the vertex set V into k sets V_1, \dots, V_k of equal cardinality such that the total weight of the edges between sets V_i and V_k , $i \neq k$, is minimized. This problem can be formulated as a QAP with distance matrix D equal to the weighted adjacency matrix of G and a flow matrix F . The flow matrix F is a block diagonal matrix with k blocks. Each block is the negative adjacency matrix of a complete subgraph with n/k vertices. For more informations on GPPs, the reader is referred to Lengauer [154].

In the MCP, we are again given a graph G with n vertices. We ask for the maximum number $k \leq n$ such that there exists a subset $V_1 \subseteq V$ with k vertices which induces a clique in G . This problem can be modeled as a QAP with distance matrix D equal to the adjacency matrix of G and flow matrix F given as adjacency matrix of a graph consisting of a clique of size k and $n - k$ isolated vertices, multiplied by -1 . There exists a clique of size k in G if and only if the optimal value of the corresponding QAP is $-k^2$. For a review on the MCP, the reader is referred to [190].

2.4 The Minimum-Weight Feedback Arc Set Problem

In the *minimum-weight FASP*, a weighted digraph $G = (V, E)$ with vertex set V and arc set E is given. The goal is to remove a set of arcs from E with minimum overall weight, such that all directed cycles, the so-called dicycles, in G are destroyed and an acyclic directed subgraph remains. Clearly, the minimum-weight FASP is equivalent to the problem of finding an acyclic subgraph of G with maximum weight. The unweighted version of the FASP (i.e., all edge weights are 0 or 1) is called *the acyclic subdigraph problem* and is treated extensively by Jünger [135].

An interesting application of the FASP is the so-called triangulation of input–output tables in economics which arises along the input–output analysis in order to forecast the development of industries; see Leontief [155]. For details, the reader is referred to Conrad [73] and Reinelt [196].

Since the vertices of an acyclic subdigraph can be labeled topologically, that is, such that in each arc the label of its head is larger than that of its tail, the FASP can be formulated as a QAP. The distance matrix of the QAP is the weighted adjacency matrix of G and the flow matrix $F = (f_{ij})$ is a *lower triangular matrix*, that is, $f_{ij} = -1$ if $i \leq j$ and $f_{ij} = 0$, otherwise.

The FASP is well known to be NP-hard (see [106, 142]).

2.5 Packing Problems in Graphs

Another well-known NP-hard problem which can be formulated as a QAP is the *graph packing problem*; see Bollobás [30]. In a graph packing problem we are given two graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$ with n vertices and edge sets E_1 and E_2 . A permutation φ of $\{1, 2, \dots, n\}$ is called a *packing of G_2 into G_1* , if $e_{ij} \in E_1$ implies $e_{\varphi(i)\varphi(j)} \notin E_2$, for all $1 \leq i, j \leq n$. In other words, a packing of G_2 into G_1 is an embedding of the vertices of G_2 into the vertices of G_1 such that no pair of edges coincides. The *graph packing problem* consists of finding a packing of G_2 into G_1 , if one exists, or proving that no packing exists. It can be formulated as a QAP with distance matrix equal to the adjacency matrix of G_2 and flow matrix equal to the adjacency matrix of G_1 . A packing of G_2 into G_1 exists if and only if the optimal value of this QAP is equal to 0. In this case the optimal solution of the QAP determines a packing.

3 Formulations and Computational Complexity

Many combinatorial optimization problems permit different but equivalent mathematical formulations, which stress different structural characteristics of the problem. Different problem statements are the basis for different solution approaches. Let us start with the observation that every permutation φ of the set $N = \{1, 2, \dots, n\}$ can be represented by an $n \times n$ matrix $X = (x_{ik})$, such that

$$x_{ik} = \begin{cases} 1 & \text{if } \varphi(i) = k, \\ 0 & \text{otherwise.} \end{cases}$$

Such a matrix X is called a *permutation matrix* and is characterized by the following *assignment constraints*:

$$\sum_{i=1}^n x_{ik} = 1, \quad k = 1, 2, \dots, n, \quad (4)$$

$$\sum_{k=1}^n x_{ik} = 1, \quad i = 1, 2, \dots, n, \quad (5)$$

$$x_{ik} \in \{0, 1\}, \quad i, k = 1, 2, \dots, n. \quad (6)$$

We denote the set of all permutation matrices by \mathbf{X}_n . A real $n \times n$ matrix $X = (x_{ik})$ is called a *doubly stochastic matrix*, if it fulfills the Eqs. (4) and (5) and $x_{ik} \geq 0$ for all $i, k = 1, 2, \dots, n$. The set of all doubly stochastic matrices forms the *assignment polytope* P_A . A famous result of Birkhoff shows the connection between doubly stochastic and permutation matrices.

Theorem 1 ([27]) *The vertices of the assignment polytope P_A correspond in a unique way to permutation matrices and vice versa.*

3.1 Quadratic Integer Programming Formulations

Using permutation matrices instead of permutations, the QAP (2) can be formulated as an integer program with a quadratic objective function (hence the name quadratic assignment problem by Koopmans and Beckmann [146]), namely,

$$\begin{aligned} \min \quad & \sum_{i=1}^n \sum_{j=1}^n \sum_{k=1}^n \sum_{l=1}^n c_{ijkl} x_{ik} x_{jl} \\ \text{s.t. } & (x_{ik}) \in \mathbf{X}_n. \end{aligned} \quad (7)$$

Many authors have proposed methods for linearizing the quadratic objective function (7) by introducing additional variables. Some of these of linearizations are discussed in Sect. 4.

The coefficients c_{ijkl} in the objective function of (2) can be arranged in an $(n^2 \times n^2)$ matrix Q such that c_{ijkl} is on row $(i-1)n + j$ and column $(k-1)n + l$. Moreover, arrange the variables x_{ik} in a vector $x = (x_{11}, x_{12}, \dots, x_{1n}, x_{21}, \dots, x_{nn})^T = (x_1, \dots, x_{n^2})^T$. Thus the objective function of (2) becomes

$$x^T Q x. \quad (8)$$

Since $x^T Q x = x^T [1/2(Q + Q^T)]x$, matrix Q can be assumed to be symmetric. Adding a constant c to the diagonal elements of Q changes all objective function values by the same constant n^2c . If we add a sufficiently large positive constant c , all eigenvalues of Q become positive, that is, Q is positive definite and $x^T Q x$ becomes a convex function. Similarly, we can achieve that Q becomes negative definite and $x^T Q x$ becomes a concave function.

3.2 Inner Product Formulation

Inner products of matrices allow a more compact formulation of QAPs in Koopmans–Beckmann form. Given two real $n \times n$ matrices A, B , their *inner product* is defined by

$$\langle A, B \rangle := \sum_{i=1}^n \sum_{j=1}^n a_{ij} b_{ij}.$$

Thus a linear assignment problem

$$\min_{\varphi} \sum_{i=1}^n c_{i\varphi(i)}$$

can be written as

$$\min_{X \in \mathbf{X}_n} \langle C, X \rangle.$$

Lawler [152] formulated the QAP as a linear assignment problem (LAP) of size n^2 with the additional constraint that only $(n^2 \times n^2)$ permutation matrices which are Kronecker products of $n \times n$ permutation matrices are feasible. The Kronecker product of the two $n \times n$ matrices A and B is defined as

$$A \otimes B := \begin{pmatrix} a_{11}B & a_{12}B & \cdots & a_{1n}B \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1}B & a_{n2}B & \cdots & a_{nn}B \end{pmatrix}.$$

Thus a QAP can be written as

$$\begin{aligned} \min \quad & \langle Q, Y \rangle \\ \text{s.t. } & Y = X \otimes X, \\ & X \in \mathbf{X}_n. \end{aligned} \tag{9}$$

Now let X_φ be the permutation matrix corresponding to permutation φ and let X_φ^T be the transposed matrix of X_φ . Given an $n \times n$ matrix A , the matrix products AX_φ^T and $X_\varphi A$ permute the columns and rows of A , respectively, according to the permutation φ . Therefore,

$$X_\varphi A X_\varphi^T = (a_{\varphi(i)\varphi(j)}).$$

Thus a Koopmans–Beckmann QAP can be formulated alternatively as

$$\begin{aligned} \min_{\varphi} \quad & \langle F, X_\varphi D X_\varphi^T \rangle + \langle B, X_\varphi \rangle \\ \text{s.t. } & X_\varphi \in \mathbf{X}_n. \end{aligned} \tag{10}$$

If in a Koopmans–Beckmann QAP one of the matrices F and D is symmetric, we can always assume that also the other matrix is symmetric. Let us assume that matrix F is symmetric, that is, $F = F^T$. From $\langle F, G \rangle = \langle F^T, G^T \rangle$ follows

$$\langle F, G \rangle = \frac{1}{2} (\langle F, G \rangle + \langle F^T, G^T \rangle) = \langle F, \frac{1}{2}(G + G^T) \rangle.$$

Setting $G = X_\varphi D X_\varphi^T$ and using $\frac{1}{2}(G + G^T) = X_\varphi \frac{1}{2}(D + D^T) X_\varphi^T$ show that also matrix D can be assumed to be symmetric.

3.3 Trace Formulation

The *trace* of an $n \times n$ matrix A is defined as the sum of its diagonal elements, that is,

$$\text{tr}A := \sum_{i=1}^n a_{ii}.$$

Well-known properties of the trace are $\text{tr}(AB) = \text{tr}(BA)$ and $\text{tr}A = \text{tr}A^T$. Obviously, the inner product $\langle A, B \rangle$ can be written as

$$\langle A, B \rangle = \text{tr}(AB^T).$$

Thus,

$$\langle F, X_\varphi DX_\varphi^T \rangle + \langle B, X_\varphi \rangle = \text{tr}(FX_\varphi D^T X_\varphi^T) + \text{tr}(BX_\varphi^T).$$

Therefore, a Koopmans–Beckmann QAP instance with input matrices F , D , and B can be formulated as

$$\begin{aligned} \min \quad & \text{tr}(FXD^T + B)X^T \\ \text{s.t. } & X \in \mathbf{X}_n. \end{aligned} \tag{11}$$

The trace formulation of the QAP appeared first in Edwards [90, 91] and was used by Finke et al. [98] to introduce lower bounds based on the eigenvalues of symmetric matrices F and D (see Sect. 7.1).

For any $n \times n$ matrix A , let $\text{vec}(A) \in \mathbb{R}^{n^2}$ be the vector formed by the columns of A . In the following, we write just x (as before) instead of $\text{vec}(X)$, if no confusion arises. A well-known identity from matrix analysis states that

$$\text{vec}(AXB) = (B^T \otimes A)\text{vec}(X). \tag{12}$$

Using

$$\text{tr}(AB^T) = \langle A, B \rangle = (\text{vec}B)^T(\text{vec}A),$$

the trace formulation of a QAP can be rewritten as

$$\text{tr}(FXD^T X^T) = x^T \text{vec}(FXD^T) = x^T(D \otimes F)x.$$

Therefore, a Koopmans–Beckmann problem can be formulated as

$$\begin{aligned} \min \quad & x^T(D \otimes F)x + \text{vec}(B)^T x, \\ \text{s.t. } & X \in \mathbf{X}_n. \end{aligned} \tag{13}$$

This formulation will be used in semidefinite relaxations of the QAP; see Sect. 6.7.

3.4 Computational Complexity

The QAP is a “very hard” problem from the theoretical point of view. Not only that the QAP cannot be solved efficiently but even it cannot be approximated efficiently within some constant approximation ratio. Furthermore, even finding local optima is a nontrivial task.

Let us recall that the TSP can be formulated as a $\text{QAP}(F, D)$ where D is the distance matrix between the n cities and F is the adjacency matrix of a cycle on n vertices (see Sect. 2.1). Since the TSP is strongly NP-hard, we get the same result for QAP. Now, let $Z(F, D, \varphi)$ denote the objective function value of a solution φ for a QAP with flow matrix F and distance matrix D . Given a real number $\epsilon > 0$, an algorithm \mathcal{A} for the QAP is said to be an ϵ -approximation algorithm if

$$\left| \frac{Z(F, D, \varphi_{\mathcal{A}}) - Z(F, D, \varphi_{\text{opt}})}{Z(F, D, \varphi_{\text{opt}})} \right| \leq \epsilon \quad (14)$$

holds for every instance $\text{QAP}(F, D)$, where $\varphi_{\mathcal{A}}$ is the solution of $\text{QAP}(F, D)$ computed by algorithm \mathcal{A} and φ_{opt} is an optimal solution of $\text{QAP}(F, D)$. Sahni and Gonzales showed by a reduction from the Hamiltonian cycle problem the following result.

Theorem 2 ([208]) *The quadratic assignment problem is strongly NP-hard.*

For an arbitrary $\epsilon > 0$, the existence of a polynomial-time ϵ -approximation algorithm for the QAP implies $\mathcal{P} = \mathcal{NP}$.

Queyranne [194] derives an even stronger result. He shows that, unless $P = NP$, $\text{QAP}(F, D)$ is not approximable in polynomial time within some finite approximation ratio, even if F is the distance matrix of some pointset on a line and D is a symmetric block diagonal matrix. Arkin et al. [15] considered the maximization version of a QAP where the entries of matrix D fulfill the triangle inequality. They designed an approximation algorithm of $O(n^3)$ time complexity which guarantees a solution value within $1/4$ from the optimum.

Complexity aspects of local search algorithms are dealt with in Sect. 8.4. Let us just mention here that no local criteria are known for deciding how good a locally optimal solution is as compared to a global one. From the complexity point of view, deciding whether a given local optimum is a globally optimal solution to a given instance of the QAP, is a hard problem; see Papadimitriou and Wolfe [185].

4 Linearizations

A first approach for solving QAPs consists in reformulating it as a linear (mixed-)integer program. The linearization of the quadratic objective function is usually achieved by introducing new variables and new linear (and binary)

constraints. Then existing methods for (mixed) linear integer programming (MILP) can be applied. The very large number of new variables and constraints, however, usually poses an obstacle for efficiently solving the resulting linear integer programs. But MILP formulations provide a means for computing lower bounds. In this context, the “tightness” of the continuous relaxation of the resulting linear integer program is a desirable property.

In this section, we present five linearizations of the QAP: Lawler’s linearization [152] which was the first, Kaufman and Broeckx’s linearization [143] which has the smallest number of variables and constraints, Frieze and Yadegar’s linearization [103], and the linearization of Adams and Johnson [4] which is a slight but relevant modification of the linearization proposed by Frieze and Yadegar and unifies most of the previous linearizations. Finally, we present the higher level reformulation technique by Adams et al. [3] which is important for improving lower bounds.

4.1 Lawler’s Linearization

Lawler [152] replaces the quadratic terms $x_{ik}x_{jl}$ in the objective function of (2) by n^4 variables

$$y_{ijkl} := x_{ik}x_{jl}, \quad i, j, k, l = 1, 2, \dots, n$$

and obtains the following 0–1 linear program (see [152] and the monograph by Burkard et al. [46]).

$$\begin{aligned} \min \quad & \sum_{i,j=1}^n \sum_{k,l=1}^n c_{ijkl} y_{ijkl} \\ \text{s.t.} \quad & (x_{ik}) \in \mathbf{X}_n, \\ & \sum_{i,j=1}^n \sum_{k,l=1}^n y_{ijkl} = n^2, \\ & x_{ik} + x_{jl} - 2y_{ijkl} \geq 0, \quad i, j, k, l = 1, 2, \dots, n, \\ & y_{ijkl} \in \{0, 1\}, \quad i, j, k, l = 1, 2, \dots, n. \end{aligned} \tag{15}$$

This 0–1 linear program has $n^4 + n^2$ binary variables and $n^4 + 2n^2 + 1$ constraints.

4.2 Kaufman and Broeckx Linearization

Recall that all cost coefficients c_{ijkl} can be assumed to be nonnegative. It is possible to rearrange the objective function in the following way:

$$\sum_{i,k=1}^n x_{ik} \sum_{j,l=1}^n c_{ijkl} x_{jl}. \quad (16)$$

Kaufman and Broeckx [143] define n^2 new real variables

$$w_{ik} := x_{ik} \sum_{j,l=1}^n c_{ijkl} x_{jl}, \quad i, k = 1, \dots, n \quad (17)$$

and plug them in the objective function (16) to obtain a linear objective function of the form

$$\sum_{i,k=1}^n w_{ik}.$$

Then they introduce n^2 constants $a_{ik} := \sum_{j,l=1}^n c_{ijkl}$ for $i, k = 1, \dots, n$ and show that the QAP (2) is equivalent to the following mixed 0–1 linear program:

$$\begin{aligned} \min \quad & \sum_{i,k=1}^n w_{ik} \\ \text{s.t.} \quad & (x_{ik}) \in \mathbf{X}_n, \\ & a_{ik} x_{ik} + \sum_{j,l=1}^n c_{ijkl} x_{jl} - w_{ik} \leq a_{ik}, \quad i, k = 1, \dots, n, \\ & w_{ik} \geq 0, \quad i, k = 1, 2, \dots, n. \end{aligned} \quad (18)$$

This formulation employs n^2 real variables, n^2 binary variables, and $n^2 + 2n$ constraints. The proof of equivalence of the QAP to the mixed integer linear program (18) can be found in [46, 143]. Similar linearizations were proposed by Balas and Mazzola [18] and Burkard and Bönniger [40]; see Burkard et al. [46]. All of them are related to general linearization strategy proposed by Glover [111].

Zhang et al. [228] observed that the bound obtained from the Kaufman–Broeckx linearization is dominated by the Gilmore–Lawler bound (see Sect. 6.2), and they proposed a way to strengthen the Kaufman–Broeckx model.

4.3 Frieze and Yadegar Linearization

Frieze and Yadegar [103] also replace the products $x_{ik} x_{jl}$ of the binary variables by continuous variables y_{ijkl} ($y_{ijkl} := x_{ik} x_{jl}$) and set up the following mixed integer linear programming formulation for the QAP (2):

$$\min \sum_{i,j=1}^n \sum_{k,l=1}^n c_{ijkl} y_{ijkl} \quad (19)$$

$$\text{s.t. } (x_{ik}) \in \mathbf{X}_n, \quad (20)$$

$$\sum_{i=1}^n y_{ijkl} = x_{jl}, \quad j, k, l = 1, \dots, n, \quad (21)$$

$$\sum_{j=1}^n y_{ijkl} = x_{jl}, \quad i, k, l = 1, 2, \dots, n, \quad (22)$$

$$\sum_{k=1}^n y_{ijkl} = x_{ik}, \quad i, j, l = 1, \dots, n, \quad (23)$$

$$\sum_{l=1}^n y_{ijkl} = x_{ik}, \quad i, j, k = 1, 2, \dots, n, \quad (24)$$

$$y_{ikik} = x_{ik}, \quad i, k = 1, 2, \dots, n, \quad (25)$$

$$0 \leq y_{ijkl} \leq 1, \quad i, j, k, l = 1, 2, \dots, n. \quad (26)$$

This mixed integer program has n^4 real variables, n^2 binary variables, and $n^4 + 4n^3 + n^2 + 2n$ constraints. For obtaining a lower bound Frieze and Yadegar, consider a Lagrangean relaxation of this mixed integer program by relaxing the constraints (23) and (26). The relaxed problem is solved approximately by applying subgradient optimization techniques. They show that the bound obtained by the Lagrangean relaxation is larger than all lower bounds derived from reduction techniques applied to the Gilmore–Lawler bound for the QAP (see Sect. 6.2). A result of Geoffrion [108] implies that the solution of the Lagrangean relaxation equals the solution of the continuous relaxation of the mixed integer program (19)–(26).

It is interesting to notice here that the gap between the optimal value of this continuous relaxation and the optimal value of the QAP can be very large. Dyer et al. [89] showed for QAPs whose coefficients c_{ijkl} are independent random variables uniformly distributed on $[0, 1]$ that the expected optimal value of the above mentioned linearization has a size of $O(n)$. On the other hand, the expected optimal value of such QAPs increases with high probability as $\Omega(n^2)$, as shown by Burkard and Fincke [50]. Consequences of this asymptotic behavior will be discussed in some detail in Sect. 11. No similar asymptotic result is known for the continuous relaxation of the linearization due to Adams and Johnson [4] which is presented in the following section.

4.4 Adams and Johnson Linearization

Adams and Johnson presented in [4] a new 0–1 linear integer programming formulation for the QAP, called *level-1 reformulation–linearization*, which resembles to a

certain extent the linearization of Frieze and Yadegar. It is based on the linearization technique for general 0–1 polynomial programs introduced by Adams and Sherali in [5, 6]. They represent again the product $x_{ik}x_{jl}$ by the variables y_{ijkl} and prove that the QAP is equivalent to the following mixed 0–1 linear program

$$\begin{aligned} \min \quad & \sum_{i,j=1}^n \sum_{k,l=1}^n c_{ijkl} y_{ijkl} \\ \text{s.t. } \quad & (x_{ik}) \in \mathbf{X}_n, \end{aligned} \tag{27}$$

$$\begin{aligned} \sum_{i=1}^n y_{ijkl} &= x_{jl}, \quad j, k, l = 1, \dots, n, \\ \sum_{j=1}^n y_{ijkl} &= x_{jl}, \quad i, k, l = 1, 2, \dots, n, \\ y_{ijkl} &= y_{jilk}, \quad i, j, k, l = 1, \dots, n, \\ y_{ijkl} &\geq 0, \quad i, j, k, l = 1, 2, \dots, n. \end{aligned} \tag{28}$$

The above formulation contains n^2 binary variables x_{ij} , n^4 continuous variables y_{ijkl} , and $n^4 + 2n^3 + 2n$ constraints excluding the nonnegativity constraints on the continuous variables. The constraint set of (27) describes a solution matrix Y which is the Kronecker product of two permutation matrices (i.e., $Y = X \otimes X$ where $X \in \mathcal{S}_n$). Hence, this formulation of the QAP is equivalent to (9). The theoretical strength of the linearization (27) lies in the fact that the constraints in the previous linearizations can be expressed as linear combinations of the constraints of (27); see [4, 134]. Many lower-bounding techniques are based on the Lagrangean dual of this relaxation. For more details on this topic, we refer to Sect. 6.4.

Adams and Johnson [4] noted already that a significant smaller formulation in terms of both the variables and constraints could be obtained, but the structure of the continuous relaxation above is favorable for solving QAPs approximately by means of the Lagrangean dual.

4.5 Level-2 Reformulation–Linearization

The level-2 reformulation of a QAP is obtained by multiplying every constraint in (28) with each variable x_{rs} [3]. Afterwards, the products $x_{ik}x_{jl}x_{rs}$ are linearized by introducing new variables z_{ijrkl} . Thus, the following constraints are added to (28):

$$\sum_{\substack{i=1 \\ i \neq j,r}}^n z_{ijrkl} = y_{jrls} \quad (j, k, l, r, s = 1, 2, \dots, n, k \neq l \neq s, j \neq r),$$

$$\sum_{\substack{k=1 \\ j \neq l, s}}^n z_{ijrkl} = y_{jrls} \quad (i, j, l, r, s = 1, 2, \dots, n, i \neq j \neq r, l \neq s), \quad (29)$$

$$z_{ijrkl} = z_{irjks} = z_{jirls} = z_{jrils} = z_{rjisl} = z_{rjislk}$$

$$(i, j, k, l, p, q = 1, 2, \dots, n, i < j < r, k \neq l \neq s),$$

$$z_{ijklp} \geq 0 \quad (i, j, k, l, p, q = 1, 2, \dots, n, i \neq k \neq p, j \neq l \neq q).$$

Adams et al. note that bounds from the continuous relaxation of (29) are at least as tight as those from (28). Indeed, numerical experiments show that considerably better bounds can be achieved by using a Lagrangean relaxation of (29).

The above technique can be extended to obtain level-3 reformulations; see Hahn et al. [126]. Level-3 reformulations provide better lower bounds but need a high computational effort. Nevertheless, Hahn et al. report favorable computational results when used in a branch-and-bound framework.

5 QAP Polytopes

All linearizations of Sect. 4 can be used as starting point for a definition of the QAP polytope. The QAP polytope is defined as the convex hull of all 0–1 vectors (x_{ik}, y_{ijkl}) , $1 \leq i, j, k, l \leq n$, which are feasible solutions of the MILP formulations given there. Jünger and Kaibel [136], however, used a graph theoretic approach for defining the QAP polytope. This has the advantage of leading to a better understanding of the relationship between the QAP polytope and related polytopes, like the traveling salesman polytope or the cut polytope (see [138]). In addition, the graph theoretic approach allows an easier use of some technical tools like projections and affine transformations.

5.1 The QAP Polytope

For each $n \in \mathbb{N}$, consider a graph $G_n = (V_n, E_n)$ with vertex set $V_n = \{(i, k) : 1 \leq i, k \leq n\}$ and edge set $E_n = \{((i, k), (j, l)) : i \neq j, k \neq l\}$. Clearly, maximal cliques in G_n have cardinality n and correspond to permutation matrices. Given an instance of the QAP (2), we view the cost coefficients c_{ikik} as vertex weights and c_{ijkl} as edge weights of the edge $((i, k), (j, l))$. Solving the above QAP instance is equivalent to finding a maximal clique with minimum total vertex and edge weight. For each clique C in G_n with n vertices, we denote its incidence vector by (x^C, y^C) , where $x^C \in \mathbb{R}^{n^2}$ and $y^C \in \mathbb{R}^{\frac{n^2(n-1)^2}{2}}$

$$x_{ik} = \begin{cases} 1 & \text{if } (i, k) \in C, \\ 0 & \text{otherwise} \end{cases} \quad y_{ijkl} = \begin{cases} 1 & \text{if } ((i, k), (j, l)) \in C, \\ 0 & \text{otherwise.} \end{cases}$$

Thus, the QAP polytope denoted by QAP_n is obtained by

$$\text{QAP}_n := \text{conv}\{(x^C, y^C) : C \text{ is a clique with } n \text{ vertices in } G_n\}.$$

Barvinok [20], Padberg and Rijal [180], as well as Jünger and Kaibel [136] determined independently the dimension of QAP_n as

$$\dim(\text{QAP}_n) = 1 + (n - 1)^2 + n(n - 1)(n - 2)(n - 3)/2 \text{ for } n \geq 3$$

and showed that the inequalities $y_{ijkl} \geq 0, i \neq k, j \neq l$ are facet defining. (These are usually called *trivial facets* of QAP_n .) Moreover, Padberg and Rijal [180], as well as Jünger and Kaibel [136], showed independently that the *affine hull* of QAP_n , for $n \geq 3$, is described by the following equations:

$$\sum_{i=1}^n x_{ik} = 1, \quad 1 \leq k \leq n, \quad (30)$$

$$\sum_{k=1}^n x_{ik} = 1, \quad 1 \leq i \leq n, \quad (31)$$

$$-x_{jl} + \sum_{i=1}^{j-1} y_{ijkl} + \sum_{i=j+1}^n y_{ijkl} = 0 \quad 1 \leq i, j, k \leq n; i \neq j, \quad (32)$$

$$-x_{ik} + \sum_{l=1}^{k-1} y_{ijkl} + \sum_{l=k+1}^n y_{ijkl} = 0 \quad 1 \leq i, k, l \leq n; k \neq l. \quad (33)$$

The rank of this equation system is $2n(n - 1)^2 - (n - 1)(n - 2)$ for $n \geq 3$.

Padberg and Rijal [180] identified additionally two classes of valid inequalities for QAP_n , the *clique inequalities* and the *cut inequalities*. The clique inequalities are derived from cliques in the graph G_n , whereas the cut inequalities are derived from cuts in the graph G_n . The authors identify some conditions under which the cut inequalities are not facet defining. It is an open problem, however, to identify facet-defining inequalities within these classes. A larger class of valid inequalities, the so-called box inequalities, has been described by Kaibel [138]. Those inequalities are obtained by exploiting the relationship between the Boolean quadric polytope and the QAP polytope. A nice feature of the box inequalities is that it can be decided efficiently whether they are facet defining or not, and in the latter case some facet defining inequality which dominates the corresponding box inequality can be derived. A further class of valid inequalities for the QAP which partly correspond to facets of the QAP polytope was proposed by Blanchard et al. [28].

Both, the *traveling salesman polytope* and the *linear ordering polytope* are projections of the quadratic assignment polytope QAP_n . Moreover, QAP_n is a face of the *Boolean quadric polytope*; see [138].

5.2 The Symmetric QAP Polytope

Koopmans–Beckmann problems (1) with symmetric coefficient matrices F and D lead to the so-called symmetric *QAP* polytope SQAP_n . (Recall that the symmetry of already one of the matrices F and D leads to a symmetric problem; see Sect. 3.3). To define SQAP_n , we start from a hypergraph $H_n = (V_n, F_n)$, where V_n is the same set of vertices as in graph G_n and F_n is the set of hyperedges $\{(i, k), (j, l), (i, l), (j, k)\}$ for all $i \neq j, k \neq l$. A set $C \subset V_n$ is called a clique in H_n if C is a clique in G_n . Again, the incidence vector (x^C, y^C) of a clique C is introduced by

$$x_{ik} = \begin{cases} 1 & \text{if } (i, k) \in C \\ 0 & \text{otherwise} \end{cases} \quad y_{ijkl} = \begin{cases} 1 & \text{if } i < j, l \neq k, (i, k), (j, l) \in C \\ 0 & \text{otherwise.} \end{cases}$$

The vector x^C has n^2 components and the vector y^C has $\frac{n^2(n-1)^2}{4}$ components. The polytope SQAP_n is defined as convex hull of the vectors (x^C, y^C) , that is,

$$\text{SQAP}_n := \text{conv}\{(x^C, y^C) : C \text{ is a clique with } n \text{ vertices in } H_n\}.$$

Similar to the general case, the following structural results were derived:

Theorem 3 ([137, 180]) *Let $n \geq 3$.*

1. *The dimension of SQAP_n is equal to $(n-1)^2 + n^2(n-3)^2/4$.*
2. *The inequalities $y_{ijkl} \geq 0$ for $i < j, k < l$, and $x_{ik} \geq 0$ for $1 \leq i, k \leq n$, define facets of SQAP_n .*

Padberg and Rijal [180] as well as Jünger and Kaibel [137] derived a minimal linear description of the affine hull of SQAP_n which is similar to (30)–(33). Moreover, Jünger and Kaibel [137] introduced a class of facet-defining inequalities, the so-called row curtain inequalities

$$\sum_{k \in K} x_{ik} - \sum_{\substack{k,l \in K \\ k < l}} y_{ijkl} \geq 0 \text{ for } i < j \text{ and } K \subseteq \{1, 2, \dots, n\} \quad (34)$$

and the column curtain inequalities

$$\sum_{i \in I} x_{ik} - \sum_{\substack{i,j \in I \\ i < j}} y_{ijkl} \geq 0 \text{ for } k < l \text{ and } I \subseteq \{1, 2, \dots, n\}. \quad (35)$$

All curtain inequalities with $3 \leq |I|, |J| \leq n-3$ define facets of SQAP_n . The other curtain inequalities define facets which are contained in trivial facets of SQAP_n . The separation problem for these inequalities has been shown to be NP-hard.

6 Lower Bounds

Since QAPs are NP-hard optimization problems, there is a special need for lower bounds on the optimal objective function value for use in implicit enumeration methods and in heuristics. In general, lower bounds should be:

- *Tight*, that is, the gap between the bound and the optimal objective function value should be small.
- They should be much easier to compute than solving the original problem.
- Their computation should be possible in the case that already some assignments are fixed.

There is no clear performance ranking of the lower bounds that will be discussed below. In light of the asymptotic behavior of the QAP (see Sect. 11), it should be fair to assume that the tightness of the lower bound probably dominates all other of the above criteria. Namely, if there is a large number of feasible solutions close to the optimum, then a lower bound which is not tight will fail to eliminate a large number of subproblems in the enumeration process.

6.1 Admissible Transformations

Admissible transformations provide a general tool for deriving lower bounds of combinatorial optimization problems; see Burkard [39]. Consider a QAP

$$\min_{\varphi \in S_n} \sum_{i=1}^n \sum_{j=1}^n c_{ij\varphi(i)\varphi(j)}$$

and denote the objective function value of permutation φ by $Z(C, \varphi)$.

Definition 1 A transformation T of the cost array C in the cost array $T(C) = \bar{C}$ is called *admissible with index* $z(T)$, if for all permutations φ the equation

$$Z(C, \varphi) = z(T) + Z(\bar{C}, \varphi) \quad (36)$$

holds.

Admissible transformations can be iterated: performing an admissible transformation T with index $z(T)$ after an admissible transformation S with index $z(S)$ corresponds to the admissible transformation $T \circ S$ with index $z(T) + z(S)$. We get the following:

Proposition 1 *Let T be an admissible transformation of the cost array C into \bar{C} with $\bar{C} \geq 0$. Then $z(T)$ constitutes a lower bound on the optimal objective function value. If there is a permutation φ^* with $Z(\bar{C}, \varphi^*) = 0$, then $z(T)$ is the optimal value of the QAP.*

Proof Let φ be any permutation. Then we get

$$Z(C, \varphi) = z(T) + Z(\bar{C}, \varphi) \geq z(T) = z(T) + Z(\bar{C}, \varphi^*) = Z(C, \varphi^*).$$

□

In order to describe admissible transformations for QAPs, let us arrange the cost elements in an $(n^2 \times n^2)$ matrix C such that c_{ijkl} is on row $(i-1)n+j$ and column $(k-1)n+l$ (cf. Sect. 3.1). Matrix C can be written as a block matrix (C^{ik}) where every C^{ik} is the matrix (c_{ijkl}) with fixed indices i and k . The coefficients c_{iilk} with $k \neq l$ and the coefficients c_{ijkk} with $i \neq j$ can never occur in the objective function, since φ is a one-to-one mapping. Therefore, we can assume

$$c_{ijkl} = \infty \quad \text{for } (i = j \text{ and } k \neq l) \text{ or } (i \neq j \text{ and } k = l). \quad (37)$$

For $n = 3$, the cost matrix C has the form (using “*” for ∞)

$$\begin{aligned} C &= \begin{pmatrix} C^{11} & C^{12} & C^{13} \\ C^{21} & C^{22} & C^{23} \\ C^{31} & C^{32} & C^{33} \end{pmatrix} \\ &= \left(\begin{array}{ccc|ccc|ccc} c_{1111} & * & * & * & c_{1122} & * & * & * & * & c_{1133} \\ * & c_{1212} & c_{1213} & c_{1221} & * & c_{1223} & c_{1231} & c_{1232} & * \\ * & c_{1312} & c_{1313} & c_{1321} & * & c_{1323} & c_{1331} & c_{1332} & * \\ \hline * & c_{2112} & c_{2113} & c_{2121} & * & c_{2123} & c_{2131} & c_{2132} & * \\ c_{2211} & * & * & * & c_{2222} & * & * & * & * & c_{2233} \\ * & c_{2312} & c_{2313} & c_{2321} & * & c_{2323} & c_{2331} & c_{2332} & * \\ * & c_{3112} & c_{3113} & c_{3121} & * & c_{3123} & c_{3131} & c_{3132} & * \\ * & c_{3212} & c_{3213} & c_{3221} & * & c_{3223} & c_{3231} & c_{3232} & * \\ c_{3311} & * & * & * & c_{3322} & * & * & * & * & c_{3333} \end{array} \right). \end{aligned}$$

Moreover, due to $x_{ik}x_{jl} = 1$, we can symmetrize the problem and set:

$$c_{ijkl} := \begin{cases} c_{ijkl} + c_{klji} & \text{for } j > i, \\ 0 & \text{for } j < i. \end{cases} \quad (38)$$

Every submatrix C^{ik} has only one entry $c_{iikk} \neq \infty$ in row i and column k , the so-called leading element. Admissible transformations for the QAP were implicitly used by Hahn and Grant [124, 125]. They can be described in the following way; see Burkard [39].

Theorem 4 Let $C = (C^{ik})$ be the cost matrix of a general QAP (2). There are two types of admissible transformations:

- I. Let C^{ik} be a fixed submatrix of C . Adding arbitrary constants to the rows and columns of C^{ik} such that the constants sum up to 0 yields an admissible transformation T with index $z(T) = 0$.

II. Adding arbitrary constants to the rows and columns of C yields an admissible transformation T whose index $z(T)$ equals the negative sum of the constants.

The first part of [Theorem 4](#) tells that we can add arbitrary constants to the rows $j \neq i$ and columns $l \neq k$, provided that we subtract the same constants from the leading element c_{iikk} . Note that the constants can also be negative. The second part of [Theorem 4](#) tells that we can collect the leading elements c_{iikk} in an $n \times n$ matrix $L = (l_{ik})$ with $l_{ik} = c_{iikk}$. Any admissible transformation applied to the linear assignment problem with cost matrix L leads to an admissible transformation for the QAP (see [\[39, 46, 51\]](#)).

Admissible transformations are a main tool for deriving lower bounds for the QAP. In particular, the Gilmore–Lawler bound as well as reductions, reformulations, and redistributions can be interpreted as special applications of admissible transformations.

6.2 Gilmore–Lawler Type Lower Bounds

Based on the formulation of the general QAP as a linear assignment problem of dimension n^2 stated in formulation [\(9\)](#), Gilmore [\[110\]](#) and Lawler [\[152\]](#) derived lower bounds for the QAP by solving linear assignment problems.

Consider an instance of the Lawler QAP [\(2\)](#) with the $n^2 \times n^2$ coefficient matrix $C = (c_{ijkl})$. First, we solve n^2 linear assignment problems

$$\bar{l}_{ik} := \min_X \langle C^{ik}, X \rangle.$$

According to the first part of [Proposition 4](#), we can replace c_{iikk} in C by $c_{iikk} + \bar{l}_{ik}$ and the coefficients c_{ijkl} by the reduced cost coefficients in the optimal solution of the linear assignment problem $\min_X \langle C^{ik}, X \rangle$. According to the second part of [Proposition 4](#), we can collect the leading elements c_{iikk} in an $n \times n$ matrix $L = (l_{ik})$ with $l_{ik} = c_{iikk}$. Since the optimal value of the linear assignment problem with cost matrix L can be found by adding constants to the rows and columns of matrix L (and therefore of matrix C !), it constitutes a lower bound for the QAP, the so-called Gilmore–Lawler bound. Let X^* be an optimal solution of the linear assignment problem with cost matrix L and let $Y^* := X^* \otimes X^*$. According to [Proposition 1](#), matrix X^* is an optimal solution of the given QAP, if $\langle C, Y^* \rangle = 0$.

Since each linear assignment problem can be solved in $O(n^3)$ time, this lower bound for the Lawler QAP [\(2\)](#) of dimension n can be computed in $O(n^5)$ time.

In case of Koopmans–Beckmann problems [\(1\)](#), the computation can be sped up as $C = D \otimes F$. The computational effort for computing the lower bound can be reduced to $O(n^3)$. Namely, instead of solving n^2 linear assignment problems by the Hungarian method, the optimal value of the assignment problem $\min_X \langle C^{ik}, X \rangle$ can be obtained by using the following result:

Proposition 2 ([127]) Let two n -dimensional real vectors $a = (a_i)$, $b = (b_i)$ with $0 \leq a_1 \leq a_2 \leq \dots \leq a_n$ and $b_1 \geq b_2 \geq \dots \geq b_n \geq 0$ be given. Then the following inequalities hold for any permutation φ of $1, 2, \dots, n$:

$$\sum_{i=1}^n a_i b_i \leq \sum_{i=1}^n a_i b_{\varphi(i)} \leq \sum_{i=1}^n a_i b_{n-i+1}.$$

Given an arbitrary nonnegative vector $a \in \mathbb{R}^n$, let ψ be a permutation which sorts a nondecreasingly and π a permutation which sorts a nonincreasingly. We denote

$$\langle a, b \rangle^- := \sum_{i=1}^n a_{\psi(i)} b_{\pi(i)} \quad \text{and} \quad \langle a, b \rangle^+ := \sum_{i=1}^n a_{\psi(i)} b_{\psi(i)}. \quad (39)$$

Consider now an instance QAP(F, D, B) of the Koopmans–Beckmann QAP (1). It can be written as a general QAP by setting

$$c_{ijkl} := \begin{cases} f_{ij}d_{kl}, & \text{for } i \neq j, k \neq l, \\ f_{ii}d_{kk} + b_{ik}, & \text{for } i = j, k = l. \end{cases}$$

Each submatrix $C^{(ik)}$ of the $n^2 \times n^2$ matrix C is given by $C^{(ik)} = (f_{ij}d_{kl})$ with fixed values i and k . The optimal objective function value of the linear assignment problem $\min_X \langle C^{(ik)}, X \rangle$ can be found by applying Proposition 2 to the $(n-1)$ -dimensional vectors $\hat{f}_{(i,.)}$ and $\hat{d}_{(k,.)} \in \mathbb{R}^{n-1}$ which are obtained from the i th and the k th row of F and D by deleting the i th and the k th element, respectively. We get

$$\min_X \langle C^{(ik)}, X \rangle = f_{ii}d_{kk} + \langle \hat{f}_{(i,.)}, \hat{d}_{(k,.)} \rangle^-. \quad (40)$$

The Gilmore–Lawler bound is obtained by solving a linear assignment problem with cost matrix $L = (l_{ik})$ where l_{ik} are given by

$$l_{ik} = b_{ik} + f_{ii}d_{kk} + \langle \hat{f}_{(i,.)}, \hat{d}_{(k,.)} \rangle^-. \quad (41)$$

The appropriate sorting of the rows and columns of F and D can be done in $O(n^2 \log n)$ time. Then the computation of all l_{ij} takes $O(n^3)$ time and the same amount of time is needed to solve the last linear assignment problem.

Li et al. [157] have shown that the decision problem whether the Gilmore–Lawler bound equals to the optimal objective function value is NP-complete.

Similar bounds have been proposed by Christofides and Gerrard [67]. The basic idea relies again on decomposing the given QAP into a number of subproblems which can be solved efficiently. First solve each subproblem, then build a matrix with the optimal values of the subproblems, and solve a linear assignment problem with that matrix as cost matrix to obtain a lower bound for the given QAP.

Christofides et al. decompose the Koopmans–Beckmann QAP(F, D) based on isomorphic subgraphs of graphs whose weighted adjacency matrices are F and D . The Gilmore–Lawler bound is obtained as a special case, if these subgraphs are star graphs. In general the Gilmore–Lawler bound outperforms the bounds obtained by employing other subgraphs, like single edges or double stars (see also [107]).

6.3 Reduction Methods

The Gilmore–Lawler bound is simple to compute, but it deteriorates fast as n increases. The quality of this lower bound can be improved if the given problem is transformed such that the contribution of the quadratic term in the objective function is decreased by moving costs to the linear term. This is the aim of the so-called reduction methods. A reduction corresponds to an admissible transformation of type I which increases the leading element c_{iikk} and reduces the other elements in C^{ik} but keeps them nonnegative. The reduction approach was introduced by Conrad [73]. Reductions have been investigated by many researchers (see [36, 91, 103, 205]).

In the case of the Koopmans–Beckman QAP, the reduction scheme is

$$f_{ij} = \bar{f}_{ij} + \lambda_j, \quad i \neq j, \quad (42)$$

$$d_{kl} = \bar{d}_{kl} + \mu_l, \quad k \neq l. \quad (43)$$

Frieze and Yadegar [103] have shown that a simultaneous reduction of rows and columns in F and D does not improve the lower bound. Therefore, it is unnecessary to consider a column reduction in matrix F and matrix D . Several rules have been suggested for the choice of λ and μ , for example,

$$\lambda_j = \min\{f_{ij} \mid 1 \leq i \leq n, i \neq j\} \quad (44)$$

$$\mu_l = \min\{d_{kl} \mid 1 \leq k \leq n, k \neq l\}. \quad (45)$$

Li et al. [157] choose λ_j and μ_l such as to minimize the variance of all off-diagonal elements in the j th column of F and the l th column of D . Let $m(F_j)$ be the arithmetic mean of the off-diagonal entries in j th column of matrix F :

$$m(F_j) = \frac{1}{n-1} \sum_{\substack{i=1 \\ i \neq j}}^n f_{ij}. \quad (46)$$

The value $m(D_l)$ is defined in an analogous way. The choice proposed in [157] is:

$$\lambda_j = m(A_n) - m(A_k), \quad (47)$$

$$\mu_l = m(B_n) - m(B_l). \quad (48)$$

Li et al. developed also another reduction scheme where the matrices F and D are replaced by $F + \Delta F$ and $D + \Delta D$, respectively. ΔF and ΔD are chosen such as to minimize the variance of the off-diagonal elements in the flow matrix F and distance matrix D . These bounds perform well on QAPs whose input matrices have high variances, but their performance reduces to that of the Gilmore–Lawler bound when the variance of the input matrices is small. For details the reader is referred to the original paper [157].

Similar reduction schemes can be applied to the general Lawler QAP (2).

As mentioned in Sect. 4.3, Frieze and Yadegar derived lower bounds for the QAP based on a Lagrangean relaxation of the mixed integer linear programming formulation (19)–(26). They include the constraints (21) and (22) in the objective function (19) by Lagrangean multipliers e and g :

$$\begin{aligned} & \sum_{ijkl} c_{ijkl} y_{ijkl} + \sum_{jkl} e_{jkl} (x_{jl} - \sum_i y_{ijkl}) + \sum_{ikl} g_{ikl} (x_{jl} - \sum_j y_{ijkl}) \\ &= \sum_{ijkl} (c_{ijkl} - e_{jkl} - g_{ikl}) y_{ijkl} + \sum_{kl} (\sum_j e_{jkl} + \sum_i g_{ikl}) x_{jl} \end{aligned}$$

and obtain the Lagrangean problem

$$\begin{aligned} \mathcal{L}(e, g) = \\ \min \quad & \{\sum_{ijkl} (c_{ijkl} - e_{jkl} - g_{ikl}) y_{ijkl} + \sum_{ij} (\sum_k e_{kij} + \sum_l g_{lij}) x_{ij}\} \\ \text{s.t.} \quad & \text{constraints (20), (23), ..., (26).} \end{aligned}$$

Frieze and Yadegar [103] showed that $\max_{e,g} \mathcal{L}(e, g)$ constitutes a lower bound for the QAP which is larger (i.e., better) than all Gilmore–Lawler bounds obtained after applying reduction methods. They propose subgradient algorithms to approximately solve $\max_{e,g} \mathcal{L}(e, g)$. The lower bounds obtained in such a way seem to be sharper than Gilmore–Lawler bounds obtained after applying reductions.

Carraresi and Malucelli [59] as well as Assad and Xu [17] suggested to apply a sequence of admissible transformations for computing a lower bound. Carraresi and Malucelli proposed to modify the coefficients of a QAP (2) iteratively by

$$\begin{aligned} c'_{ijkl} &= c_{ijkl} + \tau_{ijkl} - \alpha_{ijk} - \beta_{ikl} + \theta_{ik}, \quad 1 \leq i, j, k, l \leq n, i \neq j, k \neq l \\ c'_{iikk} &= c_{iikk} + \sum_{j=1}^n \alpha_{ijk} + \sum_{l=1}^n \beta_{ikl} - (n-1)\theta_{ik}, \quad 1 \leq i, k \leq n. \end{aligned}$$

This is obviously an admissible transformation of Type I. Carraresi and Malucelli choose in particular the following update formulae:

$$\tau_{ijkl}^{(t+1)} = c_{ijkl}^{(t)} - c_{jilk}^{(t)}, \quad (49)$$

$$\alpha_{ijk}^{(t+1)} = u_{ijk}^{(t)}, \quad (50)$$

$$\beta_{ikl}^{(t+1)} = v_{ikl}^{(t)}, \quad (51)$$

$$\theta_{ik}^{(t+1)} = \frac{1}{n-1} (c_{ik}^{(t)} + u_i^{(t)} + v_k^{(t)}), \quad (52)$$

for all $1 \leq i, j, k, l \leq n$; $i \neq j, k \neq l$. Here t is a counting index for the reformulations. $u_{ijk}^{(t)}$, $1 \leq j \leq n$, and $v_{ikl}^{(t)}$, $1 \leq l \leq n$, are the optimal values of the dual variables of the linear assignment problem with cost matrix C^{ik} , for $1 \leq i, k \leq n$. Let $l_{ik}^{(t)}$ be the optimal values of these LAPs, $1 \leq i, k \leq n$. Then $u_i^{(t)}$, $1 \leq i \leq n$, and $v_k^{(t)}$, $1 \leq k \leq n$, are optimal values of the dual variables for the linear assignment problem with cost matrix $L^t = (l_{ik}^t)$ (i.e., the final linear assignment problem solved to compute the Gilmore–Lawler bound of the t th reformulation).

The bound produced with these settings is often denoted by CMB. The reformulation schemes generally produce bounds of good quality. These bounding techniques, however, are quite time-consuming as n^2+1 linear assignment problems have to be solved per iteration. The computation of CMB (as well as the computation of the bounds obtained by applying the reformulation schemes proposed in [17, 58]) involves $O(n^5)$ elementary operations per iteration.

It has been shown in [58] that in the case $c_{ijkl} = c_{jilk}$, for all $1 \leq i, j, k, l \leq n$, the general reformulation scheme cannot produce lower bounds which are better than the optimal value of the continuous relaxation of the mixed integer programming formulation of Frieze and Yadegar.

Hahn and Grant [124, 125] suggested to use the following two operations for the bounding process:

- (R1) Add a constant to all entries of some row (column) of some submatrix $C^{(ij)}$ and either subtract the same constant from another row (column) of the same submatrix or subtract it from the leader in that submatrix.
- (R2) Add a constant to all entries of some row (column) of the $n^2 \times n^2$ matrix (c_{ijkl}) .

Clearly, operations of class R1 are admissible transformations of type I which just redistribute the entries of the submatrices C^{ik} . Operations of class R2 add a constant to the objective function, and hence, they maintain the order of permutations with respect to the corresponding values of the objective function. The goal is to transform C by applying operations of the classes R1 and R2 so as to decrease the objective function by some amount, say R , and to preserve the nonnegativity of entries of the transformed array C' . Then, R is a lower bound for the optimal solution of the given QAP. If, moreover, $\langle C', Y \rangle = 0$, where Y is the Kronecker product $X_\varphi \otimes X_\varphi$ for some permutation matrix X_φ , then R is the optimal value of the original QAP and permutation φ is an optimal solution. The whole process is a repeated computation of Gilmore–Lawler bounds on iteratively transformed problem data. The time complexity of each iteration is basically $O(n^5)$.

A deeper investigation of this bounding procedure reveals that it is an iterative approach in which the dual of some LP relaxation of the original problem is solved and reformulated iteratively (see [140]). Computational results of Hahn et al. [125] show that it is promising to involve the Hahn–Grant bound in branch-and-bound approaches.

6.4 Bounds Based on Linear Programming Relaxations

In Sect. 4 several mixed integer linear programming (MILP) formulations have been proposed for the QAP. Clearly, the optimal solution of the continuous relaxation of a MILP formulation is a lower bound for the optimal value of the corresponding QAP. Moreover, each feasible solution of the dual of this relaxation is also a lower bound. The identification of appropriate continuous relaxations of MILP formulations and the development of solution methods for solving these relaxations or their duals have been important research aspects.

In the context of lower bound computation, two MILP formulations of the QAP play a special role: the formulation of Frieze and Yadegar [103] described in Sect. 4.3 and that of Adams and Johnson [4] described in Sect. 4.4. As already mentioned, Frieze and Yadegar consider a Lagrangean relaxation of their MILP formulation and develop subgradient algorithms to approximately solve the latter. The resulting bounds perform better than the Gilmore–Lawler bound.

Adams and Johnson [4] consider a Lagrangean relaxation $AJ(\alpha)$ of (27) obtained by adding the so-called complementary constraints (28) to the objective function via Lagrangean multipliers α_{ijkl} . Let $\theta(\alpha)$ denote the optimal value of $AJ(\alpha)$. Then $\max_{\alpha} \theta(\alpha)$ equals the optimal value of the continuous relaxation of (27). Adams and Johnson show that for each fixed set of the multipliers α the problem, $AJ(\alpha)$ can be solved efficiently by solving $n^2 + 1$ linear assignment problems. Moreover, they develop an iterative dual ascent procedure to approximately solve the above maximization problem. In each iteration problem $AJ(\alpha)$ is solved to optimality and the optimal value $\theta(\alpha)$ is computed. Clearly, $\theta(\alpha)$ is a lower bound for the considered QAP. Afterwards, the multipliers α_{ijkl} are updated by using the information contained in the dual variables of the linear assignment problems solved during the previous iteration. The algorithm stops after a prespecified number of iterations. Two updating rules for the multipliers are suggested, one of them leading to a nondecreasing sequence of lower bounds $\theta(\alpha)$. In both cases, the time complexity of this bounding procedure is dominated by the solution of $n^2 + 1$ linear assignment problems. The obtained bound is called Adams–Johnson bound (AJB).

The strength of AJB relies on the fact that it generalizes and unifies all Gilmore–Lawler-like bounds (see Sect. 6.2) but not the Hahn–Grant bound (HGB). Adams et al. have shown that $\theta(0)$ equals to the Gilmore–Lawler bound. Reductions as well as the bounds of Carraresi and Malucelli [58] and Assad and Xu [17] equal $\theta(\alpha)$ for special settings of the Lagrangean multipliers α_{ijkl} . Numerical experiments with instances from QAPLIB show that AJB generally outperforms the above-mentioned bounds. However, according to the numerical results reported in [4, 124],

the Hahn–Grant bound (HGB) outperforms AJB in terms of quality while having higher computation time requirements.

The theoretical relationship between AJB and HGB has been investigated by Karisch et al. [140]. Both, AJB and HGB, can be obtained as feasible solutions of the dual of the continuous relaxation of the MILP formulation (27) proposed by Adams and Johnson. Karisch et al. propose an iterative algorithm to approximately solve this dual and show that AJB, HGB, and all other Gilmore–Lawler-like bounds can be obtained by applying this algorithm with specific settings for the control parameters. Moreover, the same authors identify a setting of parameters which seems to produce a bound which is competitive with HGB in terms of quality and provides a better time/quality trade-off. This bound denoted by KCCEB seems to be especially suitable for use within branch-and-bound algorithms (see [140] for more details).

Adams and Johnson point out that the continuous relaxation of (27) is highly degenerated, and degeneracy poses a problem for primal approaches. In order to overcome this difficulty, Resende et al. [201] solve this LP by an interior-point approach. The bounds obtained in this way have a very good quality but require rather high computation times. Moreover, memory requirements restrict this approach to problems with $n \leq 30$.

6.5 Lower Bounds Based on Eigenvalues

Bounds based on the eigenvalues of the input matrices F and D of symmetric Koopmans–Beckmann problems were introduced by Finke et al. [98]. The starting point is the trace formulation (11) of the Koopmans–Beckmann QAP. When designed and implemented carefully, these techniques produce bounds of good quality in comparison with Gilmore–Lawler-like bounds or, more generally, with bounds based on linear relaxations. However, these bounds are quite expensive in terms of computation time requirements and therefore they are not appropriate for use within branch-and-bound algorithms. Moreover, these bounds deteriorate quickly when lower levels of the branch-and-bound tree are searched, as shown by Karisch et al. [68].

Upon the introduction of the method in [98], many improvements and generalizations have appeared [120–123, 197, 200]. There is a resemblance with the Gilmore–Lawler-based lower bounds in the sense that, based upon a general eigenvalue bound, reduction techniques are applied to the quadratic terms of the objective function in order to improve its quality. In this case, however, the reduction techniques yield a significant improvement which is not really the case with the GLB.

Let F and D be real symmetric matrices. Hence all their eigenvalues are real. We denote the eigenvalues of F by $\lambda_1, \dots, \lambda_n$ and the eigenvalues of D by μ_1, \dots, μ_n . For any permutation matrix X_φ , the matrix $D_\varphi^T = X_\varphi D^T X_\varphi^T$ has the same eigenvalues as D . The matrices F and D admit diagonalizations of the form $F = P\Lambda P^T$ and $D_\varphi^T = QM Q^T$ with orthogonal matrices P and Q and diagonal matrices $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_n)$ and $M = \text{diag}(\mu_1, \dots, \mu_n)$. Let p_1, p_2, \dots, p_n

denote the columns of P and q_1, q_2, \dots, q_n the columns of Q . Then

$$F = \sum_{i=1}^n \lambda_i p_i p_i^T \quad \text{and} \quad D_\varphi^T = \sum_{k=1}^n \mu_k q_k q_k^T.$$

Therefore

$$\langle F, D_\varphi \rangle = \text{tr}(FD_\varphi^T) = \text{tr}\left(\sum_{i=1}^n \sum_{k=1}^n \lambda_i \mu_k p_i p_i^T q_k q_k^T\right) = \sum_{i=1}^n \sum_{k=1}^n \lambda_i \mu_k \langle p_i, q_k \rangle^2.$$

Thus, we get with $\lambda = (\lambda_1, \dots, \lambda_n)^T$, $\mu = (\mu_1, \dots, \mu_n)^T$, and matrix $S_\varphi = (\langle p_i, q_k \rangle^2)$

$$\text{tr}(FXDX^T) = \lambda^T S_\varphi \mu. \quad (53)$$

Matrix S_φ is a doubly stochastic matrix. According to Birkhoff's [Theorem 1](#), it can be written as convex combination of permutation matrices. This yields immediately the following bounds on the optimal objective function value of QAP(F, D):

Theorem 5 ([98]) *Let F and D be symmetric $n \times n$ matrices with real entries and eigenvalues $\lambda = (\lambda_1, \dots, \lambda_n)^T$ and $\mu = (\mu_1, \dots, \mu_n)^T$, respectively. Then*

$$\langle \lambda, \mu \rangle^- \leq \text{tr}(FXDX^T) \leq \langle \lambda, \mu \rangle^+. \quad (54)$$

In case of a symmetric Koopmans–Beckmann problem with a linear term $\langle B, X \rangle$, we obtain the lower bound

$$\text{EVB} := \langle \lambda, \mu \rangle^- + \min_{X \in \mathbf{X}_n} \text{tr}(BX^T).$$

The second term is the optimal value of a linear assignment problem. EVB is not a strong bound. It often takes a negative value, even for QAP instances with nonnegative coefficient matrices.

The smaller the interval $[\langle \lambda, \mu \rangle^-, \langle \lambda, \mu \rangle^+]$ is, the closer is $\langle \lambda, \mu \rangle^-$ to $\text{tr}(FXDX^T)$. Thus one can try to transform the given QAP so as to decrease the length of that interval.

Reduction Methods and Bound EV1

One possibility to decrease the length of the interval $[\langle \lambda, \mu \rangle^-, \langle \lambda, \mu \rangle^+]$, and hence to improve EVB, is to decompose the matrices F and D such that some amount will be transferred to the linear term, and the eigenvalues of the matrices resulting in the quadratic term are as uniform in value as possible. The *spread* $sp(F)$ of matrix F is defined by

$$sp(F) := \max \{ |\lambda_i - \lambda_j| : i, j = 1, \dots, n \}.$$

Mirsky [172] showed the following upper bound on the spread:

$$sp(F) \leq m(F) = \left[2 \sum_{i=1}^n \sum_{j=1}^n f_{ij}^2 - \frac{2}{n} (\text{tr} F)^2 \right]^{1/2}. \quad (55)$$

Minimizing $m(F)$ leads to a system of linear equations from which the coefficients of the reduction

$$f_{ij} = \bar{f}_{ij} + e_i + e_j + r_{ij} \quad (56)$$

can be computed explicitly by

$$\begin{aligned} z &= \frac{1}{2(n-1)} \left(\sum_{i=1}^n \sum_{j=1}^n f_{ij} - \sum_{i=1}^n f_{ii} \right), \\ e_i &= \frac{1}{n-2} \left(\sum_{j=1}^n f_{ij} - f_{ii} - z \right), \\ r_{ij} &= \begin{cases} f_{ii} - 2e_i & \text{for } i = j; \\ 0 & \text{otherwise.} \end{cases} \end{aligned}$$

The reduced matrix \bar{F} is again symmetric and has zeroes in the diagonal. Moreover, every row and column sum of \bar{F} equals 0. Matrix D can be reduced in an analogous way:

$$d_{kl} = \bar{d}_{kl} + g_k + g_l + s_{kl}, \quad (57)$$

where the values z , g_k , and s_{kl} can be computed as above. By replacing F and D in (11), we obtain

$$\text{tr}(FXD + B)X^T = \text{tr}(\bar{F}X\bar{D} + \bar{B})X^T,$$

where

$$\bar{b}_{ik} = b_{ik} + f_{ii}d_{kk} + 2e_i \sum_{\substack{l=1 \\ l \neq k}}^n d_{kl}.$$

Let $\bar{\lambda} = (\bar{\lambda}_1, \dots, \bar{\lambda}_n)^T$ and $\bar{\mu} = (\bar{\mu}_1, \dots, \bar{\mu}_n)^T$ be the eigenvalues of matrices \bar{F} and \bar{D} , respectively. By applying EVB to the QAP with the transformed coefficient matrices, we obtain the new eigenvalue bound EVB1

$$\text{EVB1} := \langle \bar{\lambda}, \bar{\mu} \rangle^- + \min_{X \in \mathbf{X}_n} \text{tr} \bar{B} X^T.$$

If we restrict ourselves to purely quadratic, symmetric QAPs, that is, $f_{ii} = d_{kk} = 0$, for all i and k , and $B = 0$, matrix \bar{B} in the above decomposition becomes $\bar{B} = cw^T$, where $c = 2(e_1, \dots, e_n)^T$ and $w = (\sum_l d_{1l}, \dots, \sum_l d_{nl})^T$. Therefore, $\min_{X \in \mathbf{X}_n} \text{tr}(\bar{B}X^T) = \langle c, w \rangle^-$, and

$$\text{EVB1} = \langle \bar{\lambda}, \bar{\mu} \rangle^- + \langle c, w \rangle^- \leq \min_{X \in \mathbf{X}_n} \text{tr}(\bar{F} X \bar{D} + \bar{B}) X^T.$$

Rendl [197] suggested a further improvement of this bound by ranking scalar products of the form $\langle c, Xw \rangle$ for certain permutation matrices X . Moreover, Rendl [197] defines a ratio ρ called the *degree of linearity* based on the ranges of the quadratic and linear terms that compose the lower bound

$$\rho := \frac{\langle \bar{\lambda}, \bar{\mu} \rangle^+ - \langle \bar{\lambda}, \bar{\mu} \rangle^-}{\langle c, w \rangle^+ - \langle c, w \rangle^-}.$$

The influence of the linear term on the lower bound is inversely proportional to the value of ρ . A *small* value of ρ suggests that the ranking procedure mentioned above would be beneficial for the improvement of EVB1. For large values of ρ , we can expect that the quadratic term dominates the linear term in the objective function. In this case Finke et al. [98] suggest the following improvement of EVB1. Consider **Theorem 5** applied to the reduced matrices \bar{F} and \bar{D} and denote the elements of matrix S_φ by s_{ik} , $s_{ik} = \langle p_i, q_k \rangle^2$. It is easy to see that $l_{ik} \leq s_{ik} \leq u_{ik}$, where

$$u_{ik} = \max\{(\langle p_i, q_k \rangle^-)^2, (\langle p_i, q_k \rangle^+)^2\},$$

and

$$l_{ij} = \begin{cases} 0, & \text{if } \langle p_i, q_k \rangle^- \cdot \langle p_i, q_k \rangle^+ < 0, \\ \min\{(\langle p_i, q_k \rangle^-)^2, (\langle p_i, q_k \rangle^+)^2\}, & \text{otherwise.} \end{cases}$$

Recalling the fact that s_{ik} are elements of a doubly stochastic matrix, we can then form the *capacitated transportation problem* (CTP)

$$\begin{aligned} \text{CTP}^* = \min & \sum_{i=1}^n \sum_{k=1}^n \bar{\lambda}_i \bar{\mu}_k s_{ik} \\ \text{s.t.} & \sum_{i=1}^n s_{ik} = 1, \quad k = 1, \dots, n, \\ & \sum_{k=1}^n s_{ik} = 1, \quad i = 1, \dots, n, \\ & l_{ik} \leq s_{ik} \leq u_{ik}. \end{aligned}$$

Then, a new lower bound would be

$$\text{EVB2} = \text{CTP}^* + \langle c, w \rangle^-.$$

Other Eigenvalue-Related Bounds

Rendl and Wolkowicz [200] derive a new lower bound similar to EVB2. Notice that the decomposition scheme in (56) and (57) is uniquely determined by the $4n$ -dimensional vector $d := (e^T, g^T, r^T, s^T) \in \mathbb{R}^{4n}$, where $r = (r_{11}, \dots, r_{nn})^T$ and $s = (s_{11}, \dots, s_{nn})^T$. EVB1 is then a function of d . Maximizing this function with respect to d will result in a lower bound with the best possible decomposition with respect to both the linear and the quadratic term. Maximizing EVB1 as a function of d leads to a nonlinear, nonsmooth, nonconcave maximization problem which is hard to solve to optimality. Rendl et al. propose a steepest ascent algorithm to approximately solve this problem (see [200]). The new bound, denoted EVB3, produces the best lower bounds for a number of QAP instances from QAPLIB, with the expense, however, of high computational time requirements.

A more general approach to eigenvalue-based lower bounding techniques was employed by Hadley et al. [121]. Consider the following sets of $n \times n$ matrices, where I is the $n \times n$ identity matrix and $u := (1, \dots, 1)^T$ is the n -dimensional vector of all ones:

$$\begin{aligned}\mathcal{O} &:= \{X : X^T X = I\}, && \text{set of orthogonal matrices.} \\ \mathcal{E} &:= \{X : Xu = X^T u = u\}, && \text{set of matrices with row} \\ &&& \text{and column sums equal to one.} \\ \mathcal{N} &:= \{X : X \geq 0\}, && \text{set of nonnegative matrices.}\end{aligned}\tag{58}$$

It is a well-known result that $\mathbf{X}_n = \mathcal{O} \cap \mathcal{E} \cap \mathcal{N}$, while the set Ω of *doubly stochastic matrices* is given as $\Omega = \mathcal{E} \cap \mathcal{N}$. Moreover, by Birkhoff's theorem [27], we know that Ω is a convex polyhedron with vertex set \mathbf{X}_n , that is, $\Omega = \text{conv}\{X : X \in \mathbf{X}_n\}$. The above characterization of \mathbf{X}_n implies that we get a relaxation of the QAP, if we delete one or two of the matrix sets \mathcal{O} , \mathcal{E} , and \mathcal{N} in the intersection $\mathbf{X}_n = \mathcal{O} \cap \mathcal{E} \cap \mathcal{N}$. Obviously, the relaxation, and therefore the lower bound, will be tighter if only one of the matrix sets is excluded. In relation to [Theorem 5](#), Rendl and Wolkowicz [200] have shown that

$$\begin{aligned}\min_{X \in \mathcal{O}} \text{tr}(FXDX^T) &= \text{tr}(F\Lambda_F \Lambda_D^T D \Lambda_D \Lambda_F^T) = \langle \lambda, \mu \rangle^-, \\ \max_{X \in \mathcal{O}} \text{tr}(FXDX^T) &= \text{tr}(F\Lambda_F \Lambda_D^T D \Lambda_D \Lambda_F^T) = \langle \lambda, \mu \rangle^+,\end{aligned}$$

where Λ_F and Λ_D are matrices whose columns consist of the eigenvectors of F and D , respectively, in the order specified by their minimal (maximal) inner product. In other words, the lower bound on the quadratic part of the QAP as obtained in EVB is derived by relaxing the feasible set to the set of orthogonal matrices.

All eigenvalue bounds discussed above relax the set of permutation matrices to \mathcal{O} . A tighter relaxation was proposed in [120, 122], where the set of permutation matrices was relaxed to $\mathcal{O} \cap \mathcal{E}$. The authors incorporate \mathcal{E} in the objective function by exploiting the fact that the vector of ones u is both a left and right eigenvector

with eigenvalue 1, for any $X \in \mathbf{X}_n$. More specifically, define

$$P := [u/\|u\| : V], \quad \text{where } V^T u = 0, \quad V^T V = I_{n-1}.$$

Then, V is an orthonormal basis for $\{u\}^\perp$, while $Q := VV^T$ is the orthogonal projection on $\{u\}^\perp$. The following characterization of the permutation matrices is given in [122].

Lemma 1 ([120,122]) *Let X be a real $n \times n$ matrix and Y be a real $(n-1) \times (n-1)$ matrix. If*

$$X = P \begin{bmatrix} 1 & 0 \\ 0 & Y \end{bmatrix} P^T, \quad (59)$$

then

$$X \in \mathcal{E}, \quad X \in \mathcal{N} \Leftrightarrow VYV^T \geq -uu^T/\|u\|^2, \quad \text{and} \quad X \in \mathcal{O} \Leftrightarrow Y \in \mathcal{O}_{n-1}.$$

Conversely, if $X \in \mathcal{E}$, there exists a Y such that (59) holds.

Note that the above characterization of permutation matrices preserves the orthogonality and the trace structure of the problem. By substituting $X = -uu^T/\|u\|^2 + VYV^T$ in the trace formulation of the QAP (11) as suggested by (59), we obtain an equivalent *projected problem* (PQAP) of dimension $n-1$ with variable matrix Y . The new lower bound, often called *elimination bound* and denoted by ELI, is obtained by dropping the requirement $VYV^T \geq -uu^T/\|u\|^2$ and simply requiring $Y \in \mathcal{O}_{n-1}$. In this way we derive a lower bound for the quadratic part of the PQAP. The linear part can be solved exactly as a linear assignment problem. Relations between projected eigenvalue bounds for the QAP and bounds found by semidefinite relaxations (see Sect. 6.7) are discussed by Anstreicher [11].

Concluding this section, notice that there is a possibility to apply eigenvalue bounds also to nonsymmetric QAPs, that is, QAPs where both coefficient matrices F and D are nonsymmetric. Hadley [120] and Hadley et al. [123] involve Hermitian matrices instead of orthogonal matrices. Recall that a matrix H is *Hermitian* if H equals to the transposed, conjugate complex matrix H^* . Every Hermitian matrix has real eigenvalues. In the following, let “ i ” denote $\sqrt{-1}$. For any real $n \times n$ matrix A , define

$$A_+ = \frac{1}{2}(A + A^T), \quad A_- = \frac{1}{2}(A - A^T), \quad (60)$$

$$\tilde{A}_+ = \frac{1}{2}(A_+ + iA_-), \quad \tilde{A}_- = \frac{1}{2}(A_+ - iA_-). \quad (61)$$

Note that A_+ is symmetric, A_- is skew symmetric, and \tilde{A}_+ and \tilde{A}_- are Hermitian, that is, $\tilde{A}_+ = \tilde{A}_+^*$ and $\tilde{A}_- = \tilde{A}_-^*$. \tilde{A}_+ is the positive Hermitian part of A and \tilde{A}_- is the negative Hermitian part of A . In particular, \tilde{A}_+ and \tilde{A}_- have only real eigenvalues. Hadley et al. [122] have shown the following:

Proposition 3 *Let F , D , and X be any real $n \times n$ matrices. Then*

$$\text{tr}(FXD^T X^T) = \text{tr}(\tilde{F}_+ X \tilde{D}_+^* X^T). \quad (62)$$

An immediate consequence of this relation are the following eigenvalue bounds for nonsymmetric Koopmans–Beckmann problems:

Proposition 4 *Let a Koopmans–Beckmann problem with real matrices F and D be given. Let $\lambda = (\lambda_1, \lambda_2, \dots, \lambda_n)^T$ and $\mu = (\mu_1, \mu_2, \dots, \mu_n)^T$ be the vector of the eigenvalues of the Hermitian matrices \tilde{F}_+ and \tilde{D}_+ , respectively. Then the following inequality holds for any permutation φ .*

$$\langle \lambda, \mu \rangle^- \leq \sum_{i=1}^n \sum_{j=1}^n f_{ij} d_{\varphi(i)\varphi(j)} \leq \langle \lambda, \mu \rangle^+. \quad (63)$$

6.6 Improving Bounds by Means of Decompositions

The idea of applying so-called decompositions to improve lower bounds for specially structured QAPs was initially proposed by Chakrapani and Skorin-Kapov [64] and then further elaborated by Karisch and Rendl [141]. The applicability of this approach seems to be restricted to so-called grid QAPs (or *rectilinear QAPs*). This procedure yields a good trade-off between computation time and bound quality.

A grid QAP is a Koopmans–Beckmann QAP with flow matrix F and distance matrix $D = (d_{kl})$ being the distance matrix of a uniform rectangular grid with unit distance 1. If $d_{kl} = d_{km} + d_{ml}$, we say that m is on a shortest path connecting k and l . In this case the triple $u = (k, m, l)$ is called a *shortest path triple*. A shortest path triple $v = (k, m, l)$ for which $d_{km} = d_{ml} = 1$ is called a *shortest triangle*.

We associate a matrix $R_u = (r_{ij}^{(u)})$ to each shortest path triple $u = (k, m, l)$ and a matrix $T_v = (t_{ij}^{(v)})$ to each shortest triangle $v = (k', m', l')$, where R_u and T_v are defined by

$$r_{kl}^{(u)} = r_{lk}^{(u)} = r_{ml}^{(u)} = r_{bm}^{(u)} = 1, r_{km}^{(u)} = r_{mk}^{(u)} = -1,$$

$$t_{k'm'}^{(v)} = t_{l'm'}^{(v)} = t_{m'l'}^{(v)} = t_{l'k'}^{(v)} = t_{k'm'}^{(v)} = t_{m'k'}^{(v)} = 1,$$

$$r_{ij}^{(u)} = 0, \text{ and } t_{ij}^{(v)} = 0 \text{ if } \{i, j\} \not\subseteq \{k, l, m\}.$$

The set of all shortest path triples is denoted by \mathcal{R} and the set of all shortest triangles is denoted by \mathcal{T} .

The key observation is that, for each $R_u \in \mathcal{R}$ and for each $T_v \in \mathcal{T}$, the identity permutation is an optimal solution of $\text{QAP}(R_u, D)$ and $\text{QAP}(T_v, D)$. The optimal values for these QAPs are 0 and 8, respectively, and these simple QAPs can be used to improve the quality of lower bounds for an arbitrary grid QAP. Let us decompose the flow matrix F as

$$F = \sum_{u \in \mathcal{R}} \alpha_u R_u + \sum_{v \in \mathcal{T}} \beta_v T_v + F_r, \quad (64)$$

where F_r is the *residual* matrix given as

$$F_r := F - \sum_{u \in \mathcal{R}} \alpha_u R_u - \sum_{v \in \mathcal{T}} \beta_v T_v.$$

For every choice of the parameters $\alpha_u \geq 0$, $u \in \mathcal{R}$, and $\beta_v \geq 0$, $v \in \mathcal{T}$, and for any permutation φ , we have

$$Z(F, D, \varphi) = \sum_{u \in \mathcal{R}} \alpha_u Z(R_u, D, \varphi) + \sum_{v \in \mathcal{T}} \beta_v Z(T_v, D, \varphi) + Z(F_r, D, \varphi). \quad (65)$$

This implies

$$\begin{aligned} \min_{\varphi} Z(F, D, \varphi) &\geq 8 \sum_{v \in \mathcal{T}} \beta_v + \min_{\varphi} Z(F_r, D, \varphi) \\ &\geq 8 \sum_{v \in \mathcal{T}} \beta_v + \text{LB}(F_r, D), \end{aligned}$$

where $\text{LB}(F_r, D)$ is any lower bound for the QAP with flow matrix F_r and distance matrix D . Clearly, the expression on the right-hand side of (65) is a lower bound for the original QAP. This lower bound, which depends on the vectors $\alpha = (\alpha_u)$, $\beta = (\beta_v)$, is denoted by $h(\alpha, \beta)$. Hence, $h(0, 0)$ equals $\text{LB}(F, D)$, and therefore,

$$\max_{\alpha \geq 0, \beta \geq 0} h(\alpha, \beta) \geq \text{LB}(F, D).$$

Thus $\max_{\alpha \geq 0, \beta \geq 0} h(\alpha, \beta)$ improves the bound $\text{LB}(\text{QAP}(F, D))$.

Chakrapani et al. [64] improve the Gilmore–Lawler bound (GLB), and the elimination bound (ELI), by using only the matrices R_u , $u \in \mathcal{R}$, for the decomposition. Karisch et al. [141] use the decomposition scheme (64) to improve the elimination bound (ELI) (as introduced by Hadley et al. [122]).

Palubeckis [181] used a decomposition into triangles to generate QAPs with known objective function values. Such QAPs are important for testing heuristics. Further improved test generators are suggested in Palubeckis [182–184], where simple graphs other than triangles are used in the decomposition. Cyganski et al. [74]

observed that QAP instances generated by Palubeckis' test example generator are “easy” in the sense that their optimal value can be computed in polynomial time by solving a linear program (see also Cela [60]). Notice, however, that nothing is known about the computational complexity of QAP instances generated by Palubeckis' generator. We believe that *finding an optimal solution* for these QAPs is NP-hard, although the corresponding decision problem is polynomially solvable.

6.7 Bounds Based on Semidefinite Relaxations

Semidefinite programming (SDP) is a generalization of linear programming where the variables are taken from the Euclidean space of matrices with the trace operator acting as an inner product. The nonnegativity constraints are replaced by semidefiniteness constraints and the linear constraints are formulated in terms of linear operators on the space of matrices. Semidefinite programming has been proven to be a useful tool in discrete optimization; see, for example, Goemans and Williamson [116] and Lovász and Schrijver [161].

Semidefinite programming relaxations for the QAP were considered by Karisch [139], Zhao [226], and Zhao et al. [229]; Rendl and Sotirov [199]; Roupin [207], Peng et al. [191]; and others. The SDP relaxations considered in these papers are solved by interior-point methods or cutting-plane methods. The obtained solutions provide lower bounds for the QAP. Anstreicher and Brixius [13] developed a powerful bounding technique which is based on convexity arguments for quadratic programs. In terms of quality, the bounds obtained by semidefinite programming and convex programming are competitive with the best existing lower bounds for the QAP. We refer to [139, 229] for a detailed description of SDP approaches to the QAP and illustrate the idea by describing just two semidefinite programming relaxations for the QAP.

According to (13), a Koopmans–Beckmann problem can be formulated as

$$\begin{aligned} \min \quad & x^T(D \otimes F)x \\ \text{s.t.} \quad & X \in \mathbf{X}_n, \end{aligned} \tag{66}$$

where $x = \text{vec}(X)$. Since the objective function is equivalent to

$$\text{tr}((D \otimes F)xx^T),$$

we get the equivalent formulation

$$\begin{aligned} \min \quad & \text{tr}((D \otimes F)Y) \\ \text{s.t.} \quad & Y = xx^T \\ & X \in \mathbf{X}_n. \end{aligned} \tag{67}$$

When we want to linearize this problem, we have to choose Y in the convex hull P of the $(n^2 \times n^2)$ matrices xx^T where $x = \text{vec}(X)$, X being a permutation matrix:

$$P = \text{conv}\{xx^T : x = \text{vec}(X), X \in \mathbf{X}_n\}.$$

It can be shown that the matrix $Y - yy^T$ is positive semidefinite for $Y \in P$ and $y = \text{diag}(Y)$. This leads immediately to a semidefinite relaxation of QAP(A, B). Zhao et al. [229] showed that the semidefiniteness constraint

$$Y - yy^T \succeq 0$$

can be strengthened by imposing the orthogonality constraints

$$XX^T = X^TX = I,$$

on X , where I is the $n \times n$ identity matrix. These constraints are quadratic in X but linear in Y and use $O(n^4)$ variables and constraints. One can exploit that all row and column sums of a permutation matrix X are equal to 1. This leads to a bound similar to the projection bound shown in Lemma 1. Further improvements are possible by adding the symmetry relations

$$x_{ik}x_{jl} = x_{jl}x_{ik} \text{ for } i, j, k, l = 1, \dots, n$$

and the pattern constraints

$$\begin{aligned} x_{ik}x_{il} &= 0 \text{ for } i, k, l = 1, \dots, n, k \neq l, \\ x_{ik}x_{jk} &= 0 \text{ for } i, j, k = 1, \dots, n, i \neq j. \end{aligned}$$

Interior-point methods are not well suited for solving the above semidefinite program with nonnegativity constraints $y_{ijkl} \geq 0$ and pattern constraints. Therefore, Rendl and Sotirov [199] developed a *bundle method* based on subgradient optimization for handling these additional constraints and obtained good results. Other approaches for solving the semidefinite relaxation of the QAP are a lift-and-project method, suggested by Burer and Vandenbussche [35], as well as a cutting-plane algorithm of Faye and Roupin [96]. Recently, de Klerk and Sotirov [78] describe how symmetries in the problem data of QAPs can be exploited within semidefinite programming relaxations.

In order to get a low-dimensional semidefinite relaxation, Ding and Wolkowicz [84] replace the constraint $Y = xx^T$ by $Y \succeq XX^T$ which is equivalent to

$$\begin{pmatrix} I & X^T \\ X & Y \end{pmatrix} \succeq 0.$$

Moreover, they remove D from the objective function by using the constraint $R = XD$. This results in the following significantly smaller semidefinite programming relaxation for QAP(F, D, B) which has only $O(n^2)$ variables and constraints

$$\begin{aligned} \min \quad & \text{tr}FY + \text{tr}BX^T \\ \text{s.t.} \quad & R = XD \\ & \begin{pmatrix} I & X^T & R^T \\ X & I & Y \\ R & Y & Z \end{pmatrix} \succeq 0 \\ & X \in \mathbf{X}_n \\ & Y, Z \text{ symmetric } (n \times n) \text{ matrices} \\ & R \text{ } (n \times n) \text{ matrix.} \end{aligned} \tag{68}$$

Since X is a permutation matrix, we get the additional constraints

$$\begin{aligned} \text{diag}(Y) &= X\text{diag}(D) \\ \text{diag}(Z) &= X\text{diag}(D^2) \\ Ye &= XDe \\ Ze &= XD^2e \end{aligned} \tag{69}$$

where $e = (1, 1, \dots, 1)^T$. The bound based on relaxation (68) and (69) is provably better than the projected eigenvalue bound of Hadley et al. [122] (based on Lemma 1) and competitive with the quadratic programming bound by Anstreicher and Brixius [13] (see below).

By taking advantage of the special structure of distance matrices stemming from Hamming distances or from the l_1 -norm, Mittelmann and Peng [174] arrive at semidefinite programming relaxations which have a smaller size compared to standard SDP relaxations. QAPs with such distance matrices occur in location theory and in communication systems.

In a later paper, Peng et al. [191] generalize the approach of [174]. A matrix pair (D^+, D^-) is called a *positive semidefinite splitting* (PSD splitting) of matrix D , if

$$D = D^+ - D^-, \quad D^+, D^- \succeq 0.$$

If a PSD splitting of matrix D is available, then the QAP can be relaxed to

$$\min \quad \text{tr}F(Y^+ - Y^-) + \text{tr}BX^T \tag{70}$$

$$\text{s.t.} \quad \text{constraints on } Y^+, Y^-, \text{ and } X. \tag{71}$$

Here, $Y^+ = XD^+X^\top$ and $Y^- = XD^-X^\top$ is a PSD splitting of XDX^\top . Peng et al. introduce two PSD splitting schemes, one based on a singular value decomposition of matrix D and the other based on the Laplace operator of a graph. Suppose D is the adjacency matrix of a complete, connected graph G . Let $\delta_i = \sum_{j=1}^n d_{ij}$ and $\Delta = \text{diag}(\delta_1, \dots, \delta_n)$. The *Laplace matrix* $L(G)$ of graph G is defined by $L(G) = \Delta - D$. This leads to the decomposition $D^+ = \Delta$ and $D^- = L(G)$. Numerical experiments on a large number of QAP show that these bounds are comparable to the strongest bounds known for the QAP. In particular, Wu et al. [225] use the decomposition approach based on the singular value decomposition for computing strong lower bounds for the index assignment problem (cf. [227]) in coding theory.

6.8 Bounds Based on Quadratic Programming and Conic Representations

Anstreicher and Brixius [13] developed another powerful approach which leads to a convex quadratic program. It is based on the identity

$$0 = \text{tr}(S(I - XX^\top)) = \text{tr}(S) - \text{tr}((I \otimes S)xx^\top)$$

which holds for any orthogonal matrix X and any symmetric matrix S . This identity yields, for any orthogonal matrix X and any symmetric matrices S and T ,

$$\begin{aligned} \text{tr}(FXD^\top X^\top) &= \text{tr}(S) + \text{tr}(T) + \text{tr}((D \otimes F - I \otimes S - T \otimes I)xx^\top) \\ &= \text{tr}(FXD^\top X^\top) = \text{tr}(S) + \text{tr}(T) + x^\top Qx \end{aligned} \quad (72)$$

with $Q = (D \otimes F - I \otimes S - T \otimes I)$. If S and T are fixed, the right-hand side of (72) becomes a convex, quadratic program in x .

Using diagonalizations of the symmetric flow matrix F and distance matrix D , Anstreicher and Brixius [13] showed the following result:

Proposition 5 *Let F and D be symmetric $(n \times n)$ matrices and let X be an orthogonal matrix. Then*

$$\begin{aligned} \min_X \text{tr}(FXD^\top X^\top) &= \max \{ \text{tr}(S) + \text{tr}(T) : D \otimes F - I \otimes S - T \otimes I \succeq 0; \\ &\quad S, T \text{ symmetric} \}. \end{aligned} \quad (73)$$

Anstreicher and Brixius used the optimal dual solutions $s = (s_1, s_2, \dots, s_n)^\top$ and $t = (t_1, t_2, \dots, t_n)^\top$ of (73) which correspond to the diagonal entries of the optimal symmetric matrices S and T in the program on the right-hand side of (73) and obtained

$$\sum_{i=1}^n s_i + \sum_{i=1}^n t_i + \min \{ x^\top Q : X \text{ doubly stochastic} \} \quad (74)$$

as new bound for the optimal objective function value of $\text{QAP}(F, D)$. Anstreicher et al. [14] applied this bound in a parallel branch-and-bound algorithm for the QAP which showed an excellent performance: several up to the time unsolved QAP instances were solved to optimality.

Povh and Rendl [193] investigate various conic representations of the QAP. They show that the QAP can be formulated as a linear program over the cone of completely positive matrices of order $O(n^2)$. A copositive program itself is currently computationally intractable, but the paper opens new possibilities for solving QAPs approximately.

7 Exact Solution Methods

An exact algorithm for a combinatorial optimization problem provides the global optimal solution to the problem. In this section we briefly discuss several exact algorithms that have been used for solving the QAP, like branch-and-bound, Benders' decomposition, and branch-and-cut algorithms. But also methods from global optimization have successfully been applied to the QAP; see Enkhbat and Javzandulam [93].

7.1 Branch and Bound

Branch-and-bound algorithms have been applied successfully to many hard combinatorial optimization problems, and they appear to be the most efficient exact algorithms for solving the QAP.

The basic ingredients of branch-and-bound algorithms are the *bounds*, the *branching rule*, and the *selection rule*. For a long time, all branch-and-bound algorithms used primarily variations of the Gilmore–Lawler bound, as it is simple to employ and other bounds are just too expensive in terms of computation time to be used in branch-and-bound algorithms. But meanwhile also other bounding strategies showed their strength: Pardalos et al. [189] employed the variance reduction bound with success within a branch-and-bound algorithm. Anstreicher et al. [14] used successfully the convex quadratic programming bound (74) in a parallel branch-and-bound algorithm. Moreover, Adams et al. [3] obtained very good results with lower bounds based on the level-2 reformulation–linearization technique (see Sect. 4.5).

Among branching strategies, the *single assignment branching* introduced by Gilmore [110] and Lawler [152] is widely used for the QAP. It assigns a facility to a location in each branching step, that is, each problem is divided into subproblems by fixing the location of one of the facilities which are not assigned yet. Several rules have been proposed for choosing the facility-location pair in the next level of the search tree. The appropriate rule usually depends on the bounding technique. If the Gilmore–Lawler bound is employed, the new facility-location pair is frequently determined by the reduced costs of the last linear assignment problem solved [23, 38].

The pair assignment algorithms, suggested by Gavett and Plyter [107], Land [150], and Nugent et al. [179], assign a pair of facilities to a pair of locations at a branching step. In relative positioning algorithms (see Mirchandani and Obata [171]), the fixed assignments within each subproblem are determined in terms of distances between facilities, that is, their relative positions. Numerical results show that pair assignment and relative positioning algorithms are outperformed by single-assignment algorithms.

Roucairol [206] developed the so-called polytomic or k -partite branching rule. The search tree produced by this algorithm is not binary as in most of the other approaches. The branching rule is based on the solution φ of the last linear assignment problem solved to compute the lower bound at the current node of the search tree. Let $\mathbf{X}_n^{(i)}$ be the set of permutation matrices with $x_{i\varphi(i)} = 1$. Further, $\bar{\mathbf{X}}_n^{(i)}$ is the set of permutation matrices with $x_{i\varphi(i)} = 0$. The current node is branched into $n + 1$ new nodes which correspond to the feasible solutions of $\mathbf{X}_n^{(1)}, \mathbf{X}_n^{(1)} \cap \bar{\mathbf{X}}_n^{(2)}, \dots, \mathbf{X}_n^{(1)} \cap \mathbf{X}_n^{(2)} \cap \dots \cap \mathbf{X}_n^{(n-1)} \cap \bar{\mathbf{X}}_n^{(n)}$ and $\mathbf{X}_n^{(1)} \cap \mathbf{X}_n^{(2)} \cap \dots \cap \mathbf{X}_n^{(n)}$.

Another polytomic branching strategy used in successful recent algorithms is due to Mautor and Roucairol [166]. In this strategy either one facility is assigned to all the available locations (*row branching*) or all available facilities are assigned to one location (*column branching*).

Another issue in the implementation of branch-and-bound algorithms concerns the so-called selection rule which determines the choice of the subproblem to be branched next. Several strategies, ranging from problem-independent depth or breadth-first search to instance-dependent criteria related to the maximization of lower bounds or reduced costs, have been tested by different authors. There seems to be no clear winner among the tested strategies.

The best results on solving large-size problems have been achieved with parallel and massively parallel implementations; see Pardalos and Crouse [186]; Bruengger et al. [33]; and Clausen and Perregaard [69]. In 2002, Anstreicher et al. [14] built up a network of over 2500 CPUs around the globe. They solved the test example nug30 in QAPLIB [52], a QAP with $n = 30$, in 7 CPU years. In 2007, Adams et al. [3] solved this problem with the level-2 reformulation–linearization technique in 2.5 CPU years. (The total CPU times were normalized to times on a single HP9000 C3000 workstation).

7.2 Benders' Decomposition Methods

Several authors, like Bazaraa and Sherali [24, 25], Balas and Mazzola [18, 19], as well as Kaufman and Broeckx [143], used Benders' decomposition for solving the mixed integer linear programs arising from a linearization of the QAP. The MILP formulation is decomposed into a master problem and a subproblem, called *slave problem*. The master problem contains the original assignment variables and constraints. For a fixed assignment, the slave problem is usually a linear program and hence, solvable in polynomial time. The master problem is a linear program

formulated in terms of the original assignment variables and of the dual variables of the slave problem. It is solvable in polynomial time for fixed values of those dual variables. The algorithms work typically as follows. First, a heuristic is applied to generate a starting assignment. Then the slave problem is solved for fixed values of the assignment variables implied by that assignment, and optimal values of the primal and dual variables of the slave problem are computed. If the dual solution of the slave problem satisfies all constraints of the master problem, we have an optimal solution for the original MILP formulation of the QAP. Otherwise, at least one of the constraints of the master problem is violated. In this case, the master problem is solved with fixed values for the dual variables of the slave problem and the obtained solution is given as input to the slave problem. This procedure is repeated until the solution of the slave problem fulfills all constraints of the master problem.

Clearly, any solution of the master problem obtained by fixing the dual variables of the slave problem to feasible values provides a lower bound for the considered QAP. On the other side, the objective function value of the QAP corresponding to any feasible setting of the assignment variables is an upper bound. The algorithm terminates when the lower and the upper bounds coincide.

Generally, the time needed for the convergence of the upper and the lower bounds to a common value is rather large. Hence these methods can only be applied to QAPs with small n . Heuristics derived from cutting plane approaches, however, produce good suboptimal solutions in early stages of the search; see, for example, Burkard and Bönniger [40] and Bazaraa and Sherali [25]. Miranda et al. [170] used Benders' decomposition for QAP instances arising from electronic component placement problems.

7.3 Branch-and-Cut Methods

Branch-and-cut methods are based on a polyhedral description of the underlying problem, in our case, on the QAP polytope (see Sect. 5). First, a linear relaxation of the QAP is solved by linear programming. If the optimal solution of this problem is feasible for the QAP, this solution is also optimal for the QAP. Otherwise, one tries to deduce from the polyhedral structure of the problem a valid inequality, that is, an inequality that is fulfilled by all feasible solutions of the QAP but violated by the current solution. Often, such a valid inequality can be derived from facet-defining inequalities of the QAP polytope. Valid inequalities which are violated by the current solution are added to the linear program. They cut off the current solution from the feasible region. Now the linear program is solved again. As the complete linear description of the QAP polytope is not known, it might happen that no violated valid inequality can be found. In this case the algorithm performs a branching step. The branching steps produce a *search tree* like in branch-and-bound algorithms. Each node of this tree is processed by performing cuts and finally it is branched, if necessary. Upper bounds, selection and branching rules in branch-and-cut algorithms play a similar role as in branch-and-bound algorithms.

Efforts to design branch-and-cut algorithms for the QAP have been made by Padberg and Rijal [180] who tested their algorithm on sparse problems and by Erdoğan and Tansel [95] who designed a branch-and-cut algorithm by means of a flow-based linearization technique. Kaibel [138] computed lower bounds for QAP instances from QAPLIB by a branch-and-cut approach using box inequalities (see Sect. 5.1). A large family of valid inequalities for the QAP was proposed by Blanchard et al. [28].

Fischetti et al. [99] report very favorable results of a branch-and-cut method applied to QAPs with Hamming distances. They use shifted variables as introduced by Zhang et al. [228] and improve the cuts by lifting procedures.

8 Heuristics

Although substantial improvements have been done in the development of exact algorithms for the QAP, problems of dimension $n > 20$ are still not practical to solve by exact methods because of very high computer time requirements. This makes the development of heuristics indispensable. So far there exists no performance guarantee for any of the algorithms developed for the QAP. Many heuristics, however, provide good-quality solutions in a reasonable time. This is a feature of QAPs which can be explained by the behavior of random QAPs; see Sect. 11. Much research has been devoted to the development of powerful heuristics. In the sequel we discuss shortly the following different types of heuristic algorithms:

- Construction methods
- Limited enumeration methods
- Local search methods
- Greedy randomized adaptive search procedures (GRASP)
- Tabu search (TS)
- Simulated annealing (SA)
- Genetic algorithms (GA)
- Ant colony optimization (ACO)

One possibility to evaluate the performance of heuristics and to compare different heuristics is given by QAP instances with known optimal solution. QAP instances with known optimal solution should resemble general QAPs, so they should be hard for heuristics. Two classes of QAPs with known optimal solution have been proposed so far: the generators of Palubeckis [181–184] see (Sect. 6.6) and the generators proposed by Li and Pardalos [156].

Li and Pardalos start with an instance $\text{QAP}(F, D)$ where D is a constant matrix. This is a trivial QAP, as any permutation is optimal. Now the matrices F and D are iteratively transformed such that the identical permutation id remains an optimal solution. This can be achieved by transformations which keep the property $f_{ij} \geq f_{i'j'}$ if and only if $d_{ij} \leq d'_{i'j'}$, for all i, j, i', j' , at the end of each iteration.

8.1 Construction Methods

Construction methods for the QAP are greedy-type approaches which iteratively assign some facility which has not yet been assigned to some free location. A *partial permutation* contains those facilities which are already assigned and their corresponding locations. Mathematically, a partial permutation can be described as a set of pairs $(i, \varphi(i)) | i \in M \subseteq N$ where all indices $\varphi(i)$ are different. The partial permutation which does not contain any pair is called *empty*. Starting with the empty permutation, a heuristic `heur` chooses iteratively an unassigned facility i and a free location k and adds the pair (i, k) to the current partial permutation until all facilities are assigned.

Gilmore [110] proposed to fix index k in the heuristic `heur` by using the Gilmore–Lawler bound for a QAP on currently unassigned facilities and locations. For a refinement of this argument, see Burkard [38]. In both cases, the time complexity of this heuristic is $O(n^4)$.

Another good construction method which starts with an arbitrary prefixed ordering of the facilities has been proposed by Müller-Merbach [178].

8.2 Limited Enumeration Methods

Limited enumeration methods rely on the observation that enumeration methods (e.g., branch-and-bound algorithms) find often good solutions in early stages of the search and employ then a lot of time to marginally improve that solution or prove its optimality. This behavior of enumeration methods suggests a way to save time in the case that we are interested in a good but not necessarily optimal solution: impose some limit to the enumeration process. This limit could be a time limit or a limit on the number of iterations the algorithm may perform.

Another strategy which serves the same goal is to manipulate the lower bound. This can be done by increasing the lower bound if no improvement in the solution is achieved during a large number of iterations and would yield deeper cuts in the search tree to speed up the process. Clearly, such an approach may cut off the optimal solution. Graves and Whinston [118] use probabilistic bounds (see also Burkard et al. [46]) in the branch-and-bound tree. These are stronger but may also cut off an optimal solution.

When using Benders' decomposition (cf. Sect. 7.2), there is the possibility to consider only a subset of the constraints in the master problem. A heuristic based on this idea was designed by Burkard and Bönniger [40]; see also the monograph [46].

8.3 Local Search Methods

Given a permutation φ_0 of the set $N = \{1, 2, \dots, n\}$, a neighborhood $N(\varphi_0)$ of φ_0 consists of all permutations which are in some sense *close* to φ_0 . A *locally optimal*

solution of the QAP is a permutation $\bar{\varphi}$ such that

$$Z(C, \bar{\varphi}) := \sum_{i=1}^n \sum_{j=1}^n c_{ij\bar{\varphi}(i)\bar{\varphi}(j)} = \min_{\varphi \in N(\varphi_0)} \sum_{i=1}^n \sum_{j=1}^n c_{ij\varphi(i)\varphi(j)}.$$

An algorithm which produces a locally optimal solution is called a *local search* algorithm. Basic ingredients of local search methods are the definition of *neighborhoods* and the *update strategy* for the solutions. Frequently, a local search procedure starts with an initial feasible solution and iteratively tries to improve the current solution by moving to a neighbored solution. This iterative step is repeated until no further improvement can be found. The CRAFT method introduced by Buffa et al. [34] is one of the first examples of an iterative improvement algorithm for the QAP. A comprehensive discussion of theoretical and practical aspects of local search in combinatorial optimization can be found in Aarts and Lenstra [2].

Frequently used neighborhoods for QAPs are the *pair-exchange* (or *2-opt*) neighborhood \mathcal{N}_2 and the *cyclic triple-exchange* neighborhood. Given a permutation φ_0 , the permutations $\varphi \in \mathcal{N}_2$ have the form

$$\varphi(j) = \begin{cases} \varphi_0(k), & \text{for } j = i, i \neq k, \\ \varphi_0(i), & \text{for } j = k, \\ \varphi_0(j), & \text{for } j \neq i, k. \end{cases}$$

They are obtained by swapping the locations of just two facilities. Thus the pair-exchange neighborhood of a permutation $\varphi_0 \in \mathcal{S}_n$ consists of all permutations $\varphi \in \mathcal{S}_n$ obtained from φ_0 by applying some transposition (i, j) to it, that is, $\mathcal{N}_2(\varphi_0) = \{\varphi \circ (i, j) : 1 \leq i, j \leq n, i \neq j\}$. Similarly, triple-exchange neighborhoods are obtained by a cyclic exchange of three locations for some triple of facilities.

A pair-exchange neighborhood has the size $\binom{n}{2}$. Computing the objective function values for all neighbors of a given permutation φ_0 takes $O(n^3)$ time as it takes $O(n)$ time to compute the difference of the objective function values of φ_0 and a permutation φ in the neighborhood of φ_0 . If the neighborhood of φ_0 is already scanned, then its pair-exchange neighborhood can be searched in $O(n^2)$; see Frieze et al. [104].

A Kernighan and Lin-type neighborhood structure for the Koopmans–Beckmann QAP was introduced by Murthy et al. [177]. Consider a permutation $\varphi_0 \in \mathcal{S}_n$. A *swap* (or pair exchange) of φ_0 interchanges the facilities assigned to two locations i and j . A *greedy swap* in permutation φ_0 is a swap which minimizes the difference $Z(F, D, \varphi) - Z(F, D, \varphi_0)$ with respect to all swaps in φ_0 . Let $\varphi_0, \varphi_1, \dots, \varphi_l$ be a set of permutations in \mathcal{S}_n , each of them obtained by a greedy swap of the preceding one. Such a sequence is called *monotone* if for each pair of permutations φ_k, φ_l in the sequence, $\{i_k, j_k\} \cap \{i_l, j_l\} = \emptyset$, where $\varphi_k (\pi_l)$ is obtained by applying transposition $(i_k, j_k) ((i_l, j_l))$ to the preceding permutation in the sequence. The *neighborhood* of φ_0 consists of all permutations which occur in the (unique) maximal monotone sequence obtained by greedy swaps starting with

permutation φ_0 . This neighborhood structure for the QAP is denoted as \mathcal{N}_{KL} . It is not difficult to see that given a QAP(F, D) of size n and a permutation $\varphi \in S_n$, the cardinality of $\mathcal{N}_{KL}(\pi)$ does not exceed $[n/2] + 1$.

A similar but wider neighborhood was proposed by Li et al. [158]. For $k > 3$ the size of k -exchange neighborhoods becomes so large that it is practically impossible to determine explicitly a best solution of the QAP in such a neighborhood. Several implicit enumeration techniques have been developed to overcome this difficulty like the *improvement graph* by Ahuja et al. [7] and the variable neighborhood search by Mladenović and Hansen [175].

Another important ingredient of improvement methods is the *update rule*. In the case of the *first improvement rule* the current solution is updated as soon as the first improving neighbor solution is found. The *best improvement rule* scans first the whole neighborhood and chooses the *best* improving neighbor solution (if such a solution exists at all). *Heider's rule* starts by scanning the neighborhood of the initial solution in a prespecified *cyclic* order. The current solution is updated as soon as an improving neighbor solution is found. The scanning of the neighborhood of the new solution starts there where the scanning of the previous one was interrupted (in the prespecified cyclic order).

In order to get better results, local search algorithms are performed several times starting with different initial solutions.

8.4 Complexity Results on Local Search

A pair (P, \mathcal{N}) , where P is a (combinatorial) optimization problem P and \mathcal{N} is an associated neighborhood structure, defines a *local search problem* which consists in finding a locally optimal solution of P with respect to the neighborhood structure \mathcal{N} . A *polynomial-time local search problem*, shortly *PLS problem*, (cf. Johnson et al. [133]), is a local search problem for which local optimality can be checked in polynomial time. In analogy to decision problems, there exist complete problems in the class of PLS problems. The *PLS-complete* problems are—in the usual sense of complexity—the most difficult among the PLS problems.

In connection to QAPs, the complexity with respect to two neighborhood structures has been investigated, namely, the pair-exchange neighborhood and the Kernighan–Lin-type neighborhood. In both cases the QAP turns out to be PLS-complete.

Schäffer and Yannakakis [209] have proven that the graph partitioning problem (GPP) with a 2-opt neighborhood structure is PLS-complete. A similar PLS-reduction as in Pardalos et al. [187] implies that the local search problem (QAP, \mathcal{N}_2), where \mathcal{N}_2 is the pair-exchange neighborhood, is PLS-complete. This implies that the time complexity of a general local search algorithm for the QAP involving the pair-exchange neighborhood is also exponential in the worst case.

Pardalos et al. [187] have shown that the PLS-complete *GPP* with the neighborhood structure defined by Kernighan and Lin [144] is PLS-reducible to (QAP, \mathcal{N}_{KL}). This implies the following result:

Theorem 6 ([187]) *The local search problem (QAP, \mathcal{N}_{KL}) , where \mathcal{N}_{KL} is the Kernighan–Lin-type neighborhood structure for the QAP, is PLS-complete.*

The PLS-completeness of (QAP, \mathcal{N}_{KL}) implies that, in the worst case, a general local search algorithm involving the Kernighan–Lin-type neighborhood finds a local minimum only after a time which is exponential on the problem size. Numerical results, however, show that such local search algorithms perform quite well when applied to QAP test instances, as reported in [177].

A neighborhood $N(\varphi)$ of a permutation φ of the set $N = \{1, 2, \dots, n\}$ is called *exponential*, if the size $|N(\varphi)|$ is exponential in n . For the traveling salesman problem, several neighborhoods of exponential size are known which can be searched in polynomial time. In the case of QAPs, this is not possible. Deineko and Woeginger [82] showed for several exponential neighborhoods that it is NP-hard to minimize the objective function of a Koopmans–Beckmann QAP over the permutations in such neighborhoods. They conjecture the following:

Conjecture 1 ([82]) *Under the assumption $P \neq NP$, every neighborhood of the QAP which can be searched in polynomial time has a polynomial size.*

8.5 Greedy Randomized Adaptive Search Procedure

The greedy randomized adaptive search procedure (GRASP) was introduced by Feo and Resende [97] and has been applied successfully to different hard combinatorial optimization problems, among them to the QAP [158, 188]. The reader is referred to [97] for a survey and tutorial on GRASP. GRASP is a combination of greedy elements with random search in a two-phase heuristic. It consists of a construction phase and a local improvement phase. In the construction phase good feasible solutions are constructed, whereas in the local improvement phase the neighborhood of these solution is searched for possible improvements.

For the QAP the construction of a first good solution is based on the so-called restricted candidate list (RCL). At the beginning arbitrary, two facilities i and j are assigned to all possible locations. The corresponding cost values

$$C_{ij}^\varphi = f_{ii}d_{\varphi(i)\varphi(i)} + f_{jj}d_{\varphi(j)\varphi(j)} + f_{ij}d_{\varphi(i)\varphi(j)} + f_{ji}d_{\varphi(j)\varphi(i)}$$

are sorted and the k smallest values are included in the initial RCL. In the second step of the construction method, an element of RCL and an index $p \neq i, j$ are randomly chosen. From now on, the indices i and j are fixed. Now the cost increment is evaluated, when facility p is assigned to any location different from $\varphi(i)$ and $\varphi(j)$. The corresponding costs are again sorted and RCL is replaced to contain now the k partial permutations for the facilities i, j , and p with smallest cost. This procedure is continued, until a location for all facilities has been fixed.

Finally, the second phase of the algorithm completes a GRASP iteration by applying an improvement method starting from the solution constructed in the first phase and employing the 2-exchange neighborhood (see also [Sect. 8.3](#)).

8.6 Tabu Search

Tabu search is a local search method introduced by Glover [[112](#), [113](#)] which uses a technique to leave neighborhoods of local optima. The basic idea of tabu search is to “remember” which solutions have already been visited in the course of the algorithm and which might be promising for a further search in their neighborhoods. Thus, the search is driven by the memory and the neighborhood investigation of the current solution. For a comprehensive introduction to tabu search algorithms, the reader is referred to the book by Glover and Laguna [[115](#)].

The main ingredients of tabu search are the *neighborhood structure*, the *moves*, the *tabu list*, and the *aspiration criterion*. A *move* applied to a feasible solution φ generates a neighbor φ' of it. In the case of QAPs, the pair-exchange neighborhood is used and the moves are usually swaps. A *tabu list* is a list of forbidden or *tabu* moves, that is, moves which are not allowed to be applied to the current solution. The tabu status of the moves changes along with the search and the tabu list is updated during the search. When a tabu move fulfills an *aspiration criterion*, its tabu status is cancelled.

A generic tabu search procedure starts with an initial feasible solution φ_0 and selects a *best-quality* solution among (a part of) the neighbors of φ_0 obtained by non-tabu moves. Note that this neighboring solution does not necessarily improve the value of the objective function. Then the current solution is updated, that is, it is substituted by the selected solution. Obviously, this procedure can *cycle*, that is, visit some solution more than once. To avoid this phenomenon, a tabu criterion is introduced in order to identify moves which are expected to lead to cycles. Such moves are declared to be tabu and are added to the tabu list. As forbidding certain moves, however, could prohibit visiting “interesting” solutions, an aspiration criterion distinguishes the potentially interesting moves among the forbidden ones. The search stops when a stop criterion (running time limit, limited number of iterations) is fulfilled.

There is a lot of freedom in the implementation of tabu search algorithms. The performance of tabu search algorithms depends very much on the implementation chosen for its basic ingredients, for example, the tabu list (length and maintenance), the aspiration criterion, and the tabu criteria. There is no general agreement about the best implementation of any of those.

Different tabu search implementations for the QAP have been proposed by Skorin-Kapov [[210](#), [211](#)] who uses a tabu search with a fixed size for the tabu list, by Taillard [[216](#)] where the size of the tabu list is randomly chosen between a maximum and a minimum value (the so-called robust tabu search), and by Battiti and Tecchiolli [[21](#)]. Their *reactive tabu search* involves a mechanism for properly adopting the size of the tabu list: the algorithm notices when a cycle occurs, that is, when a certain solution is revisited, and increases the tabu list size according to the

length of the detected cycle. The numerical results show that generally the reactive tabu search outperforms other tabu search algorithms for the QAP (see [21]).

Tabu search algorithms allow a natural parallel implementation by dividing the burden of the search in the neighborhood among several processors. The first parallel tabu search implementation for the QAP was proposed by Taillard [216]. This approach was later improved by Chakrapani and Skorin-Kapov [63]. In a recent paper, James et al. [132] implement several multi-start strategies and possibilities to diversify the search. They report on a large number of computational experiments and comparisons with other heuristics.

8.7 Simulated Annealing

Simulated annealing is a local search approach which exploits the analogy between combinatorial optimization problems and problems from statistical mechanics. Kirkpatrick et al. [145] and, independently, Černý [62] were the first authors who recognized this analogy and showed how to apply the Metropolis algorithm [168] which simulates the behavior of a physical many-particle system as a heuristic to the TSP.

The analogy between a combinatorial optimization problem and a many-particle physical system basically relies on two facts:

- Feasible solutions of the combinatorial optimization problem correspond to states of the physical system.
- The objective function values corresponds to the energy of the states of the physical system.

In *condensed matter physics*, *annealing* is known as a cooling process which produces low-energy *thermal equilibrium* states of a solid in a heat bath. The aim is to reach the so-called ground state which is characterized by a minimum of energy.

In 1984, Burkard and Rendl [55] showed that a simulated cooling process yields a general heuristic for any combinatorial optimization problem, as soon as a neighborhood structure has been introduced in the set of its feasible solutions. In particular, these authors applied simulated annealing to the QAP. Other simulated annealing (SA) algorithms for the QAP have been proposed by Wilhelm and Ward [223] and Connolly [72]. All these algorithms employ the pair-exchange neighborhood. They differ in the way the *cooling process* or the *thermal equilibrium* is implemented. The numerical experiments show that the performance of SA algorithms strongly depends on the values of the control parameters and particularly on the choice of the cooling schedule.

Simulated annealing (SA) can be modeled mathematically by an inhomogeneous ergodic Markov chain. Under natural conditions on the involved neighborhood structure and on not very restrictive conditions on the slowness of the cooling process, it can be shown that SA asymptotically converges to an optimal solution of the considered problem. The investigation of the speed of this convergence remains an (apparently difficult) open problem. For a detailed discussion on the convergence and other theoretical aspects of simulated annealing, the reader is referred to the books by Aarts and Korst [1] and Laarhoven and Aarts [149].

8.8 Genetic Algorithms

The basic idea of *genetic algorithms* (GA) is to adapt the evolutionary mechanisms acting in the selection process in nature to combinatorial optimization problems. The first genetic algorithm for optimization problems was proposed by Holland [130] in 1975.

A genetic algorithm starts with an initial set of feasible solutions (generated randomly or by using some heuristic) called the *initial population*. The elements of a population are usually termed “individuals.” The algorithm *selects* several pairs of individuals or *parents* from the current population and uses so-called cross-over rules to produce a new feasible solution, called *child*, from each pair of parents. Afterwards, “bad” solutions, that is, solutions yielding too high objective function values, are thrown out of the current population. This process is repeated until a *stop criterion*, for example, a time limit, a limit on the number of iterations, or some measure of convergence, is fulfilled. In course of the algorithm, *mutations* or *immigrations* are periodically applied to the current population to improve the overall quality by *modifying* some of the individuals or *replacing* them by better ones, respectively. Often, local optimization tools are periodically used within GAs resulting in so-called hybrid algorithms. The search is diversified by means of so-called tournaments. A tournament consists of applying several runs of a GA starting from different initial populations and stopping them before they converge. A “better” population is derived as a union of the final populations of these different runs, and then a new run of the GA is started over this population. For a good coverage of theoretical and practical issues on genetic algorithms, the reader is referred to Davis [76] and Goldberg [117].

A number of authors have proposed genetic algorithms for the QAP. The quality of standard algorithms like that by Tate and Smith [217] is rather modest even for QAPs of small or moderate size. Hybrid approaches, however, like combinations of GA techniques with tabu search like the methods by Fleurent and Ferland [100], Misevicius [173], Drezner [87, 88], and Rodríguez et al. [204] yield much better results. Also another hybrid algorithm, the so-called greedy genetic algorithm proposed by Ahuja et al. [8], produces very good results on large-scale QAPs from QAPLIB. It generates the initial population by the GRASP heuristic (see Sect. 8.5). Three crossover strategies are suggested, among them a *path relinking strategy*; see Glover [114]. Finally, Lim et al. [159] suggested a hybrid genetic algorithm using the k -exchange neighborhood.

8.9 Ant Colony Optimization

Ant colony optimization (ACO) is a heuristic for combinatorial optimization which imitates the behavior of ants in search for food. This approach was introduced by Dorigo [86] and Colomi et al. [70] and has already produced good results for the TSP and the QAP [71, 105].

Initially, the ants search for food in the vicinity of their nest in a random way. As soon as an ant finds a source of food, it takes some food from the source and carries

it back to the nest. During this trip back, the ant leaves a trail of a substance called *pheromone* on the ground. The pheromone trail serves to guide the future search of ants towards the already found food source. The intensity of the pheromone on the trail is proportional to the richness of the food source.

To translate this search to a combinatorial optimization problem, we note the following analogies:

- The area searched by the ants resembles the set of feasible solutions of a combinatorial optimization problem.
- The amount of food at food sources resembles the value of the objective function.
- The pheromone trail resembles a component of adaptive memory.

In the case of the QAP, the pheromone trail which is the key element of ACO is implemented by a matrix $T = (\tau_{ij})$. τ_{ij} is a measure for the desirability of locating facility i at location j in the solutions generated by the ants (the algorithm). To illustrate the idea, we briefly describe the algorithm of Gambardella et al. [105].

The algorithm is iterative and constructs a fixed number, say m , of solutions in each iteration. (This number is a control parameter and is also thought of as number of ants.) In the first iteration, these solutions are generated randomly, whereas in the subsequent iteration they are updated by exploiting the information contained in the pheromone trail matrix T . Initially, the pheromone trail matrix is a constant matrix; the constant is inversely proportional to the best value of the objective function found so far. This is in compliance with the behavior of ants whose search directions are initially chosen at random. Let us denote the best solution found so far by φ^* and its corresponding objective function value by $Z(\varphi^*)$. In the further iterations, the entries $\tau_{i\varphi^*(i)}$ of T are increased by the same value which is proportional to $Z(\varphi^*)$. The update of the m solutions in each iteration is done first by means of the pheromone trail matrix and then by applying some improvement method. In both cases the update consists of swapping the locations for a sequence of facility pairs. First, the current solution is updated by swapping the locations of pairs of facilities chosen so as to maximize the (normalized) sum of the corresponding pheromone trail entries. Then, the solution obtained after this update is improved by applying some improvement methods; see Sect. 8.3. As soon as an improvement of the best-known solution is detected, an intensification component “forces the ants” to further explore the part of the solution space where the improvement was found. If after a large number of iterations there is no improvement of the best-known solution, a diversification – which is basically a new random start – is performed.

Tseng and Liang [218] combine ACO with a genetic algorithm. They propose to start the ACO with solutions found by a hybrid genetic algorithm. Another population-based ant algorithm has been described by Ramkumar et al. [195]. A parallel ant colony optimization procedure for the QAP has been proposed by Tsutsui [219].

Numerical results presented in [71, 105] show that ant systems are competitive heuristics especially for real-life instances of the QAP with a few very good clustered solutions. For randomly generated instances which have many good solutions distributed somehow uniformly in the search space, AS are outperformed by other heuristics, for example, genetic algorithms or tabu search approaches.

9 Available Computer Codes for the QAP

Burkard et al. [52] compiled a library of QAP instances (QAPLIB) which is widely used to test bounds, exact algorithms, and heuristics for the QAP. The instances collected in QAPLIB stem from different authors and range from instances arising in real-life applications to instances generated randomly only for test purposes. Among them are the often-tested test instances due to Nugent et al. [179]. QAPLIB is currently maintained by Peter Hahn at the University of Pennsylvania at <http://www.seas.upenn.edu/qplib/>. There is a mirror site at the University of Waterloo at <http://qplib.uwaterloo.ca/>. New benchmark instances for the QAP have been published by Stützle and Fernandes [214].

A number of codes can be downloaded from QAPLIB, namely:

- `qapbb.f` A FORTRAN code for the branch-and-bound algorithm described by Burkard and Derigs [47]. Currently the code is dimensioned to handle problems with $n \leq 30$.
- `qapglb.f` A FORTRAN code from [47] to compute the Gilmore–Lawler bound (see Sect. 6.2) for problems with $n \leq 256$.
- `qapeli.f` A FORTRAN code for the elimination bound developed by Karisch and Rendl [141] for symmetric QAPs with $n \leq 256$ which fulfill the triangle inequality.
- GRASP The user is redirected to the homepage of Mauricio Resende, where FORTRAN codes for the GRASP heuristic (see Sect. 8.5) for dense and sparse QAPs can be found.
- Ro-TS A PASCAL implementation of the robust tabu search (see Sect. 8.6) by Taillard [216]. Dimensioned for $n \leq 150$.
- `qapsim.f` A FORTRAN code for the simulated annealing algorithm (cf. Sect. 8.7) by Burkard and Rendl [55]. Dimensioned for $n \leq 256$.
- SA A C-implementation due to Taillard for the simulated annealing algorithm of Connally [72].
- FANT A C++ code by Taillard for the ACO approach (see Sect. 8.9). Applicable to QAPs with $n \leq 51$.

10 Polynomially Solvable Cases

Since the QAP is NP-hard, restricted versions which can be solved in polynomial time are an interesting aspect of the problem. A basic question arising with respect to polynomially solvable versions is the identification of those versions and the investigation of the border line between hard and easy versions of the problem. There are two ways to approach this topic: first, certain structural conditions imposed on the coefficient matrices of the QAP lead to polynomially solvable QAPs. Second, certain graph problems formulated as QAPs lead to polynomially solvable versions of QAPs. These two approaches yield two groups of restricted QAPs which

are briefly reviewed in this section. For a detailed information on this topic, the reader is referred to the monographs of Burkard et al. [46] and Çela [60].

If in a Koopmans–Beckmann problem QAP(F, D), matrix F is symmetric and matrix D is skew symmetric, then all solutions φ yield the same objective function value 0. A QAP with the property that all feasible solutions yield the same value is called *constant QAP*. Another example for a constant QAP is given by QAP(F, D) with a sum matrix F and a circulant matrix D . A *sum matrix* $A = (a_{ij})$ is generated by two vectors $u = (u_1, \dots, u_n)$ and $v = (v_1, \dots, v_n)$ such that $a_{ij} = u_i + v_j$. An $n \times n$ matrix $D = (d_{ij})$ is called a *circulant matrix* if there exist numbers $c_{-n+1}, \dots, c_{-1}, c_0, c_1, \dots, c_{n-1}$ with $c_i = c_{n-i}$, for $0 \leq i \leq n - 1$, such that $d_{ij} = c_{j-i}$, for all i, j .

A Koopmans–Beckmann problem QAP(F, D) where F is a sum matrix and either F or D is symmetric or skew symmetric can be reduced to a special linear assignment problem, whose optimal solution can be found in $O(n \log n)$ time by applying [Proposition 2](#). This time requirement, however, is majorized by the time $O(n^2)$ needed to compute the coefficients of the linear assignment problem.

A product matrix $A = (a_{ij})$ is generated by two vectors $u = (u_1, \dots, u_n)$ and $v = (v_1, \dots, v_n)$ such that $a_{ij} = u_i \cdot v_j$. A QAP(F, D) where F and D are symmetric product matrices generated by vectors u and v whose components have all the same sign can be solved in $O(n \log n)$ time. A matrix $A = (a_{ij})$ is a *chessboard matrix* if the entries are given by $a_{ij} = (-1)^{i+j}$. The Koopmans–Beckmann problem where F and D are chessboard matrices can be solved in polynomial time. The problem, however, where F is a symmetric product matrix and D is a chessboard matrix is NP-hard.

Product matrices play a role in the so-called Wiener QAP; see Çela et al. [61]. The *Wiener index* of a connected, undirected graph G is the sum of all shortest distances between all pairs of vertices of G . This index was introduced by the chemist Harold Wiener [222] as it characterizes structural properties of saturated hydrocarbons. For a survey on theoretical and practical aspects of the Wiener index, see Dobrynin et al. [85]. Çela et al. showed that finding a tree with prescribed degree sequence and maximum Wiener index can be accomplished in $O(n^2)$ time by maximizing the objective function of a special QAP(F, D), where F is a product matrix and D is the distance matrix of points on a line. Here, n denotes the vertices in the degree sequence with a degree > 1 .

A matrix $A = (a_{ij})$ is called *small* if it is generated by two vectors $u = (u_1, \dots, u_n)$ and $v = (v_1, \dots, v_n)$ such that $a_{ij} = \min(u_i, v_j)$. It is called *large* if $a_{ij} = \max(u_i, v_j)$. A Koopmans–Beckmann QAP where F is a symmetric small or large matrix and D is a chessboard matrix can be solved in $O(n^2)$ time.

Sum, product, and small and large matrices are special cases of so-called Monge matrices. A matrix $A = (a_{ij})$ is a *Monge matrix* if the following inequalities are fulfilled for each 4-tuples of indices i, j, k, l , $i < k, j < l$:

$$a_{ij} + a_{kl} \leq a_{il} + a_{kj}, \quad (\text{Monge inequalities}).$$

A matrix $A = (a_{ij})$ is an *anti-Monge matrix* if the following inequalities are fulfilled for each 4-tuples of indices $i, j, k, l, i < k, j < l$:

$$a_{ij} + a_{kl} \geq a_{il} + a_{kj}, \quad (\text{anti-Monge inequalities}).$$

Another class of matrices similar to the Monge matrices are the *Kalmanson matrices*. A matrix $A = (a_{ij})$ is a Kalmanson matrix if it is symmetric and if its elements satisfy the following inequalities for all indices $i, j, k, l, i < j < k < l$:

$$a_{ij} + a_{kl} \leq a_{ik} + a_{jl}, \quad a_{il} + a_{jk} \leq a_{ik} + a_{jl}.$$

For more information on Monge, anti-Monge, and Kalmanson matrices and their properties, the reader is referred to the survey article of Burkard et al. [53].

Whereas the TSP with a Monge matrix as distance matrix is polynomially solvable, it turns out that the QAP where both coefficient matrices are Monge or anti-Monge is NP-hard. The complexity of a QAP with one coefficient matrix being Monge and the other one being anti-Monge is still open; see Burkard et al. [42]; Burkard et al. [46]; and Cela [60]. An interesting case is a QAP(F, D), where the $n \times n$ matrix F is a Monge matrix and D is a chessboard matrix. If $n = 2m$ is even, then the fixed permutation $\varphi = (1, m+1, 2, m+2, \dots, n)$ is an optimal solution. In the case of an odd n , the problem may have several optimal solutions and it is conjectured to be NP-hard.

Other restricted versions of the QAP involve matrices with a specific diagonal structure. An $n \times n$ matrix $A = (a_{ij})$ is called a *Toeplitz matrix* if there exist numbers $c_{-n+1}, \dots, c_{-1}, c_0, c_1, \dots, c_{n-1}$ such that $a_{ij} = c_{j-i}$, for all i, j . A circulant matrix is a special Toeplitz matrix where the generating numbers c_i fulfill the conditions $c_i = c_{n-i}$. A Toeplitz matrix has constant entries along lines parallel to the diagonal, whereas a circulant is given by its first row and the entries of the i th row resemble the first row shifted by $i - 1$ places to the right.

A well-studied problem is the so-called anti-Monge–Toeplitz QAP where the rows and columns of the anti-Monge matrix are nondecreasing; see Burkard et al. [45]. It has been shown that this problem is NP-hard and contains as a special case the so-called turbine problem introduced by Bolotnikov [31] and Stoyan et al. [213]. Laporte and Mercure [151] observed that the turbine problem can be formulated as a quadratic assignment problem; see also Mosevich [176]. In the turbine problem, we are given a number of blades to be welded in regular spacing around the cylinder of the turbine. Due to inaccuracies in the manufacturing process, the weights of the blades differ slightly and consequently the gravity center of the system does not lie on the rotation axis of the cylinder, leading to instabilities. In an effort to make the system as stable as possible, it is desirable to locate the blades so as to minimize the distance between the center of gravity and the rotation axis. The mathematical formulation of this problem leads to an NP-hard anti-Monge–Toeplitz QAP. (For more details and for a proof of NP-hardness, see Burkard et al. [45].) The *maximization* version of this problem, however, is polynomially solvable. Further polynomially solvable special cases of the anti-Monge–Toeplitz

QAP arise if additional constraints, for example, *benevolence* or *k-benevolence*, are imposed on the Toeplitz matrix. These conditions are expressed in terms of properties on the coefficients $c_{-1}, c_0, c_1, \dots, c_{n-1}$; see Burkard et al. [45]. In this case the cyclic permutation

$$\langle 1, 3, 5, \dots, n, \dots, 6, 4, 2 \rangle \quad (75)$$

becomes the optimal solution. Demidenko et al. [80] specify other conditions on the matrices F and D such that permutation (75) becomes an optimal solution of $\text{QAP}(F, D)$. Further results in this direction are due to Demidenko and Dolgui [79].

The polynomially solvable QAPs where F is an anti-Monge (Monge) matrix and D is a Toeplitz (or circulant) matrix with special properties as mentioned above have a permutation with a certain well-defined structure as optimal solution. The techniques used to prove this fact and to identify the optimal permutation is called *reduction to extremal rays*. This technique exploits two facts: first, the involved matrix classes form cones, and second, the objective function of the QAP is linear with respect to each of the coefficient matrices. These two facts allow us to restrict the investigations to instances of the QAP with 0–1 coefficient matrices which are extremal rays of the above-mentioned cones. Such instances can then be handled by elementary means (exchange arguments, bounding techniques) more easily than the general given QAP.

The Koopmans–Beckmann QAP where the coefficient matrix F is a Kalmanson matrix and matrix D is a symmetric decreasing circulant matrix has been investigated by Deineko and Woeginger [81]. A symmetric $n \times n$ circulant matrix $D = (d_{ij})$ is called *decreasing* if $d_{11} \leq d_{12} \leq \dots \leq d_{1\lceil \frac{n+1}{2} \rceil}$. Deineko and Woeginger investigated the cones generated by these two matrix classes. By reduction to extremal rays, they showed that the identical permutation is an optimal solution.

A matrix $A = (a_{ij})$ is called *left-higher graded* if both its rows and columns are nondecreasing, that is, $a_{ij} \leq a_{i,j+1}$ and $a_{ij} \leq a_{i+1,j}$ for all i, j . A matrix is called *right-lower graded* if both its rows and columns are nonincreasing, that is, $a_{ij} \geq a_{i,j+1}$ and $a_{ij} \geq a_{i+1,j}$ for all i, j . The following proposition generalizes an earlier result by Krushevski [148]:

Proposition 6 *Let F be a left-higher graded matrix and let D be a right-lower graded matrix. Then the identical permutation solves $\text{QAP}(F, D)$.*

The complexity of $\text{QAP}(F, D)$ where F is left-higher graded and D is right-higher graded is not known; see Burkard et al. [43].

Further polynomially solvable cases of $\text{QAP}(F, D)$ arise, when F and D are viewed as weighted adjacency matrices of graphs. For example, Erdogan and Tansel [94] showed the following: let F be the adjacency matrix of a graph whose vertices have only the degrees 0, 1, and 2 and let D be the weighted adjacency matrix of a grid with a rows and b columns such that $ab = n$. In this case the optimal solution of $\text{QAP}(F, D)$ can be found in polynomial time. Moreover, polynomially

solvable versions of the linear arrangement problem, the minimum FASP, or packing problems in graphs lead to polynomially solvable cases of the QAP. The coefficient matrices of these QAPs are the (weighted) adjacency matrices of the underlying graphs, and the special structure of these matrices is imposed by properties of these graphs.

Finally, graph isomorphism problems lead to polynomially solvable QAPs. Christofides and Gerrard [67] showed the following: let T_1 and T_2 be two isomorphic trees with n vertices and arbitrary weights on the edges. Moreover, let F and D be the symmetric weighted adjacency matrices of T_1 and T_2 , respectively. Let $\mathcal{I}(T_1, T_2)$ denote the set of all permutations φ which are isomorphisms between T_1 and T_2 . Then the quadratic assignment problem

$$\min_{\varphi \in \mathcal{I}(T_1, T_2)} \sum_{i=1}^n \sum_{k=1}^n a_{ik} b_{\varphi(i)\varphi(k)} \quad (76)$$

can be solved by a polynomial time dynamic programming algorithm. On the other hand, the cheapest embedding of a tree with n vertices in a weighted complete graph K_n is \mathcal{NP} -hard. Rendl [198] generalized the result on two isomorphic trees to certain vertex series parallel digraphs.

11 Asymptotic Behavior

Quadratic assignment problems show an interesting asymptotic behavior: under certain probabilistic conditions on the coefficient matrices of QAPs, the ratio between its “best” and “worst” objective function values approaches 1, as the size of the problem tends to infinity. This asymptotic behavior suggests that any heuristic finds almost always an almost optimal solution when applied to sufficiently large QAP instances. In other words, the QAP becomes in some sense trivial as the size of the problem tends to infinity. Burkard and Fincke [50] identify a common combinatorial property on a number of combinatorial optimization problems which, under natural probabilistic conditions on the problem data, behave as described above. This property seems to govern also the specific asymptotic behavior of QAPs.

In an early work, Burkard and Fincke [49] investigate the relative difference between the worst and the best value of the objective function for Koopmans–Beckmann QAPs. They first consider the case where the coefficient matrix D is the matrix of pairwise distances of points chosen independently and uniformly from the unit square in the plane. Then the general case where entries of the flow and distance matrices F and D are independent random variables taken from a uniform distribution on $[0, 1]$ is considered. In both cases it is shown that the relative difference mentioned above approaches 0 with probability tending to 1 as the size of the problem tends to infinity.

Later Burkard and Fincke [50] consider the ratio between the objective function values corresponding to an optimal (or best) and a worst solution of a generic combinatorial optimization problem described below.

Consider a sequence (P_n) , $n \in \mathbb{N}$, of combinatorial optimization (minimization) problems with sum objective function. Let \mathcal{E}_n and \mathcal{F}_n be the ground set and the set of feasible solutions of problem P_n , respectively. Moreover, let $c_n: \mathcal{E}_n \rightarrow \mathbb{R}^+$ and $f: \mathcal{F}_n \rightarrow \mathbb{R}^+$ be the nonnegative cost function and the objective function for problem P_n , respectively. For $n \in \mathbb{N}$, let

$$BV(n) = \min_{X \in \mathcal{F}_n} f(X),$$

$$WV(n) = \max_{X \in \mathcal{F}_n} f(X).$$

In [50] it is shown that the behavior of the ratio $WV(n)/BV(n)$) is strongly related to the ratio $\ln |\mathcal{F}_n|/|X_n|$ between the cardinality of the set of feasible solutions \mathcal{F}_n and the cardinality of an arbitrary feasible solution X_n of P_n , under the assumption that all feasible solutions have the same cardinality.

Theorem 7 ([50]) *Let (P_n) be a sequence of combinatorial minimization problems with sum objective function as described above. Assume that the following conditions are fulfilled:*

- (BF1) *All feasible solutions $X \in \mathcal{F}_n$ have the same cardinality $|X|_n$.*
- (BF2) *For all n the costs $c_n(x)$, $x \in X$, $X \in \mathcal{F}_n$ are independent random variables identically distributed on $[0, 1]$ with finite expected value $\mu = E(c_n(x))$ and finite variance $\sigma^2 = \text{Var}(c_n(x))$.*
- (BF3) *$|\mathcal{F}_n|$ and $|X|_n$ tend to infinity as n tends to infinity and moreover*

$$\lim_{n \rightarrow \infty} \lambda_0 |X|_n - \ln |\mathcal{F}_n| \rightarrow +\infty$$

where λ_0 is defined by $\lambda_0 := (\epsilon_0 \sigma / (\epsilon_0 + 2\sigma^2))^2$ and ϵ_0 fulfills

$$0 < \epsilon_0 < \sigma^2 \quad \text{and} \quad 0 < \frac{\mu + \epsilon_0}{\mu - \epsilon_0} \leq 1 + \epsilon, \quad (77)$$

for a given $\epsilon > 0$.

Then, as $n \rightarrow \infty$

$$P \left\{ \frac{WV(n)}{BV(n)} < 1 + \epsilon \right\} \geq 1 - 2|\mathcal{F}_n| \exp(-|X|_n \lambda_0) \rightarrow 1.$$

The combinatorial condition represented by the limit in (BF3) says that the cardinality of the feasible solutions is large enough with respect to the cardinality of the set of feasible solutions. Namely, the result of the theorem is true if the following equality holds:

$$\lim_{n \rightarrow \infty} \frac{\ln |\mathcal{F}_n|}{|X|_n} = 0.$$

The other conditions of [Theorem 7](#) are natural probabilistic requirements on the coefficients of the problem. [Theorem 7](#) states that for each $\epsilon > 0$, the ratio between the best and the worst value of the objective function lies in $(1 - \epsilon, 1 + \epsilon)$, with probability tending to 1, as the “size” of the problem approaches infinity. Thus, we have convergence with probability. Under one additional natural (combinatorial) assumption (condition (S3) of the theorem below), Szpankowski strengthens this result and improves the range of the convergence to almost surely. In the almost sure convergence, the probability that the above-mentioned ratio tends to 1 is equal to 1.

Theorem 8 ([215]) Let P_n be a sequence of combinatorial minimization problems with sum objective function as above. Assume that the following conditions are fulfilled:

- (S1) All feasible solutions $X \in \mathcal{F}_n$ have the same cardinality $|X|_n$.
- (S2) For all n the costs $c_n(x)$, $x \in X$, $X \in \mathcal{F}_n$ are random variables identically and independently distributed on $[0, 1]$. The expected value $\mu = E(c_n(x))$, the variance, and the third moment of the common distribution are finite.
- (S3) For increasing values of n , the worst objective function values $WV(n)$ are nondecreasing.
- (S4) $|\mathcal{F}_n|$ and $|X|_n$ tend to infinity as n tends to infinity and moreover $\ln |\mathcal{F}_n| = o(|X|_n)$.

Then, the following equalities hold almost surely:

$$BV(n) = |X|_n \mu - o(|X|_n)$$

$$WV(n) = |X|_n \mu + o(|X|_n).$$

[Theorems 7](#) and [8](#) can be applied to the QAP. The reason is that the QAP fulfills the combinatorial condition (S4) in [Theorem 8](#) [and, therefore, also condition (BF3) in [Theorem 7](#)]. Thus, we immediately get the following corollary:

Corollary 1 Consider a sequence of problems QAP($F^{(n)}, D^{(n)}$) for $n \in \mathbb{N}$, with $n \times n$ coefficient matrices $F^{(n)} = (f_{ij}^{(n)})$ and $D = (d_{ij}^{(n)})$. Assume that $f_{ij}^{(n)}$ and $d_{ij}^{(n)}$, $n \in \mathbb{N}$, $1 \leq i, j \leq n$, are independently distributed random variables on $[0, M]$, where M is a positive constant. Moreover, assume that entries $f_{ij}^{(n)}$, $n \in \mathbb{N}$, $1 \leq i, j \leq n$, have the same distribution, and entries $d_{ij}^{(n)}$, $n \in \mathbb{N}$, $1 \leq i, j \leq n$, have also the same distribution (which does not necessarily coincide with that of $f_{ij}^{(n)}$). Furthermore, assume that these variables have finite expected values, variances, and third moments.

Let $\pi_{\text{opt}}^{(n)}$ and $\pi_{\text{wor}}^{(n)}$ denote an optimal and a worst solution of QAP($F^{(n)}, D^{(n)}$), respectively. Then the following equality holds almost surely:

$$\lim_{n \rightarrow \infty} \frac{Z(F^{(n)}, D^{(n)}, \pi_{\text{opt}}^{(n)})}{Z(F^{(n)}, D^{(n)}, \pi_{\text{wor}}^{(n)})} = 1.$$

The above result suggests that the value of the objective function of the problem $\text{QAP}(F^{(n)}, D^{(n)})$ (corresponding to an arbitrary feasible solution) gets somehow close to its expected value $n^2 \mu(F)\mu(D)$, as the size of the problem increases, where $\mu(F)$ and $\mu(D)$ are the expected values of $f_{ij}^{(n)}$ and $d_{ij}^{(n)}$, $n \in \mathbb{N}$, $1 \leq i, j \leq n$, respectively. Frenk et al. [101] and Rhee [202, 203] provide different analytical evaluations for this “getting close,” by imposing different probabilistic conditions on the data. The following theorem states two important results proved in [101] and [203]:

Theorem 9 ([101, 203]) Consider the sequence of $\text{QAP}(F^{(n)}, D^{(n)})$, $n \in \mathbb{N}$, as in Corollary 1. Assume that the following conditions are fulfilled:

- (C1) $f_{ij}^{(n)}, f_{ij}^{(n)}, n \in \mathbb{N}, 1 \leq i, j \leq n$ are random variables independently distributed on $[0, M]$.
- (C2) $f_{ij}^{(n)}, n \in \mathbb{N}, 1 \leq i, j \leq n$ have the same distribution on $[0, M]$. $d_{ij}^{(n)}, n \in \mathbb{N}, 1 \leq i, j \leq n$ have also the same distribution on $[0, M]$.

Let $\mu(F), \mu(D)$ be the expected values of the variables $f_{ij}^{(n)}$ and $d_{ij}^{(n)}$, respectively. Then, there exists a constant K_1 (which does not depend on n), such that the following inequality holds almost surely, for $\pi \in \mathcal{S}_n$:

$$\limsup_{n \rightarrow \infty} \frac{\sqrt{n}}{\sqrt{\log n}} \left| \frac{Z(F^{(n)}, D^{(n)}, \pi)}{n^2 \mu(F)\mu(D)} - 1 \right| \leq K_1.$$

Moreover, let Y be a random variable defined by

$$Y = Z(F^{(n)}, D^{(n)}, \pi_{\text{opt}}^{(n)}) - n^2 \mu(F)\mu(D),$$

where $\pi_{\text{opt}}^{(n)}$ is an optimal solution of $\text{QAP}(F^{(n)}, D^{(n)})$. Then there exists another constant K_2 , also independent of the size of the problem, such that

$$\begin{aligned} \frac{1}{K_2} n^{3/2} (\log n)^{1/2} &\leq E(Y) \leq K_2 n^{3/2} (\log n)^{1/2} \\ P \{|Y - E(Y)| \geq t\} &\leq 2 \exp \left(\frac{-t^2}{4n^2 \|F\|_\infty^2 \|D\|_\infty^2} \right) \end{aligned}$$

for each $t \geq 0$, where $E(Y)$ denotes the expected value of variable Y and $\|F\|_\infty$ ($\|D\|_\infty$) is the so-called row sum norm of matrix F (D) defined by $\|F\|_\infty = \max_{1 \leq i \leq n} \sum_{j=1}^n |f_{ij}|$.

These results on the asymptotic behavior of the QAP have been exploited by Dyer et al. [89] to analyze the performance of branch-and-bound algorithms for QAPs with coefficients generated randomly as described above. In this case the gap between the optimal value of the continuous relaxation due to Frieze–Yadegar and the optimal value of the QAP grows like $O(n)$ with probability tending to 1 as n tends to infinity. This result leads to the following theorem:

Theorem 10 ([89]) *Consider any branch-and-bound algorithm for solving a QAP with randomly generated coefficients as in Corollary 1 that uses a single assignment branching and employs a bound obtained by solving the continuous relaxation of the linearization (19)–(26). The number of branched nodes explored is at least $n^{(1-o(1))n/4}$ with probability tending to 1 as the size n of the QAP tends to infinity.*

It is interesting to note that the asymptotic results on generic combinatorial optimization problems can also be derived by means of statistical mechanics. Recall that also *simulated annealing*, Sect. 8.7, is a technique from statistical mechanics. Bonomi and Lutton [32] applied the framework of statistical mechanics to the QAP: the feasible solutions of a combinatorial optimization problem correspond to the states of a physical system, the objective function models the energy of the state. Albrecher et al. [10] define a *partition function* by

$$Q(\tau) = \sum_{X \in \mathcal{F}} \exp(-f(X)\tau), \quad (78)$$

where τ mimics the inverse temperature $1/T$. They assign the probability

$$\mathbb{P}(X) = \frac{\exp(-f(X)\tau)}{Q(\tau)} \quad (79)$$

to each feasible solution $X \in \mathcal{F}$. Let $E(f(X), \tau)$ denote the expected value of the objective function $f(X)$ for fixed τ . It can easily be shown that

$$\mathbb{E}(f(X), \tau) = -\frac{d}{d\tau}(\log Q(\tau)). \quad (80)$$

A careful investigation of $\log Q(\tau)/|X|$ finally yields

$$\mathbb{P}\left(\lim_{n \rightarrow \infty} \frac{BV(n)}{|X|_n} = \mu\right) = 1 \quad (81)$$

where μ is the expectation value of the cost coefficients of the generic problem.

12 Quadratic Bottleneck Assignment Problems

The *quadratic bottleneck assignment problem (QBAP)* asks for a permutation φ which minimizes the *maximum* of the cost terms $f_{ij}d_{\varphi(i)\varphi(j)}$. Given an $n \times n$ flow matrix F and an $n \times n$ distance matrix D , we want to find a permutation $\varphi \in S_n$ which minimizes the objective function

$$\max\{f_{ij}d_{\varphi(i)\varphi(j)} : 1 \leq i, j \leq n\}.$$

A more general QBAP analogous to the QAP in (2) is obtained if the coefficients of the problem are of the form c_{ijkl} , $1 \leq i, j, k, l \leq n$:

$$\min_{\varphi \in S_n} \max_{1 \leq i, j \leq n} c_{ij\varphi(i)\varphi(j)}.$$

The QBAP has many applications. Basically, all QAP applications give rise to QBAPs because often it makes sense to minimize the largest cost instead of the overall cost incurred by some decision. A well-studied problem in graph theory which can be modeled as a QBAP is the *bandwidth problem*. In the bandwidth problem, we are given an undirected graph $G = (V, E)$ with vertex set $V = \{1, 2, \dots, n\}$ and edges $(i, j) \in E$. A labeling φ of the vertices has to be found such that

$$\max_{(i,j) \in E} |\varphi(i) - \varphi(j)|$$

is minimized. It is easy to see that this problem can be modeled as a special QBAP with the flow matrix equal to the adjacency matrix of G and distance matrix $D = (d_{kl}) = (|k - l|)$.

The QBAP is NP-hard since it contains the bottleneck TSP as a special case. In order to solve QBAP by branch-and-bound methods (or more generally, implicit enumeration methods), lower bounds can be derived in a similar way as in the case of QAPs. In practice, however, QBAPs are often easier to solve than QAPs, since threshold techniques can be applied which reduce the problem to the decision problem whether or not there exists a permutation φ such that for a given constant K $c_{ij\varphi(i)\varphi(j)} \leq K$ holds for all $1 \leq i, j \leq n$.

For computing lower bounds, one can proceed as follows: let matrix C be written as a block matrix (C^{ik}) where every C^{ik} is the matrix (c_{ijkl}) with fixed indices i and k . As in the sum case we can assume

$$c_{ijkl} = \infty \quad \text{for } (i = j \text{ and } k \neq l) \text{ or } (i \neq j \text{ and } k = l). \quad (82)$$

and

$$c_{ijkl} := \begin{cases} \max(c_{ijkl}, c_{klji}) & \text{for } j > i, \\ 0 & \text{for } j < i. \end{cases} \quad (83)$$

For every i, k denote the optimal solution value of a linear bottleneck assignment problem with cost matrix C^{ik} by l_{ik} . A lower bound for the optimum objective

function value of the QBAP is obtained by the optimal objective function value of a linear bottleneck assignment problem with cost matrix $L = (l_{ik})$.

In case of a QBAP in Koopmans–Beckmann form, one can proceed like in the Gilmore–Lawler bound. In particular a modification of Hardy et al. [127] inequality holds also for bottleneck problems (cf. [Proposition 2](#)).

Proposition 7 *Let two n -dimensional real vectors $a = (a_i)$, $b = (b_i)$ with $0 \leq a_1 \leq a_2 \leq \dots \leq a_n$ and $b_1 \geq b_2 \geq \dots \geq b_n \geq 0$ be given. Then the following inequalities hold for any permutation φ of $1, 2, \dots, n$:*

$$\max_{1 \leq i \leq n} a_i b_i \leq \max_{1 \leq i \leq n} a_i b_{\varphi(i)} \leq \max_{1 \leq i \leq n} a_i b_{n-i+1}.$$

This proposition yields that a linear bottleneck assignment problem with cost coefficients $c_{ik} = a_i b_k$ can be solved by ordering the vectors $a = (a_i)$ and $b = (b_k)$.

The lower bounds can be used in branch-and-bound algorithms; see Burkard [37].

Like in the sum case, there exist a number of special cases of the QBAP which can be solved in polynomial time; see Burkard and Rissner [56]. In particular, a result like [Proposition 6](#) holds also in the bottleneck case. Moreover, a QBAP with two symmetric, nonnegative product matrices can be solved in $O(n \log n)$ time.

The Monge condition of sum problems can be replaced by the bottleneck Monge condition; see Burkard et al. [53].

$$\max(a_{ij}, a_{kl}) \leq \max(a_{il}, a_{kj}).$$

A careful study of matrices endowed with the bottleneck Monge structure (so-called bottleneck Monge matrices) shows, for example, that a QBAP of Koopmans–Beckmann form where F is a bottleneck Monge matrix and D is a chessboard matrix with even $n = 2m$ is solved by the permutation

$$\varphi(i) = \begin{cases} 2i - 1 & 1 \leq i \leq m \\ 2(i - m) & m + 1 \leq i \leq n. \end{cases}$$

For further polynomial special cases, see [56].

QBAP show a similar asymptotic behavior as QAPs. Burkard and Fincke [48] proved the following: if the coefficients of a QBAP are independent random variables taken from a uniform distribution on $[0, 1]$, then the relative difference between the worst and the best value of the objective function approaches 0 with probability tending to 0 as the size of the problem approaches infinity. Albrecher [9] sharpened the convergence rate by showing the following result. Let

$$BV(n) = \min_{\varphi} \max_{1 \leq i, j \leq n} c_{ij\varphi(i)\varphi(j)},$$

$$WV(n) = \max_{\varphi} \max_{1 \leq i, j \leq n} c_{ij\varphi(i)\varphi(j)}.$$

If the cost coefficients are independent and identically distributed random variables in $[0, 1]$, then

$$\frac{WV(n) - BV(n)}{BV(n)} \leq \sqrt{\frac{2 \log n}{n}} \left(1 - \frac{1}{2 \log n} - \frac{1}{8(\log n)^2} \right) \text{ almost surely.}$$

The asymptotic behavior of generic combinatorial optimization problems (cf. Sect. 11) with a bottleneck objective function was studied by Burkard and Fincke [50] and Szpankowski [215].

The QBAP and the QAP are special cases of a more general quadratic assignment problem which is called *the algebraic QAP* (in analogy to the algebraic linear assignment problem (LAP) introduced by Burkard et al. [51]). If $(H, *, \preceq)$ is a totally ordered commutative semigroup with composition $*$ and order relation \preceq , the algebraic QAP with cost coefficients $c_{ijkl} \in H$ is formulated as

$$\min_{\varphi \in S_n} c_{11\varphi(1)\varphi(1)} * c_{12\varphi(1)\varphi(2)} * \dots * c_{1n\varphi(1)\varphi(n)} * \dots * c_{nn\varphi(n)\varphi(n)}.$$

The study of the bottleneck QAP and more generally the algebraic QAP was the starting point for the investigation of a number of algebraic combinatorial optimization problems with coefficients taken from linearly ordered semimodules, for example, linear assignment and transportation problems and flow problems. The reader is referred to Burkard and Zimmermann [57] for a detailed discussion on this topic.

13 Related Problems

In this section several of generalizations and problems related to the QAP are presented.

13.1 Cubic and Biquadratic Assignment Problems

One possibility to generalize the QAP is to consider objective functions of higher degree. In this way *cubic*, *biquadratic*, and generally N -adic assignment problems (see, e.g., [152]) are obtained. The cubic assignment problem, for example, has n^6 cost coefficients c_{ijklmp} with $i, j, k, l, m, p = 1, \dots, n$ and can be stated as follows:

$$\begin{aligned} \min & \sum_{i,j=1}^n \sum_{k,l=1}^n \sum_{m,p=1}^n c_{ijklmp} x_{ij} x_{kl} x_{mp} \\ \text{s.t } & (x_{ij}) \in \mathbf{X}_n. \end{aligned}$$

As noted by Lawler [152], we can construct an $n^3 \times n^3$ matrix S containing the cost coefficients, such that the cubic assignment problem is equivalent to the linear assignment problem

$$\begin{aligned} \min \quad & \langle S, Y \rangle \\ \text{s.t.} \quad & Y = X \otimes X \otimes X, \\ & X \in \mathbf{X}_n. \end{aligned}$$

In an analogous way, the LAP can be extended to any N -adic assignment problem, by considering the solution matrix Y to be the Kronecker $N - th$ power of a permutation matrix in \mathbf{X}_n .

The *biquadratic assignment problem* denoted BiQAP is essentially a quartic assignment problem with cost coefficients formed by the products of two four-dimensional arrays. More specifically, consider two $n^4 \times n^4$ arrays $F = (f_{ijkl})$ and $D = (d_{mpst})$. Then the BiQAP has the form

$$\begin{aligned} \min \quad & \sum_{i,j=1}^n \sum_{k,l=1}^n \sum_{m,p=1}^n \sum_{s,t=1}^n f_{ijkl} d_{mpst} x_{im} x_{jp} x_{ks} x_{lt} \\ \text{s.t.} \quad & \sum_{i=1}^n x_{ij} = 1, \quad j = 1, 2, \dots, n, \\ & \sum_{j=1}^n x_{ij} = 1, \quad i = 1, 2, \dots, n, \\ & x_{ij} \in \{0, 1\}, \quad i, j = 1, 2, \dots, n. \end{aligned}$$

Equivalently, the BiQAP can be stated as

$$\min_{\varphi \in \mathcal{S}_n} \sum_{i=1}^n \sum_{j=1}^n \sum_{k=1}^n \sum_{l=1}^n f_{ijkl} d_{\varphi(i)\varphi(j)\varphi(k)\varphi(l)},$$

where \mathcal{S}_n denotes the set of all permutations of $N = \{1, 2, \dots, n\}$. All different formulations for the QAP can be extended to the BiQAP, as well as most of the linearizations that have appeared for the QAP.

An application of the BiQAP arises in very-large-scale integrated (VLSI) circuit design. The majority of VLSI circuits are sequential circuits, and their design process consists of two steps: first, translate the circuit specifications into a state transition table by modeling the system using finite state machines, and second, try to find an encoding of the states such that the actual implementation is of minimum size. A detailed description of the mathematical modeling of the VLSI problem to a BiQAP is given by Burkard et al. [44].

Burkard et al. [44] compute lower bounds for the BiQAP derived from lower bounds of the QAP. The computational results showed that these bounds are weak and deteriorate as the dimension of the problem increases. This observation suggests that branch-and-bound methods will only be effective on very small instances. For larger instances, efficient heuristics, which find good-quality approximate solutions, are needed. Several heuristics for the BiQAP have been developed by Burkard and Çela [41], in particular deterministic improvement methods and variants of simulated annealing and tabu search algorithms. Computational experiments on test problems of size up to $n = 32$, with known optimal solutions (a test problem generator is presented in [44]), suggest that one version of simulated annealing is best among those tested. The GRASP heuristic has also been applied to the BiQAP by Mavridou et al. [167] and produced the optimal solution for all the test problems generated in [44].

Quartic assignment problems show the same asymptotic behavior as QAPs. Burkard et al. [44] proved for quartic assignment problems under natural probabilistic assumptions that

$$\lim_{n \rightarrow \infty} \mathbb{P} \left\{ \frac{WV(n)}{BV(n)} < 1 + \varepsilon \right\} = 1.$$

13.2 The Quadratic Semi-assignment Problem

The quadratic semi-assignment problem (SQAP) assigns n “objects” to m “locations” with $n > m$ so as to minimize the overall distance covered by the flow of materials (or people) moving between different objects. The objective function is the same as that of the QAP, the only difference concerns the feasible solutions which are not any more one-to-one mappings (permutations) between the set of objects and locations, but arbitrary functions mapping the set of objects to the set of locations. Given two coefficient matrices, the flow matrix $F = (f_{ij})$ and the distance matrix $D = (d_{ij})$, the SQAP can be formulated in the following way:

$$\min \sum_{i=1}^n \sum_{j=1}^m \sum_{k=1}^n \sum_{l=1}^m f_{ij} d_{kl} x_{ik} x_{jl} + \sum_{i,j=1}^n b_{ij} x_{ij} \quad (84)$$

$$\text{s.t. } \sum_{j=1}^m x_{ij} = 1, \quad i = 1, 2, \dots, n, \quad (85)$$

$$x_{ij} \in \{0, 1\}, \quad i, j = 1, 2, \dots, n. \quad (86)$$

The SQAP unifies some interesting combinatorial optimization problems like *clustering* and *m-coloring*. In a clustering problem, we are given n objects and a dissimilarity matrix $F = (f_{ij})$. The goal is to find a partition of these objects into m classes so as to minimize the sum of dissimilarities of objects belonging to the

same class. Obviously, this problem is an SQAP with coefficient matrices F and D , where D is an $m \times m$ identity matrix. In the m -coloring problem, we are given a graph with n vertices and we want to check whether its vertices can be colored by m different colors such that each two vertices which are joined by an edge receive different colors. This problem can be modeled as an SQAP with F equal to the adjacency matrix of the given graph and D the $m \times m$ identity matrix. The m -coloring has an answer “yes” if and only if the above SQAP has the optimal value equal to 0. The first application of the SQAP concerned the supply of space stations; see Freeman et al. [102]. Other applications of the SQAP include distributed computing [212], schedule synchronization in transit networks [75, 164], and scheduling [66].

The SQAP was originally introduced by Greenberg [119]. As pointed out by Malucelli [163], this problem is NP-hard. Milis and Magirou [169] propose a Lagrangean relaxation algorithm for this problem and show that similarly as for the QAP, it is very hard to provide optimal solutions even for SQAPs of small size. Lower bounds for the SQAP have been provided by Malucelli and Pretolani [165], as well as by Billionet and Elloumi [26]. Polynomially solvable special cases have been discussed by Bokhari [29], Chhajed and Lowe [65], and Malucelli [163]. A survey of heuristics for SQAP is provided by Voß [221].

Abstract

Learning and Intelligent Optimization (LION) and Reactive business intelligence (RBI) consider techniques based on data analysis, model building, and feedback by the users for the realization of effective computer-supported tools for business analytics and decision making.

The systematic usage of online machine learning methods is instrumental to raise the level of automation, therefore permitting a wider adoption of real-time self-tuning systems. This development liberates the decision maker from the burden of routine operations and from the rigidity of many current BI tools.

Optimization, and Learning and Intelligent OptimizatioN (LION) methods play a crucial role for solving the various complex problems arising in nontrivial business intelligence and analytics applications and for identifying models through machine learning schemes.

This chapter positions the LION and RBI fields in the context of different related approaches and summarizes some paradigmatic applications.

1 Introduction

Business intelligence (BI) denotes an automated (computer-supported) process to systematically transform raw data originated in business activities into models and insight, which can be used to decide, act, and improve business processes and results.

The term was coined in [54] as “the ability to apprehend the interrelationships of presented facts in such a way as to guide action towards a desired goal” and later publicized under different and related keywords, starting from *decision support systems* (DSS) in the 1960s. DSS purpose was to use computers and algorithms to assist with decision making and planning. From DSS, data warehouses (integrated databases providing collection, storage, and distributions of business data), executive information systems, OLAP (online analytical processing), and business intelligence came into focus beginning in the late 1980s with the growing adoption of computers. The usage of “business intelligence”—according to H. Dresner an umbrella term to describe “concepts and methods to improve business decision making by using fact-based support systems”—became widespread the late 1990s. Related terms are *data mining* (extracting patterns from large data sets, usually part of a wider business intelligence effort), *business analytics* (the application of computer technology, optimization, and statistics to solve problems in business and industry), and *KDD* (knowledge discovery in databases [33]).

The term *reactive*, originated from the reactive search optimization framework [5, 8, 12], is related to designing optimization schemes with an automated and rapid capability to adapt by responding to stimuli, to changes in the external environment. Analogies are in complex biological systems, in which *reactivity* as response to current and past inputs is crucial in living organisms [34]. Reactive systems “live” in order to react. The automation is obtained through machine learning schemes acting in real-time, in an online manner, while the system is running. *Reactive business intelligence* (RBI) advocates a holistic approach that integrates data mining, modeling, and interactive visualization into an end-to-end discovery and continuous innovation process powered by human and automated learning [11].

The RBI methodology stands on the shoulders of the tradition of experimental science going back at least to Galileo (measurements, models, experimental validation, refinement of models) but departs from the tradition in its use of online machine learning in the process of continuous adaptation of the models. The traditional laws of nature, like the law of gravitation, are immutable, while the laws of business need to account for unexpected changes in the competition, in the users' preferences, in the available information, and in the technology. In hard science like physics no self-tuning is needed, and the cyclic process of building explanatory models converges when the model reproduces the experimental results, at least to a sufficient degree, while in business the iterated modeling and organization of activities never ends.

One of the main criticisms to traditional BI systems is that they tend to be static and difficult to change. Usually, a huge investment is required and changes are extremely costly. Managers using new information for decisions usually need to interact with technical people to realize new software, a long and costly iteration. Reactive BI starts by the assumption that change is *inherent* in the business activities and prepares for that, with growing levels of self-adaptation. Applications of neural networks and machine learning for selected business applications starting from the late eighties go in this direction [76,79], as well the autonomic management of computer systems and telecommunication networks advocated in the nineties [49,69].

The reactive trend in business intelligence is in essence related to reaching higher levels of automation, by transferring the capability to execute changes in response to business stimuli—traditionally requiring human intervention—directly to the BI system, starting from the simplest changes and progressively attacking higher and higher levels and the decision and implementation hierarchy. The human decision maker (DM) is always in charge of the final decisions, but the preparatory work to mine data and prepare potential solutions according to the DM preferences allows seamless decision processes.

Note that *reactive* denotes a property of the software system, not of the system designer, the decision maker, or the final user of the system. In fact, the system designer must act in a very proactive (anticipatory) manner to endow the software with the capability to be reactive. The main reason why a software system needs to be reactive is that businesses are confronted with a rapidly changing context and, in some cases, with dramatic events requiring very fast reactive automated responses.

The role of *optimization* in RBI is crucial for different reasons. The first and most obvious one is to solve the various complex problems arising in nontrivial business intelligence applications. Most problems are NP-hard so that optimization heuristics, often based on stochastic local search [46], are the only practical way to deliver *satisficing* solutions. A second reason is related to the intensive use of machine learning in RBI: most machine learning schemes employ optimization to identify effective and simple models. A third nontrivial reason is related to a *separation of concerns* between problem definition and problem solution. By delegating the problem solution to optimization schemes, the decision maker is free to concentrate his energies on defining the objectives in a clear, understandable, and measurable form. Furthermore, different formulations of the objectives can be

experimented with, and to increase the automation, systems can be developed to progressively *learn the problem definition* from the user feedback during interactive problem-solving sessions.

The issues of evolving problem definitions and finding approximate solutions are often neglected by traditional computer science approaches to business intelligence. Some relevant scientific results are summarized in the following paragraphs.

Starting at least from the pioneering work of Herbert Simon [67], it is recognized that human decision processes are severely constrained and that models must depart from abstract mathematical formulations of traditional economics, based on an abstract *homo economicus*, rational and narrowly self-interested in his exact optimization of clearly defined objectives. The term *bounded rationality* is used to designate rational choice that takes into account the cognitive limitations of both knowledge and cognitive capacity. Bounded rationality is concerned with the ways in which the actual decision-making process influences decisions. In particular, the modeling (problem definition) and solution processes are never ending in nontrivial situations and characterized by changes caused by the acquisition of new information, modifications of expectations, and longer time devoted to searching. More recently, interactive multi-objective optimization [37], discussed in Sect. 7, acknowledges that tentative solutions are built through an iterative process alternating phases of problem definitions, presentations of candidate solutions, evaluations by the decision maker, and modifications of his preferences. The relevance of the “test and learn” approach to business, based on systematically assembled data and analysis, and of high-performance business processes as differentiation point is discussed in [27]. Opportunities for the optimization research community to contribute to data mining are summarized in [19]. A review of optimization use for data mining focussed onto customer relationship management (CRM) is presented in [60], including feature selection, active learning, DM model selection and optimization, classification using mathematical programming, clustering, and rule and constraint discovery. Limitations of current BI technologies are discussed in [28], which advocates supporting tools for systematically capturing business requirements to be translated into optimized designs, in particular automated or semi-automated ways to help in dealing with the complexity of business data integration and processes. Reactive components capable of monitoring operational processes to allow DMs to tune their actions according to the company strategy and real-time data are proposed in [39]. Real-time business intelligence taking actions in response to analysis results is proposed in [3], while autonomic self-optimization for e-commerce is used in [2]. The integration of business intelligence and knowledge management is reviewed in [26]. Emerging trends in business analytics including integration with action and measurements in an incremental and cyclic manner, real-time BI and business performance management, and knowledge discovery in databases are considered in [50, 78].

A related and growing area is that of “Learning and Intelligent OptimizatioN” (LION); see [16] and the other proceedings of the LION conference. The large variety of heuristic algorithms for hard optimization problems raises issues related to selecting the most appropriate method, in many cases through an expensive

algorithm configuration and parameter tuning process, and subject to a steep learning curve. LION aims at designing and engineering ways of “learning” about the performance of different techniques and ways of using past experience about the algorithm behavior to improve performance in the future. Intelligent learning schemes for mining the knowledge obtained from different runs or during a single run can improve the algorithm development and design process and simplify the applications of high-performance optimization methods. Combinations of algorithms can further improve the robustness and performance of the individual components, provided that sufficient knowledge of the relationship between problem instance characteristics and algorithm performance is obtained. Most of the LION techniques are relevant for many business intelligence applications.

The following part of this chapter will mention the main research results and directions related to using optimization techniques for relevant RBI applications. A mixture of combinatorial and continuous optimization techniques, depending on the specific problem, is the characteristic of RBI, and it reflects the complexity of the real world of business. Completeness in this huge area is beyond the limited scope of this chapter. A more detailed presentation of some topics, in particular related to combining interactive visualization with problem solving, is present in the authors’ recent book [11] and in the recent paper [20].

The following description is organized around some paradigmatic problems and issues encountered in business applications, with references to some representative research papers.

2 Clustering

A first motivation to consider computer-assisted analysis and decision methods is related to the growing amount of data generated daily in modern business environments. The human decision maker represents a bandwidth bottleneck unless the raw data is reduced to a quantity which he can handle. The role of models is indeed that of describing in a summarized—and understandable—way a large number of related entities. *Clustering* is an extremely used and effective technique to reduce the number of items under consideration by grouping similar items together. Actually, giving names (labels) to different cases in a human understandable ways is an application of clustering, although in some cases names are not required. Clustering means identifying structure in the data which is often hidden and non-obvious, collecting similar or related entities together, often identifying important dimensions capturing most of the data diversity. In many cases, a prototype for each cluster (e.g., a cluster centroid) is sufficient to describe an entire cluster and to reason about it, in this manner reducing the information overload. Relevant business applications of clustering are in marketing, when huge number of customers can be reduced to a selected number of classes to be handled by specific marketing campaigns, in social network analysis and identification of communities (e.g., in the web), in collaborative recommendation, in the grouping of search results, and in the analysis of shopping items.

Clustering techniques are usually separated between bottom-up (agglomerative) and top-down techniques. There are two different contexts in clustering, depending on the source of information guiding the process. In some cases one starts from an *internal representation* of each entity (typically an M -dimensional vector \mathbf{x}_d assigned to entity d) and derives mutual dissimilarities or mutual similarities from the internal representation. In this case one can derive *prototypes* (*or centroids*) for each cluster, for example, by averaging the characteristics of the contained entities (the vectors). In other cases only an *external representation* of dissimilarities is available, and the resulting model is an undirected and weighted graph of entities connected by edges. This short summary concentrates on hard and top-down clustering, where “hard” means that each entity belongs to one and only one cluster.

The effectiveness of a clustering method depends on the *similarity metric* between items \mathbf{x} and \mathbf{y} , $\delta(\mathbf{x}, \mathbf{y})$, which needs to be strongly problem dependent. If an internal representation is present, a metric can be derived by the usual Euclidean distance:

$$\delta_E(\mathbf{x}, \mathbf{y}) = \|\mathbf{y} - \mathbf{x}\|$$

In the general case, a positive definite matrix \mathbf{M} can be determined to transform the original metric:

$$d_{ij} = \sqrt{(\mathbf{x}_i - \mathbf{x}_j)^T \mathbf{M} (\mathbf{x}_i - \mathbf{x}_j)}$$

An example is the Mahalanobis distance [55].

2.1 Hard and Soft Clustering

The *hard clustering problem* consists of partitioning the entities D into k disjoint subsets $C = \{C_1, \dots, C_k\}$ to reach the following objectives:

- Minimization of the average intra-cluster dissimilarities:

$$\min \sum_{d_1, d_2 \in C_i} \delta(\mathbf{x}_{d_1}, \mathbf{x}_{d_2}). \quad (1)$$

If an internal representation is available, the cluster centroids \mathbf{p}_i can be derived as the average of the internal representation vectors over the members of the i -th cluster $\mathbf{p}_i = (1/|C_i|) \sum_{d \in C_i} \mathbf{x}_d$.

In these cases the intra-cluster distances can be measured with respect to the cluster centroid \mathbf{p}_i , obtaining the related but different minimization problems:

$$\min \sum_{d \in C_i} \delta(\mathbf{x}_d, \mathbf{p}_i). \quad (2)$$

- Maximization of inter-cluster distance. One wants the different clusters to be clearly separated.

As one can imagine, the various objectives are not always compatible, clustering is indeed a *multi-objective optimization* task. It is left to the final user to weigh the importance of achieving clusters of very similar entities *versus* achieving clusters which are well separated, also depending on the chosen number of clusters.

Divisive algorithms are among the simplest clustering algorithms. They begin with the whole set and proceed to divide it into successively smaller clusters. One simple method is to subdivide the data set into k subsets.

If one wants to have groups of entities represented by a single vector, obtaining a more *compact* way to express them, a suitable approach is to select the prototypes which minimize the average *quantization error*, the error incurred when the entities are substituted with their prototypes:

$$\text{Quantization Error} = \sum_d \|\mathbf{x}_d - \mathbf{p}_{c(d)}\|^2, \quad (3)$$

where $c(d)$ is the cluster associated with data d .

In statistics and machine learning, *k-means clustering* is a method of cluster analysis which aims at partitioning the observations into k clusters represented by *centroids* (prototypes for cluster c , denoted as \mathbf{p}_c), so that each observation belongs to the cluster with the *nearest* centroid. The iterative method to determine the prototypes in *k-means* consists of the following steps:

1. Randomly generate k clusters and determine the cluster centroids \mathbf{p}_c or directly generate k random points as cluster centroids.
2. Repeat the following steps until some convergence criterion is met: usually when the last assignment has not changed, or a maximum number of iterations has been executed.
 - a. Assign each point \mathbf{x} to the nearest cluster centroid, the one minimizing $\delta(\mathbf{x}, \mathbf{p}_c)$.
 - b. Recompute the new cluster centroid by averaging the points assigned in the previous step:

$$\mathbf{p}_c \leftarrow \frac{\sum_{\text{entities in cluster } c} \mathbf{x}}{\text{number of entities in cluster } c}.$$

K-means clustering can be seen as a skeletal version of the *expectation maximization* algorithm, a method for finding maximum likelihood or maximum a posteriori (MAP) estimates of parameters in statistical models, where the model depends on unobserved latent variables. EM is an iterative method which alternates between performing an expectation (E) step, which computes the expectation of the log-likelihood evaluated using the current estimate for the latent variables, and a maximization (M) step, which computes parameters maximizing the expected log-likelihood found on the E step [57]. Scaling of EM to large databases is considered, for example, in [18].

Hard clustering and k -means are related to some classic combinatorial optimization problems. Hyper-graph partitioning for finding association rules is proposed in [42]: a weighted hyper-graph represents the relationships between items and partitioning identifies highly related items. Graph partitioning is used for clustering in [17] for web documents clusterization. RSO methods for graph and hyper-graph partitioning are considered in [10]. To mention some relevant applications, He et al. [44] considers spectral graph partitioning methods based on the normalized cut measure [66] to identify topics (communities) in the web. Efficient clustering techniques for spatial data mining (with spatial attributes related to maps, satellite images, etc.) including randomized search techniques are considered in [59]. An extended survey of clustering techniques applied to data mining, including relevant BI applications like CRM is presented in [13], and includes an updated discussion of general algorithmic issues like assessment of results, choice of number of clusters, data preparation, proximity measures, and handling of outliers.

Clustering is example of *unsupervised learning*, one searches for structure in the data without the need of a teacher labeling a set of example data. In fact, in clustering, giving names (labels) to the clusters is not part of the process and must be dealt with in a second step, if needed. The advantage of most clustering techniques is that they are simple to implement and easy to explain in a manner similar to *case-based reasoning* (CBR): a human explanation for a cluster is the prototype (centroid) associated to the cluster. In marketing, this represents the typical characteristics of a customer in a specific group.

More sophisticated clustering techniques can be obtained as a side effect of projecting data to a lower-dimensional space (usually two-dimensional) with constraints intended to enforce the similarity of points mapped to close low-dimensional positions. For example, a *self-organizing map* (SOM) is a type of artificial neural network that is trained by using unsupervised learning to produce a two-dimensional representation of the training samples, called a map. This model was introduced as an artificial neural network by Teuvo Kohonen and is also called a *Kohonen map* [51]. The extension to discrete symbol strings is presented in [52].

2.2 Visualization by Linear Transformations

In *exploratory data analysis* of entities, it is often useful to map them to two dimensions, so that they can be analyzed by our eyes. The mapping has to preserve as much as possible the relevant information present in the original data, describing *similarities and diversities* between entities. A discussion of visualization for knowledge discovery and exploration is present in [25], with particular emphasis on hierarchical clustering. The integration of constraint-based and multidimensional mining into a unified interactive and exploratory framework is present in [43].

To establish a suitable notation, let the n entities be characterized by some mutual dissimilarities δ_{ij} . Some of the dissimilarities may be unknown. An appropriate model is an undirected graph, in which each entity is represented by a node, and a connection with weight δ_{ij} is present between two nodes, if and only if a distance d_{ij} is defined for the corresponding entities. The set of edges in the graph is denoted by E .

A way to distinguish the different contexts has to do with the *level of supervision* in the visualization, that is, the type of hints given to the process. The type of supervision ranges from a purely *unsupervised* approach (only coordinates are given) to a *supervised* approach (relationships or dissimilarities are fully specified) and to mixed approaches combining unsupervised exploration in the vector space of coordinated and labeling methods.

Methods derived from linear algebra include traditional techniques like principal component analysis (PCA), see [62] for an application to vendor selection, and Fisher linear discrimination, a critical assessment is present in [31]. The following part concentrates on the methods based on more general *nonlinear* mappings which are more challenging and requiring advanced optimization methods.

2.3 Visualizing Graphs and Networks by Nonlinear Maps

An appropriate model for this situation is an *undirected weighted graph* $G(V, E)$, given by a set of vertices (or nodes) V , and edges $E \subset V \times V$, in which each entity is represented by a node, and a connection (i, j) labeled d_{ij} is present between two nodes if and only if a dissimilarity is defined for the corresponding entities.

The problem is the following: given a set of (positive) dissimilarities d_{ij} between items, find the two-dimensional or three-dimensional coordinates p_i for all items that provide a convenient placement of such items on the plane. The simplest approach is *stress minimization*. A straightforward error measure can be defined to quantify by how much the distances in the plane are different with respect to the original dissimilarities. For simplicity, consider a two-dimensional visualization.

Let $\delta_{ij} = \|p_i - p_j\|$ be the distance between the coordinates of items i and j on the plane. A natural “global mapping error” can be defined as the sum of the individual errors, squared:

$$\sum_{(i,j) \in E} (d_{ij} - \delta_{ij})^2.$$

Additional flexibility can be obtained by adding an arbitrary weight w_{ij} representing the impact that an individual error has on the overall stress:

$$\text{Global Mapping Error} = \text{Stress} = \sum_{(i,j) \in E} w_{ij} (d_{ij} - \delta_{ij})^2. \quad (4)$$

For example, if $w_{ij} = 1/d_{ij}^2$, one considers the *relative errors* $(\delta_{ij} - d_{ij})/d_{ij}$ instead of the absolute errors.

Obtaining low error values means that many distances tend to be rather close to the original ones. In other words, the problem is now to *minimize* the global mapping error measure by changing the point positions p_i . There is a physical model related to minimizing the above *global mapping error*, where points are connected by springs of strength related to the mutual similarity, and this explains the widely used term *stress* to denote the function to be minimized. This model leads to what is called the *force-directed approach* for drawing graphs. Methods based on this approach consist of two main components. The first is the *model that quantifies the quality of a drawing* (or of the two-dimensional map if you prefer a more technical term). The second is an *optimization method* for computing a drawing that is locally optimal with respect to this model. The resulting final layout brings the system to equilibrium, where the total force on each vertex is zero or, equivalently, the potential energy is locally minimal with respect to the vertex positions.

Introducing additional terms in the global mapping error function is in some cases crucial to obtain smoother and less entangled drawings. For example, one can complete the distance matrix by the *shortest path* calculation. All distances between nodes which are not directly connected are set equal to the *shortest path* between such nodes.

More complex functions to be minimized for graph layout consider *additional aesthetic criteria*, like minimizing the number of edge crossings, or guaranteeing a certain minim angle between edges connected to a node (small angles make readability difficult), or allowing curved edges. A complete enumeration is out of the scope of this introductory chapter. In all cases, after defining in quantitative terms a suitable compromise between the desirable aesthetic criteria, one has to search for an effective minimization algorithm, in most cases looking for an approximate but fast solution. For example, graph layout is considered for visualizing online activity in e-commerce in [30] and for visualizing semantic meta-data and ontologies in information management systems in [58].

3 Supervised Learning

A separate class of business intelligence models is the so-called *predictive models*. The objective is to predict an output value (e.g., a classification). Predictive models can be used in *what-if* scenario analysis, to reason about the effects of different possible decisions. In many cases the model is built by starting from labeled data. In this case one talks about *supervised learning*: a system is trained by a supervisor (teacher) giving *labeled examples*. Each example is a vector of input parameters x called *features* with an associated output label y . Features are the individual measurable properties of the phenomena being observed.

In *classification* (recognition of the class of a specific object described by features x), the output is a suitable code for the class. To take care of indecision, a

real-valued output ranging between zero and one can be interpreted as the posterior probability for a given class, given the input values. In *regression*, the output is from the beginning of a real number, and the objective is to model the relationship between a dependent variable (the output y) and one or more independent variables (the input features x).

3.1 Learning from Labeled Examples: Minimization and Generalization

By using the examples, a supervised learning method builds an association $y = \hat{f}(x)$ between input x and output y . The association is selected within a flexible model $\hat{f}(x; w)$, where the flexibility is given by some tunable parameters—or weights— w , and the best choice for the value w^* of the parameter depends on the examples analyzed.

The learned model has to work correctly on the examples in the *training set*, and this requires that the error between the correct answer (given by the example label) and the outcome predicted by the model is minimized. Supervised learning therefore becomes *minimization of a specific error function*, depending on parameters w . If the function is differentiable, a simple but effective approach is the traditional *gradient descent*; this is in fact the popular technique in neural networks known as learning by *back-propagation* of the error [79]. If the weights are quantized (actually real numbers are always discretized when represented as floating point numbers in a computer) and a suitable representation like Gray coding is used, combinatorial techniques like reactive search optimization method can be used for the training process [9].

Now, minimization of an error function is a first critical component, but not the only one. If the complexity (the flexibility, the number of tunable parameters) of the model is too large, learning the examples with zero errors becomes trivial, but predicting outputs for new data may fail brutally. This is related to the *bias-variance* dilemma and requires care in model selection or minimization of a weighted combination of model error plus model complexity. The preference of simple models to avoid overcomplicated models has also been called *Occam's razor*, referring to “shaving away” unnecessary complications in theories.

A summary of the main techniques used in supervised learning, with a focus on optimization techniques, follows. To fix the notation, a training set of ℓ tuples is considered, where each tuple is of the form (x_i, y_i) , $i = 1, \dots, \ell$, $x_i \in R^d$ being a vector of input parameter values, y_i being the measured outcome to be learned by the algorithm.

It is useful to distinguish between two families of methods for supervised classification. *Generative methods* try to model the process by which the measured data x are generated by the different classes y . In other words, one learns a class-conditional density $p(x|y)$. Then, given a fresh measurements, an assignment can be made by maximizing the posterior probability of a class given a measurement,

obtained by Bayes theorem:

$$p(y|x) = \frac{p(x|y)p(y)}{\int_y p(x|y)p(y)} \quad (5)$$

where $p(x|y)$ is known as the likelihood of the data and $p(y)$ is the prior probability, which reflect the probability of the outcome before any measure is performed.

Discriminative algorithms do not attempt at modeling the data generation process, they just aim at directly estimating $p(y|x)$, a problem which is in some cases simpler than the two-step process implied by generative methods. Multilayer perceptron neural networks, as well as support vector machines (SVM) are examples of discriminative methods.

3.2 Nearest Neighbors Methods

A basic form of learning, a.k.a. *instance-based learning* or *case-based* or *memory-based*, works as follows. The examples are stored and no action is taken until a new input pattern demands an output value. These systems are called *lazy learners*: they do nothing but storing the examples until the teacher interrogates them. When a new input pattern arrives, the memory is searched for examples which are *near* the new pattern, and the output is obtained by retrieving the stored outputs of the close patterns.

A simple version is that the output for the new input is simply that of the *closest* example in memory. A more robust and flexible technique considers a set of k nearest neighbors instead of one, called *k -nearest-neighbors* (KNN). In the *weighted k -nearest-neighbors* technique (WKNN), the weights determining the linear combination to obtain the predicted output as a function of the nearest neighbors output depend on the distance. The WKNN algorithm is simple to implement, and it often achieves low estimation errors. Its main drawbacks are the massive amounts of memory required and the computational cost of the testing phase. A way to reduce the amount of memory required considers clustering the examples and then storing only the prototypes (centroids) of the identified clusters.

Kernel methods and locally weighted regression can be seen as flexible and smooth generalizations of the nearest-neighbors idea; instead of applying a brute exclusion of the distant points, all points contribute to the output but with a significance (“weight”) related to their distance from the query point.

3.3 Linear Regression

A linear dependence of the output from the input features is a widely used model. The hypothesis of a linear dependence of the outcomes on the input parameters can

be expressed as

$$y_i = w^T \cdot x_i + \varepsilon_i,$$

where $w = (w_1, \dots, w_d)$ is a (column) vector of *weights* to be determined and ε_i is the error, which is normally assumed to have Gaussian distribution. The weight vector w must be found so that the linear function

$$\hat{f}(x) = w^T \cdot x \quad (6)$$

approximates as closely as possible our experimental data. This goal is achieved by finding the vector w^* that minimizes the sum of the squared errors:

$$\text{error}(w) = \sum_{i=1}^{\ell} (w^T \cdot x_i - y_i)^2. \quad (7)$$

By equating the gradient to zero, one obtains the following optimal value for w :

$$w^* = (X^T X)^{-1} X^T y \quad (8)$$

where $y = (y_1, \dots, y_\ell)$ and X is the matrix whose rows are the x_i vectors. The matrix $(X^T X)^{-1} X^T$ is called *pseudo-inverse*.

3.3.1 Dealing with Nonlinear Dependencies

A function in the form $f(x) = w^T x$ is too restrictive to be useful in most cases. To admit nonlinear dependencies while remaining in the (easier) context of linear least-squares approximations, the linear model can be applied to *nonlinear features* calculated from the raw input data instead of the original input.

It is possible to define a set of functions

$$\phi_1, \dots, \phi_n : R^d \rightarrow R^n$$

that map the parameters space into some more complex space, in order to apply the linear regression to the vector $\phi(x) = (\phi_1(x), \dots, \phi_n(x))$ rather than to x directly.

More precisely, a dependence will be given by a scalar product between a vector of weights w and a vector of features $\phi(x)$, as follows:

$$\hat{f}(x) = w^T \cdot \phi(x).$$

The output is a weighted sum of the features. Let $x'_i = \phi(x_i)$, $i = 1, \dots, \ell$, be the transformations of the training input tuples x_i . If X' is the matrix whose rows are the x'_i vectors, then the optimal weights with respect to the least-squares approximation are computed as above:

$$w^* = (X'^T X')^{-1} X'^T y. \quad (9)$$

3.3.2 Preventing Numerical Instabilities

When the number of examples is large, Eq. (9) is the solution of a linear system in the overdetermined case (more linear equations than variables). In particular, matrix $X^T X$ must be nonsingular, and this can only happen if the training set points x_1, \dots, x_ℓ do not lie in a proper subspace of \mathbb{R}^d . In many cases, even though $X^T X$ is invertible, the distribution of the training points is not generic enough to make it *stable*. *Stability* here means that small perturbations of the sample points lead to small changes in the results. The standard mathematical tool to ensure numerical stability consists of the addition of a *regularization* term to the (least squares) error function to be minimized:

$$\text{error}(w; \lambda) = \sum_{i=1}^{\ell} (w^T \cdot x_i - y_i)^2 + \lambda w^T \cdot w.$$

The minimization with respect to w leads to the following:

$$w^* = (\lambda I + X^T X)^{-1} X^T y.$$

The insertion of a small diagonal term makes the inversion more robust. The theory justifying the approach is based on *Tichonov regularization*, which is the most commonly used method for curing *ill-posed* problems [71].

3.3.3 Linear Regression for Classification

Moving to *classification* problems, let the outcome variable be two-valued (e.g., ± 1). In this case, linear functions can be used as discriminants; the idea is to have a hyperplane defined by a vector w separating the two classes. The goal of the training procedure becomes that of finding the best coefficient vector w so that the classification procedure:

$$y = \begin{cases} +1 & \text{if } w^T \cdot x \geq 0 \\ -1 & \text{otherwise} \end{cases} \quad (10)$$

performs the best classification. Depending on the problem, the criterion for deciding the “best” classification changes.

3.4 Multilayer Perceptrons

A multilayer perceptron (MLP) neural network, capable on nonlinear models, is composed of a large number of highly interconnected units (*neurons*) organized in layers with a feed-forward information flow. Many training techniques have been

proposed for determining the weights. An example is the *one-step-secant* (OSS) method with fast line searches using second-order derivative information described in [4]. The time complexity of the learning phase is usually high, although it varies greatly according to the heuristic adopted for calculating the weights (usually iterative) and to the halting condition. A large number of passes is required, each involving computation of the outcome for every training set point, followed by modification of weights. On the other hand, calculating the outcome of an MLP neural network is a straightforward procedure.

3.5 Statistical Learning Theory and SVMs

As mentioned before, minimizing the error on a set of examples is not the only objective of a statistically sound learning algorithm, also the modeling architecture has to be considered. Statistical Learning Theory [74] provides mathematical tools for *deriving unknown functional dependencies* on the basis of observations. A shift of paradigm occurred in statistics starting from the sixties: previously, following Fisher's research in the 1920–1930s, in order to derive a functional dependency from observations one had to know the detailed form of the desired dependency and to determine only the values of a finite number of *parameters* from the experimental data. The new paradigm does not require the detailed knowledge and proves that some general properties of the set of functions to which the unknown dependency belongs are sufficient to estimate the dependency from the data. *Nonparametric techniques* is a term used for these flexible models, which can be used even if one does not know a detailed form of the input–output function.

A brief summary of the main methodological points of Statistical Learning Theory is useful to motivate the use of SVMs as a learning mechanism. Let $P(x, y)$ be the unknown probability distribution from which the examples are drawn. The learning task is to learn the mapping $x_i \rightarrow y_i$ by determining the values of the parameters of a function $f(x, w)$. The function $f(x, w)$ is called *hypothesis*, the set $\{f(x, w), w \in \mathcal{W}\}$ is called the *hypothesis space* and denoted by \mathcal{H} , and \mathcal{W} is the set of abstract parameters. A choice of the parameter $w \in \mathcal{W}$, based on the labeled examples, determines a “trained machine.”

The *expected test error* or *expected risk* of a trained machine for the classification case is

$$R(w) = \int \|y - f(x, w)\| dP(x, y), \quad (11)$$

while the *empirical risk* $R_{\text{emp}}(w)$ is the mean error rate measured on the training set:

$$R_{\text{emp}}(w) = \frac{1}{\ell} \sum_{i=1}^{\ell} \|y_i - f(x_i, w)\|. \quad (12)$$

The classical learning method is based on the *empirical risk minimization* (ERM) inductive principle: one approximates the function $f(x, w^*)$ which minimizes the risk in (11) with the function $f(x, \hat{w})$ which minimizes the empirical risk in (12).

The rationale for the ERM principle is that, if R_{emp} converges to R in probability (as guaranteed by the law of large numbers), the minimum of R_{emp} may converge to the minimum of R . If this does not hold, the ERM principle is said to be *not consistent*.

As shown by Vapnik and Chervonenkis [75], consistency holds if and only if convergence in probability of R_{emp} to R is *uniform*, meaning that as the training set increases the probability that $R_{\text{emp}}(w)$ approximates $R(w)$ uniformly tends to 1 on the whole \mathcal{W} . Necessary and sufficient conditions for the consistency of the ERM principle is the finiteness of the *Vapnik-Chervonenkis dimension* (VC-dimension) of the hypothesis space \mathcal{H} .

The VC-dimension of the hypothesis space \mathcal{H} is, loosely speaking, the largest number of examples that can be separated into two classes in all possible ways by the set of functions $f(x, w)$. The VC-dimension h measures the complexity and descriptive power of the hypothesis space and is often proportional to the number of free parameters of the model $f(x, w)$. The choice of an appropriate value of the VC-dimension h is crucial to get good generalization performance, especially when the number of data points is limited.

The method of *structural risk minimization* (SRM) has been proposed by Vapnik based on the above bound, as an attempt to overcome the problem of choosing an appropriate value of h . For the SRM principle, one starts from a nested structure of hypothesis spaces

$$\mathcal{H}_1 \subset \mathcal{H}_2 \subset \cdots \subset \mathcal{H}_n \subset \cdots \quad (13)$$

with the property that the VC-dimension $h(n)$ of the set \mathcal{H}_n is such that $h(n) \leq h(n+1)$. As the subset index n increases, the minima of the empirical risk decrease, but the term responsible for the confidence interval increases. The SRM principle chooses the subset \mathcal{H}_n for which minimizing the empirical risk yields the best bound on the actual risk. Disregarding logarithmic factors, the following problem must be solved:

$$\min_{\mathcal{H}_n} \left(R_{\text{emp}}(w) + \sqrt{\frac{h(n)}{\ell}} \right). \quad (14)$$

The SVM algorithm described in the following is based on the SRM principle, by minimizing a bound on the VC-dimension and the number of training errors at the same time.

The mathematical derivation of SVMs is summarized first for the case of a linearly separable problem. Assume that the labeled examples are linearly separable, meaning that there exist a pair (w, b) such that

$$\begin{aligned} w \cdot x + b &\geq 1 \quad \forall x \in \text{Class}_1 \\ w \cdot x + b &\leq -1 \quad \forall x \in \text{Class}_2. \end{aligned}$$

The hypothesis space contains the functions

$$f_{w,b} = \text{sign}(w \cdot x + b).$$

Because scaling the parameters (w, b) by a constant value does not change the decision surface, the following constraint is used to identify a unique pair:

$$\min_{i=1,\dots,\ell} |w \cdot x_i + b| = 1.$$

A structure on the hypothesis space can be introduced by limiting the norm of the vector w . It has been demonstrated by Vapnik that if all examples lie in an n -dimensional sphere with radius R , then the set of functions $f_{w,b} = \text{sign}(w \cdot x + b)$ with the bound $\|w\| \leq A$ has a VC-dimension h that satisfies

$$h \leq \min\{\lceil R^2 A^2 \rceil, n\} + 1.$$

The problem can be formulated as

$$\begin{aligned} & \text{Minimize}_{w,b} && \frac{1}{2} \|w\|^2 \\ & \text{subject to} && y_i(w \cdot x_i + b) \geq 1 \quad i = 1, \dots, \ell. \end{aligned}$$

The problem can be solved by using standard quadratic programming (QP) optimization tools. The dual quadratic program, after introducing a vector $\Lambda = (\lambda_1, \dots, \lambda_\ell)$ of nonnegative Lagrange multipliers corresponding to the constraints is as follows:

$$\begin{aligned} & \text{Maximize}_{\Lambda} && \Lambda \cdot \mathbf{1} - \frac{1}{2} \Lambda \cdot D \cdot \Lambda \\ & \text{subject to} && \begin{cases} \Lambda \cdot y = 0 \\ \Lambda \geq 0 \end{cases} \end{aligned} \tag{15}$$

where y is the vector containing the example classification and D is a symmetric $\ell \times \ell$ matrix with elements $D_{ij} = y_i y_j x_i \cdot x_j$.

If the hypothesis set is unchanged but the examples are not linearly separable, one introduces a penalty proportional to the constraint violation ξ_i (collected in vector Ξ), solving the following problem:

$$\begin{aligned} & \text{Minimize}_{w,b,\Xi} && \frac{1}{2} \|w\|^2 + C \left(\sum_{i=1}^{\ell} \xi_i \right)^k \\ & \text{subject to} && \begin{cases} y_i(w \cdot x_i + b) \geq 1 - \xi_i & i = 1, \dots, \ell \\ \xi_i \geq 0 & i = 1, \dots, \ell \\ \|w\|^2 \leq c_r; \end{cases} \end{aligned} \tag{16}$$

where the parameters C and k determine the cost caused by constraint violation, while c_r limits the norm of the coefficient vector. In fact, the first term to be

minimized is related to the VC-dimension, while the second is related to the empirical risk. (See the above described SRM principle). Often, k is set to 1. Extending the above techniques to nonlinear classifiers is based on mapping the input data x into a higher-dimensional vector of *features* $\varphi(x)$ and using *linear* classification in the transformed space, called the *feature space*. Large-scale business applications require scalable SVM implementations [48]. Text classification is considered in [47]. An example of SVM usage for real-time business intelligence is [77].

Obtaining models which are self-explanatory is of crucial importance in business, when the user demands a verbal or probabilistic explanation of the causes for reaching a specific result. The result can be a classification, an illness or the effects of pharmaceuticals in the medical field, the success of a marketing campaign, etc. *Learning causal Bayesian networks* from business data is a possibility. A Bayesian network (BN), or belief network, is a probabilistic graphical model that represents a set of random variables and their conditional dependencies via a directed acyclic graph (DAG). A theoretical negative result about the possibility to learning BN structure is demonstrated in [23]. Algorithms for learning Bayesian networks from data have two components: a scoring metric and a search procedure. The scoring metric computes a score measuring the goodness of fit of the structure to the data. The search procedure tries to identify network structures with high scores. This chapter [23] shows that the search problem of identifying a Bayesian network among those where each node has at most K parents that has a relative posterior probability greater than a given constant is NP-complete, when the BDe metric is used, computing the relative posterior probability of a network structure given data. The decision theoretic approach in [45] uses the information of observational data to learn a completed partially directed acyclic graph (a DAG) using a structure learning technique and try to discover the directions of the remaining edges by means of experiment. Their adaptive algorithm assumes that experiments are performed during learning. In general, computational algorithms for learning Bayesian network (BN) structures from experimental data are still an open challenge. For example, greedy search for optimal structure identification is used in [24]. Monte Carlo techniques to generate sample of the BN structure are considered in [32].

4 Semi-Supervised Learning

In many cases labeling examples is costly. Fortunately, one can use some information from the *unlabeled* data to improve classification, or one can use some supervised data to aid unsupervised learning and clustering.

Semi-supervised learning (SSL) uses both supervised and unsupervised data to improve performance. This brief summary and its notation derive from the introductory chapter of [22] and from [80].

The standard forms of supervision are labels associated with some examples. In this case the training set X is divided into a labeled portion $X_L = \{x_1, \dots, x_l\}$, for

which labels $Y_L = \{y_1, \dots, y_l\}$ and an unlabeled portion $X_U = \{x_{l+1}, \dots, x_{l+u}\}$ are given. Other forms of supervision can be related to constraints or *hints* given to the system [1]. For example, the hints can take the form “the output function must be growing as a function of one input coordinate,” while constraints can be formulated as “these two points must be in the same class” (*must-link*) or “these two points cannot be in the same class” (*cannot-link*).

A first idea, originated in the sixties [65] related to SSL, is the so-called self-learning or *self-labeling* method where a wrapper algorithm repeatedly uses a supervised learning method. Initially, learning is executed on the labeled examples. Then, some additional unlabeled examples are labeled by using the current trained system, and learning is repeated by adding the newly labeled examples. The effect of the wrapper depends on the supervised method enclosed, and the assumptions to make it work effectively are unclear.

A context related to SSL was introduced by Vapnik as *transductive learning*. Inductive learning wants to derive a prediction function valid for arbitrary inputs, while transductive learning just aims at predicting only a fixed set of test points, by using all available information. Usually, transductive learning is based on a *labeled graph representation of the data*, labeled nodes are classified training examples, and edges represent similarity/dissimilarity relationships or constraints. A combinatorial optimization on the labels to maximize an overall consistency measure is then performed. Because of the graph representation with edges to represent similarity a graph *mincut* problem is obtained under specific assumptions [15]. An extended literature survey is presented in [82].

In general, SSL looks promising if the unsupervised information about the density $p(x)$ is useful in deriving $p(y|x)$. By analogy with the supervised learning smoothness assumption, the *semi-supervised smoothness assumption* states that if two input points x_1 and x_2 in a *high-density region* are close, the corresponding outputs y_1 and y_2 should also be close. By transitivity, if two points are linked by a path in a high-density region (they belong to the same cluster), they should be close. If points are close but in a low-density area, the requirement that outputs are similar is less stringent.

Some SSL techniques are based on encouraging the separation between classes (the decision boundaries) to pass through low-density areas, away from most data examples.

An immediate algorithm is obtained by adopting a margin-maximization algorithm like SVM and maximizing the margin for both labeled and unlabeled examples, this is called *transductive SVM* (TSVM). To the function to be minimized, one adds a term like

$$\lambda_2 \sum_{\text{unlabeled data } i} (1 - |f(x_i)|), \quad (17)$$

$f(x_i)$ being the classification function which has to be greater than 1 for one class, less than -1 for the other class. The penalty introduced in the function is of λ_2 when $f(x_i) = 0$, and it linearly becomes equal to zero when $f(x_i)$ becomes 1 or, in the other direction, when $f(x_i)$ becomes -1 (the penalty has a triangular form

centered around zero). In other words, a penalty is incurred if an unlabeled data point falls in the “gray” boundary region where $|f(x_i)| \leq 1$: therefore unlabeled data tend to guide the linear boundary away from the dense regions. The corresponding problem is not convex, and therefore robust heuristic optimization schemes have to be adopted, for example, deterministic annealing strategies starting from an easy problem and gradually transforming it into the TSVM optimization function [68] or the continuation approach of [21] following a similar paradigm of first optimizing an “ironed” version of the function and then gradually introducing finer and finer details.

4.1 Graph-Based Algorithms

The graph-based methods for semi-supervised learning are based on representing the problem as a graph, where the nodes correspond to the examples and edges are labeled with the pairwise similarity w_{ij} of two nodes i and j .

As usual, one can think in terms of similarities or in terms of dissimilarities/distances. If the distance is calculated from an initial estimate by obtaining the *minimum-path distances* between two points, this can be seen as an approximation of the geodesic *distance of two points along the manifold* of the data points.

Matrix \mathbf{W} is introduced to represent similarities: $\mathbf{W}_{ij} = w_{ij}$ if the edge is present, zero otherwise, and the diagonal degree matrix \mathbf{D} , so that $\mathbf{D}_{ii} = \sum_j w_{ij}$.

The basic method to encourage *smoothness along light edges* (smoothness when connected nodes are similar) is related to defining and using the *graph Laplacian* operator. The normalized \mathcal{L} and un-normalized combinatorial graph Laplacian operator \mathcal{L} are defined as

$$\mathcal{L} = \mathbf{I} - \mathbf{D}^{-1/2} \mathbf{W} \mathbf{D}^{-1/2} \quad (18)$$

$$\mathbf{L} = \mathbf{D} - \mathbf{W}. \quad (19)$$

The graph Laplacian is related to the more traditional Laplace operator used for continuous functions $f(x_1, \dots, x_n)$:

$$\nabla \phi = \sum_{i=1}^n \frac{\partial^2 f}{\partial x_i^2}. \quad (20)$$

In fact, the Laplacian matrix of a lattice, when applied to the values of f at the vertices, corresponds to the finite differences approximation of the continuous operator on a regular grid of points. The Laplacian matrix of a graph can be seen as a generalization of the lattice definition.

A semi-supervised learning using Gaussian fields and harmonic function is proposed in [81]. Classification algorithms for Gaussian fields can be seen as a form of nearest-neighbor approach, where the nearest labeled examples are computed by a random walk on the graph. The method’s equations are related to electrical

networks and to spectral graph theory. The problem is represented as a graph, with some nodes labeled with $y \in \{0, 1\}$ (a binary labeling is considered for simplicity). Weighted edges represent similarities: w_{ij} is large for similar cases. For example $w_{ij} = \exp\{-\|\mathbf{x}_i - \mathbf{x}_j\|_A^2\}$ for a suitable metric. The strategy is to first compute a “smooth” real-valued function f for all nodes and then assign labels based on f . The “smoothness” desire of having similar values between similar points is expressed by formulating the problem as one of minimizing the quadratic energy function:

$$E(f) = \frac{1}{2} \sum_{i,j} w_{ij} (f(i) - f(j))^2. \quad (21)$$

The minimum energy function is *harmonic*: it satisfies $Lf = 0$ on unlabeled points and is equal to the label value on the labeled ones. L is the graph Laplacian defined above, and the harmonic property means that the value of f at an unlabeled point is equal to the weighted average of f at neighboring points:

$$f(j) = \frac{\sum_i w_{ij} f(i)}{\sum_i w_{ij}}. \quad (22)$$

In matrix notation: $f = \mathbf{P}f$, where $\mathbf{P} = \mathbf{D}^{-1} \mathbf{W}$. This is consistent with the intuitive notion of smoothness with respect to the similarity relationships. A simple rule to assign label is to label a node i with 1 if $f(i) > 1/2$, 0 otherwise. Ways to incorporate class prior knowledge (desirable proportions of the two classes) by modifying the threshold to label the nodes, as well as possible ways to learn a weight matrix \mathbf{W} from labeled and unlabeled data are described in [81].

4.2 Learning the Metric

Some semi-supervised algorithms proceed in two steps: first *a new metric or representation is identified* by performing an unsupervised step on all data (ignoring the existence of labels), then a pure supervised learning phase is executed by using the newly identified metric or representation. In many cases, when dealing with an optimization problem defined over more than one variable, a sequential method which first minimizes over the first variable, then over the second (leaving the first variable untouched), etc., gives in general a solution which can be improved if all variables are considered at the same time. This holds also for SSL. For example, the work in [14] shows how to combine constraints and metric learning into semi-supervised clustering.

Constraint-based clustering approaches start from pairwise *must-* or *cannot-link* constraints (requests that two points fall or do not fall in the same cluster) and insert into the objective function to be minimized a penalty for violating constraints. For example, the Euclidean k -means algorithm partitions the points into k sets so that the function:

$$\sum_i \|\mathbf{x}_i - \boldsymbol{\mu}_{l_i}\|^2$$

is locally minimized. In it, the vector $\boldsymbol{\mu}_{l_i}$ is the winning centroid associated with point \mathbf{x}_i , the one minimizing the distance.

If two sets of must-link pairs \mathcal{M} and cannot-link pairs \mathcal{C} are available, one can encourage a placement of the centroids in order to satisfy the constraints by adding a penalty w_{ij} for a single violation of a constraint in \mathcal{M} and a penalty \bar{w}_{ij} for a single violation of a constraint in \mathcal{C} , obtaining the following function to be minimized (*pairwise constrained k-means*):

$$E_{\text{pkmeans}} = \sum_i \|\mathbf{x}_i - \boldsymbol{\mu}_{l_i}\|^2 + \sum_{(\mathbf{x}_i, \mathbf{x}_j) \in \mathcal{M} \text{ and } l_i \neq l_j} w_{ij} + \sum_{(\mathbf{x}_i, \mathbf{x}_j) \in \mathcal{C} \text{ and } l_i = l_j} \bar{w}_{ij}. \quad (23)$$

Pairwise constraints can also be used for *metric learning*. If the metric is parameterized with a symmetric positive-definite matrix \mathbf{A} as follows:

$$\|\mathbf{x}_i - \mathbf{x}_j\|_{\mathbf{A}} = \sqrt{(\mathbf{x}_i - \mathbf{x}_j)^T \mathbf{A} (\mathbf{x}_i - \mathbf{x}_j)},$$

the problem amounts to determining appropriate values of the matrix coefficients. If the matrix is diagonal, the problem becomes that of *weighing* the different features.

After the metric is modified, one can use a traditional clustering algorithm like *k-means*. Asking for a single metric for the entire space can be inappropriate and a different metric \mathbf{A}_h can be used for each *k-means* cluster h . The MPCK-MEANS algorithm in [14] uses the method of expectation maximization and alternates between cluster assignment in the E-step and centroid estimation and metric learning in the M-step. Constraints are used during cluster initialization and when assigning points to clusters. The distance metric is adapted by reestimating \mathbf{A}_h during each iteration based on the current cluster assignment and constraint violations. An interesting paper dealing with metric learning for text documents is [53].

5 Text and Web Mining

When the data consist of a collection of nonnumerical elements, for example, documents, many of the techniques used to analyze numerical data are still available, but they need to be adapted by suitably preprocessing the documents and fine tuning the methods. *Information visualization* denotes the visual representation of large-scale collections of nonnumerical information, such as files and lines of software, library and bibliographic databases, and social networks.

Information retrieval deals mostly with searching for documents and for information within documents, and *web mining* is related to adapting methods to the context of the World Wide Web. The web is an *unstructured* (or, at most, *semi-structured*) collection of data mostly in form of human readable texts and images, connected by hyperlinks.

5.1 From Documents to Vectors: The Vector-Space Model

To use standard techniques designed for vector spaces to search, cluster, and classify documents, each document is mapped onto a vector (the *vector-space model*). After preprocessing, the document is reduced to a *bag of words*, actually a bag of tokens, and the most straightforward way to obtain a vector is to (a) fix a set of terms (tokens), (b) have a separate axis to represent each term (token), and (c) set the value of the vector along the axis t to zero if the document does not contain the token t , to a number greater than zero if the document contains the token one or more times.

If $n(d, t)$ is the number of times that document d contains the term t , the *term frequency* $\text{TF}(d, t)$ of term t in document d is defined as a figure that increases monotonically with the relative frequency of t in d . Some possible definitions are the following:

$$\begin{aligned}\text{TF}(d, t) &= \frac{n(d, t)}{\sum_{\tau} n(d, \tau)} \\ \text{TF}_{\text{SMART}}(d, t) &= \begin{cases} 0 & \text{if } n(d, t) = 0 \\ 1 + \log(1 + \log n(d, t)) & \text{otherwise.} \end{cases}\end{aligned}$$

The TF_{SMART} formula is meant to avoid an exaggerated value along a dimension if a term is present too many times. This was a frequent case in the initial years of the web, when simple search engines were just counting term occurrences. Actually, often the most interesting terms are the ones which do not appear in many documents (rare terms), and an *inverse document frequency* can be defined as a figure that monotonically *decreases* as the overall frequency of a term in the whole document corpus increases:

$$\text{IDF}(t) = \log \frac{1 + |D|}{|D_t|},$$

where D_t is the set of documents containing term t and the logarithm is used to avoid an exaggerated multiplier for very rare terms. After discounting the importance of weak terms appearing in too many documents, a specific document d in TFIDF-space (term-frequency inverse-document-frequency) is represented by vector

$$d = (d_t)_{t \in \text{terms}} \in \mathbb{R}^{\text{terms}},$$

where component d_t is

$$d_t = \text{TF}(d, t) \text{ IDF}(t).$$

A query q is a sequence of terms; therefore, it admits a representation $q = (q_t)$ in the same space as documents. Given the query q and the document d , one can now measure their proximity, by considering vector-space similarity measures.

The analysis of *social networks* of employers, customers, and business units is another interesting method in business intelligence. In particular, ranking nodes in

the network, assigning a measure of importance, is critical in many applications. After a seminal paper by Marchiori [56] highlighting the importance of *hyper-information* (information in the hyperlinks), Larry Page and Sergey Brin developed the PageRank algorithm, which follows the same basic social networks principles, by substituting “recommendations” and “citations” with hyperlinks [61]. They define a “measure of prestige” such that the prestige of a page is related to how many pages of prestige link to it. Note that this is a *recursive definition*.

After defining a matrix which derives from the graph of links between documents, a stationary solution is obtained by calculating the eigenvector of the matrix corresponding to the largest eigenvalue. Of special importance are iterative techniques which can be applied to huge networks and matrices.

6 Collaborative Filtering and Recommendation

A possible application of business intelligence techniques related to having a network of consumers is called *collaborative recommendation*. Word of mouth has always been a powerful and effective technique to spread information and opinions from person to person, in a viral manner. It is effective because human beings naturally tend to speak with people similar to them, who share their habits, opinions, and way of life. By choosing to interact with a selected and small number of similar people, persons effectively *filter* the data. It is then up to them to integrate and weigh the information that they receive, to reach their final decisions. A similar process can be simulated through data mining and modeling methods.

An interesting application is in the marketing sector: data collected about users and products, either bought or at least evaluated, can be used to estimate how a customer would evaluate a product he did not see before.

Collaborative filtering and recommendation is a method of predicting the interests of a person by collecting taste information from many other collaborating people.

A simple method to predict an unknown rating r_{ui} considers the ratings of other users on the same item i and the *similarity* between user u and other users. A generic unknown rating r_{ui} is calculated by the following equation:

$$r_{ui} = \frac{\sum_{\text{known } r_{ki}} \text{similarity}(u, k) \cdot r_{ki}}{\sum_{\text{known } r_{ki}} \text{similarity}(u, k)}. \quad (24)$$

The vote is predicted with a weighted average of the other users’ votes, with weights given by similarities. The *sparsity* of the raw user-item evaluation matrix can be a problem. Each users evaluates only a very small subset of items and most entries are unknown. By *compressing and summarizing the user characteristics* into

a much smaller vector, one hopes to reach better generalization results and possibly a better understanding of the model, as explained by the Occam's razor principle.

A possible way to determine the interest or the vote of a user for an item is to associate a small vector of characteristics with each user and with each item and then deriving votes by observing the similarity between the user and item characteristic vectors. Vector $q_i \in \mathfrak{N}^f$ will be defined to contain the characteristics (factors) of item i , and vector $p_u \in \mathfrak{N}^f$ to denote the extent of interest that user u has in each item factor. One would like to obtain the rating of a user u for an item i by a simple scalar product of the corresponding vectors:

$$\hat{r} = q_i^T p_u. \quad (25)$$

Among automated ways to build effective factors to predict ratings, the traditional singular value decomposition (SVD) can be used to find informative q_i 's and p_u 's. By using SVD, one decomposes a matrix R containing *all* ratings as $R = U\Sigma M^T$, where the rows of matrix U and M are the set of p_u and q_i , scaled by the diagonal matrix Σ . By considering the size of the diagonal values in Σ , one can then reduce the dimension of the vectors and keep only the most relevant components. Unfortunately, in most cases one does *not* have the value of all cells in the rating matrix. More flexible and robust learning algorithms based on optimization can be adopted to find effective approximations of the factor vectors q_i and p_u . As usual, examples of expressed votes guide the learning process: to learn the factor vectors q_i and p_u , one aims at minimizing the *regularized squared error (RSE)* on the set of *known* ratings:

$$\text{RSE} = \frac{1}{|K|} \sum_{(u,i) \in K} (r_{ui} - q_i^T p_u)^2 + \lambda(\|q_i\|^2 + \|p_u\|^2). \quad (26)$$

Here, K is the set of the (u, i) pairs for which r_{ui} is known (the training set). The first term in the summation is the squared error between the model $q_i^T p_u$ and the known result r_{ui} . To facilitate *generalization* (prediction of novel ratings), it is useful to penalize the magnitudes of the factor vectors in a manner proportional to a constant λ . This term is called a *regularizing term*. When example ratings abound, most of the contribution to RSE derives from errors in reconstructing the expressed votes. On the other hand, when ratings are scarce, the regularizing term becomes crucial and it acts to discourage very large vectors with potentially dramatic (and wrong) effects on the predictions. The problem is now one of minimizing a continuous function of the free parameters p_u and q_i .

Other examples of discrete structures related to identification problems and learning are related to industrial and business processes. The task is known as *process mining*. Process mining techniques [72,73] extract process information from event logs. For example, the audit trails of a workflow management system or the transaction logs of an enterprise resource planning (ERP) system can be used to discover models describing processes, organizations, and products. Petri nets [64]

are a widely used modeling tool. Relevant problems in process mining are NP-hard; the work in [38] shows that the computational problem of finding a minimum finite-state acceptor compatible with given data is NP-hard. Suitable heuristic optimization schemes are used, for example, in [40, 41].

7 Multi-Objective Optimization and Pareto Optimality

Consider now one of the most expensive and crucial issue in business intelligence: that of building a suitable model. If the tool is optimization, it must work on a suitable function to be optimized, which is hard, costly, and time-consuming to be defined. Consultants are aware that most of their time is spend on working with the customer to define the model, not to solve it. A traditional formulation which recognizes that a detailed function can be missing is as a *multi-objective optimization problem* (MOOP), which assumes partial knowledge in the form of a series of desirable objectives, but lack of their detailed combination into a comprehensive *utility function*. A MOOP can be stated as

$$\begin{aligned} & \text{minimize } \mathbf{f}(\mathbf{x}) = \{f_1(\mathbf{x}), \dots, f_m(\mathbf{x})\} \\ & \text{subject to} \quad \mathbf{x} \in \Omega, \end{aligned}$$

where $\mathbf{x} \in \mathbb{R}^n$ is a vector of n decision variables and $\Omega \subset \mathbb{R}^n$ is the *feasible region* and is typically specified as a set of constraints on the decision variables.

The vector $\mathbf{f} : \Omega \rightarrow \mathbb{R}^m$ is made of m objective functions which need to be jointly minimized. Objective vectors are images of decision vectors and can be written as $\mathbf{z} = \mathbf{f}(\mathbf{x}) = \{f_1(\mathbf{x}), \dots, f_m(\mathbf{x})\}$. The above problem is ill-posed whenever objective functions are conflicting, a situation which typically occurs in real world applications. In these cases, an objective vector is considered optimal if none of its components can be improved without worsening at least one of the others. An objective vector \mathbf{z} is said to *dominate* \mathbf{z}' , denoted as $\mathbf{z} \prec \mathbf{z}'$, if $z_k \leq z'_k$ for all k and there exist at least one h such that $z_h < z'_h$. A point $\hat{\mathbf{x}}$ is *Pareto optimal* if there is no other $\mathbf{x} \in \Omega$ such that $\mathbf{f}(\mathbf{x})$ dominates $\mathbf{f}(\hat{\mathbf{x}})$. The *Pareto frontier* (or Pareto front) consists of all Pareto-optimal points and is particularly useful in decision making: by restricting attention to the set of choices that are Pareto-efficient, a designer can make tradeoffs within this set, rather than considering the full range of every parameter. A critical review of MOOP in data mining is considered in [36]. No single criterion exists to judge models, but different measures, like precision, recall, simplicity, and unexpectedness (surprisingness) [35]. A rule like “IF (patient is pregnant) THEN (gender is female)” is accurate and simple but not very surprising. An explicit MOOP formulation empowers the decision maker with the freedom to guide the final solution towards his detailed goals in a systematic and explicit manner.

As mentioned, asking a user to quantify his utility function (e.g., by choosing weights of a linear combination of the different objectives) *a priori*, before seeing

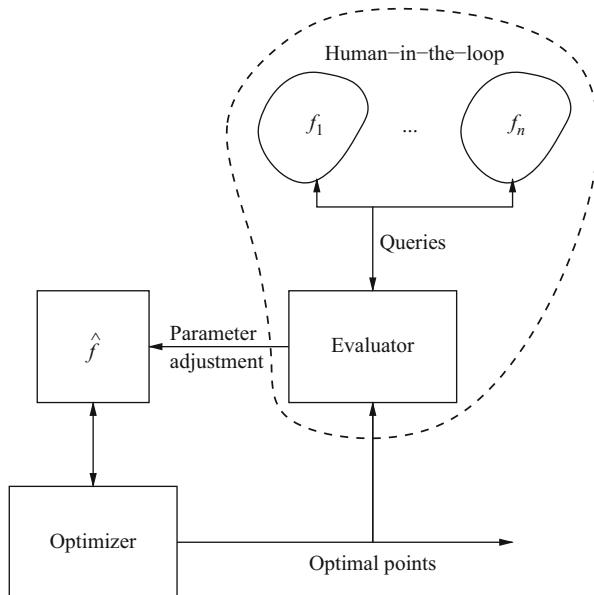

Fig. 1 Brain–computer optimization: learning the problem definition from the final user in the case of interactive multi-objective optimization (adapted from [6])

the actual optimization results, is in some cases extremely difficult. If the final user is cooperating with an optimization expert, misunderstanding between the persons may arise. This problem can become dramatic when the number of the conflicting objectives in MOOP increases. As a consequence, the final user may be dissatisfied with the solutions presented by the optimization expert. Different drawbacks are present in *a posteriori* approaches, which present to the final user a representative set of solutions on the entire Pareto front so that the user can pick his most preferred solution.

Although providing explicit weights and mathematical formulas can be difficult for the user, for sure he can *evaluate the returned solutions*. In most cases, the strategy to overcome this situation consists of a joint interactive work between the final user and the optimization expert to change the definition of the problem itself. The optimization tool will then be re-executed over the new version of the problem. This process may be iterated an arbitrary number of times, as shown in Fig. 1.

As mentioned, as a rule of thumb, most of the problem-solving effort in the real world is spent on *defining the problem*, on specifying in a computable manner the function to be optimized. After this modeling work is completed, optimization becomes in certain cases a commodity. The implication for researchers and developers is that much more effort should be devoted to designing supporting techniques and tools to help the final user, often without expertise in mathematics and in optimization, to define and refine the function to be optimized which corresponds to his real objectives.

Reactive search optimization is dedicated to online learning techniques to support the quest for a solution by self-adapting a local search method in a manner depending on the previous history of the search. The learning signals consist of data about the structural characteristics of the instance collected while the algorithm is running, for example, data about sizes of basins of attraction, entrapment of trajectories, and repetitions of previously visited configurations. The algorithm learns by interacting from a previously unknown environment given by an existing (and fixed) problem definition.

It can be argued that there is a second interesting online learning loop, where learning signals originate from a final user and are intended to *modify and refine the problem definition* itself. This context is potentially very wide, depending on the amount of knowledge about the problem given a priori, on the allowed modifications, on the form of the questions posed to the user.

An example of interactive multi-objective optimization with RSO is described in [6]. The methods considered in our approach share with the work in [29, 70, 83] the interaction with the final user realized via pairwise comparison of solutions but tackles a broader class of problems with nonlinear preference functions. This case is of interest because many (maybe most) decision problems are *nonlinear*, to reflect our preference for reasonable compromise solutions. The reader interested in state of the art results for learning arbitrary (*nonlinear*) models may consider reading the recent technical publication [7].

The focus here is on the simpler and classical linear case [6], and the goal consists of *learning the non-dominated solution preferred by the final user*. Assume that the user provides the different objectives in the MOOP problem, but he cannot quantify the *weights* of the different objectives before seeing the actual optimization results. The system aims at learning the weights vector $w = (w_1, w_2, \dots, w_m)$ optimizing the linear combination g :

$$g(x, w) = w_1 f_1(x) + w_2 f_2(x) + \dots + w_m f_m(x).$$

In a more compact form:

$$g(x_1, x_2, \dots, x_n, w) = f(x)^T w$$

where $f = (f_1, f_2, \dots, f_m)$. Without loss of generality, assume that g must be minimized.

The feedback from the decision maker at each iteration is obtained by presenting two solutions and asking him to indicate his favorite solution among them, if any. The preferences stated by the final user are translated into *constraints* that the weights must satisfy. This guarantees that the obtained utility function is consistent with the user's judgments. If $a = (a_1, a_2, \dots, a_n)$ and $b = (b_1, b_2, \dots, b_n)$ are the two solutions provided by the system, the preference $a \prec b$ of the final user for the solution **a** w.r.t. the solution **b** is represented by the following constraint:

$$g(a, w) < g(b, w).$$

The problem of learning the user preference then becomes that of finding a solution w for the set of constraints on the weights generated by the user's feedback.

All the weights are initialized with random values in the interval $(0,1)$ and then normalized so that their sum is 1. At each iteration, two non-dominated solutions a and b are compared by the final user. Both solutions are obtained by minimizing a linear combination of the objective functions of the input problem:

$$\min_x g(x, w).$$

In particular, the first solution \mathbf{a} is obtained by using the current weights vector w^{curr} found by applying the *middlemost weights* technique [63], by solving the following linear programming problem:

$$\begin{aligned} \max_w \quad & \gamma \\ \text{subject to} \quad & \begin{cases} g(a, w) \leq g(b, w) - \gamma & \forall a \prec b \\ w_i \geq \gamma & \forall i = 1, \dots, m \\ \gamma \geq 0. \end{cases} \end{aligned}$$

The meaning of the above is to search for a weight which is *consistent* but also *far from the boundaries* of the consistent region. The bigger the positive γ parameter, the safer the inequalities. Even if limited noise is added (e.g., caused by physical quantities with measurement errors) and the g values are slightly changed, there is still a *safety margin* before the direction of the inequality is changed.

The second solution \mathbf{b} can be obtained by using the weights vector w^{pert} , generated by perturbing w^{curr} , and by ensuring that the two generated solutions are sufficiently dissimilar. Issues related to considering possible infeasible sets of linear constraints (which can be generated by a confused decision maker or because a linear approximation is a too rough) are considered in [6]. The more complex nonlinear case is solved with machine learning techniques based on the SVM method in [7].

8 Conclusion

Understanding and optimizing business processes through a sound data-based *experimental science* approach is becoming critical to ensure competitiveness. The growing amount of data produced and the growing complexity of the interrelationships demand computer-assisted means for monitoring and making decisions in real time. This fact has to be translated into *reactive* business intelligence (RBI) systems,

with internal mechanisms based on machine learning and intelligent optimization (LION) to change processes and decisions based on new data and to identify critical situations, anomalies, and opportunities for improvement, without the need for a human intervention in the daily operation.

For challenging business intelligent applications, the *reactive* capability to modify the optimization process while the system is running can help both to *define* exactly what one wants to accomplish and to actually *compute* one or more solutions. Reactive BI objective is to make it easier to create dynamic and flexible systems, though LION intelligent optimization methods, without the direct intervention of technical people and programmers for every required change. Furthermore, by hiding most of the data mining and modeling complexity from the human decision maker he is free to concentrate on the most relevant and top level decisions.

Representative combinatorial and continuous optimization techniques were reviewed, with examples of their use in selected and representative business contexts.

Among the open issues for future research are scalability to massive data sets and larger network of relationships, implementations supported by massively parallel and distributed computing systems, simplicity of use for the decision maker and comprehensibility of the extracted models, strategic use of interaction with the decision maker (which need to be limited) to build more accurate models of utility functions, and seamless integration of combinatorial optimization tools (usually needed to handle discrete data like networks, categories, processes) with continuous optimization tools intended for numerical data.

Abstract

This chapter describes the reformulation – linearization technique (RLT) for solving mixed-integer 0-1 and general mixed-discrete optimization problems. The use of RLT for directly lifting mixed-integer programs (MIPs) into higher-dimensional representations as well as for deriving strong valid inequalities in the space of the original variables is discussed. Methods for exploiting inherent special structures for particular applications as well as for enhancing RLT-based relaxations in general through conditional logic deductions and semidefinite cuts are also presented. Finally, certain persistency results and extensions to solving general mixed-discrete convex programs, as well as continuous, nonconvex factorable programming problems, along with implementation guidelines are outlined.

1 Introduction

Discrete and continuous nonconvex programming problems arise in a host of practical applications in the context of production, location – allocation, distribution, economics and game theory, process design, and engineering design situations. Several recent advances have been made in the development of branch-and-cut algorithms for discrete optimization problems and in polyhedral outer-approximation methods for continuous nonconvex programming problems. At the heart of these approaches is a sequence of linear programming problems that drive the solution process. The success of such algorithms is strongly related to the strength or tightness of the linear programming representations employed.

This chapter addresses the generation of equivalent representations having tight linear programming (LP) relaxations via an automatic reformulation technique for solving discrete mixed-integer linear (and polynomial) programming problems. The particular approach of this type that is the focus of the present chapter is called the *reformulation – linearization technique (RLT)*, a procedure that can be used to generate tight linear (or sometimes convex) programming representations. Such equivalent, lifted representations facilitate the design of effective exact as well as heuristic solution procedures. The tight relaxations produced can often be used to derive good quality solutions (in polynomial time) to problems of practical sizes that arise in the aforementioned applications.

The RLT procedure is capable of generating representations of increasing degrees of strength, although with an accompanied increase in problem size. Coupled with recent advances in linear programming (LP) technology, this permits the incorporation of tighter RLT-based representations within the context of exact or heuristic methods to enhance problem solvability. Also, the RLT methodology can be extended to solve continuous nonconvex factorable programs as well – the interested reader is referred to Sherali and Tuncbilek [82–84] and Sherali and Wang [86] for an introduction to this subject (see Sherali and Adams [68], for an extensive treatise on this topic).

The motivation for constructing good models, that is, models that have tight underlying linear programming representations, rather than simply mathematically correct models, has led to some crucial and critical research on the model formulation process as in Balas [13], Jeroslow and Lowe [35, 36], Johnson [37], Meyer [49], Sherali and Adams [64, 65], Williams [103], and Wolsey [105]. Much work has also been done in converting classes of separable or polynomial nonlinear integer programming problems into equivalent linear integer programs and, for generating tight, valid inequalities for such problems, as in Adams et al. [7], Adams and Sherali [3–5], Balas and Mazzola [14, 15], Glover [32], and Sherali and Adams [64, 65]. Sometimes, a special variable redefinition technique may be applicable depending on the problem structure as in Martin [48]. In this approach, a linear transformation is defined on the variables to yield an equivalent formulation that tightens the continuous relaxation by constructing a partial convex hull of a specially structured subset of constraints. A more generally applicable technique is to augment the formulation through the addition of valid or implied inequalities that typically provide some partial characterization for the convex hull of feasible solutions. Some cutting plane generation schemes in this vein include the ones described in Nemhauser and Wolsey [51], Padberg [56], Van Roy and Wolsey [100], and Wolsey [104, 106]. Automatic reformulation procedures utilizing such constraint generation schemes within a branch-and-bound or branch-and-cut framework are presented in Crowder et al. [24], Hoffman and Padberg [34], Johnson et al. [38], Nemhauser et al. [52], Oley and Sjouquist [54], Padberg and Rinaldi [57], and Van Roy and Wolsey [101]. Besides these studies, ample evidence is available in the literature on the efficacy of providing tight linear programming relaxations for pure and mixed zero-one programming problems as in Adams and Sherali [3–5], Crowder and Padberg [25], Geoffrion and McBryde [31], and Magnanti and Wong [47], among many others.

This chapter details the reformulation – linearization technique (RLT) of Sherali and Adams [64, 65] along with its several enhancements and extensions. The RLT procedure is an automatic reformulation technique that can be used to derive tight LP representations as well as to generate strong valid inequalities. Consider a mixed-integer zero-one linear programming problem whose feasible region X is defined in terms of some inequalities and equalities in binary variables $x = (x_1, \dots, x_n)$ and a set of bounded continuous variables $y = (y_1, \dots, y_m)$. Given a value of $d \in \{1, \dots, n\}$, the fundamental RLT procedure constructs various polynomial factors of degree d comprised of the products of some d binary variables or their complements. These factors are then used to multiply each of the constraints defining X (including the variable bounding restrictions), to create a (nonlinear) polynomial mixed-integer zero-one programming problem. Using the relationship $x_j^2 = x_j$ for each binary variable x_j , $j = 1, \dots, n$; substituting a variable w_j and v_{jk} , respectively, in place of each nonlinear term of the type $\prod_{j \in J} x_j$ and $y_k \prod_{j \in J} x_j$; and relaxing integrality, the nonlinear polynomial problem is re-linearized into a higher-dimensional polyhedral set X_d defined in terms of the original variables (x, y) and the new variables (w, v) . For X_d to be equivalent to X , it is only necessary to enforce x to be binary-valued, and the remaining variables

may be treated as continuous, since the binariness on the x -variables is shown to automatically enforce the required product relationships on the w - and v -variables. Denoting the projection of X_d onto the space of the original (x, y) variables as X_{Pd} , it can be shown that the following holds true as d varies from 1 to n :

$$X_{P0} \supseteq X_{P1} \supseteq X_{P2} \supseteq \dots \supseteq X_{Pn} = \text{conv}(X),$$

where X_{P0} is the ordinary linear programming relaxation and $\text{conv}(X)$ represents the convex hull of X . The hierarchy of higher-dimensional representations produced in this manner markedly strengthens the usual continuous relaxation, as evidenced by the fact not only that the convex hull representation is obtained at the highest level but that in computational studies on many classes of problems, even the first-level representation helps design algorithms that significantly dominate existing procedures in the literature (see Sherali and Adams [67, 68]). The theoretical implications of this hierarchy are noteworthy; the resulting representations subsume and unify many published linearization methods for nonlinear 0-1 programs, and the algebraic representation available at level n promotes new methods for identifying and characterizing facets and valid linear inequalities in the original variable space as well as for providing information that directly bridges the gap between discrete and continuous sets. Indeed, since the level- n formulation characterizes the convex hull, all valid inequalities in the original variable space must be obtainable via a suitable projection; thus such a projection operation serves as an all-encompassing tool for generating valid inequalities.

Sherali and Adams [65] and Sherali [62] also demonstrate the relationship between their hierarchy of relaxations and that generated through disjunctive programming techniques. Balas [13] has shown how a hierarchy spanning the spectrum from the linear programming relaxation to the convex hull of feasible solutions can be generated for linear mixed-integer zero-one programming problems by inductively representing the feasible region at each stage as a conjunction of disjunctions and then taking its hull relaxation. This hull relaxation amounts to constructing the intersection of the individual convex hulls of the different disjunctive sets and hence yields a relaxation. Sherali and Adams show that their hierarchy produces a different, stronger set of intermediate relaxations that lead to the underlying convex hull representation. To view their relaxations as Balas' hull relaxations requires manipulating the representation at any stage d to write it as a conjunction of a *non-standard* set of disjunctions. Moreover, by the nature of the RLT approach, Sherali and Adams also show (see Sect. 5) how a hierarchy of *linear* relaxations leading to the convex hull representation can be readily constructed for mixed-integer zero-one *polynomial* programming problems that have no cross-product terms among the continuous variables.

In connection with the final comment above, Boros et al. [21] have also independently developed a similar hierarchy for the special case of the unconstrained, quadratic pseudo-Boolean programming problem. For this case, they construct a standard linear programming relaxation that coincides with the RLT relaxation at level $d = 1$ and then show in an *existential* fashion how a hierarchy of

relaxations, indexed by $d = 1, \dots, n$, can be generated that leads to the convex hull representation at level n . At any level d , this is done by including constraints corresponding to the extreme directions of the cone of nonnegative quadratic pseudo-Boolean functions that involve at most d of the n -variables. Each such relaxation can be viewed as the projection of one of the *explicitly* stated higher-order RLT relaxations onto the variable space of the first level for this special case. Moreover, the RLT approach further accommodates the consideration of general pseudo-Boolean polynomials, constrained problems, as well as general mixed-discrete situations.

Lovasz and Shrijver [46] have also independently proposed a similar hierarchy of relaxations for linear, *pure* 0-1 programming problems, which essentially amounts to deriving X_1 from X_0 , finding the projection X_{P1} , and then repeating this step by replacing X_0 with X_{P1} . Continuing in this fashion, they show that in n steps, $\text{conv}(X)$ is obtained. However, from a practical viewpoint, while the relaxations X_1, X_2, \dots, X_n of Sherali and Adams are explicitly available and directly implementable, the projections required by Lovasz and Shrijver for level-2 and higher-order relaxations are computationally burdensome, necessitating the potentially exponential task of vertex enumeration. Moreover, extensions to mixed-integer or to nonlinear zero-one problems are not evident using this development.

Another hierarchy along the same lines has been proposed by Balas et al. [19]. In this hierarchy, the set X_1 is generated as in Sherali and Adams but using factors involving only one of the binary variables, say, x_1 . Projecting the resulting formulation onto the space of the original variables produces the convex hull of feasible solutions to the original LP relaxation with the added restriction that x_1 is binary-valued. This follows from Sherali and Adams [65] since it is equivalent to treating only x_1 as binary-valued and the remaining variables as continuous, and then generating the convex hull representation. Using the fact that x_1 is now binary-valued at all vertices, this process is then repeated using another binary variable, say, x_2 , in order to determine the convex hull of feasible vertices at which both x_1 and x_2 are binary-valued. Continuing with the remaining binary variables x_3, \dots, x_n in this fashion produces the convex hull representation at the final stage. Based on this construct, which amounts to a specialized application of Sherali and Adams' hierarchy, Balas et al. describe and test a so-called *lift-and-project* cutting plane algorithm. Encouraging computational results are reported, despite the fact that this specialization produces weaker relaxations than the original Sherali–Adams' relaxations. Since this cutting plane generation scheme is based simply on the first level of Sherali and Adams' hierarchy in which binariness is enforced on only a single variable at a time, the prospect of enhancing computational performance by considering multiple binary variables at a time appears to be promising. Balas and Perregaard [16, 17] provide further discussion and connections related to such lift-and-project cuts.

The remainder of this chapter is organized as follows. Section 2 presents the basic RLT procedure of Sherali and Adams [64, 65]. Its various properties are summarized in Sect. 3, and ideas for characterizing and generating facets of the convex hull of feasible solutions (or strong valid inequalities) are presented in Sect. 4.

Extensions to multilinear programs and specializations for equality constrained problems are addressed in Sect. 5 and are illustrated using the popular quadratic assignment problem. Section 6 deals with a different RLT process proposed by Sherali, Adams, and Driscoll [90] that can be used to exploit special structures inherent in the problem, and Sect. 7 provides illustrations for some such structures, including generalized/variable upper bounding, covering, partitioning, and packing constraints, and even problem sparsity. In any RLT approach, a significant additional tightening can be obtained by using conditional logic while generating the RLT constraints. This is discussed in Sect. 8 and is illustrated on the extensively studied traveling salesman problem. Section 9 discusses classes of semidefinite cuts for enhancing RLT relaxations, along with extensions to continuous global optimization. Section 10 concludes the chapter by briefly discussing some special persistency results, extensions to general integer and mixed-discrete linear and convex programs, and various computational guidelines. To lighten the reading, proofs are omitted in this exposition, and the reader is referred to the original cited papers for such details.

2 RLT Hierarchy for Mixed-Integer Zero-One Problems

Consider a linear mixed-integer 0-1 programming problem whose (nonempty) feasible region is given as follows:

$$X = \left\{ (x, y) : \sum_{j=1}^n \alpha_{rj} x_j + \sum_{k=1}^m \gamma_{rk} y_k \geq \beta_r, \text{ for } r = 1, \dots, R, \right. \\ \left. 0 \leq x \leq e_n, \text{ } x \text{ integer}, 0 \leq y \leq e_m \right\}, \quad (1)$$

where e_n and e_m are, respectively, column vectors of n and m entries of 1 and where the continuous variables y_k are assumed to be bounded and appropriately scaled to lie in the interval $[0, 1]$ for $k = 1, \dots, m$. (Upper bounds on the continuous variables are imposed here only for convenience in exposition, as discussed further in the sequel.) Note that any equality constraints present in the formulation can be accommodated in a similar manner as are the inequalities in the following derivation. However, as shown later, it is worthwhile noting that the equality constraints can be treated in a special manner which, in fact, might sometimes encourage the writing of the R inequalities in (1) as equalities by using slack variables.

For the region described in (1), the basic construction process of the *reformulation – linearization technique* (RLT), given any level $d \in \{0, \dots, n\}$, proceeds as follows. In essence, this technique first converts the constraint set into a polynomial mixed-integer zero-one set of restrictions by multiplying the constraints with some suitable d -degree polynomial factors involving the n binary variables and their complements and subsequently linearizes the resulting problem through appropriate variable transformations. For each level d , this produces a higher-dimensional representation of the feasible region (1) in terms of the original

variables x and y and some new RLT variables (w, v) that are defined to linearize the problem. Relaxing integrality, the projection, or *shadow*, of this higher-dimensional polyhedral set onto the original variable space produces a tighter envelope for the convex hull of feasible solutions to (1) than does its ordinary linear programming (LP) or continuous relaxation. In fact, as d varies from zero to n , a hierarchy of such relaxations results, each nested within the previous one, spanning the spectrum from the ordinary linear programming relaxation to the convex hull of feasible solutions. As mentioned earlier, the first-level relaxation has itself proven to be sufficiently tight to benefit solution algorithms for several classes of problems.

More specifically, the RLT process for constructing a relaxation X_d of the region X defined in (1) corresponding to any level $d \in \{0, 1, \dots, n\}$, proceeds as follows. For $d = 0$, the relaxation X_0 is simply the LP relaxation obtained by deleting the integrality restrictions on the x -variables. In order to construct the relaxation for any level $d \in \{1, \dots, n\}$, consider the *bound factors* $x_j \geq 0$ and $(1 - x_j) \geq 0$ for $j = 1, \dots, n$ and compose *bound-factor products of degree (or order) d* by selecting some d distinct variables from the set x_1, \dots, x_n and by using either the bound factor x_j or $(1 - x_j)$ for each selected variable in a product of these terms. Mathematically, for any $d \in \{1, \dots, n\}$ and for each possible selection of d distinct variables, these (nonnegative polynomial) *bound-factor products of degree (or order) d* are given by

$$F_d(J_1, J_2) = \left[\prod_{j \in J_1} x_j \right] \left[\prod_{j \in J_2} (1 - x_j) \right] \text{ for each } J_1, J_2 \subseteq N \equiv \{1, \dots, n\} \quad (2)$$

such that $J_1 \cap J_2 = \emptyset$ and $|J_1 \cup J_2| = d$.

Any (J_1, J_2) satisfying the conditions in (2) is said to be of *order d*. For example, for $n = 3$ and $d = 2$, these factors are $x_1x_2, x_1x_3, x_2x_3, x_1(1 - x_2), x_1(1 - x_3), x_2(1 - x_3), (1 - x_1)x_2, (1 - x_1)x_3, (1 - x_2)x_3, (1 - x_1)(1 - x_2), (1 - x_1)(1 - x_3)$, and $(1 - x_2)(1 - x_3)$. In general, there are $\binom{n}{d} 2^d$ such factors. For convenience, the single factor of degree 0 is defined to be $F_0(\emptyset, \emptyset) \equiv 1$, and accordingly products over null sets are assumed to be one. Using these factors, a relaxation X_d of X , for any given $d \in \{0, \dots, n\}$, is constructed using the following two steps that comprise the reformulation – linearization technique (RLT):

Step 1 (Reformulation Phase): Multiply each of the inequalities in (1), including $0 \leq x \leq e_n$ and $0 \leq y \leq e_m$ by each of the factors $F_d(J_1, J_2)$ of degree d as defined in (2). Upon using the identity $x_j^2 \equiv x_j$ (and so $x_j(1 - x_j) = 0$) for each binary variable $x_j, j = 1, \dots, n$, this gives the following set of additional, implied, nonlinear constraints:

$$\begin{aligned} & \left[\sum_{j \in J_1} \alpha_{rj} - \beta_r \right] F_d(J_1, J_2) + \sum_{j \in N - (J_1 \cup J_2)} \alpha_{rj} F_{d+1}(J_1 + j, J_2) \\ & + \sum_{k=1}^m \gamma_{rk} y_k F_d(J_1, J_2) \geq 0 \end{aligned}$$

for $r = 1, \dots, R$, and for each (J_1, J_2) of order d ; (3)

$F_D(J_1, J_2) \geq 0$ for each (J_1, J_2) of order $D \equiv \min\{d + 1, n\}$; (4)

$F_d(J_1, J_2) \geq y_k F_d(J_1, J_2) \geq 0$

for $k = 1, \dots, m$ and for each (J_1, J_2) of order d . (5)

Step 2 (Linearization Phase): Viewing the constraints in (3)–(5) in expanded form as a sum of monomials, linearize them by substituting the following variables for the corresponding nonlinear terms for each $J \subseteq N$:

$$w_J \equiv \prod_{j \in J} x_j \text{ and } v_{Jk} \equiv y_k \prod_{j \in J} x_j, \text{ for } k = 1, \dots, m, \quad (6)$$

where, for convenience, it is assumed that

$$w_j \equiv x_j \text{ for } j = 1, \dots, n, w_\emptyset \equiv 1, \text{ and } v_{\emptyset k} \equiv y_k \text{ for } k = 1, \dots, m. \quad (7)$$

Denoting by $f_d(J_1, J_2)$ and $f_d^k(J_1, J_2)$ the respective linearized forms of the polynomial expressions $F_d(J_1, J_2)$ and $y_k F_d(J_1, J_2)$ under such a substitution, the following polyhedral set X_d is obtained, whose projection onto the (x, y) space is claimed to yield a relaxation for X :

$$\begin{aligned} X_d = \{(x, y, w, v): & \\ & \left[\sum_{j \in J_1} \alpha_{rj} - \beta_r \right] f_d(J_1, J_2) + \sum_{j \in N - (J_1 \cup J_2)} \alpha_{rj} f_{d+1}(J_1 + j, J_2) \\ & + \sum_{k=1}^m \gamma_{rk} f_d^k(J_1, J_2) \geq 0 \\ & \text{for } r = 1, \dots, R, \text{ and for each } (J_1, J_2) \text{ of order } d; \end{aligned} \quad (8)$$

$$f_D(J_1, J_2) \geq 0 \text{ for each } (J_1, J_2) \text{ of order } D \equiv \min\{d + 1, n\}; \quad (9)$$

$$\begin{aligned} & f_d(J_1, J_2) \geq f_d^k(J_1, J_2) \geq 0 \\ & \text{for } k = 1, \dots, m, \text{ and for each } (J_1, J_2) \text{ of order } d \}. \end{aligned} \quad (10)$$

Denote the projection of X_d onto the space of the original variables (x, y) by

$$X_{Pd} = \{(x, y) : (x, y, w, v) \in X_d\} \text{ for } d = 0, 1, \dots, n. \quad (11)$$

Then, Sherali and Adams [65] show that

$$X_{P0} \equiv X_0 \supseteq X_{P1} \supseteq X_{P2} \supseteq \dots \supseteq X_{Pn} = conv(X), \quad (12)$$

where $X_{P0} \equiv X_0$ (for $d = 0$) denotes the ordinary LP relaxation and $\text{conv}(X)$ denotes the convex hull of X .

Notice that the nonlinear product constraints generated by this RLT process are implied by the original constraints, and were it not for the fact that Step 1 explicitly imposes $x_j^2 = x_j$ (or $x_j(1 - x_j) = 0$) for each binary variable, this process would have simply produced a relaxation that is equivalent to the ordinary LP relaxation. Hence, the key to the tightening lies in the recognition of the binary nature of x_j in replacing x_j^2 by x_j for each $j = 1, \dots, n$.

Example 1 Consider the following mixed-integer 0-1 constraint region:

$$X = \{(x, y) : x + y \leq 2, \quad -x + y \leq 1, \quad 2x - 2y \leq 1, \quad x \text{ binary and } y \geq 0\}. \quad (13)$$

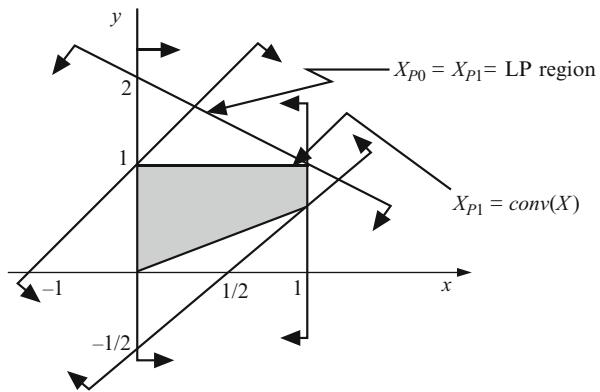

The corresponding LP relaxation of X is depicted in Fig. 1. Note that no explicit upper bound on the continuous variable y is included in (13), although the other defining constraints of X imply the boundedness of y . The RLT process can be applied directly to X as above, without creating any explicit upper bound on y . Notice that $n = 1$ for this instance, and so by the foregoing discussion, the relaxation X_1 at level $d = 1$ should produce the convex hull representation. This is verified below. For $d = 1$, the bound-factor products of order 1 are simply x and $(1 - x)$. Multiplying the constraints of X by x and by $(1 - x)$ and using $x^2 = x$ along with the linearizing substitution $v = xy$ as given by (6) produces the following constraints in the higher-dimensional space of the variables (x, y, v) , representing the set X_1 :

$$\begin{aligned} x + y \leq 2 * x &\Rightarrow -x \leq -v \\ *(1 - x) &\Rightarrow 2x + y \leq 2 + v \\ -x + y \leq 1 * x &\Rightarrow -2x \leq -v \\ *(1 - x) &\Rightarrow x + y \leq 1 + v \\ 2x - 2y \leq 1 * x &\Rightarrow x \leq 2v \\ *(1 - x) &\Rightarrow x - 2y \leq 1 - 2v \\ y \geq 0 * x &\Rightarrow v \geq 0 \\ *(1 - x) &\Rightarrow -y \leq -v \end{aligned}$$

along with $0 \leq x \leq 1$. To examine the projection X_{P1} of X_1 onto the space of the (x, y) variables, consider a restatement of X_1 as follows:

$$\begin{aligned} X_1 = \{(x, y, v) : v &\geq 2x + y - 2, \quad v \geq x + y - 1, \quad v \geq x/2, \quad v \geq 0, \\ v \leq x, \quad v \leq 2x, \quad v \leq (1-x+2y)/2, \quad v \leq y\}. \end{aligned}$$

Fig. 1 Illustration of RLT relaxations for Example 1

Then, using Fourier–Motzkin elimination, the projection X_{P1} is given by

$$\begin{aligned} X_{P1} &= \{(x, y) : \max\{2x + y - 2, x + y - 1, x/2, 0\} \\ &\leq \min\{x, 2x, (1 - x + 2y)/2, y\}\}. \end{aligned}$$

Writing the corresponding equivalent linear inequalities and dropping redundant constraints, this yields

$$X_{P1} \equiv X_{Pn} = \{(x, y) : x \leq 2y, 0 \leq x \leq 1, y \leq 1\},$$

which describes $\text{conv}(X)$ as seen in the shaded region of Fig. 1.

Example 2 Consider the set

$$X = \{(x, y) : \alpha_1 x_1 + \alpha_2 x_2 + \gamma_1 y_1 + \gamma_2 y_2 \geq \beta, 0 \leq x \leq e_2, x \text{ integer}, 0 \leq y \leq e_2\}.$$

Hence, $n = m = 2$. Consider $d = 2$, so that $D = \min\{n + 1, d\} = 2$ as well. The various sets (J_1, J_2) of order 2 and the corresponding factors are given below:

(J_1, J_2)	$\{\{1, 2\}, \emptyset\}$	$\{\{1\}, \{2\}\}$	$\{\{2\}, \{1\}\}$	$(\emptyset, \{1, 2\})$
$F_2(J_1, J_2)$	$x_1 x_2$	$x_1(1 - x_2)$	$x_2(1 - x_1)$	$(1 - x_1)(1 - x_2)$
$f_2(J_1, J_2)$	w_{12}	$x_1 - w_{12}$	$x_2 - w_{12}$	$1 - (x_1 + x_2) + w_{12}$
$f_2^k(J_1, J_2)$	v_{12k}	$v_{1k} - v_{12k}$	$v_{2k} - v_{12k}$	$y_k - (v_{1k} + v_{2k}) + v_{12k}$

Hence, this yields the following constraints (14)–(16) corresponding to (8)–(10), respectively, where v_{jk} has been written as $v_{J,k}$ for clarity:

$$X_2 = \{(x, y, w, v) :$$

$$\left. \begin{aligned} & (\alpha_1 + \alpha_2 - \beta)w_{12} + \gamma_1 v_{12,1} + \gamma_2 v_{12,2} \geq 0, \\ & (\alpha_1 - \beta)[x_1 - w_{12}] + \gamma_1(v_{1,1} - v_{12,1}) + \gamma_1(v_{1,2} - v_{12,2}) \geq 0, \\ & (\alpha_2 - \beta)[x_2 - w_{12}] + \gamma_1(v_{2,1} - v_{12,1}) + \gamma_2(v_{2,2} - v_{12,2}) \geq 0, \\ & \beta[-1 + (x_1 + x_2) - w_{12}] + \gamma_1[y_1 - (v_{1,1} + v_{2,1}) + v_{12,1}] \\ & \quad + \gamma_2[y_2 - (v_{1,2} + v_{2,2}) + v_{12,2}] \geq 0, \end{aligned} \right\} \quad (14)$$

$$w_{12} \geq 0, x_1 - w_{12} \geq 0, x_2 - w_{12} \geq 0, 1 - (x_1 + x_2) + w_{12} \geq 0, \quad (15)$$

$$\left. \begin{aligned} & w_{12} \geq v_{12,k} \geq 0, (x_1 - w_{12}) \geq (v_{1,k} - v_{12,k}) \geq 0, \\ & (x_2 - w_{12}) \geq (v_{2,k} - v_{12,k}) \geq 0, \\ & \text{and } [1 - (x_1 + x_2) + w_{12}] \geq [y_k - (v_{1,k} + v_{2,k}) + v_{12,k}] \geq 0, \end{aligned} \right\} \quad (16)$$

for $k = 1, 2\}$.

Some comments and illustrations are in order at this point. First, note that inner-products of other defining constraints could have been used in constructing the relaxation at level d , so long as the degree of the intermediate polynomial program generated at the reformulation step remains the same and no nonlinearities are created with respect to the y -variables. Hence, linearity would be preserved upon using the substitution (6) and (7). While the additional inequalities thus generated would possibly yield tighter relaxations for levels $1, \dots, n-1$, by the convex hull assertion in (12), these constraints would be implied by those defining X_n . Hence, the RLT hierarchy can be directly extended to include such additional constraints, which have been omitted for simplicity. Nonetheless, these types of additional restrictions can be advantageously included in a computational scheme employing the sets X_d for $d < n$.

Second, as alluded to earlier, note that for the case $d = 0$, using the fact that $f_0(\emptyset, \emptyset) \equiv 1$; that $f_0^k(\emptyset, \emptyset) \equiv y_k$ for $k = 1, \dots, m$; and that $f_1(j, \emptyset) = x_j$ and $f_1(\emptyset, j) = (1 - x_j)$ for $j = 1, \dots, n$, it follows that X_0 given by (8)–(10) is precisely the continuous (LP) relaxation of X in which the integrality restrictions on the x -variables are dropped. Finally, for $d = n$, note that the inequalities (9) are implied by (10) and can therefore be omitted from the representation X_n .

3 Properties of the RLT Relaxation

Equation (12) asserts the main RLT result that for $d = 0, 1, \dots, n$, the (conceptual) projections of the sets X_d represent a sequence of nested, valid relaxations leading up to the convex hull representation. Below are some salient properties of the RLT relaxations that lead to this result.

Property 1 Constraints (8)–(10) for any level's relaxation can be surrogated in a particular fashion using nonnegative multipliers to produce the constraints of the lower level relaxations. Hence, the hierarchy among these relaxations is established

via this property, whereby lower-level constraints are directly implied by higher-level constraints.

Property 2 Consider the RLT constraints (10) that are generated by multiplying the bound factors of order d with the constraints $0 \leq y \leq e_m$. If \hat{x} is any binary vector for which $(\hat{x}, \hat{y}, \hat{w}, \hat{v})$ is feasible to these constraints, then $0 \leq \hat{y} \leq e_m$, and, moreover, the identities (6) hold true. Hence, these constraints serve to ensure the nonlinear relationship (6) within the linear set X_d for any solution having binary values for x . In fact, for any binary vector \hat{x} , the solution $(\hat{x}, \hat{y}, \hat{w}, \hat{v}) \in X_d$ if and only if $(\hat{x}, \hat{y}) \in X$ and (6) holds true.

Property 3 The highest level relaxation is equivalent, via a nonsingular affine transformation, to the polytope generated by taking the convex hull of all feasible solutions to X . Hence, this result along with *Property 1* establishes (12). In fact, $(\hat{x}, \hat{y}, \hat{w}, \hat{v})$ is a vertex of X_n if and only if \hat{x} is binary-valued, (6) holds true, and \hat{y} is an extreme point of the set $\{y : (\hat{x}, y) \in X\}$.

A few remarks are pertinent at this point.

Remark 1 Observe that the upper bounds on the y -variables are not needed in X of (1) for (12) to hold true and that the foregoing analysis follows by simply eliminating any RLT product constraints that correspond to nonexistent bounding restrictions. Given feasibility of the underlying mixed-integer program, it holds that x is binary-valued at an optimum to any linear program $\max\{cx + dy : (x, y) \in X_{Pn}\}$ for which there exists an optimal solution, that is, for which this LP is not unbounded. Hence, by the foregoing properties, (12) holds true in this case as well.

Remark 2 A direct consequence of the convex hull result stated in (12) is that the convex hull representation over subsets of the x -variables can be computed in an identical fashion. In particular, suppose that the first $p \leq n$ variables are treated as binary in the set X of (1), with the remaining $(n - p)$ x -variables relaxed to be continuous. Then it directly follows that the p th level representation of this relaxed problem produces $\text{conv}\{X_0 \cap \{(x, y) : x_j \text{ is binary, } \forall j = 1, \dots, p\}\}$. The special case in which $p = 1$ precisely recovers the main step in the convexification argument of Balas et al. [19] mentioned in Sect. 1.

Remark 3 Finally, consider a situation in which there exist certain constraints from the first set of inequalities in (1) that involve only the x -variables. In this case, such constraints can be multiplied with the factors y_k and $(1 - y_k)$ for $k = 1, \dots, m$, and then the resulting constraints can be linearized using (6) and (7), similar to the other constraints (3)–(5). By *Property 2*, these additional constraints are implied when x is binary-valued in any feasible solution, but they might serve to tighten the continuous relaxations at the intermediate levels. Naturally, these constraints are implied by the other constraints defining the highest level relaxation X_n . In a likewise fashion, inequalities defining X that involve only the x -variables can be used as constraint

factors in the same spirit as the bound factors $x_j \geq 0$ and $(1 - x_j) \geq 0$ to generate products of inequalities up to a given order level for further tightening intermediate level relaxations.

4 Generating Valid Inequalities and Facets Using RLT

The discussion thus far has focused on presenting a hierarchy of relaxations leading to the convex hull representation for zero-one mixed-integer programming problems. A key advantage of this development is that the RLT produces an algebraically explicit convex hull representation at the highest level. Whereas it might not be computationally feasible to actually generate and solve the linear program based on this convex hull representation because of its potentially exponential size, there are other ways to exploit this information or facility to advantage.

One obvious strategy is to identify a subset of variables along with either original or implied constraints involving these variables for which such a convex hull representation (or some higher-order relaxation) is manageable sized. Another approach is to exploit any special structures in order to derive a simplified algebraic form of the convex hull representation for which the polyhedral cone that identifies all defining facets itself possesses a special structure. Exploiting this structure, it might then be possible to generate specific extreme directions of this cone and hence identify certain (classes of) facets that could be used to strengthen the original problem formulation. Perhaps, this algebraic simplification could yield more compact, specially structured, representations of each level in the hierarchy, hence enabling an actual implementation of a full or partial application of RLT at some intermediate level for composing tight relaxations.

Each of these ideas has been explored in different particular contexts. For example, for the Boolean quadric polytope, Sherali et al. [88] derived a characterization for all its defining facets via the extreme directions of a specially structured polyhedral cone. Accordingly, they demonstrated how various known classes of facets, including the clique, cut, and generalized cut inequality facets, emerge via the enumeration of different types of extreme directions. Moreover, by examining a particular lower-dimensional projected restriction of this polyhedral cone, they discovered a new class of facets. (This class can also be recovered via a combination of two types of facets for the related cut cone.) This type of an analysis was also used by Sherali and Lee [76] for generalized upper bounding (GUB) constrained knapsack polytopes, for which new classes of facets were characterized through a polynomial-time sequential-simultaneous lifting procedure. Known lower bounds on the coefficients of lifted facets derived from minimal covers associated with the ordinary knapsack polytope were also tightened using this framework. For the set partitioning polytope, Sherali and Lee [77] exhibited that a number of published valid inequalities along with constraint tightening procedures are automatically captured within the first- and second-level RLT relaxations themselves. A variety of partial applications of the RLT scheme were also described for deleting fractional linear programming solutions while tightening

the relaxation in the vicinity of such solutions, and various simplified forms of RLT relaxations were derived by exploiting their special structures. The polyhedral structure of many other specially structured combinatorial optimization problems can be studied using similar constructs, and tight relaxations and strong valid inequalities can be generated for such problems. As shown by Sherali [61], even convex envelopes of some special multilinear nonconvex functions can be generated using this approach.

Finally, the following strategy can be used to derive strong valid inequalities in the space of the original variables through the intermediate higher-dimensional RLT relaxations X_d , for $d \geq 1$. Note that by linear programming duality, the set of inequalities that define the projection X_{Pd} onto the (x, y) space of the higher-dimensional set X_d is characterized via the set of surrogates of the constraints defining X_d that zero out the coefficients of the new variables (w, v) in the lifted space. Whereas the enumeration of all such projected inequalities might be prohibitive, it is possible to formulate linear programming separation problems in this fashion to derive specific facets of X_{Pd} that delete a given infeasible continuous solution. The lift-and-project cutting plane algorithm of Balas et al. [19] precisely does this for the special case of $d = 1$, using RLT bound-factor products involving only a single binary variable that turns out to be fractional at an optimum to the current LP relaxation. Stronger level 1 or higher relaxations can potentially lead to improved cuts within this framework.

5 Multilinear Programs and Equality Constraints with Applications to the Quadratic Assignment Problem

This section presents two important extensions of the RLT procedure described in Sect. 2. The first of these concerns multilinear mixed-integer zero-one *polynomial* programming problems in which the continuous variables $0 \leq y \leq e_m$ appear linearly in the constraints and the objective function. This is discussed next.

Extension 1 *Multilinear mixed-integer zero-one polynomial programming problems.*

Consider the set

$$X = \{(x, y) : \sum_{t \in T_{r0}} \alpha_{rt} p(J_{1t}, J_{2t}) + \sum_{k=1}^m y_k \sum_{t \in T_{rk}} \gamma_{rkt} p(J_{1t}, J_{2t}) \geq \beta_r, \quad (17)$$

$$\forall r = 1, \dots, R, \quad 0 \leq x \leq e_n \text{ and integer, } 0 \leq y \leq e_m\},$$

where $p(J_{1t}, J_{2t}) \equiv [\prod_{j \in J_{1t}} x_j][\prod_{j \in J_{2t}} (1 - x_j)]$ are polynomial terms for the various sets (J_{1t}, J_{2t}) , for all t indexed by the sets T_{r0} and T_{rk} in (17). For $d = 0, 1, \dots, n$, a polyhedral relaxation X_d for X can be constructed as before by using the bound factors $F_d(J_1, J_2)$ to multiply the first set of constraints, where the sets (J_1, J_2) are of order d . However, denoting δ_1 as the maximum degree of the polynomial terms in x not involving the y -variables and δ_2 as the maximum

degree of the polynomial terms in x that are associated with products involving y -variables, in lieu of (4), the RLT process now uses $F_{D_1}(J_1, J_2) \geq 0$ for each (J_1, J_2) of order $D_1 \equiv \min\{d + \delta_1, n\}$, and, in lieu of (5), it employs the constraints $F_{D_2}(J_1, J_2) \geq y_k F_{D_2}(J_1, J_2) \geq 0$ for $k = 1, \dots, m$ and for each (J_1, J_2) of order $D_2 \equiv \min\{d + \delta_2, n\}$. Of course, if $D_2 \geq D_1$, then the former restrictions are unnecessary, as they are implied by the latter. Note that the computation of δ_1 and δ_2 in an optimization context must consider the terms in the objective function as well and that $\delta_1 = 1$ and $\delta_2 = 0$ for the linear case.

Now, linearizing the resulting constraints under the substitution (6) and (7) produces the desired set X_d . Because of [Property 2](#), which again holds true here, when the integrality on the x -variables is enforced, each such set X_d is equivalent to the set X . Moreover, similar to [Property 1](#), each constraint from the first set of inequalities in X_d for any $d < n$ is obtainable by surrogating two appropriate constraints from X_{d+1} . In fact, the following similar hierarchy of relaxations results:

$$\text{conv}(X) = X_{Pn} \subseteq X_{P(n-1)} \subseteq \dots \subseteq X_{P1} \subseteq X_0.$$

Extension 2 Construction of Relaxations Using Equality Constraint Representations.

Note that given any set X of the form (1), by adding slack variables to the first R inequalities, determining upper bounds on these slacks as the sum of the positive constraint coefficients minus the right-hand-side constant, and accordingly scaling these slack variables onto the unit interval, the set X can be equivalently written as follows:

$$\begin{aligned} X = \{(x, y) : & \sum_{j=1}^n \alpha_{rj} x_j + \sum_{k=1}^m \gamma_{rk} y_k + \gamma_{r(m+r)} y_{m+r} = \beta_r \text{ for } r = 1, \dots, R, \\ & 0 \leq x \leq e_n, x \text{ integer}, 0 \leq y \leq e_{m+R}\}. \end{aligned} \tag{18}$$

Now, for any $d \in \{1, \dots, n\}$, observe that the bound factor $F_d(J_1, J_2)$ for any (J_1, J_2) of order d is a linear combination of the factors $F_p(J, \emptyset)$ for $J \subseteq N$, $p \equiv |J| = 0, 1, \dots, d$. Hence, the constraint derived by multiplying an *equality* from (18) by $F_d(J_1, J_2)$ and then linearizing it via (6) and (7) is obtainable via an appropriate surrogate (with mixed-sign multipliers) of the constraints derived similarly, but using the factors $F_p(J, \emptyset)$ for $J \subseteq N$, $p \equiv |J| = 0, 1, \dots, d$. Hence, these latter factors produce constraints that can generate the other constraints, and so X_d defined by (8)–(10) corresponding to X as in (18) is *equivalent* to the following, where $f_p(J, \emptyset) \equiv w_J$ and $f_p^k(J, \emptyset) \equiv v_{Jk}$ for all $p = 0, 1, \dots, d+1$, as in (6) and (7):

$$X_d = \{(x, y, w, v) : \text{constraints of types (9) and (10) hold, and for } r = 1, \dots, R,$$

$$\left[\sum_{j \in J} \alpha_{rj} - \beta_r \right] w_J + \sum_{j \in N-J} \alpha_{rj} w_{J+j} + \sum_{k=1}^m \gamma_{rk} v_{Jk} + \gamma_{r(m+r)} v_{J(m+r)} = 0$$

$$\text{for all } J \subseteq N \text{ with } |J| = 0, 1, \dots, d\}. \quad (19)$$

Note that the savings in the number of constraints in (19) over that in (8)–(10) corresponding to the set X as in (18) is given by

$$R \left[2^d \binom{n}{d} - \sum_{i=0}^d \binom{n}{i} \right].$$

Also, observe that for $J = \emptyset$, the equalities in (19) are precisely the original equalities defining X in (18). Of course, because (19) is equivalent to the set of the types (8)–(10) that would have been derived using the factors $F_d(J_1, J_2)$ of degree d , all the foregoing results continue to hold true for (19).

Whereas the RLT approach developed for the inequality constrained case in Sect. 2 was convenient for theoretical proof purposes, note that from a computational viewpoint, when $d < n$, the representation in (19) has fewer type (8) complicating constraints and variables (when slacks for (8) are included) than does (8)–(10) as given by the above savings expression but has $R \times 2^d \binom{n}{d}$ additional constraints of the type (10), counting the nonnegativity restrictions on the slacks in (8), as compared with the inequality constrained case. Hence, depending on the structure, either form of the representation of these relaxations may be employed, as convenient.

To summarize, in general, when constructing the level d relaxation X_d in the presence of (perhaps original) equality constraints, each equality constraint needs to be multiplied by the factors $F_p(J, \emptyset)$ for $J \subseteq N$, $p \equiv |J| = 0, 1, \dots, d$ in the RLT reformulation phase. Naturally, factors $F_p(J, \emptyset)$ that are known to be zeros (and so we explicitly set $w_J \equiv 0$), that is, any such factor for which we know that there does not exist a feasible solution that has $x_j = 1$, $\forall j \in J$, need not be used in constructing these product constraints. The RLT linearization phase is then applied as before.

Example 3 To illustrate both the foregoing extensions, consider the celebrated quadratic assignment problem defined as follows:

$$\mathbf{QAP : Minimize} \sum_{i=1}^m \sum_{j=1}^m \sum_{k>i} \sum_{\ell \neq j} c_{ijkl} x_{ij} x_{k\ell} \quad (20)$$

$$\text{subject to } \sum_{i=1}^m x_{ij} = 1, \quad \forall j = 1, \dots, m \quad (21)$$

$$\sum_{j=1}^m x_{ij} = 1, \quad \forall i = 1, \dots, m \quad (22)$$

$$x \geq 0 \text{ and integer.} \quad (23)$$

This problem has equality restrictions, so additional slack variables as in (18) are not needed. Furthermore, there exist no continuous variables y , and the restrictions $x \leq e_n$ found in (1) and (18) are implied by the remaining constraints.

First Level Relaxation: To construct the relaxation at the first level, in addition to the constraints (21) and (22) and the nonnegativity restrictions on x in (23), the lifted representation includes the product constraints obtained by multiplying each constraint in (21) and (22) by each $x_{k\ell} = F_1(\{x_{k\ell}\}, \emptyset)$, and then the rest of the RLT procedure is applied as usual, using the substitution $w_{ijk\ell} = x_{ij} x_{k\ell}$, $\forall i, j, k, \ell$. Note that for any $j \in \{1, \dots, m\}$, multiplying (21) by x_{kj} for each $k \in \{1, \dots, m\}$ produces upon using $x_{kj}^2 = x_{kj}$ that

$$\sum_{i \neq k} w_{ijkj} = 0, \quad \forall k = 1, \dots, m. \quad (24)$$

Hence, since $w \geq 0$, this implies that $w_{ijkj} \equiv 0$, $\forall i \neq k$. Similarly, from (22), $w_{ijil} = 0$, $\forall j \neq l$. Furthermore, noting that $w_{ijkl} \equiv w_{klij}$, it is only necessary to define w_{ijkl} , $\forall i < k, j \neq l$. (For convenience, however, the exposition below defines w_{ijkl} , $\forall i \neq k, j \neq l$, and explicitly imposes $w_{ijkl} \equiv w_{klij}$.) Additionally, and as alluded to above, since the continuous relaxation only needs to impose $x_{ij} \geq 0$ in (23) because $x_{ij} \leq 1$ is implied by the constraints (21) and (22), the reformulation phase only multiplies the factors $x_{k\ell} \geq 0$ and $(1 - x_{k\ell}) \geq 0$ with each constraint $x_{ij} \geq 0$. This produces the restrictions $w_{ijkl} \leq x_{ij}$ and $w_{ijkl} \leq x_{k\ell}$, $\forall i, j, k, \ell$, along with $w \geq 0$. However, the former variable upper bounding constraints are implied by the constraints (28)–(30) below. Hence, the first-level relaxation (that yields a lower bound on QAP) is given as follows:

$$\text{Minimize } \sum_i \sum_j \sum_{k>i} \sum_{\ell \neq j} c_{ijkl} w_{ijkl} \quad (25)$$

$$\text{subject to } \sum_i x_{ij} = 1, \quad \forall j \quad (26)$$

$$\sum_j x_{ij} = 1, \quad \forall i \quad (27)$$

$$\sum_{i \neq k} w_{ijkl} = x_{k\ell}, \quad \forall j, k, \ell \neq j \quad (28)$$

$$\sum_{j \neq \ell} w_{ijkl} = x_{k\ell}, \quad \forall i, \ell, k \neq i \quad (29)$$

$$x \geq 0, \quad w \geq 0, \quad w_{ijkl} \equiv w_{klij}, \quad \forall i < k, j \neq \ell. \quad (30)$$

Second Level Relaxation: Following the same procedure as above and eliminating null variables as well as null and redundant constraints produces the same

relaxation as in (25)–(30) with additional constraints (and variables) corresponding to multiplying each equality constraint in (21) by each factor $x_{k\ell}x_{pq}$ for $k < p$, $\ell \neq q \neq j$, and by multiplying each constraint in (22) by each factor $x_{k\ell}x_{pq}$ for $k < p$, $k \neq i \neq p$, $\ell \neq q$. This generates the additional constraints

$$\sum_{i \neq k, p} w_{ijk\ell pq} = w_{k\ell pq}, \quad \forall j, k, \ell, p, q, \text{ where } k < p, \text{ and } \ell \neq q \neq j, \quad (31)$$

$$\sum_{j \neq \ell, q} w_{ijk\ell pq} = w_{k\ell pq}, \quad \forall j, k, \ell, p, q, \text{ where } k < p, k \neq i \neq p, \text{ and } \ell \neq q, \quad (32)$$

along with $w_{ij,k\ell,pq} \geq 0$, noting that this is the same variable for each permutation of

$$ij, k\ell, pq \text{ for all distinct } i, k, p \text{ and } j, \ell, q. \quad (33)$$

Such relaxations have been computationally tested by Ramakrishnan et al. [59], Ramachandran and Pekny [58], Adams and Johnson [2], and Adams et al. [10] with promising results. Extensions of such specializations for general set partitioning problems are discussed by Sherali and Lee [77], and concise representations having the strengths of the different level RLT relaxations for set partitioning structures are explored in Adams et al. [9]. In fact, Adams and Johnson [2] show that the lower bound produced by the first-level relaxation itself subsumes a multitude of known lower bounding techniques in the literature, including a host of matrix reduction strategies. These authors designed a heuristic dual ascent procedure for the level-1 relaxation, to quickly solve the large linear program by exploiting special structures. In an effort to make this algorithm generally applicable, no special exploitation of flow and/or distance symmetries was considered. This work was extended in Adams et al. [10] where a similar type of dual ascent algorithm was applied to the level-2 representation. This enabled the solution of the largest $m = 30$ test cases from the standard test bed of Nugent et al. [53] to optimality. Only one other paper by Anstreicher et al. [12] was successful in verifying an optimal solution, and this paper reported enumerating approximately 11.9 billion nodes in the binary search tree. The RLT enumerated 543,000 nodes and required less than 40% of the CPU time. As far as the strength of the RLT relaxations is concerned, on a set of standard test problems of sizes $m = 8$ –20, the lower bounds from the level-1 RLT produced by the dual ascent procedure in Adams and Johnson [2] uniformly dominated 12 other competing lower bounding schemes except for one problem of size 20, where the RLT procedure yielded a lower bound of 2145 (later improved to 2,179 in Adams et al. [10]), while an eigenvalue-based procedure produced a lower bound of 2,229, the optimum value being 2,570 for this problem. The bounds obtained from the dual ascent applied to the level-2 RLT representation formulated in Adams et al. [10] improved this bound to 2,508. Also, Resende et al. [60] have been able to solve the first-level RLT relaxation exactly for problems of size up to 30 using an interior point method that employs a preconditioned conjugate gradient technique to solve the system of equations for computing the

search directions. (For the problem of size 20, the exact solution value of the lower bounding RLT relaxation turned out to be 2,182, compared to a value of 2,179 using the aforementioned dual ascent scheme.) Sherali and Brown [70] have also applied RLT to the problem of assigning aircraft to gates at an airport, with the objective of minimizing passenger walking distances. The problem is modeled as a variant of the quadratic assignment problem with partial assignment and set packing constraints. The quadratic problem is then equivalently linearized by applying the first level of the RLT. In addition to simply linearizing the problem, the application of this technique generates additional constraints that provide a tighter linear programming representation. Since even the first-level relaxation can get quite large, several alternative relaxations are investigated that either delete or aggregate classes of RLT constraints. All these relaxations are embedded in a heuristic that solves a sequence of such relaxations, automatically selecting at each stage the tightest relaxation that can be solved with an acceptable estimated effort, and based on the solution obtained, it fixes a suitable subset of variables to 0-1 values. This process is repeated until a feasible solution is constructed. The procedure was computationally tested using realistic data obtained from *USAir* for problems having up to 7 gates and 36 flights. For all the test problems ranging from 4 gates and 36 flights to 7 gates and 14 flights, for which the size of the first-level relaxation was manageable (having 14,494 and 4,084 constraints, respectively, for these two problem sizes), this first-level RLT relaxation itself always produced an optimal 0-1 solution.

As a final note, Adams and Sherali [3] had earlier developed a technique for solving general 0-1 quadratic programming problems using a relaxation that turns out to be precisely the level-1 RLT relaxation discussed above. This relaxation was shown to theoretically dominate other existing linearizations and was demonstrated to computationally produce far tighter lower bounds, where the test cases involved quadratic set covering problems having up to 70 variables and 40 constraints. For example, for this largest size problem, where the optimum objective value was 1,312, the first-level RLT relaxation produced an initial lower bound of 1,289 at the root node and enumerated 14 nodes to solve the problem in 79 cpu seconds on an IBM 3081 Series D24 Group K computer. When the same algorithmic strategies were used on a relaxation that did not include the special RLT constraints, the initial lower bound obtained was only 398, and the algorithm enumerated 2,130 nodes, consuming 197 cpu seconds.

6 Exploiting Special Structures to Generate Tighter RLT Representations

The basic RLT procedure discussed in Sect. 2 generates a hierarchy of relaxations that spans the spectrum from the continuous LP relaxation to the convex hull of feasible solutions for linear mixed-integer 0-1 programming problems. The key construct here is to compose a set of multiplication factors based on the bounding constraints $0 \leq x \leq e_n$ for the binary variables x and to use these factors to generate implied nonlinear product constraints, then tighten these constraints using the fact

that $x_j^2 = x_j$, $\forall j = 1, \dots, n$, and subsequently linearize the resulting polynomial problem through a variable substitution process. This process then yields a family of tighter representations of the problem in higher-dimensional spaces.

It should seem intuitive that given a set S of constraints involving the x -variables that imply the bounding restrictions $0 \leq x \leq e_n$, it might be possible to generate a similar hierarchy by utilizing multiplicative factors that are composed from the constraints defining S itself. Indeed, as exemplified in this section, such generalized so-called *S-factors* can not only be used to construct a hierarchy of relaxations leading to the convex hull representation, but they also provide an opportunity to exploit inherent special structures. An artful application of this strategy can produce relaxations that are more compact than the ones available through the traditional RLT process of Sect. 2 while at the same time being tighter as well as affording the opportunity to construct the convex hull representation at lower levels in the hierarchy in certain cases.

Consider the feasible region of a mixed-integer 0-1 programming problem stated in the following form:

$$X = \{(x, y) \in R^n \times R^m : Ax + Dy \geq b, x \in S, x \text{ binary}, y \geq 0\}, \quad (34)$$

where

$$S \equiv \{x : g_i x - g_{0i} \geq 0 \text{ for } i = 1, \dots, p\}. \quad (35)$$

Here, the constraints defining the set S have been specially composed to generate useful, tight relaxations as revealed in the sequel. For now, in theory, all that is required of the set S is that it implies the bounds $0 \leq x \leq e_n$ on the x -variables where, as before, e_n is a vector of n -ones. Specifically, assume that for each $t = 1, \dots, n$,

$$\min\{x_t : x \in S\} = 0 \text{ and } \max\{x_t : x \in S\} = 1. \quad (36)$$

Note that $\min\{x_t\} > 0$ implies that $x_t \equiv 1$ and $\max\{x_t\} < 1$ implies that $x_t \equiv 0$, and if both these conditions hold for any t , then the problem is infeasible. Therefore, without loss of generality, assume that the equalities of (36) hold for all $t = 1, \dots, n$. Furthermore, note that (36) ensures that $p \geq n + 1$.

Now, define the sets P and \bar{P} as follows, where \bar{P} is a multi-set that duplicates each index in P n times:

$$P = \{1, \dots, p\}, \text{ and } \bar{P} = \{n \text{ copies of } P\}. \quad (37)$$

The construction of the new hierarchy proceeds in a manner similar to that of Sect. 2. At any chosen level of relaxation $d \in \{1, \dots, n\}$, a higher-dimensional relaxation \bar{X}_d is constructed by considering the *S-factors* of order d defined as follows:

$$g(J) \equiv \prod_{i \in J} (g_i x - g_{0i}) \text{ for each distinct } J \subseteq \bar{P}, |J| = d. \quad (38)$$

Note that the S -factors of order d are composed by examining the collection of *constraint factors* $g_i x - g_{0i} \geq 0$, $i = 1, \dots, p$, and constructing the product of some d of these constraint factors, *including possible repetitions*, where the multi-set \bar{P} defined in (37) permits such repetitions as d varies from 1 to n . Since the relaxation described below will recover the convex hull representation for $d = n$, it is not necessary to consider $d > n$. Using $(d - 1)$ suitable dummy indices to represent duplications, it can be easily verified that there are a total of

$$\binom{p + d - 1}{d} = (p + d - 1)!/d!(p - 1)!$$

distinct factors of this type at level d .

These factors are then used in a *special structures reformulation – linearization technique*, abbreviated SSRLT, as stated below, for generating the relaxation \bar{X}_d .

- (a) *Reformulation Phase.* Multiply each inequality defining the feasible region (34) (including the constraints defining S) by each S -factor $g(J)$ of order d , and apply the identity $x_j^2 = x_j$ for all $j \in \{1, \dots, n\}$.
- (b) *Linearization Phase.* Linearize the resulting polynomial program by using the substitution defined in (39) below, to produce the d th level relaxation \bar{X}_d :

$$w_J = \prod_{j \in J} x_j, \quad \forall J \subseteq N \text{ and } v_{Jk} = y_k \prod_{j \in J} x_j, \quad \forall J \subseteq N, \quad \forall k = 1, \dots, m. \quad (39)$$

For conceptual purposes, as in Sect. 2, define the projection of \bar{X}_d onto the space of the original variables as

$$\bar{X}_{Pd} = \{(x, y) : (x, y, w, v) \in \bar{X}_d\}, \quad \forall d = 1, \dots, n. \quad (40)$$

Additionally, as before, denote $\bar{X}_{P0} \equiv \bar{X}_0$ (for $d = 0$) as the ordinary linear programming relaxation. Sherali et al. [90] then show that similar to (12),

$$\bar{X}_{P0} \equiv \bar{X}_0 \supseteq \bar{X}_{P1} \supseteq \bar{X}_{P2} \supseteq \dots \supseteq \bar{X}_{Pn} = \text{conv}(X), \quad (41)$$

where $\text{conv}(\cdot)$ denotes the convex hull of feasible solutions. Moreover, this hierarchy dominates that of Sect. 2 in the sense that

$$\bar{X}_d \subseteq X_d \text{ and } \bar{X}_{Pd} \subseteq X_{Pd}, \quad \forall d = 0, 1, \dots, n. \quad (42)$$

For convenience in notation, let $\{\cdot\}_L$ henceforth denote the process of linearizing a polynomial expression $\{\cdot\}$ in x and y via the substitution defined in (39), following the use of the identity $x_j^2 = x_j$, $\forall j = 1, \dots, n$.

Before proceeding further, some important comments pertaining to the application of SSRLT are worth highlighting. First, in an actual implementation, note that under the substitution $x_j^2 = x_j$ for all j , several terms defining the factors in (38)

might be zeros, either by definition or due to the restrictions of the set X in (34). For example, if $S \equiv \{x : 0 \leq x \leq e_n\}$, when $d = 2$, one such factor of type (38) is $x_j(1 - x_j)$ for $j \in \{1, \dots, n\}$, which is clearly null when x_j^2 is equated with x_j . Additionally, if $S \equiv \{x : 0 \leq x \leq e_n\}$, then multiplying the inequalities defining X in (34) by any factor $F_d(J_1, J_2)$ for which the remaining constraints of \bar{X}_d enforce $f_d(J_1, J_2) = 0$ will yield null constraints. Second, some of these factors might be implied in the sense that they can be reproduced as a nonnegative surrogate of other such factors that are generated in (38). For example, when $d = 3$ for $S \equiv \{x : 0 \leq x \leq e_n\}$, the factor $x_t^2 x_r \geq 0$ of order 3 is equivalent to $x_t x_r \geq 0$ of order 2, which is implied by other nonnegative factors of order 3 generated by the RLT constraints by [Property 1](#). All such null and implied factors and terms should be eliminated in an actual application of SSRLT. Third, if any constraint in \bar{X}_0 of (34) and (41) is implied by the remaining constraints, then this constraint can be removed from X without changing any resulting set \bar{X}_d . (This same logic holds relative to the foregoing RLT process and the sets X_d .) To illustrate, any single constraint in (21) or (22) can be removed from the QAP formulation of [Example 3](#) while preserving the strengths of the prescribed relaxations at levels 1 and 2, saving $1 + m(m - 1)$ and $1 + m(m - 1) + m(m - 1)^2(m - 2)$ constraints, respectively.

As evident from the foregoing comments, the RLT process described in [Sect. 2](#) is a special case of SSRLT when $S \equiv \{x : 0 \leq x \leq e_n\}$. Note that one obvious scheme for generating tighter relaxations via SSRLT is to include in the latter set S certain suitable additional constraints depending on the problem structure and hence generate S -factors at level d that include $f_d(J_1, J_2)$ of order d as defined in [Sect. 2](#), along with any collection of additional S -factors as obtained via (38). Eliminating any null terms or implied factors thus generated, a hierarchy of relaxations can be derived using SSRLT that would dominate the ordinary RLT hierarchy at each level. The focus in the discussion that follows largely resides on less obvious, and richer, instances where the set S possesses a special structure that implies the restrictions $0 \leq x \leq e_n$, without explicitly containing these bounding constraints.

Observe that SSRLT could be conceptually visualized as being an inductive process, with the relaxation at level $(d + 1)$ being produced by multiplying each of the constraints in the relaxation at level d with each S -factor defining S . Constraints produced by this process that effectively use null (zero) factor expressions $g(J)$ of order d are null constraints. Constraints produced by this process that effectively use factors $g(J)$ that are implied by other factors in (38) are themselves implied by the constraints generated using the latter factors. Hence, the processes of reducing the set of factors based on eliminating the use of null or implied factors at the reformulation step, or that of eliminating the corresponding redundant constraints generated by such factors, are equivalent steps. It follows that an equivalent relaxation at level d would be produced by using only the non-null, non-implied factors, recognizing any zero variable terms in the resulting relaxation as identified by the S -factors. Furthermore, such non-redundant/non-null factors can be generated inductively through the levels, recognizing zero terms revealed at previous levels. This latter relaxation is what should actually be generated in practice. [Sections 7](#) and [8](#) provide several examples. In a similar fashion to the

RLT process of Sect. 2, a hierarchy leading to the convex hull representation can be generated in a piecewise manner by sequentially enforcing binariness on sets of variables and constructing the highest level relaxation for each considered set in turn.

Finally, consider the treatment of equality constraints and equality factors. Note that whenever an equality constraint factor defines an S -factor, any resulting product constraint is an equality restriction. Consequently, in the presence of equality constrained factors, in general, it is only necessary to multiply the corresponding equality constraint factors simply with each x and y variable alone as well as by the constant 1, since the product with any other expression in x and y can be composed using these resulting products. Moreover, since the products with the x -variables are already being generated via other SSRLT constraints by virtue of the corresponding defining equality constraints of S already being included within X and since $x \geq 0$ is implied by the inequality restrictions of $x \in S$, only products using the y -variables are necessary.

Furthermore, in this connection, note that if X contains equality structural constraints, in general, then these can be treated as in Sect. 5. That is, at level d , these equality constraints would simply need to be multiplied by the factors $F_p(J, \emptyset)$ for $J \subseteq N$, $p \equiv |J| = 0, 1, \dots, d$. Naturally, factors $F_p(J, \emptyset)$ that are known to be zeros (and so we explicitly set $w_J \equiv 0$), that is, any such factor for which no feasible solution exists that has $x_j = 1$ for all $j \in J$, need not be used in constructing these product constraints and can be set equal to zero in the relaxation.

Example 4 For example, consider a set $S = \{x : e_n \cdot x = 1, x \geq 0\}$. Then the S -factors of order 1 are the expressions that define the restrictions

$$\{(1 - e_n \cdot x) = 0, x_1 \geq 0, \dots, x_n \geq 0\}, \quad (43)$$

which include the equality constraint factor along with the bound factors $x_1 \geq 0, \dots, x_n \geq 0$. To compose the S -factors of order 2, note that

$$x_t(1 - e_n \cdot x) = 0 \text{ yields } \sum_{j \neq t} w_{(jt)} = 0, \forall t, \quad (44)$$

upon using $x_t^2 \equiv x_t$ and substituting $w_{(jt)}$ for $x_j x_t$, $\forall j \neq t$ according to (39). (Note that $w_{(jt)}$ is defined only for $j < t$, and accordingly, the notation in (44) denotes $w_{(jt)} \equiv w_{jt}$ if $j < t$ and $w_{(jt)} \equiv w_{tj}$ if $t < j$.) Equation (44) along with

$$w_{(jt)} \equiv x_j x_t \geq 0, \forall j \neq t, \quad (45)$$

where (45) is produced by the other S -factors of order 2, imply that $w_{(jt)} \equiv 0, \forall j \neq t$, hence yielding null factors via (44) and (45). The only non-null S -factors of order 2 are therefore produced by pairwise self-products of the constraints defining S . But $(1 - e_n \cdot x)^2 = 0$ and $x_j^2 \geq 0, \forall j = 1, \dots, n$,

respectively, yield $(1 - e_n \cdot x) = 0$ and $x_j \geq 0$, $\forall j = 1, \dots, n$, upon using $x_j^2 = x_j$ and $x_j x_t = 0$, $\forall j \neq t$, as above. Hence, the reduced set of factors of order 2 is precisely the same as those of order 1, and this continues for all levels $2, \dots, n$. Consequently, by (41), the convex hull representation is produced at the first level itself for this example.

To produce this level-1 representation, all the constraints defining X (including the ones in S) are first multiplied by each factor $x_j \geq 0$, $j = 1, \dots, n$, from (43). However, for the equality factor $(1 - e_n \cdot x) = 0$, by the foregoing discussion, it is only necessary to construct the RLT constraints $\{y_k(1 - e_n \cdot x)\}_L = 0$, $\forall k = 1, \dots, m$, and retain $e_n \cdot x = 1$. The resulting relaxation produces the convex hull representation as asserted above.

To further reinforce some of the preceding ideas before presenting additional specific details, consider another example that includes an equality constraint in S but also explicitly includes the bound restrictions $0 \leq x \leq e_n$. As mentioned above, since the S -factors would now include the regular RLT bound factors, the use of any S -factors other than these bound factors is optional.

Example 5 Suppose that $n = 4$ and consider $S = \{x \in R^4 : x_1 + x_2 + x_3 + x_4 = 2$, $0 \leq x \leq e_4\}$. The following factors are derived that can be applied in SSRLT, noting the equality constraint defining S :

- (a) *Level-1 factors:* Bound factors $x_j \geq 0$ and $(1 - x_j) \geq 0$, $\forall j = 1, \dots, 4$, and optionally $(e_4 \cdot x - 2) = 0$ (to be multiplied by 1 and by each y -variable alone as noted above).
- (b) *Level-2 factors:* Bound factors of order 2 given by $\{x_i x_j, (1 - x_i)x_j, x_i(1 - x_j)$ and $(1 - x_i)(1 - x_j)$, $\forall 1 \leq i < j \leq 4\}$, and optionally any factors (to be applied to $y \geq 0$ alone) from the set $\{x_i - \sum_{j \neq i} x_i x_j = 0$, $\forall i = 1, \dots, 4$, obtained by multiplying $e_4 \cdot x - 2$ by each x_i , $i = 1, \dots, 4$, and $(e_4 \cdot x - 2) = 0$ itself, obtained from $(e_4 \cdot x - 2)^2 = 0$ upon using $\sum_{j \neq i} x_i x_j = x_i$, $\forall i\}$.
- (c) *Level-d factors, d=3, 4:* Bound factors $F_d(J_1, J_2) \geq 0$ of order d , with the additional restriction that all third and fourth order terms are zeros, plus optionally factors from the optional set at level 2. Note that the valid implication of polynomial terms of order 3 being zero, for example, is obtained through the RLT process by multiplying $x_i - \sum_{j \neq i} x_i x_j = 0$ with x_k , for each i, k , $i \neq k$. This gives $\sum_{j \neq i, k} x_i x_j x_k = 0$, which, by the nonnegativity of each triple product term, implies that $x_i x_j x_k = 0$, $\forall i \neq j \neq k$.

In a likewise fashion, for set partitioning problems, for example, any quadratic or higher-order products of variables that involve a pair of variables that appear together in any constraint are zeros. More generally, any product term that contains variables or their complements that cannot simultaneously take on a value of 1 in any feasible solution can be restricted to zero. Sherali and Lee [77] use this structure to present a specialization of RLT to derive explicit reduced level- d representations in their analysis of set partitioning problems.

7 Applications of RLT for Some Particular Special Structures

This section demonstrates how some specific special structures can be exploited in designing an application of the general framework of SSRLT. This discussion will also illuminate the relationship between RLT and SSRLT, beyond the simple dominance result stated in (42). For this purpose, various commonly occurring special structures are examined, such as generalized upper bounding (GUB) constraints, variable upper bounding (VUB) constraints, and, to a lesser degree of structure, problem sparsity. These illustrations are by no means exhaustive; the motivation here is to present the basic framework for this approach and encourage the reader to design similar constructs for other applications on a case-by-case basis.

7.1 Generalized Upper Bounding (GUB) or Multiple Choice Constraints

Suppose that the set S of (35) is given as follows:

$$S = \left\{ x : \sum_{j \in N_i} x_j \leq 1, \forall i \in Q \equiv \{1, \dots, q\}, x \geq 0 \right\}, \quad (46)$$

where $\bigcup_{i \in Q} N_i \equiv N \equiv \{1, \dots, n\}$. Problems possessing this particular special structure arise in various settings including maximum cardinality node packing, set packing, capital budgeting, and menu planning problems, among others (see Nemhauser and Wolsey [50]).

First, suppose that $q \equiv 1$ in (46), so that

$$S \equiv \{x : e_n \cdot x \leq 1, x \geq 0\}.$$

The S -factors of various orders for this particular set can be derived as follows:

- (a) *S -factors at level 1.* These factors are directly obtained from the set S via the constraint factors $(1 - e_n \cdot x) \geq 0$ and $x_j \geq 0, \forall j = 1, \dots, n$.
- (b) *S -factors at level 2.* The linearization operation $[x_t(1 - e_n \cdot x)]_L \geq 0$ produces an expression

$$\sum_{j \neq t} w_{(jt)} \leq 0, \forall t = 1, \dots, n,$$

where $w_{(jt)} \equiv w_{jt}$ if $j < t$ and $w_{(jt)} \equiv w_{tj}$ if $t < j$. Moreover, the pairwise products of x_j and x_t , $j \neq t$, produces factors of the type

$$(x_j x_t) \geq 0, \forall j \neq t, \text{ or } w_{(jt)} \geq 0, \forall j \neq t.$$

Similar to (44) and (45), the foregoing two sets of inequalities imply that

$$w_{(jt)} = 0, \forall j \neq t. \quad (47)$$

Consequently, under (47), the only non-null S -factors of order 2 that survive are self-product factors of the type $(x_t x_t) \geq 0$, $\forall t$, and $(1 - e_n \cdot x) \cdot (1 - e_n \cdot x) \geq 0$. These yield the same factors as at level 1, upon using $x_t^2 = x_t$, $\forall t$, along with (47), as seen in Sect. 6. Hence, the factors that need to be used for constructing the set \bar{X}_2 are

$$(1 - e_n \cdot x) \geq 0 \text{ and } x_j \geq 0, \quad j = 1, \dots, n.$$

Hence, notice that $\bar{X}_2 = \bar{X}_1$, and this equivalence relation continues through all levels of relaxations up to \bar{X}_n . Therefore, the first-level relaxation itself produces the convex hull representation in this case. There are two insightful points worthy of note in the context of this example. First, as illustrated next, although RLT recognizes that (47) holds true at each relaxation level, it may not produce the convex hull representation at the first level as does SSRLT.

Example 6 Let

$$X = \{(x_1, x_2) : 6x_1 + 3x_2 \geq 2, \quad x_1 + x_2 \leq 1, \quad x \text{ binary}\},$$

and consider the generation of the first-level RLT relaxation. Note that the factors used in this context are x_j and $(1 - x_j)$ for $j = 1, 2$. Examining the product of $x_1 + x_2 \leq 1$ with x_1 yields $w_{12} \leq 0$, which together with $w_{12} \equiv \{x_1 x_2\}_L \geq 0$ yields $w_{12} = 0$. Other products of the factors x_j and $(1 - x_j)$, $j = 1, 2$, with $x_1 + x_2 \leq 1$ and $0 \leq x \leq e_2$ simply reproduce these same latter constraints.

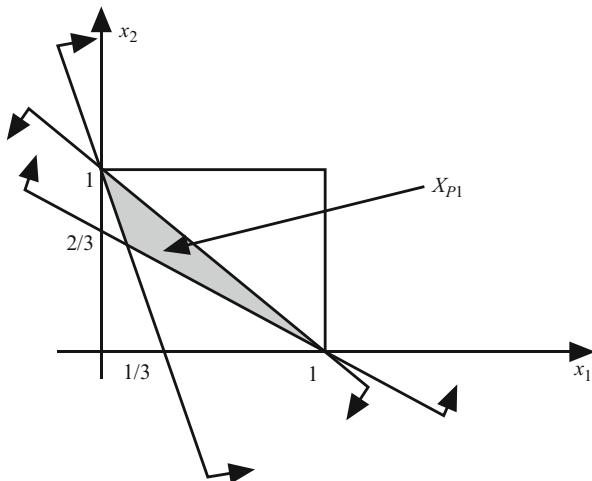

Examining the products of $6x_1 + 3x_2 \geq 2$ with these first-level factors yields nonredundant inequalities when the factors $(1 - x_1)$ and $(1 - x_2)$ are used, thus generating the constraints $2x_1 + 3x_2 \geq 2$ and $3x_1 + x_2 \geq 1$, respectively, since $w_{12} = 0$. Hence, the first-level relaxation (directly in projected form in this case) is obtained as follows:

$$X_{P1} = \{(x_1, x_2) : 2x_1 + 3x_2 \geq 2, \quad 3x_1 + x_2 \geq 1, \quad x_1 + x_2 \leq 1, \quad x \geq 0\}.$$

Figure 2 depicts the shaded region X_{P1} . However, using SSRLT and noting the above argument, results in $\bar{X}_{P1} = \text{conv}(X) \equiv \{x : x_1 + x_2 = 1, \quad x \geq 0\}$, which is a strict subset of X_{P1} .

A second point to note is that the generalized upper bounding inequality $e_n \cdot x \leq 1$ could have been written as an equality $e_n \cdot x + x_{n+1} = 1$ by introducing a slack variable x_{n+1} , and then, *recognizing the binariness of this slack variable*, it could have been used as an additional variable in composing the bound-factor products while applying RLT. Although this would have produced the same relaxation as with SSRLT, the process would have generated several more redundant constraints while applying the factors x_j and $(1 - x_j)$, $\forall j = 1, \dots, n + 1$, to the constraints, as opposed to using the fewer factors $(1 - e_n \cdot x)$ and x_j , $\forall j = 1, \dots, n$, as needed by SSRLT. However, in more general cases of the set S , such a transformation that yields the same representation using RLT as obtained via SSRLT may not be accessible (see Example 7 below, for instance).

Fig. 2 The first-level relaxation using RLT

Example 7 Next, consider the case of $q = 2$ in (46). For the sake of illustration, suppose that

$$S = \{x \in R^5 : x_1 + x_2 + x_3 \leq 1, x_3 + x_4 + x_5 \leq 1, \text{ and } x \geq 0\}. \quad (48)$$

- (a) *S-factors at level 1*: These are simply the constraints defining S .
- (b) *S-factors at level 2*: As before, the pairwise products within each GUB set of variables will reproduce the same factors as at the first level, since (47) holds true within each GUB set. However, examining mixed factors across the two GUB sets produces the nonnegative quadratic bound-factor products x_1x_4 , x_1x_5 , x_2x_4 , and x_2x_5 , along with the following factor products, recognizing that any quadratic product involving x_3 is zero because this variable appears in both GUB sets:

$$x_4 \cdot (1 - x_1 - x_2 - x_3) \geq 0 \text{ yielding } x_4 - x_1x_4 - x_2x_4 \geq 0,$$

$$x_5 \cdot (1 - x_1 - x_2 - x_3) \geq 0 \text{ yielding } x_5 - x_1x_5 - x_2x_5 \geq 0,$$

$$x_1 \cdot (1 - x_3 - x_4 - x_5) \geq 0 \text{ yielding } x_1 - x_1x_4 - x_1x_5 \geq 0,$$

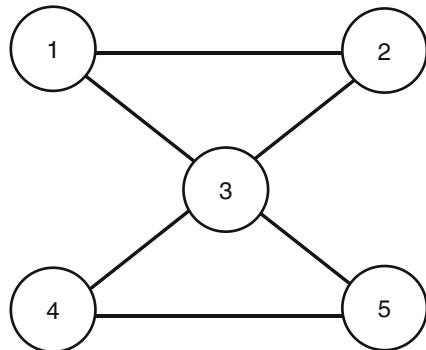

$$x_2 \cdot (1 - x_3 - x_4 - x_5) \geq 0 \text{ yielding } x_2 - x_2x_4 - x_2x_5 \geq 0,$$

and

$$(1 - x_1 - x_2 - x_3) \cdot (1 - x_3 - x_4 - x_5) \geq 0 \text{ yielding}$$

$$1 - x_1 - x_2 - x_3 - x_4 - x_5 + x_1x_4 + x_1x_5 + x_2x_4 + x_2x_5 \geq 0.$$

These can now be applied to the constraints defining X , recognizing the terms that have been identified to be zeros.

Fig. 3 Vertex packing graph

(c) *S-factors at levels ≥ 3* : Since there are only two GUB sets in this example and since any triple product of distinct factors must involve a pair of factors coming from the defining constraints corresponding to the same GUB set and the latter product is zero, all such products must vanish. Hence, all factors at level 3, and similarly at levels 4 and 5, coincide with those at level 2. In other words, the relaxation at level 2 (defined as \bar{X}_2) itself yields the convex hull representation.

In general, the *level equal to the independence number of the underlying intersection graph corresponding to the GUB constraints, which simply equals the maximum number of variables that can simultaneously be 1, is sufficient to generate the convex hull representation*. In the case of (46), the convex hull representation would be obtained at level q or earlier.

An enlightening special case of (46) deals with the vertex packing problem. Given a graph $G = (V, E)$ with vertex set $V = \{v_1, v_2, \dots, v_n\}$, an edge set E connecting pairs of vertices in V , and a weight c_j associated with each vertex v_j , the *vertex packing problem* is to select a maximum weighted subset of vertices such that no two vertices are connected by an edge. For each $j = 1, \dots, n$, by denoting the binary variable x_j to equal 1 if vertex j is chosen and 0 otherwise, the vertex packing problem can be stated as follows: Maximize $\{\sum_{j=1}^n c_j x_j : x_i + x_j \leq 1, \forall (i, j) \in E, x \text{ binary}\}$. The convex hull representation over any subset P of the variables can be obtained as above by considering any clique cover of the subgraph induced by the corresponding vertices, with each set N_i corresponding to the variables defining some clique i . In fact, given a cover that has q cliques, where each edge of E is included in some clique, the S -factors of level q themselves define the convex hull representation, since their products with the packing constraints, as well as with the nonnegativity restrictions on x , are implied by these factors. To illustrate, the inequalities of (48) can be considered as a (maximum cardinality) clique cover of the vertex packing problem on the graph in Fig. 3, and so, the stated S -factors of level 2 themselves define the convex hull representation. This general observation may have widespread applicability since, as noted by Garfinkel and Nemhauser [29], any finite integer linear program can be reformulated as a packing problem.

Table 1 Computational results for set packing problems

Ordinary LP relaxation				Level 1 via RLT			Level 1 via SSRLT		
(q, n)	Density	% gap	Iter	(m', n')	% gap	Iter	(m', n')	% gap	Iter
(15, 25)	60	34.7	23	(327, 25)	8.98	119	(277, 25)	0	17
(35, 65)	20	29.8	68	(3,706, 545)	6.17	1,012	(2,466, 545)	0	1,491
(35, 60)	25	25.7	90	(3,178, 167)	6.43	1,727	(2,202, 167)	0	1,968
(35, 65)	30	34.7	64	(3,294, 98)	16.7	916	(2,260, 98)	0	1,464
(55, 45)	27	37.0	103	(2,256, 45)	2.0	344	(1,896, 45)	0	171

To illustrate the computational benefits of SSRLT over RLT in this particular context, Sherali et al. [90] conducted the following experiment using pseudo-randomly generated set packing problems of the type: Maximize $\{\sum_{j=1}^n c_j x_j : \sum_{j \in N_i} x_j \leq 1, \forall i = 1, \dots, q, x \text{ binary}\}$. For several instances of such problems, the optimal value of the 0-1 packing problem, the optimal value of its ordinary LP relaxation, and the optimal values of the first-level relaxations produced by applying RLT and SSRLT were computed, where SSRLT was generated by using all of the defining clique constraints, together with $x \geq 0$, to represent the set S . **Table 1** gives the percentage gaps obtained for the latter three upper bounds with respect to the optimal 0-1 value, along with the sizes of the respective relaxations ($m' \equiv$ number of constraints, $n' \equiv$ number of variables), and the number of simplex iterations (Iter) needed by the OSL solver version 2.001, to achieve optimality. Note that for all instances, the first-level application of SSRLT was sufficient to solve the underlying integer program. On the other hand, although RLT appreciably improved the upper bound produced by the ordinary LP relaxation, it still left a significant gap that remains to be resolved in these problem instances. Moreover, the relatively simpler structure of SSRLT results in far fewer simplex iterations being required to solve this relaxation as compared with the effort required to solve RLT.

7.2 Variable Upper Bounding Constraints

This illustration points out that in the presence of variable upper bounding (VUB) types of restrictions, a further tightening of relaxations via SSRLT, beyond that of RLT, can be similarly produced.

Example 8 Consider a set S that is composed as follows in a particular problem instance:

$$S = \{x \in R^6 : 0 \leq x_1 \leq x_2 \leq x_3 \leq 1, 0 \leq x_4 \leq x_5 \leq 1, 0 \leq x_6 \leq 1\}.$$

The first-level factors for this instance are given by $x_1 \geq 0, x_2 - x_1 \geq 0, x_3 - x_2 \geq 0, 1 - x_3 \geq 0, x_4 \geq 0, x_5 - x_4 \geq 0, 1 - x_5 \geq 0, x_6 \geq 0$, and $1 - x_6 \geq 0$. Compared with the RLT factors, these yield tighter constraints as they imply the RLT factors.

For $d \in \{1, \dots, 6\}$, taking these factors d at a time, including self-products, and simplifying these factors by eliminating null or implied factors would produce the relaxation \bar{X}_d .

It is interesting to note in this connection that the VUB constraints of the type $0 \leq x_1 \leq x_2 \leq \dots \leq x_k \leq 1$ used in this example can be equivalently transformed into GUB constraints via the substitution $z_j = x_j - x_{j-1}$ for $j = 1, \dots, k$, where $x_0 \equiv 0$. The inverse transformation yields $x_j = \sum_{t=1}^j z_t$ for $j = 1, \dots, k$, thereby producing the equivalent representation $z_1 + z_2 + \dots + z_k \leq 1$, $z \geq 0$ for each such constraint. Under this transformation and imposing binary restrictions on all the z -variables, the reformulation strategies described above in Sect. 7.1 can be employed. However, note that the process of applying RLT to the original or to the transformed problem can produce different representations. This is illustrated next.

Example 9 Consider the set

$$X = \{(x_1, x_2) : -6x_1 + 3x_2 \leq 1, 0 \leq x_1 \leq x_2 \leq 1, x \text{ binary}\}.$$

The convex hull of feasible solutions is given by $0 \leq x_1 = x_2 \leq 1$ (see Fig. 4a). This representation is produced by the level-1 SSRLT relaxation using the VUB constraints to define S , where the relevant constraint $x_1 \geq x_2$, which yields $x_1 = x_2$, is obtained by noting that the factor products $\{x_1(x_2-x_1)\}_L \geq 0$ and $\{x_1(1-x_2)\}_L \geq 0$, respectively, give $w_{12} \geq x_1$ and $w_{12} \leq x_1$ or that $w_{12} = x_1$. This together with the constraint $\{(x_2-x_1)(1+6x_1-3x_2)\}_L \geq 0$ yields $-2(x_2-x_1) \geq 0$ or that $x_1 \geq x_2$.

On the other hand, constructing RLT at level 1 by applying the factors x_j and $(1-x_j)$, $j = 1, 2$, to the inequality restrictions of X produces the following relaxation (directly in projected form):

$$X_{P1} = \{(x_1, x_2) : 2x_1 - 3x_2 \geq -1, 3x_1 \geq x_2, 0 \leq x_1 \leq x_2 \leq 1\},$$

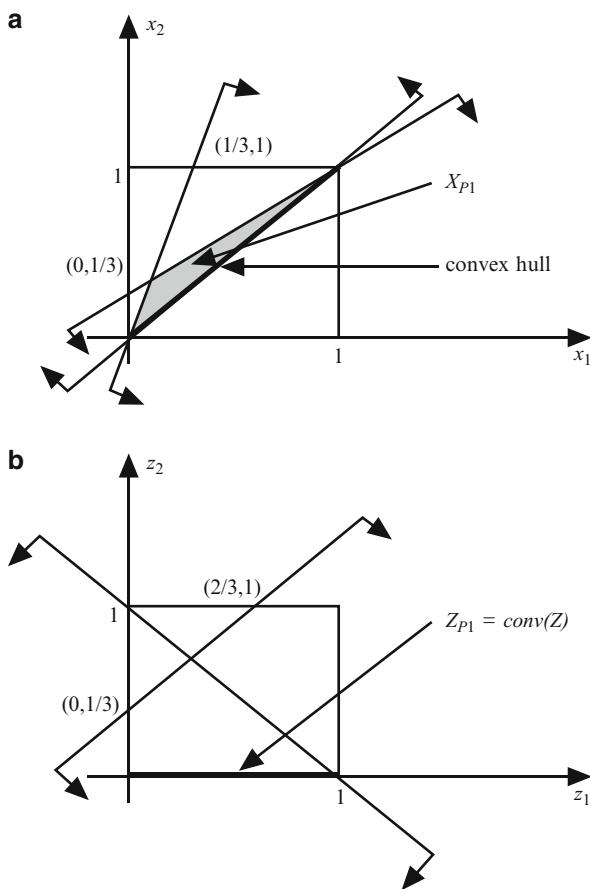

where $w_{12} = x_1$ is produced as with SSRLT and where the first two constraints defining X_{P1} result from the product constraints $\{(1+6x_1-3x_2)(1-x_1)\}_L \geq 0$ and $\{(1+6x_1-3x_2)x_2\}_L \geq 0$, respectively. The shaded area of Fig. 4a depicts the region defined by this relaxation.

However, applying the transformation $z_1 = x_1$, $z_2 = x_2 - x_1$ to X , where the inverse transformation is given by $x_1 = z_1$ and $x_2 = z_1 + z_2$, results in the following problem representation in z -space:

$$Z = \{(z_1, z_2) : -3z_1 + 3z_2 \leq 1, z_1 + z_2 \leq 1, z \text{ binary}\},$$

where the *binary restriction on z_2 has been additionally recognized*. Figure 4b illustrates that the set $\text{conv}(Z)$ is given by the constraints $0 \leq z_1 \leq 1$, $z_2 = 0$. Now, applying RLT to this transformed region, the relevant constraint $z_2 = 0$ is produced via $z_2 \geq 0$ and the first-level product constraint $\{(1+3z_1-3z_2)z_2\}_L \geq 0$, which

Fig. 4 Depiction of the first-level relaxations using RLT for Example 9

yields $-2z_2 \geq 0$, where $\{z_1 z_2\}_L = 0$, from $\{z_1 z_2\}_L \geq 0$ and $\{z_1(1 - z_1 - z_2)\}_L \geq 0$. Hence, for this transformed problem, RLT produces the first-level relaxation $Z_{P1} = \text{conv}(Z)$, while we had $X_{P1} \supset \text{conv}(X)$ when applying RLT to the original problem. However, as with Example 6 for the case $q = 1$ (treating that as the transformed z -variable problem), it is possible to obtain $Z_{P1} \supset \text{conv}(Z)$ as well, whereas SSRLT would necessarily produce the convex hull representation at level 1 in either case.

7.3 Sparse Constraints

This example illustrates how problem sparsity can be exploited. Consider a 0-1 mixed-integer programming problem that contains the following knapsack constraint (either inherent in the problem or implied by it): $2x_1 + x_2 + 2x_3 \geq 3$.

The facets of the convex hull of the set $\{(x_1, x_2, x_3) : 2x_1 + x_2 + 2x_3 \geq 3, x_i \text{ binary}, i = 1, 2, 3\}$ can be readily obtained as $\{x_1 + x_2 + x_3 \geq 2, x_1 \leq 1, x_2 \leq 1, x_3 \leq 1\}$. Similarly, another knapsack constraint in the problem might be of the type $x_4 + 2x_5 + 2x_6 \leq 2$, where the corresponding facets of the convex hull of feasible 0-1 solutions are given by $\{x_4 + x_5 + x_6 \leq 1, x_4 \geq 0, x_5 \geq 0, x_6 \geq 0\}$. The set S can now be composed of these two sets of facets, along with other similar constraints involving the remaining variables on which binary restrictions are being enforced, including perhaps simple bound-factor constraints. Note that in order to generate valid tighter relaxations, binarity might simply be enforced only on a subset of variables that fractionate in the original linear programming relaxation in the present framework. Furthermore, entire convex hull representations of underlying knapsack polytopes are not necessary – simply, the condition (36) needs to be satisfied, perhaps by explicitly including simple bounding constraints. This extends the strategy of Crowder et al. [24] in using facets obtained as liftings of minimal covers from knapsack constraints within this framework, in order to generate tighter relaxations.

8 Using Conditional Logic to Strengthen RLT Constraints with Application to the Traveling Salesman Problem

In all of the foregoing discussion, depending on the structure of the problem, there is another idea that can be exploited to even further tighten the RLT constraints that are generated. This trick deals with the use of *conditional logic* in the generation of RLT-based constraints for tightening a relaxation at any level, which would otherwise have been possible only at some higher level in the hierarchy. In effect, this captures within the RLT process the concepts of branching and logical preprocessing, which are features that are critical to the efficient solution of discrete optimization problems.

To introduce the basic concept involved, for simplicity, consider the following first-level SSRLT constraint that is generated by multiplying a factor $(\alpha x - \beta) \geq 0$ with a constraint $(\gamma x - \delta) \geq 0$, where x is supposed to be binary-valued and where the data is all integer (similar extensions can be developed for mixed-integer constraints, as well as for higher-order SSRLT constraints in which some factor is being applied to some other valid constraint- or bound-factor product of order greater than one):

$$\{(\alpha x - \beta)(\gamma x - \delta)\}_L \geq 0. \quad (49)$$

Observe that if $\alpha x = \beta$, then $(\alpha x - \beta)(\gamma x - \delta) \geq 0$ is valid regardless of the validity of $\gamma x \geq \delta$. Otherwise, it must be that $\alpha x \geq \beta + 1$ (or possibly greater than $\beta + 1$, if the structure of $\alpha x \geq \beta$ so permits), and so, standard logical preprocessing tests (zero-one fixing, coefficient reduction, etc. – see, e.g., Nemhauser and Wolsey [50]) can be performed on the set of constraints $\alpha x \geq \beta + 1, \gamma x \geq \delta, x \text{ binary}$, along with possibly other problem-defining constraints, to tighten $\gamma x \geq \delta$ to the form $\gamma' x \geq \delta'$. For example, if $\alpha x \geq \beta$ is of the type $(1 - x_j) \geq 0$, for some $j \in \{1, \dots, n\}$,

then the restriction $\alpha x \geq \beta + 1$, x binary, asserts that $x_j = 0$, and so, $\gamma x \geq \delta$ can be tightened under the condition that $x_j = 0$. (Similarly, in a higher-order constraint, if a factor $F_d(J_1, J_2)$ multiplies $\gamma x \geq \delta$, then the latter constraint can be tightened under conditional logical tests based on setting $x_j = 1$, $\forall j \in J_1$, and $x_j = 0$, $\forall j \in J_2$.)

Additionally, the resulting constraint $\gamma'x \geq \delta'$ can potentially be further tightened by finding the maximum $\theta \geq 0$ for which $\gamma'x \geq \delta' + \theta$ is valid when $\alpha x \geq \beta + 1$ is imposed by considering the problem

$$\theta = -\delta' + \min \{ \gamma'x : \gamma'x \geq \delta', \alpha x \geq \beta + 1, \text{any other valid inequalities, } x \text{ binary} \}, \quad (50)$$

and by increasing δ' by this quantity θ . Note that a valid value of θ can be derived by simply solving the continuous relaxation of (50) and rounding the resulting value upward (using $\theta = 0$ if this value is negative). In either case, the following SSRLT constraint can be imposed in lieu of the relatively weaker restriction (49) within the underlying problem:

$$\{(\alpha x - \beta)(\gamma'x - \delta' - \theta)\}_L \geq 0. \quad (51)$$

Interestingly, the sequential lifting process studied by Balas and Zemel [18] for lifting a minimal cover inequality into a facet for a full dimensional knapsack polytope can be viewed as a consequence of this RLT construct (see Sherali et al. [90]).

Example 10 To illustrate, consider the following knapsack constraint in binary variables x_1 , x_2 , and x_3 : $2x_1 + 3x_2 + 3x_3 \geq 4$. Examine the RLT constraint

$$\{x_3(2x_1 + 3x_2 + 3x_3 - 4)\}_L \geq 0. \quad (52)$$

Applying the foregoing idea, (52) can be tightened under the restriction that $x_3 = 1$, knowing that it is always valid when $x_3 = 0$ regardless of the nonnegativity of any expression contained in (\cdot) . However, when $x_3 = 1$, the given knapsack constraint becomes $2x_1 + 3x_2 \geq 1$, which by coefficient reduction, can be tightened to $x_1 + x_2 \geq 1$. Hence, (52) can be replaced by the tighter restriction

$$\{x_3(x_1 + x_2 - 1)\}_L \geq 0. \quad (53)$$

Similarly, consider the RLT constraint

$$\{(1 - x_3)(2x_1 + 3x_2 + 3x_3 - 4)\}_L \geq 0. \quad (54)$$

This time, imposing $(1 - x_3) \geq 1$, that is, $x_3 = 0$, the knapsack constraint becomes $2x_1 + 3x_2 \geq 4$, which implies via standard logical tests that $x_1 = x_2 = 1$. Hence, the following *equality* restrictions can be imposed in lieu of (54), which is now implied:

$$\{(1 - x_3)(x_1 - 1)\}_L = 0 \text{ and } \{(1 - x_3)(x_2 - 1)\}_L = 0. \quad (55)$$

Observe that in this example, the sum of the RLT constraints in (53) and (55) yields $x_1 + x_2 + x_3 \geq 2$, which happens to define a facet of the knapsack polytope $\text{conv}\{x : 2x_1 + 3x_2 + 3x_3 \geq 4, x \text{ binary}\}$. This facet can alternatively be obtained by lifting the minimal cover inequality $x_1 + x_2 \geq 1$ as in Balas and Zemel [18].

Example 11 To illustrate the use of the foregoing conditional logic-based tightening procedure in the context of solving an optimization problem using general S -factors, consider the following problem:

$$\text{Minimize } \{x_1 + x_2 : 6x_1 + 3x_2 \geq 2, x \in S, x \text{ binary}\}, \quad (56)$$

$$\text{where } S \equiv \{(x_1, x_2) : 2x_1 + x_2 \leq 2, x_1 + 2x_2 \leq 2, x \geq 0\}.$$

Figure 5 depicts this problem graphically. The integer problem has the optimal value $v(\text{IP}) = 1$, attained at the solution $(1, 0)$ or $(0, 1)$. The ordinary LP relaxation, with extreme points $(0, 2/3)$, $(0, 1)$, $(2/3, 2/3)$, $(1, 0)$, and $(1/3, 0)$, has the optimal value $v(\text{LP}) = 1/3$, attained at the solution $(1/3, 0)$.

Next, consider the first-level relaxation (RLT-1) produced by RLT, using the factors x_j and $(1 - x_j)$, $j = 1, 2$, to multiply all the problem constraints. Note that $\{(2 - 2x_1 - x_2)x_1\}_L$ yields $w_{12} \leq 0$, which, together with $\{x_1x_2\}_L = w_{12} \geq 0$, gives $w_{12} = 0$. The other non-redundant constraints defining this relaxation are produced via the product constraints $\{(1 - x_1)(1 - x_2)\}_L \geq 0$, $\{(6x_1 + 3x_2 - 2)(1 - x_1)\}_L \geq 0$, and $\{(6x_1 + 3x_2 - 2)(1 - x_2)\}_L \geq 0$, which respectively yield (using $w_{12} = 0$) $x_1 + x_2 \leq 1$, $2x_1 + 3x_2 \geq 2$, and $3x_1 + x_2 \geq 1$. This gives (directly in projected form)

$$X_{P1} = \{(x_1, x_2) : x_1 + x_2 \leq 1, 2x_1 + 3x_2 \geq 2, 3x_1 + x_2 \geq 1\}.$$

Figure 5 depicts this region, with extreme points $(1, 0)$, $(0, 1)$, and $B = (1/7, 4/7)$. The optimal value using this relaxation is given by $v(\text{RLT-1}) = 5/7$, attained at the solution $(1/7, 4/7)$.

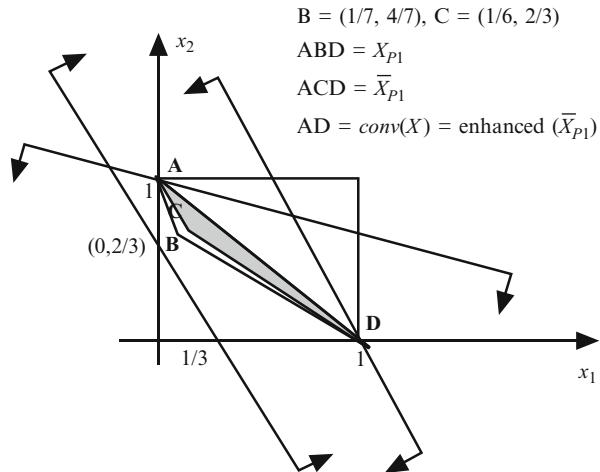

On the other hand, the first-level relaxation (SSRLT-1) produced by SSRLT would employ the S -factors given by the constraints in (56). As in RLT, this yields $w_{12} = 0$. Using this identity, the other nonredundant constraints defining the relaxation SSRLT-1 are produced via the following product constraints:

$$\{(2 - 2x_1 - x_2)(2 - x_1 - 2x_2)\}_L \geq 0,$$

$$\{(6x_1 + 3x_2 - 2)(2 - 2x_1 - x_2)\}_L \geq 0, \text{ and}$$

$$\{(6x_1 + 3x_2 - 2)(2 - x_1 - 2x_2)\}_L \geq 0,$$

Fig. 5 Depiction of the various first-level RLT relaxations

which respectively yield $x_1 + x_2 \leq 1$, $4x_1 + 5x_2 \geq 4$, and $2x_1 + x_2 \geq 1$. This gives (directly in projected form)

$$\bar{X}_{P1} = \{(x_1, x_2) : x_1 + x_2 \leq 1, 4x_1 + 5x_2 \geq 4, 2x_1 + x_2 \geq 1\}.$$

Figure 5 depicts this region, with extreme points $(1, 0)$, $(0, 1)$, and $C = (1/6, 2/3)$. Note that $\bar{X}_{P1} \subset X_{P1}$ and that the optimal value of this relaxation is given by $v(\text{SSRLT-1}) = 5/6 > v(\text{RLT-1})$ and is attained at the solution $(1/6, 2/3)$.

Now, consider an enhancement of SSRLT-1 using conditional logic (a similar enhancement can be exhibited for RLT-1). Specifically, consider the RLT product constraint $\{(2 - 2x_1 - x_2)(6x_1 + 3x_2 - 2)\}_L \geq 0$ of the form (49). Imposing $(2 - 2x_1 - x_2) \geq 1$ as for (49), that is, $2x_1 + x_2 \leq 1$, yields $x_1 = 0$ by a standard logical test. This, together with $6x_1 + 3x_2 \geq 2$, implies that $x_2 = 1$. Hence, the tightened form of the foregoing RLT product constraint is $(2 - 2x_1 - x_2)(x_1) = 0$ and $(2 - 2x_1 - x_2)(1 - x_2) = 0$. The first constraint asserts that $w_{12} = 0$ (as before), while the second constraint asserts that $x_1 + x_2 = 1$. This produces the convex hull representation, and so, this enhanced relaxation now recovers an optimal integer solution.

The paper by Lougee-Heimer and Adams [45] further explores the idea of conditional logic. It shows that the basic constructs provide a framework that can be used to motivate a variety of cut strengthening techniques, including single- and multiple-coefficient adjustments, which are found throughout the literature. Special structures arising within plant location, capacity expansion, resource allocation, variable upper bounds, cover inequalities, and SOS inequalities are examined. Relationships to the

foundation-penalty cuts of Glover and Sherali [33] and extensions to compound conditional logic that involve higher-order RLT products are also explored.

8.1 Application to the Traveling Salesman Problem

Sherali and Driscoll [74] have demonstrated the potential utility of the various concepts developed in Sects. 6–8 by applying them to the celebrated traveling salesman problem (TSP). To elucidate, consider the case of a general (asymmetric) TSP defined on a totally dense graph (see, e.g., Lawler et al. [42]). For this problem, Desrochers and Laporte [27] have derived a strengthened version of the Miller–Tucker–Zemlin (MTZ) formulation obtained by lifting the MTZ-subtour elimination constraints into facets of the underlying TSP polytope. While it is well known that the traditional MTZ formulation of TSP yields weak relaxations, Desrochers and Laporte exhibited computationally that their lifted-MTZ formulation significantly tightens this representation. The discussion below shows that an application of SSRLT concepts to the MTZ formulation of TSP, used in concert with the conditional logic-based strengthening procedure, *automatically recovers* the formulation of Desrochers and Laporte as well as affords a further tightening for this problem.

Toward this end, consider the following statement of the asymmetric traveling salesman problem, where $x_{ij} = 1$ if the tour proceeds from city i directly to city j and is 0 otherwise, for all $i, j = 1, \dots, n, i \neq j$:

$$\text{ATSP: Minimize } \sum_{i=1}^n \sum_{j \neq i} c_{ij} x_{ij}$$

$$\text{subject to } \sum_{j \neq i} x_{ij} = 1, \quad \forall i = 1, \dots, n, \quad (57)$$

$$\sum_{i \neq j} x_{ij} = 1, \quad \forall j = 1, \dots, n, \quad (58)$$

$$u_j \geq (u_i + 1) - (n - 1)(1 - x_{ij}), \quad \forall i, j \geq 2, i \neq j, \quad (59)$$

$$1 \leq u_j \leq (n - 1), \quad \forall j = 2, \dots, n, \quad (60)$$

$$x_{ij} \text{ binary}, \quad \forall i, j = 1, \dots, n, i \neq j. \quad (61)$$

Note that (57), (58), and (61) represent the assignment constraints and (59) and (60) are the MTZ-subtour elimination constraints. These latter constraints are derived based on letting u_j represent the rank order in which city j is visited, using $u_1 \equiv 0$, and enforcing that $u_j = u_i + 1$ whenever $x_{ij} = 1$ in any binary feasible solution. Now, in order to construct a suitable reformulation using SSRLT, compose the set S as follows and include this set of implied inequalities within the problem ATSP stated above:

$$S \equiv \{x : x_{ij} + x_{ji} \leq 1, \forall 2 \leq i < j \leq n; x_{1j} + x_{j1} \leq 1, \forall j \geq 2; \\ x_{ij} \geq 0, \forall i, j, i \neq j\}. \quad (62)$$

Note that S is comprised of simple two-city subtour elimination constraints of the form proposed by Dantzig, Fulkerson, and Johnson [26]. Next, construct the following selected S -factor constraint products. First, consider the product constraint generated by multiplying (59) with the S -factor x_{ij} . Using conditional logic as with (49) and noting that $u_j = (u_i + 1)$ when $x_{ij} = 1$, this yields the constraint

$$x_{ij} u_j = x_{ij}(u_i + 1), \forall i, j \geq 2, i \neq j. \quad (63)$$

Similarly, considering $\{x_{1j}(u_j - 1)\}_L \geq 0$ from (60) and enhancing this by the conditional logic that $u_j = 1$ when $x_{1j} = 1$ yields

$$x_{1j} u_j = x_{1j}, \forall j = 2, \dots, n. \quad (64)$$

Repeating this with the upper bounding constraint in (60), the restriction $\{x_{j1}(n - 1 - u_j)\}_L \geq 0$ can be enhanced to yield the following constraint, noting that $u_j = (n - 1)$ if $x_{j1} = 1$:

$$x_{j1} u_j = (n - 1)x_{j1}, \forall j = 2, \dots, n. \quad (65)$$

Next, consider the product of (59) with the S -factor $(1 - x_{ij} - x_{ji}) \geq 0$. This gives the constraint $\{(1 - x_{ij} - x_{ji})(u_j - u_i - 1 + (n - 1)(1 - x_{ij}))\}_L \geq 0$. Using $x_{ij}^2 = x_{ij}$ and $x_{ij} x_{ji} = 0$ (since $x_{ij} + x_{ji} \leq 1$), the foregoing constraint becomes

$$(u_j - u_i) \geq (u_j - u_i)(x_{ij} + x_{ji}) - (n - 2)(1 - x_{ij}) + (n - 2)x_{ji}.$$

Note that $(u_j - u_i)x_{ij} = x_{ij}$ from (63). Interchanging i and j , this yields $(u_j - u_i)x_{ji} = -x_{ji}$. Substituting this into the foregoing SSRLT constraint produces the valid inequality

$$u_j \geq (u_i + 1) - (n - 1)(1 - x_{ij}) + (n - 3)x_{ji}, \forall i, j \geq 2, i \neq j. \quad (66)$$

Similarly, multiplying (60) with the S -factor $(1 - x_{1j} - x_{j1}) \geq 0$ yields $\{(1 - x_{1j} - x_{j1})(u_j - 1)\}_L \geq 0$ and $\{(1 - x_{1j} - x_{j1})(n - 1 - u_j)\}_L \geq 0$. Using the conditional logic procedure, under $x_{1j} = x_{j1} = 0$, these constraints can be respectively tightened to $\{(1 - x_{1j} - x_{j1})(u_j - 2)\}_L \geq 0$ and $\{(1 - x_{1j} - x_{j1})(n - 2 - u_j)\}_L \geq 0$. Simplifying these products and using (64) and (65) yields the constraints

$$1 + (1 - x_{1j}) + (n - 3)x_{ji} \leq u_j \leq (n - 1) - (1 - x_{j1}) - (n - 3)x_{1j}. \quad (67)$$

Observe that (66) and (67) are tightened versions of (59) and (60), respectively, and are precisely the facet-defining, lifted-MTZ constraints derived by Desrochers and Laporte [27]. Hence, the above discussion reveals that a selected application

of SSRLT used in concert with the conditional logic-based strengthening procedure *automatically* generates this improved MTZ formulation. Sherali and Driscoll [74] have developed further enhancements that tighten and subsume this formulation for both the ordinary as well as for the precedence constrained version of the asymmetric traveling salesman problem, using these SSRLT constructs along with conditional logic implications. Using a different flow-based model, Sherali et al. [94] apply RLT concepts with conditional logic to derive a significantly tighter, yet polynomial length, lifted formulation for the ATSP.

9 Semidefinite Cuts and Extensions to Continuous Global Optimization

Motivated by the semidefinite relaxations of Lovasz and Schrijver [46] and Sherali and Fraticelli [75] derive a class of so-called *semidefinite cuts* that can be used to further tighten RLT relaxations while maintaining linearity, thus facilitating the use of robust, commercial linear programming software as routines for solving such relaxations within the framework of branch-and-cut algorithms. To illustrate,

consider the first-level relaxation for 0-1 MIPs, and let $x_{(1)} \equiv \begin{bmatrix} 1 \\ x \end{bmatrix}$, represent an $(n + 1)$ -dimensional extension of the binary vector x , and consider the matrix $M_1 \equiv \{x_{(1)}x_{(1)}^T\}_L$, whereas before, $\{\cdot\}_L$ denotes the linearization of the expression $\{\cdot\}$ under the RLT variable substitution process, including the application of the identity $x_j^2 = x_j$, $\forall j \in N$. Noting that $x_{(1)}x_{(1)}^T$ is symmetric and positive semidefinite (denoted $\succeq 0$), we could require that $M_1 \succeq 0$, that is,

$$\alpha^T M_1 \alpha = \{(\alpha^T x_{(1)})^2\}_L \geq 0, \quad \forall \alpha \in \mathbb{R}^{n+1}, \|\alpha\| = 1.$$

As such, letting \bar{M}_1 represent the evaluation of M_1 at a given solution to an underlying RLT relaxation in the lifted space of the original and new RLT variables, Sherali and Fraticelli [75] present a polynomial-time procedure, having a worst-case complexity $O(n^3)$, which either verifies that $\bar{M}_1 \succeq 0$ or else generates a suitable $\bar{\alpha} \in \mathbb{R}^{n+1}$ for which $\bar{\alpha}^T \bar{M}_1 \bar{\alpha} < 0$, thus yielding the semidefinite cut $\bar{\alpha}^T M_1 \bar{\alpha} = \{(\bar{\alpha}^T x_{(1)})^2\}_L \geq 0$. Furthermore, motivated in part by the moment matrices utilized by Lasserre [40, 41] in the context of continuous polynomial programs, Sherali and Desai [73] and Sherali et al. [95] extend this concept by replacing $x_{(1)}$ with a vector v that is comprised of the components of $x_{(1)}$ plus other suitable higher-order monomials and then invoking $\{vv^T\}_L \succeq 0$ to generate so-called v -semidefinite cuts. Different techniques are described by Sherali et al. [95] for generating various classes of such v -semidefinite cuts, along with encouraging computational results, actually, for continuous polynomial programming problems as discussed next.

The RLT methodology addressed herein provides a unifying framework for solving not only mixed-discrete polynomial programming problems but also continuous,

nonconvex polynomial and factorable optimization problems to global optimality (see Sherali and Tuncbilek [82] and Sherali and Wang [86]). Here, the *bound factors* ($x_j - \ell_j$) and ($u_j - x_j$) are defined with respect to the general bounding restrictions $\ell_j \leq x_j \leq u_j$, for all the variables x_j defining the given nonconvex program, and are used in concert with the aforementioned constraint factors to generate tight relaxations, which are then embedded within a branch-and-bound algorithm. These relaxations can be further augmented by semidefinite cuts (see Sherali et al. [95]) as well as with other valid inequalities based on grid factors, Lagrange interpolating polynomials, and Chebyshev polynomials (see Sherali and Tuncbilek [83, 84] and Sherali and Dalkiran [72]). By utilizing a suitable partitioning process, Sherali and Tuncbilek [82] and Sherali and Wang [86] show that such an enumeration process can be induced to converge to a global optimal solution. Sherali and Adams [68] provide additional reading on applications of RLT to several special problems (including bilinear, indefinite quadratic location – allocation, and linear complementarity problems) in the domain of both discrete and continuous nonconvex optimization.

10 Conclusion

The hierarchy of relaxations emerging from the RLT can be intuitively viewed as *stepping stones* between continuous and discrete sets, leading from the usual linear programming relaxation to the convex hull representation at level n . By inductively progressing along these stepping-stone formulations, Adams et al. [8] have studied *persistency* issues for certain constrained and unconstrained pseudo-Boolean programming problems. Given the tight linear programming relaxations afforded by RLT, a pertinent question that can be raised is that if the solution obtained for a particular d th level LP relaxation in the RLT hierarchy yields some of the n 0-1 variables as binary-valued, then can these binary values be expected to persist at optimality to the original problem? Adams et al. [8] derive sufficient conditions in terms of the dual solution that guarantee such a persistency result. For the unconstrained pseudo-Boolean program, it is proven that for $d = 1$ or for $d \geq n - 2$, persistency always holds. However, using an example with $d = 2$ and $n = 5$, it is shown that without the additional prescribed sufficient conditions, persistency will not hold in general. These results are also extended to constrained polynomial 0-1 programming problems. In particular, the analysis here reveals a class of 0-1 linear programs that possess the foregoing persistency property. Included within this class as a special case is the popular vertex packing problem, shown earlier in the literature to possess this property.

Thus far, the discussion has focused on binary discrete variables. Conceptually, for a more general *discrete integer program*, a binary transformation could be applied to rewrite the problem as a 0-1 mixed-integer program, to which the foregoing RLT constructs could be applied. Sherali and Adams [68] show that such a specialization can be equivalently translated into a novel direct approach applied to the original problem itself, which leads to more insightful and compact

representations. To see the basic form of this approach, consider the following feasible region of a discrete mixed-integer program:

$$X = \{(x, y) \in R^n \times R^m : Ax + Dy \geq b\}, \quad (68)$$

$$x_j \in S_j \equiv \{\theta_{jk}, k = 1, \dots, k_j\}, \forall j = 1, \dots, n, \quad (69)$$

$$y \geq 0\}, \quad (70)$$

where $\theta_{jk}, k = 1, \dots, k_j, j = 1, \dots, n$ are discrete real numbers (of either sign). As a generalization of the bound factors x_j and $(1 - x_j)$ that are used when x_j is binary, examine the *Lagrange interpolation polynomials* (LIPs) (see Volkov [102]):

$$L_{jk} = \frac{\prod_{p \neq k} (x_j - \theta_{jp})}{\prod_{p \neq k} (\theta_{jk} - \theta_{jp})}, \forall k = 1, \dots, k_j, j = 1, \dots, n. \quad (71)$$

Note that $L_{jk} = 1$ if $x_j = \theta_{jk}$ and $L_{jk} = 0$ if $x_j = \theta_{jp}$ for any $p = \{1, \dots, k_j\} \setminus \{k\}$, $\forall j = 1, \dots, n$. Hence, for each $j = 1, \dots, n$, the LIPs $L_{jk}, k = 1, \dots, k_j$, are akin to 0-1 weights attached to the respective discrete values $\theta_{jk}, k = 1, \dots, k_j$, where it follows from (71) upon algebraic simplifications that

$$\sum_{k=1}^{k_j} L_{jk} = 1, \quad \forall j = 1, \dots, n. \quad (72)$$

Over the discrete restrictions $x_j \in S_j, \forall j = 1, \dots, n$, it also holds that

$$\begin{aligned} & \{L_{jk_1} L_{jk_2} = 0, \forall k_1 \neq k_2\}, \{L_{jk}^2 = L_{jk}, \forall k\}, \text{ and} \\ & \{x_j L_{jk} = \theta_{jk} L_{jk}, \forall k\}, \forall j = 1, \dots, n. \end{aligned} \quad (73)$$

The RLT process in this case employs *LIP factors of order d* composed by selecting some d distinct indices j and, for each selected index, choosing some LIP $L_{jk}, k \in \{1, \dots, k_j\}$. The procedure then proceeds as follows for constructing the relaxation \tilde{X}_d , for any $d \in \{0, 1, \dots, n\}$:

Reformulation phase:

1. Multiply (68) and (70) by all possible LIP factors of order d .
2. Include nonnegativities on all possible LIP factors of order D , where $D \equiv \min\{d+1, n\}$.
3. Use the following identity in the resulting nonlinear program (see (73)):

$$x_j L_{jk} = \theta_{jk} L_{jk} \text{ (i.e., } (x_j - \theta_{jk})L_{jk} = 0\text{), } \forall k = 1, \dots, k_j, j = 1, \dots, n. \quad (74)$$

Linearization phase: Linearize the resulting problem obtained via Steps 1–3 of the reformulation phase by substituting a particular variable for each distinct product of the x -variables thus generated and similarly for each distinct product of y_t with the x -variables, $\forall t$. (Note that these product terms can include self-products of variables.) This produces the required polyhedral relaxation \tilde{X}_d in higher dimensions.

In regard to the foregoing RLT process, first of all, note that whenever x_j is a binary variable as in the previous analysis, (74) corresponds to the step of letting $x_j^2 = x_j$, that is, setting $x_j(1 - x_j) = 0$. Indeed if $S_j \equiv \{0, 1\}$, then L_{jk} in (71) reduces to $(1 - x_j)$ and x_j for $k = 1, 2$, respectively, and (74) yields the familiar identities $x_j(1 - x_j) = 0$ and $x_j^2 = x_j$ for $k = 1, 2$, respectively, which coincide in this binary case. Second, by (72) and (73), observe that for converting the polyhedral relaxation \tilde{X}_d into an equivalent *representation* (not relaxation) of the discrete set X , it suffices to require the LIPs L_{jk} to take on binary values, $\forall k = 1, \dots, k_j, j = 1, \dots, n$, for example, by equating them to distinct binary variables. Third, similar to (12), by defining \tilde{X}_{P_d} as the projection of \tilde{X}_d onto the space of the original variables (x, y) , it can be shown that this RLT process produces the following hierarchy of relaxations:

$$\tilde{X}_{P_0} \supseteq \tilde{X}_{P_1} \supseteq \dots \supseteq \tilde{X}_{P_n} = \text{conv}(X). \quad (75)$$

Moreover, the relationship between the binary transformed problem and the original discrete problem can be used to translate valid inequalities that are derived in the former space to those represented in the original (x, y) variable space. This construct can be useful in implementing a cutting plane or a branch-and-cut approach for general integer programs.

Adams and Sherali [6] provide an alternative elegant proof of (75) for the foregoing RLT procedure by recognizing that the collection of LIPs can be expressed as Kronecker products of matrices given by the inverses of the transposes of Vandermonde matrices. Noting that the Kronecker product of the inverses of a given set of matrices is the inverse of their Kronecker products directly leads to (75) and also thereby generalizes the application of RLT for 0-1 mixed-integer programs.

Furthermore, Sherali and Adams [69] have shown that (12) or (75) holds true even for general mixed-discrete, linear semi-infinite programs. As such, this enables the extension of RLT to bounded 0-1 mixed-integer and mixed-discrete *convex programs*, where such problems can be equivalently written (implicitly) as semi-infinite programs by using suitable supporting hyperplanes for the region defined by each convex constraint based on the first-order characterization of convexity (see Bazaraa et al. [20]). Sherali and Adams [69] present an inverse transformation mechanism whereby the resulting lifted semi-infinite relaxation at any level can be transformed back into an equivalent finitely constrained convex relaxation defined in terms of the original constraint functions. The hierarchy (75) is thus shown to hold true for the latter set of relaxations. In particular, for 0-1 mixed-integer

convex programs, this analysis recovers at the highest level the convex hull representation derived by Stubbs and Mehrotra [97]. Sherali and Adams [69] also present useful first-level lifted relaxations that can be judiciously applied to solve practical mixed-integer convex programs arising in a wide range of contexts such as robotics, optimal control, finance, and various chemical process and engineering design problems.

As far as the use of RLT as a practical computational aid for solving mixed-integer 0-1 problems is concerned, one may simply work with the relaxation X_1 itself, which has frequently proven to be beneficial or even utilize the reduced level-1 relaxation proposed by Sherali et al. [93], which can, in theory, achieve the same strength as the full level-1 relaxation. Using variations on the first-level RLT relaxation (a partial generation of X_1 enhanced by additional constraint products), Adams and Johnson [2], Adams and Sherali [3–5], Sherali and Adams [63, 66, 67], Sherali and Brown [70], Sherali et al. [89], and Sherali et al. [87] have shown how highly effective algorithms can be constructed for various classes of discrete problems and related applications. A study of special cases of this type has provided insights into useful implementation strategies based on tightening a given model formulation via first-order RLT product constraints. Additionally, techniques for generating tight valid inequalities that are implied by higher-order relaxations may be devised, or explicit convex hull representations or facetial inequalities could be generated by applying the highest order RLT scheme to various subsets of sparse constraints that involve a manageable number of variables. The lattermost strategy would be a generalization of using facets of the knapsack polytope derived from minimal covers (see Balas and Zemel [18] and Zemel [107, 108]), which were implemented by Crowder et al. [24] and Hoffman and Padberg [34] with great success. An alternative would be to apply a higher-order scheme on a subset of binary variables that turn out to be fractional in the initial linear programming solution. Letting x_j , $j \in J_f$, represent such a subset, it follows from Sherali and Adams [65] that by deriving $X_{|J_f|}$ based on this subset, which is manageable if $|J_f|$ is relatively small, the resulting linear program will yield binary values for x_j , $\forall j \in J_f$. This would be akin to employing judicious partial convex hull representations. Sherali and Smith [80] discuss how cuts implied by such (implicitly derived) higher-level RLT relaxations can be expeditiously generated. Moreover, the RLT-based formulations give rise to special structures that can be suitably exploited. Works of Sun [98] and Adams and Hadavas [1] have shown how select subsets of constraints that naturally arise in the level-1 RLT formulation can be transformed, via suitable substitutions of variables, into maximum flow networks.

Finally, consider the task of solving RLT-based relaxations. While the RLT process leads to tight linear programming relaxations for the underlying discrete problem being solved as discussed above, one has to contend with the repeated solutions of such large-scale linear programs. By the nature of the RLT process, these linear programs possess a special structure induced by the replicated products of the original problem constraints (or its subset) with certain designated variables.

At the same time, this process injects a high level of degeneracy in the problem since blocks of constraints automatically become active whenever the factor expression that generated them turns out to be zero at any feasible solution, and the condition number of the bases can become quite large. As a result, simplex-based procedures and even interior point methods experience difficulty in coping with such reformulated linear programs (see Adams and Sherali [5], for some related computational experience). On the other hand, a Lagrangian duality-based scheme can not only exploit the inherent special structures, but can quickly provide near optimal primal and dual solutions that serve the purpose of obtaining tight lower and upper bounds. In this vein, Sherali and Smith [81] present a dynamic Lagrangian dual scheme in which suitable level-1 RLT constraints are dynamically generated within a Lagrangian dual ascent process. However, for a successful use of this technique, there are two critical issues. First, an appropriate formulation of the underlying Lagrangian dual must be constructed (see Fisher [28]). Sherali and Myers [79] also discuss and test various strategies and provide guidelines for composing suitable Lagrangian dual formulations. Second, an appropriate nondifferentiable optimization technique must be employed to solve the Lagrangian dual problem. For the size of problems encountered in the context of RLT, it appears imperative to use conjugate subgradient methods as in Camerini et al. [22], Sherali and Ulular [85], and Sherali et al. [88], which employ higher-order information but in a manner involving minor additional effort and storage over traditional subgradient algorithms. For large-scale Lagrangian dual optimization problems, the proximal bundle algorithm of Kiwiel [39], the variable target value method of Sherali et al. [92] (see also Sherali and Lim [78] and Lim and Sherali [43]), and the trust region target value method of Lim and Sherali [44] might be more appropriate. Since these types of algorithms are not usually dual adequate [30], for algorithms that require primal solutions for partitioning purposes, some extra work becomes necessary. For this purpose, one can either use powerful LP solvers such as CPLEX [23] on suitable surrogate versions of the problem based on the derived dual solution or apply primal solution recovery procedures as in Shor [96] or Sherali and Choi [71] along with primal penalty function techniques as in Sherali and Ulular [85].

It is anticipated that automatic reformulation techniques, such as the RLT scheme discussed in this chapter, will continue to play a crucial role in enhancing problem solving capability. Ongoing advances in solving large-scale linear programming problems will provide a further impetus to such techniques, which typically tend to derive tighter representations in higher dimensions and with additional constraints. Furthermore, relaxations based on semidefinite programming approaches as motivated by the work of Lovasz and Shrijver [46], along with interior point approaches for solving such relaxations (see Overton and Wolkowicz [55], Anstreicher [11], and Terlaky [99]), hold promise for future advancements.

Abstract

The resource allocation problem seeks to find an optimal allocation of a fixed amount of resources to activities so as to minimize the cost incurred by the allocation. A simplest form of the problem is to minimize a separable convex function under a single constraint concerning the total amount of resource to be allocated. The amount of resource to be allocated to each activity is treated as a continuous or integer variable, depending on the situations. Hence, this problem can be viewed as a special case of the nonlinear programming problem or the nonlinear integer programming problem.

Due to its simple structure, the resource allocation problem is encountered in a variety of application areas, including load distribution, production planning, computer resource allocation, queueing control, portfolio selection, and apportionment. The first explicit investigation of the resource allocation problem was due to a paper by Koopman [89] published in 1953, where he discussed optimal distribution of efforts which arises from the problem of searching for an object whose position is a random variable. Since then, a great number of papers on the resource allocation problem have been published. Efficient algorithms have also been developed, depending on the types of objective functions, constraints, and variables (i.e., continuous or integer).

In 1988, two of the present authors, Ibaraki and Katoh, have published a book [69] that gave a comprehensive review of the state of the art of the resource allocation problem. Since then, more than 20 years have passed, during which, many papers on this problem have been published. A significant progress has been made on the algorithm side. Also, new generalizations and variants of the problem have been investigated, and new application fields have been discovered. The main purpose of this chapter is to give a brief overview of the recent progress on the theory and applications, putting emphasis on the cases with integer variables.

1 Introduction

The resource allocation problem seeks to find an optimal allocation of a fixed amount of resources to activities so as to minimize the cost incurred by the allocation. A simplest form of the problem is to minimize a separable convex function under a single constraint concerning the total amount of resource to be allocated. The amount of resource to be allocated to each activity is treated as a continuous or integer variable, depending on the situations. Hence, this problem can be viewed as a special case of the nonlinear programming problem or the nonlinear integer programming problem.

Due to its simple structure, this problem is encountered in a variety of application areas, including load distribution, production planning, computer resource allocation, queueing control, portfolio selection, and apportionment. The first explicit investigation of the resource allocation problem was due to a paper by Koopman [89] published in 1953, where he discussed optimal distribution of efforts which arises in the problem of searching for an object whose position is a random variable. Since then, a great number of papers have been published on the resource allocation problem. Efficient algorithms have also been developed, depending on the types of objective functions, constraints, and variables (i.e., continuous or integer).

In 1988, two of the present authors, Ibaraki and Katoh, have published a book [69] that gave a comprehensive review of the state of the art of the problems. Since then, more than 20 years have passed, during which, many papers have been published on resource allocation problems. A significant progress has been made on the algorithm side. Also new generalizations and variants of the problem have been investigated, and new application fields have been discovered. The main purpose of this chapter is to give a brief overview of the recent progress on the theory and applications, putting emphasis on the cases with integer variables. Notice that, in addition to the first edition of this chapter published in 1999, two survey papers have been recently published by Hochbaum [63] and by Patricksson [120].

To get an idea of some of topics included in this chapter, a perspective view of these years is briefly given here by using the simplest type of the problem, which is the separable convex resource allocation problem with integer variables described as follows:

$$\begin{aligned} & \text{minimize} \quad \sum_{j=1}^n f_j(x_j) \\ & \text{subject to} \quad \sum_{j=1}^n x_j = N, \\ & \quad x_j \geq 0, \quad \text{integer } j = 1, \dots, n. \end{aligned}$$

Because of its simple constraint, this problem is also referred to as *the simple resource allocation problem*. For this problem, a simple greedy-type algorithm was developed by Gross [54] (the same algorithm has been rediscovered by many

researchers, e.g., Fox [41] and Shih [128]). The running time of this algorithm is $O(N \log n + n)$. However, this time complexity is not polynomial but is pseudo-polynomial in the input size, which is $O(n + \log N)$. Thus, efficient polynomial-time algorithms have been studied by Frederickson and Johnson [42], Galil and Megiddo [48], and Katoh et al. [78]. The fastest among them is due to Frederickson and Johnson [42] and runs in $O(\max\{n, n \log(N/n)\})$ time.

In 1980s, the constraint in the above problem has been generalized, while the polynomial-time solvability is preserved. One such generalization is the problem with submodular constraint, which includes nested, tree, and network constraints as special cases. For this problem, polynomial-time algorithms have been developed in [43, 45, 53, 69]. It was shown that a greedy procedure for the simple allocation problem also works for the one with submodular constraint [39, 69]. The book by Fujishige [45] gives a comprehensive overview on the resource allocation problem under submodular constraint.

Later, Ando, Fujishige, and Naitoh [4, 5] considered the separable convex resource allocation problem with two types of constraints, one given by a bisubmodular system and the other given by a finite jump system; these constraints can be viewed as a generalization of submodular constraint. They developed greedy algorithms for such problems. For the case of a bisubmodular system, a polynomial-time algorithm has been developed by Fujishige [44]. Also, Hochbaum and Shanthikumar [65] showed that, for a class of general linear constraints, efficient algorithms can be developed. The running time of their algorithm depends on the maximum absolute value of the subdeterminants Δ of the constraint matrix, and if $\Delta = 1$ (i.e., the constraint matrix is totally unimodular), the running time becomes polynomial. The idea is based on the proximity theorem between integral and continuous optimal solutions. For the case of $\Delta = 1$, Karzanov and McCormick [76] proposed another polynomial-time algorithm. Hochbaum [61] strengthened the proximity result in Hochbaum and Shanthikumar [65] and improved the previous algorithm for the separable convex resource allocation problem with submodular constraint. It has been also shown that, if specialized to the separable convex resource allocation problem with a nested or tree constraint, the existing algorithms can be improved. Later, it was pointed out that the proximity theorems in Hochbaum [61] contained some errors, and they were fixed in Moriguchi and Shioura [107] and Moriguchi, Shioura, and Tsuchimura [108].

In addition to these efforts to generalize the constraints, several attempts have been directed to generalizing objective functions for which efficient algorithms can still be developed. One of them was done by Murota [109, 110] who identified a subclass of nonseparable convex functions, *M-convex functions*, which is defined on the base polyhedron of a submodular system. The *M*-convex functions can enjoy nice theorems of *discrete* convex analysis in a parallel manner to the traditional convex analysis. A polynomial-time algorithm has been developed for this class of problems [129].

Another interesting research field is the minimax resource allocation problem. The simplest of this type is described as follows:

$$\begin{aligned}
& \text{minimize} && \max_{1 \leq j \leq n} f_j(x_j) \\
& \text{subject to} && \sum_{j=1}^n x_j = N, \\
& && x_j \geq 0, \quad \text{integer } j = 1, \dots, n.
\end{aligned}$$

Here all $f_j(x_j)$ are nonincreasing (or nondecreasing) in x_j . This class of problem has been extensively studied due to its simple structure as well as rich applications. Theoretically, the minimax resource allocation problem can be equivalently transformed into the above simple resource allocation problem with a separable convex objective function. Therefore, equally efficient algorithms can be developed for minimax problems. As for the extensions and generalizations, minimax resource allocation problems with multiple resources and multiperiod resource allocation problems have been studied in connection with applications to production planning in high-tech industries [82–86, 88, 99].

To extend applications of resource allocation problems, a few new fields have been pointed out, such as (1) optimal allocation of computer resources, for example, determining optimal buffer size or optimal cache size; (2) computer scheduling; (3) software reliability; and (4) queueing control.

The organization of this chapter is as follows. [Section 2](#) prepares basic concepts and defines several types of resource allocation problems to be discussed in this chapter. [Section 3](#) gives fundamental algorithms for the separable convex and minimax resource allocation problems with several different types of constraints. All the algorithms presented in [Sect. 3](#) are more than 20 years old and were surveyed in the book of [69]. The correctness proofs given in [Sect. 3](#) for these problems with submodular constraint are however much simplified, based on the result by Murota [110]. [Sections 4 through 6](#) review rather new results developed in the 1990s and 2000s. [Sect. 4](#) explains proximity theorems between integer and continuous optimal solutions for separable convex resource allocation problems under submodular constraints as well as under linear constraints with totally unimodular constraint matrix. In [Sect. 5](#), improved algorithms, developed in Hochbaum [61] by using the proximity theorem, are presented for several types of separable convex resource allocation problems. All these algorithms, however, are not strongly polynomial time. Then, two lower bound results for the simple resource allocation problem are shown. This result, also due to Hochbaum [61], denies the existence of a strongly polynomial-time algorithm even if each f_j is a polynomial of degree 3. In addition, strongly polynomial-time algorithms are presented for several types of quadratic separable convex resource allocation problems. These algorithms are given by Hochbaum and Hong [64] and based on the proximity theorems. [Section 6](#) reviews a new development of *nonseparable* convex resource allocation problem related to minimizing an M-convex function. [Section 7](#) explains several new application areas. [Section 8](#) touches upon further related topics, such as allocation of multiple resources, multiperiod allocation, and other variants of resource allocation problems.

2 Preliminaries and Problem Classification

2.1 Preliminaries

Definitions and basic concepts, which are necessary for the discussion in this chapter, are given.

Let R and Z be the set of reals and the set of integers, respectively. A function $f : R^n \rightarrow R \cup \{+\infty\}$ is *convex* if $f(\alpha x + (1 - \alpha)y) \leq \alpha f(x) + (1 - \alpha)f(y)$ holds for every $x, y \in R^n$ and every α with $0 \leq \alpha \leq 1$. A function $f : Z^n \rightarrow R \cup \{+\infty\}$ is also defined to be *convex* if it can be extended to a convex function in the usual sense, that is, there exists a convex function $\tilde{f} : R^n \rightarrow R \cup \{+\infty\}$ such that $\tilde{f}(x) = f(x)$ for all $x \in Z^n$. For $l, u \in Z$ with $l \leq u$, let $[l, u]$ denote the closed interval from l to u . In the following, a function f of the form $f : [l, u] \cap Z \rightarrow R$ is often considered. Define

$$d(x) \equiv f(x) - f(x - 1) \text{ for } x \in [l + 1, u] \cap Z,$$

which is called the *increment* of f at x . A function $f : [l, u] \cap Z \rightarrow R$ is called *convex* if $d(x)$ is nondecreasing in x (this definition coincides with the above if $l = -\infty$ and $u = +\infty$).

Computation Model Throughout this chapter, $f(x)$ is assumed to be real-valued. Note that representing a real number may require infinite data length in the strict mathematical sense. On the other hand, in order to derive the computational complexity of an algorithm, it is assumed in this chapter (as is done in most of the complexity analysis) an evaluation of $f(x)$ can be done in a unit time, unless otherwise stated. It is also assumed that basic operations such as an arithmetic operation and a comparison operation concerning real numbers require a unit time. Although the assumptions may sound unrealistic, it does not produce serious troubles because an approximate evaluation of $f(x)$ (in finite digits) done in a unit of time is usually sufficient for practical purposes. Even if an evaluation of $f(x)$ requires not constant but $O(g(x))$ time, it is often straightforward to reevaluate the computation time for this more general situation.

Submodular System Let n be a positive integer and let

$$E = \{1, 2, \dots, n\}.$$

Let 2^E denote the family of all subsets of E , and $\mathcal{D} \subseteq 2^E$ be given. If \mathcal{D} is closed under union and intersection operations, \mathcal{D} is called a *distributive lattice*. Assume throughout this chapter that \mathcal{D} denotes a distributive lattice and that $\emptyset, E \in \mathcal{D}$, and $r(\emptyset) = 0$. A function $r : \mathcal{D} \rightarrow Z$ is *submodular* over \mathcal{D} if

$$r(X) + r(Y) \geq r(X \cup Y) + r(X \cap Y) \tag{1}$$

for all $X, Y \in \mathcal{D}$. Such a pair (\mathcal{D}, r) is called a *submodular system*. At the first glance, it may be difficult to understand the intuitive meaning of (1), but it captures the essence of combinatorial structures that are common to apparently different problems [45, 96]. In fact, as will be described in Sects. 2.2 and 3.2, the set of additional constraints that are often required in real applications can be defined in terms of a submodular system.

Define

$$R^E = \{x = (x_1, x_2, \dots, x_n) \mid x_j \in R, j \in E\}, \quad (2)$$

$$Z^E = \{x = (x_1, x_2, \dots, x_n) \mid x_j \in Z, j \in E\}. \quad (3)$$

The unit basis vector $e(j) = (e_1(j), \dots, e_n(j)) \in Z^E$ is defined by $e_i(j) = 1$ for $i = j$ and 0 for $i \neq j$. For vectors $x, y \in R^E$, write $x \leq y$ if $x_j \leq y_j$ for all $j \in E$, and write $x < y$ if $x \leq y$ and $x_j < y_j$ for some $j \in E$. For $x \in R^E$ and $S \subseteq E$, define

$$x(S) \equiv \sum_{j \in S} x_j,$$

where $x(\emptyset) = 0$ is assumed by convention. For a submodular system (\mathcal{D}, r) ,

$$P(r) = \{x \mid x \in R^E, x(S) \leq r(S), \text{ for all } S \in \mathcal{D}\} \quad (4)$$

is called the *submodular polyhedron* of (\mathcal{D}, r) . A subset of $P(r)$,

$$B(r) = \{x \mid x \in P(r) \text{ and } x(E) = r(E)\} \quad (5)$$

is called the *base polyhedron* of (\mathcal{D}, r) , and $x \in B(r)$ is a *base* of (\mathcal{D}, r) . In particular, $x \in B(r) \cap Z^E$ is called an *integral base* of (\mathcal{D}, r) . $B(r) \cap Z^E$ is called an *integral base polyhedron*. The notation $B(r)$ is also used to denote $B(r) \cap Z^E$, unless confusion occurs.

Section 3.2 provides basic properties of a submodular system that are necessary to develop efficient algorithms for the resource allocation problem with a submodular constraint.

2.2 Problem Classification

A generic form of the resource allocation problem discussed in this chapter is described as follows:

$$\text{RESOURCE: minimize } f(x_1, x_2, \dots, x_n) \quad (6)$$

$$\text{subject to } \sum_{j=1}^n x_j = N, \quad (7)$$

$$x_j \geq 0, \quad j = 1, 2, \dots, n. \quad (8)$$

That is, given one type of resource whose total amount is equal to N , it is required to allocate it to n activities so that the objective value $f(x_1, x_2, \dots, x_n)$ is minimized. The objective value may be interpreted as the cost or loss, or the profit or reward, incurred by the resulting allocation. In case of profit or reward, it is natural to maximize f ; in such a case, maximization problem is considered. The difference between maximization and minimization is not essential because maximizing f is equivalent to minimizing $-f$.

Each variable x_j represents the amount of resource allocated to activity j . If the resource is divisible, x_j is a continuous variable that can take any nonnegative value. If it represents persons, processors, or trucks, on the other hand, variable x_j becomes a discrete variable that takes nonnegative integer values, and the constraint

$$x_j : \text{integer}, \quad j = 1, 2, \dots, n \quad (9)$$

is added to (7) and (8). The resource allocation problem with this constraint is referred to as *discrete resource allocation problem*.

As for the objective function, it usually has some special structure according to the intended applications. Typically, the following special case, called *separable*, is often considered:

$$f(x) = \sum_{j=1}^n f_j(x_j). \quad (10)$$

If each f_j is convex, the objective function is called *separable convex*.

Resource allocation problems are classified according to the types of objective functions, constraints, and variables. The classification scheme used in this chapter as well as several types of problem formulations according to the classification scheme are described below. In general, the notation $\alpha/\beta/\gamma$ is used to denote the type of a resource allocation problem. Here α specifies the type of objective function, β the constraint type, and γ the variable type. Here

$$\gamma = D \quad \text{and} \quad \gamma = C$$

denote the integer variable and the continuous variable, respectively. The notations for α and β are given as follows.

α : Objective Functions The objective function $f(x_1, \dots, x_n)$ may take the following special structures:

1. *Separable* (S for short): $\sum_{j=1}^n f_j(x_j)$, where each f_j is a function of one variable.
2. *Separable and convex* (SC for short): $\sum_{j=1}^n f_j(x_j)$, where each f_j is a convex function of one variable. In particular, denote by SQC the subclass where each f_j is quadratic and convex.

3. *Minimax*: minimize $\max_{1 \leq j \leq n} f_j(x_j)$,
Maximin: maximize $\min_{1 \leq j \leq n} f_j(x_j)$,
where all f_j are monotone nondecreasing in x_j .
4. *Lexicographically minimax* (Lexico-Minimax for short): Since the objective value of Minimax is determined by the single-variable x_k^* satisfying $f_k(x_k^*) = \max_j f_j(x_j^*)$, there may be many optimal solutions. To remove such ambiguity, the lexicographical ordering is introduced for n -dimensional vectors: given $a = (a_1, \dots, a_n)$ and $b = (b_1, \dots, b_n)$, a is *lexicographically smaller* than b (i.e., b is *lexicographically greater* than a) if $a_j = b_j$ for $j = 1, \dots, k-1$ and $a_k < b_k$ some k . This is denoted by $a \leq_{lex} b$ or $b \geq_{lex} a$. For $a = (a_1, \dots, a_n)$, denote $DEC(a)$ (respectively, $INC(a)$) the n -tuple of $a_j, j = 1, \dots, n$, arranged in nonincreasing order (respectively, nondecreasing order) of their values (e.g., for $a = (4, 3, 1, 5)$, it holds that $DEC(a) = (5, 4, 3, 1)$ and $INC(a) = (1, 3, 4, 5)$). The objective of Lexico-Minimax is to find an allocation vector $x = (x_1, \dots, x_n)$ such that $DEC(x)$ is lexicographically minimum. Notice that an optimal solution to Lexico-Minimax is also optimal to Minimax, but the converse is not generally true. Similarly, define Lexico-Maximin as the one that lexicographically maximizes $INC(x)$.
5. *Fair*: minimize $g(\max_{1 \leq j \leq n} f_j(x_j), \min_{1 \leq j \leq n} f_j(x_j))$, where $g(u, v)$ is nondecreasing (resp. nonincreasing) in u (resp. v). Intuitively, this objective makes $\max_j f_j(x) - \min_j f_j(x)$ small in the criterion defined by g and is a generalization of Minimax and Maximin.

β : Constraints In addition to the simple resource constraint of (7), other additional constraints are also imposed. Typical additional constraints which appeared in various resource allocation problems are as follows. The case of no additional constraints other than (7) is referred to as Simple (see Fig. 1a).

1. *Lower and upper bounds* (LUB for short): $l_j \leq x_j \leq u_j, j = 1, \dots, n$.
2. *Generalized upper bounds* (GUB for short): $\sum_{j \in S_i} x_j \leq b_i, i = 1, \dots, m$, where S_1, S_2, \dots, S_m is a partition of $\{1, 2, \dots, n\}$ (see Fig. 1b).
3. *Nested constraints* (Nested for short): $\sum_{j \in S_i} x_j \leq b_i, i = 1, \dots, m$, where $S_1 \subset S_2 \subset \dots \subset S_m$. It can be assumed that $b_1 \leq b_2 \leq \dots \leq b_m$ since if $b_i > b_{i+1}$, the i -th constraint is redundant (see Fig. 1c).
4. *Tree constraints* (Tree for short): $\sum_{j \in S_i} x_j \leq b_i, i = 1, \dots, m$, where the sets S_i are derived by some hierarchical decomposition of E into disjoint subsets (see Fig. 1d).
5. *Network constraints* (Network for short): The constraint is defined in terms of a directed network with a single source and multiple sinks (see Fig. 1e). Given a directed graph $G = (V, A)$ with node set V and arc set A , let $s \in V$ be the source and $T \subseteq V$ be the set of sinks. The amount of supply from the source is $N > 0$, and the capacity of arc (u, v) is $c(u, v)$. Denote the flow vector by $\varphi = \{\varphi(u, v) \mid (u, v) \in A\}$. φ is a *feasible flow* in G if it satisfies

$$0 \leq \varphi(u, v) \leq c(u, v), \quad (u, v) \in A, \quad (11)$$

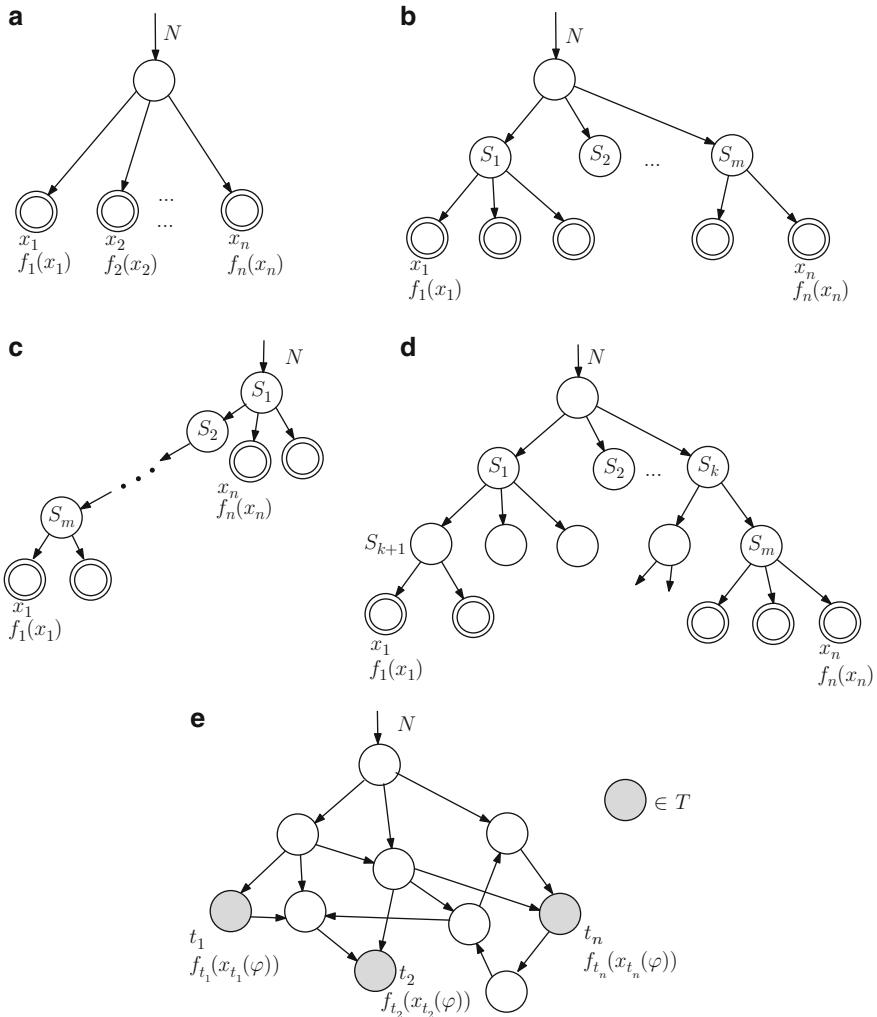

Fig. 1 Illustration of several constraints. (a) Simple. (b) GUB. (c) Nested. (d) Tree. (e) Network

$$\sum_{(v,w) \in A_+(v)} \varphi(v, w) - \sum_{(u,v) \in A_-(v)} \varphi(u, v) = 0, \quad v \in V - T - \{s\}, \quad (12)$$

$$\sum_{(s,v) \in A_+(s)} \varphi(s, v) - \sum_{(u,s) \in A_-(s)} \varphi(u, s) = N, \quad (13)$$

$$x_t(\varphi) \equiv \sum_{(u,t) \in A_-(t)} \varphi(u, t) - \sum_{(t,v) \in A_+(t)} \varphi(t, v) \geq 0, \quad t \in T, \quad (14)$$

$$\sum_t x_t(\varphi) = N, \quad (15)$$

where for $v \in V$, $A_+(v)$ (resp., $A_-(v)$) denotes the set of arcs leaving v (resp., entering v). The value $x_t(\varphi)$ denotes the amount of flow entering a sink $t \in T$. For a feasible flow φ , the vector $\{x_t(\varphi) | t \in T\}$ is called the *feasible flow vector* with respect to φ . For instance, the problem *SC/Network/C* (i.e., the separable convex resource allocation problem under network constraints) is defined as follows:

$$\begin{aligned} & \text{minimize: } \sum_{t \in T} f_t(x_t(\varphi)) \\ & \text{subject to } (11)-(15), \end{aligned} \quad (16)$$

where f_t for each $t \in T$ is a convex function.

6. *Submodular constraints* (SM for short): A set of feasible solutions x is defined by a base polyhedron $B(r)$ of (4) and (5) for a submodular system (\mathcal{D}, r) , that is,

$$x \in B(r). \quad (17)$$

In this case, notice that the constraint (7) is a part of constraint (17) since it is included as $x(E) = r(E)$ of the definition of $B(r)$. In the case of integer variables, the constraint becomes

$$x \in B(r) \cap Z^E.$$

It is assumed throughout this chapter that $B(r)$ is not explicitly given as an input, but is implicitly given through an *oracle* that tells us the value $r(S)$ whenever $S \in \mathcal{D}$ is input.

7. *General linear constraints* (Linear for short): Constraint is defined by a set of linear inequalities.

$$\sum_{j=1}^n a_{ij} x_j \leq b_i, \quad i = 1, 2, \dots, m. \quad (18)$$

No other special assumption is imposed on the structure of the constraints.

Notice that all the constraints, LUB, GUB, Nested, Tree, Network, are special cases of SM (see [69]), and SM is a special case of Linear.

3 Fundamental Algorithms

This section first deals with the simplest problem SC/Simple/D and reviews two basic algorithms. Then, a more general problem SC/SM/D is considered, and two algorithms are presented. A relationship between SC/-/D and Minimax (or Maximin)/-/D is also discussed.

3.1 SC/Simple/D

3.1.1 Incremental Algorithm

An incremental algorithm for problem SC/Simple/D is first presented. It is assumed that each f_j is defined over the interval $[0, N]$. Since f_j is convex, it holds that

$$d_j(1) \leq d_j(2) \leq \cdots \leq d_j(N), \quad (19)$$

where

$$d_j(y_j) = f_j(y_j) - f(y_j - 1).$$

The incremental algorithm is a kind of *greedy algorithm* and is also called a *marginal allocation* method. Starting with the initial solution $x = (0, 0, \dots, 0)$, one unit of resource is allocated at each iteration to the most favorable activity (in the sense of minimizing the increase in the current objective value) until $\sum x_j = N$ is attained.

Procedure INCREMENT

Input: An instance of SC/Simple/D.

Output: An optimal solution x^* .

Let $x := (0, 0, \dots, 0)$ and $k := 0$;

while $k < N$ **do**

begin

 Find j^* such that $d_{j^*}(x_{j^*} + 1) = \min_{1 \leq j \leq n} d_j(x_j + 1)$;

$x_{j^*} := x_{j^*} + 1$;

$k := k + 1$

end;

Output x as x^* .

Theorem 1 Given an instance of SC/Simple/D, define the following matrix M :

$$M = \begin{bmatrix} d_1(1) & d_2(1) & \cdots & d_n(1) \\ d_1(2) & d_2(2) & \cdots & d_n(2) \\ \vdots & \vdots & \ddots & \vdots \\ d_1(N) & d_2(N) & \cdots & d_n(N) \end{bmatrix}. \quad (20)$$

Let X be the set of N smallest elements in M , where if $d_j(y-1) = d_j(y)$, $d_j(y-1)$ is given a higher priority to be chosen in X . Then the following x^* is an optimal solution of SC/Simple/D:

$$x_j^* = \begin{cases} 0, & d_j(1) \notin X, \\ N, & d_j(N) \in X, \\ y, & d_j(y) \in X \text{ and } d_j(y+1) \notin X. \end{cases} \quad (21)$$

Proof Suppose that x^* is not optimal, and let \hat{x} be the optimal solution such that

$$\delta = \sum_{j=1}^n |\hat{x}_j - x_j^*|$$

is minimum. Then from $\sum_{j=1}^n \hat{x}_j = \sum_{j=1}^n x_j^* = N$, there exist i and k such that $x_i^* > \hat{x}_i$ and $x_k^* < \hat{x}_k$. It follows from (19) that

$$d_i(\hat{x}_i) \leq d_i(\hat{x}_i + 1) \leq d_i(x_i^*), \quad d_k(x_k^*) \leq d_k(x_k^* + 1) \leq d_k(\hat{x}_k).$$

Since $d_i(x_i^*) \leq d_k(x_k^* + 1)$ from $d_k(x_k^* + 1) \notin X$ and $d_i(x_i^*) \in X$, it follows $d_i(\hat{x}_i + 1) \leq d_k(\hat{x}_k)$. For the feasible solution $x' = \hat{x} + e(i) - e(k)$, it holds that

$$\sum_{j=1}^n f_j(x'_j) - \sum_{j=1}^n f_j(\hat{x}_j) = d_i(\hat{x}_i + 1) - d_k(\hat{x}_k) \leq 0.$$

This says that x' is also an optimal solution of SC/Simple/D, contradicting the minimality of δ . \square

Theorem 2 Procedure INCREMENT correctly computes an optimal solution in $O(N \log n + n)$ time.

Proof Let x^k denote the solution after k increments are made in the **while** loop. Then it is an easy exercise to prove by induction that

$$X^k = \{d_j(y) \mid y = 1, 2, \dots, x_j^k, j = 1, 2, \dots, n\}$$

is a set of k smallest elements in M . Thus, the correctness immediately follows from **Theorem 1**. For the running time, the set

$$S = \{d_j(x_j + 1) \mid j = 1, 2, \dots, n\}$$

is maintained in an appropriate data structure such as heap. In each iteration of **while** loop, the minimum element $d_{j^*}(x_{j^*} + 1)$ is chosen and S is thereby updated. Since the initial construction of S requires $O(n)$ time and finding the minimum element of S and the update of S require $O(\log n)$ time, and **while** loop is iterated N times, the running time of $O(N \log n + n)$ is derived. \square

Algorithm INCREMENT is easy to be implemented and efficient if N is not too large. However, it is not polynomial in the input size because the input size is $O(n + \log N)$, where it is assumed that the description of each f_j requires a constant input length.

3.1.2 Polynomial-Time Algorithms

Several polynomial-time algorithms have been developed for problem SC/Simple/D [42, 48, 78]. The fastest among them is proposed by Frederickson and Johnson [42]. Its running time is $O(\max\{n, n \log(N/n)\})$, but the algorithm is very complicated. For this reason, the $O(n(\log N)^2)$ time algorithm by Galil and Megiddo [48] is presented here, which is a *divide-and-conquer* method to find the N -th smallest element in matrix M of (20). Recall that each column M_j of M is already sorted in the nondecreasing order by property (19).

Once the N -th smallest element $d_{j^*}(y^*)$ in M is found, let $\lambda = d_{j^*}(y^*)$ and construct an optimal solution x^* as follows, where care is needed in the situation that many $d_j(y)$ may satisfy $d_j(y) = \lambda$. First, compute the following $p_j(\lambda)$ and $q_j(\lambda)$ for each j with $j = 1, 2, \dots, n$ by binary search.

$$\begin{aligned} p_j(\lambda) &= \max\{y \mid y \in \{1, 2, \dots, N\} \text{ and } d_j(y) < \lambda\}, \\ q_j(\lambda) &= \max\{y \mid y \in \{1, 2, \dots, N\} \text{ and } d_j(y) \leq \lambda\}. \end{aligned} \tag{22}$$

Then, compute the index j' such that

$$j' = \max \left\{ j \mid \sum_{k=1}^j q_k(\lambda) + \sum_{k=j+1}^n p_k(\lambda) \leq N \right\},$$

and let

$$x_j^* = \begin{cases} q_j(\lambda), & j \leq j' \\ N - \left(\sum_{k=1}^{j'} q_k(\lambda) + \sum_{k=j'+2}^n p_k(\lambda) \right), & j = j' + 1 \\ p_j(\lambda), & j \geq j' + 2. \end{cases} \tag{23}$$

Notice that, after $\lambda = d_{j^*}(y^*)$ is computed, the time required to compute x^* in this way is $O(n \log N)$ because the computation of $p_j(\lambda)$ and $q_j(\lambda)$ can be done in $O(\log N)$ time for each j by applying the binary search over $[1, N]$. Then it is easy to see that set $\{d_j(y) \mid 1 \leq y \leq x_j^*, j = 1, \dots, n\}$ is the set of N smallest elements of M . Thus, the x^* defined above is optimal to SC/Simple/D.

Now, it is explained how to compute the N -th smallest element $d_{j^*}(y^*)$ in M . Let s denote the size of M (initially, $s = nN$). First, compute the medians $d_j(y_j^m)$ of columns M_j for all j , which can be computed in $O(1)$ time for each j because each M_j is already sorted. Sort these medians in the nondecreasing order

$$d_{j_1}(y_{j_1}^m) \leq d_{j_2}(y_{j_2}^m) \leq \cdots \leq d_{j_n}(y_{j_n}^m)$$

and compute the k such that

$$\sum_{i=1}^{k-1} |M_{j_i}| < s/2 \text{ and } \sum_{i=1}^k |M_{j_i}| \geq s/2. \quad (24)$$

Then, choose

$$\lambda = d_{j_k}(y_{j_k}^m)$$

as a candidate for the N -th smallest element of M . For this λ , define

$$\begin{aligned} M^1 &= \{d_j(y) \in M \mid d_j(y) < \lambda\}, \\ M^2 &= \{d_j(y) \in M \mid d_j(y) = \lambda\}, \\ M^3 &= \{d_j(y) \in M \mid d_j(y) > \lambda\}. \end{aligned}$$

If $|M^1| \geq N$, the N -th smallest element of M must be in M^1 , and the above procedure is recursively applied to M^1 . If $|M^1| + |M^2| \geq N > |M^1|$, $\lambda = d_{j_k}(y_{j_k}^m)$ is the N -th smallest element of M . If $|M^1| + |M^2| < N$, the N -th smallest element is in M^3 . In this case, the above procedure is recursively applied to M^3 after setting $N = N - (|M^1| + |M^2|)$.

At each iteration, the size of the current matrix M systematically decreases, while maintaining the property that it contains the target M^i selected in the previous iterations; this property implies that eventually the N -th smallest element of M is found. It is claimed that, at each iterations; this property implies that at most three-fourths of the elements in the current matrix M remain in the M of the next iteration. To see this, first note that by the choice of k , the set M' of Fig. 2 contains $\sum_{i=1}^k \lceil M_{j_i}/2 \rceil (\geq |M|/4)$ elements. Since each element in M' is not larger than $\lambda = d_{j_k}(y_{j_k}^m)$, $M' \subseteq M^1 \cup M^2$ follows. Hence,

$$|M^1| + |M^2| \geq |M'| \geq |M|/4$$

holds. A similar argument applied to M'' of Fig. 2 implies that

$$|M^2| + |M^3| \geq |M|/4.$$

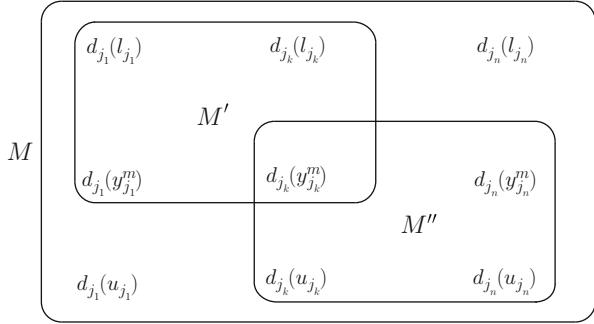

From these, it is concluded that

$$|M^1| \leq 3|M|/4 \text{ and } |M^3| \leq 3|M|/4,$$

proving the above claim.

From this observation, it is concluded that $O(\log N)$ iterations are required before $|M| \leq n$ holds. At this point, a linear-time selection algorithm is directly applied to the current M of size $O(n)$ to identify the N -th smallest element. The algorithm is described as follows:

Fig. 2 Illustration of M , M' and M''

Procedure SELECT

Input: An instance of problem SC/Simple/D.

Output: An optimal solution x^* .

Let $l_j := 1$ and $u_j := N$ for $j = 1, 2, \dots, n$;

Let $L_j := u_j - l_j + 1$ for $j = 1, 2, \dots, n$ and $s := \sum_{j=1}^n L_j$;

while $s > n$ **do**

begin

 Find the medians of all $d_j(y_j^m)$ in M_j , $j = 1, 2, \dots, n$, and sort them in nondecreasing order, $d_{j_1}(y_{j_1}^m) \leq d_{j_2}(y_{j_2}^m) \leq \dots \leq d_{j_n}(y_{j_n}^m)$;

 Compute the k such that $\sum_{i=1}^{k-1} |M_{j_i}| < s/2$ and $\sum_{i=1}^k |M_{j_i}| \geq s/2$, and let $\lambda = d_{j_k}(y_{j_k}^m)$;

 Compute $p_j(\lambda)$ and $q_j(\lambda)$ of (22) for $j = 1, 2, \dots, n$, and let

$L^1 := \sum_{j=1}^n (p_j(\lambda) - l_j + 1)$, and $L^2 := \sum_{j=1}^n (q_j(\lambda) - l_j + 1)$;

if $L^1 \leq N \leq L^2$ **then** output $\lambda = d_{j_k}(y_{j_k}^m)$ and halt.

else

if $L^1 \geq N$ **then** let $u_j := p_j(\lambda)$, $j = 1, \dots, n$

else let $N := N - L^2$ and $l_j := q_j(\lambda) + 1$, $j = 1, \dots, n$.

end;

Find the N -th smallest element $\lambda = d_{j^*}(y^*)$ in M and construct an optimal solution x^* by (23).

It is assumed in the algorithm that M_j denotes the j -th column of the current M with lower and upper bounds, that is, $M_j = \{d_j(l_j), \dots, d_j(u_j)\}$. Thus, the current M is given by $M = \cup_{1 \leq j \leq n} M_j$.

Theorem 3 Given an instance of problem SC/Simple/D, procedure SELECT correctly finds the N -th smallest element in M of (20) in $O(n(\log N)^2)$ time.

Proof The correctness directly follows from the discussion prior to the description of the algorithm. The running time is analyzed as follows. First, the medians of $d_j(y_j^m)$ of M_j , $j = 1, 2, \dots, n$ are computed in $O(n)$ time because each

column is already sorted as (19). Sorting these n medians requires $O(n \log n)$ time. Computation of $p_j(\lambda)$ and $q_j(\lambda)$ for each j is done by binary search and requires $O(\log |M_j|) = O(\log N)$ time. Thus, $O(n \log N)$ time is required in total. As mentioned earlier, the **while** loop of SELECT is iterated $O(\log N)$ times, and the total running time is

$$O((n \log N + n \log n) \log N).$$

This running time is further improved by repeatedly applying linear-time median finding algorithm for identifying the k of (24) and $\lambda = d_{j_k}(y_{j_k}^m)$, instead of sorting all medians $d_j(y_j^m)$. The details are omitted (see [48] or the book [69] for details). Using this strategy, the running time is reduced to

$$O((n \log N + n) \log N) = O(n(\log N)^2).$$

□

It is clear that the two algorithms INCREMENT and SELECT can be generalized in a straightforward manner to deal with the constraints of LUB without changing the time complexity.

3.2 SC/SM/D

The problem SC/SM/D is described as follows:

$$\begin{aligned} & \text{minimize} \sum_{j \in E} f_j(x_j), \\ & \text{subject to } x = (x_1, x_2, \dots, x_n) \in B(r), \\ & \quad x_j : \text{nonnegative integer}, \quad j \in E, \end{aligned} \tag{25}$$

where $E = \{1, \dots, n\}$ and $B(r)$ denotes the base polyhedron of a submodular system, as defined in Sect. 2.1.

Before describing algorithms for solving (25), some definitions and properties concerning a submodular system are given, which are used to develop the algorithms. Proofs of the properties are omitted except for Lemma 4.

Lemma 1 *For a submodular system (\mathcal{D}, r) and a vector $y \in R^E$, define a function $r^y : 2^E \rightarrow R$ by*

$$r^y(X) = \min\{r(Z) + y(X - Z) \mid Z \subseteq X, Z \in \mathcal{D}\}, \quad X \subseteq E. \tag{26}$$

Then r^y is a submodular function defined over 2^E .

□

This submodular system $(2^E, r^y)$ is called the *restriction of (\mathcal{D}, r) by vector y* . The base polyhedron $B(r^y)$ of $(2^E, r^y)$ is given by

$$\{x \mid x \in B(r), x \leq y\}. \quad (27)$$

Lemma 2 For a submodular system (\mathcal{D}, r) and a vector $y \in R^E$, define a function $r_y : 2^E \rightarrow R$ by

$$r_y(X) = \min\{r(Z) - y(Z - X) \mid X \subseteq Z, Z \in \mathcal{D}\}, \quad X \subseteq E. \quad (28)$$

Then r_y is a submodular function defined over 2^E . \square

This submodular system $(2^E, r_y)$ is called the *contraction* of (\mathcal{D}, r) by vector y . The base polyhedron $B(r_y)$ of $(2^E, r_y)$ is given by

$$\{x \mid x \in B(r), x \geq y\}. \quad (29)$$

Since nonnegative integer x_j is mainly considered in this section, it is assumed throughout this section that the underlying submodular system is equal to $(2^E, r_0)$ which is obtained by contracting a submodular system (\mathcal{D}, r) by zero vector $\mathbf{0}$. Therefore, $B_0(r)$ denotes in what follows the base polyhedron corresponding to $(2^E, r_0)$, and the following problem is considered instead of (25):

$$\begin{aligned} & \text{minimize} \sum_{j \in E} f_j(x_j) \\ & \text{subject to } x : \text{an integral base of } B_0(r). \end{aligned} \quad (30)$$

For a submodular system (\mathcal{D}, r) and a vector $x \in P(r)$ (see (4) for the definition of $P(r)$), define the *saturation function* $sat : P(r) \rightarrow 2^E$ by

$$sat(x) = \{j \mid j \in E, x + d \cdot e(j) \notin P(r) \text{ for any } d > 0\}. \quad (31)$$

Also, define *dependence function* $dep : P(r) \times E \rightarrow 2^E$ by

$$dep(x, j) = \begin{cases} \{j' \mid j' \in E, x + d \cdot (e(j) - e(j')) \in P(r) \text{ for some } d > 0\} \\ \emptyset \text{ otherwise.} \end{cases} \quad (32)$$

The following lemma characterizes sat and dep (see [45] for its proof).

Lemma 3 (i) For $x \in P(r)$, it holds that

$$sat(x) = \bigcup_{X \in \mathcal{D}: x(X)=r(X)} X. \quad (33)$$

(ii) For $x \in P(r)$ and $j \in E$, it holds that

$$dep(x, j) = \bigcap_{X \in \mathcal{D}: j \in X, x(X) = r(X)} X. \quad (34)$$

□

For $x \in P(r)$ and $j \in E$, define the *saturation capacity* as

$$\hat{c}(x, j) = \max\{d \mid d \geq 0, x + d \cdot e(j) \in P(r)\}. \quad (35)$$

Similarly, for $x \in P(r)$, $j \in sat(x)$, and $j' \in dep(x, j) - \{j\}$, define the *exchange capacity* as

$$\tilde{c}(x, j, j') = \max\{d \mid d > 0, x + d \cdot (e(j) - e(j')) \in P(r)\}. \quad (36)$$

The following lemma is a basis of the algorithms presented in this section and [Sect. 6](#).

Lemma 4 (i) For any integral base x of $B_0(r)$, $j \in E$, and $j' \in dep(x, j) - \{j\}$,

$$x + e(j) - e(j')$$

is also an integral base of $B_0(r)$.

(ii) For any two distinct integral bases $x, y \in B_0(r)$, and for any $i \in E$ with $x_i > y_i$, there exists $j \in E$ with $x_j < y_j$ such that

$$x - e(i) + e(j) \in B_0(r) \text{ and } y + e(i) - e(j) \in B_0(r).$$

Proof Only the proof of (ii) is given since the proof of (i) is done in almost the same fashion as that of [Claim 1](#) below. It starts with the following two claims.

Claim 1 For any two distinct integral bases $x, y \in B_0(r)$, and for any $i \in E$ with $x_i > y_i$, there exists $j \in E$ with $x_j < y_j$ such that

$$y + e(i) - e(j) \in B_0(r).$$

Proof Let $Y = dep(y, i)$. First, it is shown that $y(Y) = r(Y)$ holds. Notice that, for any X, X' with $i \in X \cap X'$ such that $y(X) = r(X)$ and $y(X') = r(X')$ hold, $y(X \cap X') = r(X \cap X')$ also holds because

$$\begin{aligned} y(X \cap X') &\leq r(X \cap X') \\ &\leq r(X) + r(X') - r(X \cup X') \quad (\text{from submodularity of } r(\cdot)) \\ &\leq r(X) + r(X') - y(X \cup X') \\ &= y(X) + y(X') - y(X \cup X') \quad (\text{from } y(X) = r(X) \text{ and}) \end{aligned}$$

$$\begin{aligned} & y(X') = r(X')) \\ &= y(X \cap X'). \end{aligned}$$

Therefore, repeating this argument, $y(Y) = r(Y)$ follows from (34). Also, $|Y| \geq 2$ holds since otherwise $Y = \{i\}$ holds and thus $r(Y) = y(Y) = y_i < x_i = x(Y)$ holds, violating $x \in B_0(r)$. Thus, there exists $j \in Y$ with $j \neq i$. Then it is shown that $y + e(i) - e(j) \in B_0(r)$. From the definition of Y , all X with $i \in X$ and $y(X) = r(X)$ satisfies $X \supseteq Y$. Thus, $(y + e(i) - e(j))(X) = r(X)$ for all such X . For other X , either $y(X) < r(X)$ or $i \notin X$ and $y(X) = r(X)$ holds, and hence, $(y + e(i) - e(j))(X) \leq r(X)$ follows from the integrality of y and r . This proves the claim. \square

Claim 2 For any two distinct integral bases $x, y \in B_0(r)$ with $\|x - y\| (= \sum_j |x_j - y_j|) = 4$, the lemma assertion (ii) holds.

Proof The claim is proved by case analysis. There are two cases.

- Case 1.* There exists exactly one i such that $x_i > y_i$. From $\|x - y\| = 4$, $x_i - y_i = 2$. From [Claim 1](#), there exists j with $x_j < y_j$ such that $y + e(i) - e(j) \in B_0(r)$. For the j , applying [Claim 1](#) to y , $x - e(i) + e(j) \in B_0(r)$ must follow because the i is the unique element such that $x_i > y_i$.
- Case 2.* There are i, i' with $i \neq i'$ such that $x_i > y_i$ and $x_{i'} > y_{i'}$. From $\|x - y\| = 4$, $x_i - y_i = 1$ and $x_{i'} - y_{i'} = 1$. Then, the claim can be proved in a manner similar to Case 1. \square

Now the lemma shall be proven. Assume, to the contrary, that the following set is not empty:

$$\begin{aligned} \mathcal{S} = \{(x, y) \mid x, y \in B_0(r), \exists i^* \text{ with } x_{i^*} > y_{i^*} \text{ such that} \\ \forall j \text{ with } x_j < y_j, \text{ it holds that } x - e(i^*) + e(j) \notin B_0(r) \text{ or} \\ y + e(i^*) - e(j) \notin B_0(r)\}. \end{aligned} \tag{37}$$

Choose (x, y) from \mathcal{S} such that $\|x - y\|$ is minimum. It is assumed that $\|x - y\| \geq 6$ since otherwise the lemma is immediate from [Claims 1](#) and [2](#). Let i^* be the index satisfying the condition of (37) for the (x, y) . Consider first the case such that i^* is the unique element satisfying $x_{i^*} > y_{i^*}$. From [Claim 1](#), there exists j_0 with $y + e(i^*) - e(j_0) \in B_0(r)$, and again by applying [Claim 1](#) with roles of x and y interchanged, $x - e(i^*) + e(j_0) \in B_0(r)$ follows since i^* is the unique element satisfying $x_{i^*} > y_{i^*}$. Thus, the lemma follows. Therefore, assume that there exists i_0 with $i_0 \neq i^*$ and $x_{i_0} > y_{i_0}$. Let

$$\begin{aligned} X &= \{j \in E \mid x - e(i^*) + e(j) \in B_0(r)\}, \\ Y &= \{j_0 \in E \mid x_{j_0} < y_{j_0}, y + e(i_0) - e(j_0) \in B_0(r)\}. \end{aligned}$$

Recall that $Y \neq \emptyset$ holds from [Claim 1](#).

Case 1: $X \cap Y \neq \emptyset$. Fix a j_0 such that $j_0 \in X \cap Y$. Let $y' = y + e(i_0) - e(j_0)$. A contradiction shall be derived by showing $(x, y') \in \mathcal{S}$ because $\|x - y'\| = \|x - y\| - 2$. Consider an arbitrary j with $x_j < y'_j$ and $x - e(i^*) + e(j) \in B_0(r)$, and let

$$y'' = y' + e(i^*) - e(j) = y + e(i_0) + e(i^*) - e(j_0) - e(j).$$

Notice that $y + e(i^*) - e(j_0) \notin B_0(r)$ and $y + e(i^*) - e(j) \notin B_0(r)$ follow from $(x, y) \in \mathcal{S}$. Thus, $y'' \notin B_0(r)$ follows since otherwise at least one of $y + e(i^*) - e(j_0)$ or $y + e(i^*) - e(j)$ belongs to $B_0(r)$, if [Claim 1](#) is applied to y and y'' .

Case 2: $X \cap Y = \emptyset$. Let j and y'' be chosen as in case 1. Then, $y + e(i^*) - e(j) \notin B_0(r)$ holds from $(x, y) \in \mathcal{S}$, and $y + e(i_0) - e(j) \notin B_0(r)$ holds from $X \cap Y = \emptyset$ and the definition of Y . Thus, $y'' \notin B_0(r)$ follows since otherwise at least one of $y + e(i^*) - e(j)$ or $y + e(i_0) - e(j)$ belongs to $B_0(r)$ if [Claim 2](#) is applied to y and y'' . \square

The following lemma is well known (see [45, 55, 69] for its proof).

Lemma 5 *Given a submodular system (\mathcal{D}, r) , the following computations can be done in polynomial time in $|E|$ and in $\log r(E)$, provided that an oracle to compute $r(X)$ for a given X in polynomial time is available:*

1. *Membership test of $x \in P(r)$ for a given $x \in R^E$.*
2. *Computation of $\text{sat}(x)$ and $\text{dep}(x, j)$ for a given $x \in P(r)$ and $j \in E$.*
3. *Computation of $\hat{c}(x, j)$ of (36) for given $x \in P(r)$ and $j \in E$.*
4. *Computation of $r^x(X)$ of (26) and $r_x(X)$ of (27) for $x \in R^E$ and $X \in 2^E$.* \square

For a general submodular system, polynomial algorithms based on ellipsoid method can be used for all the above computations (see [55]). However, for most of particular cases, more efficient polynomial-time algorithms are available.

The following fundamental results are useful to develop efficient algorithms, which will be presented below.

Lemma 6 *Consider the base polyhedron $B_0(r)$ of a submodular system $(2^E, r_0)$ and a function $f(x) = \sum_{j \in E} f_j(x_j)$, where $f_j(x_j)$ is convex for all j . Then, for any two distinct integral bases $x, y \in B_0(r)$ and for any $i, j \in E$ with $x_i > y_i$ and $x_j < y_j$ such that*

$$x - e(i) + e(j), y + e(i) - e(j) \in B_0(r), \quad (38)$$

it holds that

$$f(x) + f(y) \geq f(x - e(i) + e(j)) + f(y + e(i) - e(j)). \quad (39)$$

Proof Inequality (39) follows from

$$\begin{aligned} & f(x) + f(y) - (f(x - e(i) + e(j)) + f(y + e(i) - e(j))) \\ &= d_i(x_i) - d_i(y_i + 1) + d_j(y_j) - d_j(x_j + 1), \end{aligned}$$

and the convexity of f_i and f_j . \square

The following theorem demonstrates that local optimality guarantees global optimality for a submodular system.

Theorem 4 Let $B_0(r)$ be the base polyhedron of a submodular system $(2^E, r_0)$. An integral base $x \in B_0(r)$ is an optimal solution of problem SC/SM/D if and only if

$$f(x - e(i) + e(j)) \geq f(x) \text{ (i.e., } d_j(x_j + 1) \geq d_i(x_i)) \quad (40)$$

holds for all $i, j \in E$ with $x - e(i) + e(j) \in B_0(r)$.

Proof Since the *only if* part is obvious, only the *if* part will be proven, that is,

$$f(y) \geq f(x) \text{ for all } y \in B_0(r). \quad (41)$$

Suppose, to the contrary, that the x satisfying assumption (40) is not optimal. Let y be an optimal solution such that $\|x - y\| (= \sum_{j \in E} |x_j - y_j|)$ is minimum. By Lemma 4 (ii), there exist two integral bases $x' = x - e(i) + e(j)$ and $y' = y + e(i) - e(j)$ with $x_i > y_i$ and $x_j < y_j$. Then, $f(x) + f(y) \geq f(x') + f(y')$ holds from (39). Since $f(x') \geq f(x)$ from (40), $f(y') \leq f(y)$ must follow. Thus, $f(y')$ is also an optimal solution and $\|x - y'\| < \|x - y\|$ holds, contradicting the minimality of $\|x - y\|$. \square

Two algorithms for finding an optimal solution of problem SC/SM/D will be presented below.

3.2.1 Incremental Algorithm

It will be shown that the incremental algorithm presented in Sect. 3.1.1 also works for problem SC/SM/D. In this case, among all the elements such that $x + e(j) \in P(r)$ (i.e., feasible except for the constraint $(x + e(j))(E) = r(E)$), the x_j with the minimum increase in $f_j(x_j)$ is incremented by one. This process is repeated until $x(E) = r(E)$ is finally attained.

Procedure SM-INCREMENT

Input: An instance of problem SC/SM/D.

Output: An optimal solution x^* .

```

Let  $x_j := 0$  for all  $j \in E$ ,  $E' := E$  and  $k := 0$ ;
while  $k < r(E)$  do
  begin
    Find  $j^* \in E'$  such that  $d_{j^*}(x_{j^*} + 1) = \min\{d_j(x_j + 1) \mid j \in E'\}$ .
    if  $x + e(j^*) \in P(r)$  then
      let  $x_{j^*} := x_{j^*} + 1$ ,  $k := k + 1$ ;
    else delete  $j^*$  from  $E'$ 
  end;
  Output  $x$  as  $x^*$ .

```

To prove the correctness of SM-INCREMENT, it is remarked here that, during the execution of the algorithm, it arrives at the following situation (A) from time to time:

- (A) For the solution x obtained in the **while** loop, some $X \in 2^E$ becomes newly saturated (i.e., $x(X) = r(X)$), as a result of increasing x_i by one (where $i = j^*$).

Once (A) occurs, such x_i will never be increased again. Let E_A denote the set of all i for which (A) occurs before the algorithm halts. Without loss of generality, assume $E_A = \{1, 2, \dots, p\}$, for which (A) has occurred in the order of $i = 1, 2, \dots, p$. Define

$$S_i = \bigcup_{x(Y)=r(Y), Y \in 2^E} Y, \quad (42)$$

whenever condition (A) has occurred for solution x and $i \in E$, where $S_0 = \emptyset$ by convention. Thus, S_i satisfies $x(S_i) = r(S_i)$ by the submodularity of r . When SM-INCREMENT halts, $i = p$ and $S_p = E$ hold. Now three lemmas and two theorems will be given, in which x^* denotes the solution obtained by SM-INCREMENT.

Lemma 7 *If condition (A) holds for the solution x and $i \in E$ during the execution of SM-INCREMENT, the optimal solution x^* output by SM-INCREMENT satisfies $x_j^* = x_j$ for all $j \in S_i$, and hence, $x^*(S_i) = r(S_i)$.*

Proof Once condition (A) holds with $i \in E$, x_j for any $j \in S_i$ cannot be incremented later by the test $x + e(j^*) \in P(r)$ in the algorithm. Thus, the lemma follows. \square

Lemma 8 *For the subsets $S_i, i = 1, 2, \dots, p$, constructed in SM-INCREMENT, the following properties hold:*

- (i) $S_0 \subset S_1 \subset \dots \subset S_p = E$.

(ii) For all i with $1 \leq i \leq p$, $\{x_j^* \mid j \in S_i - S_{i-1}\}$ is an optimal solution of the following problem of SC/Simple/D:

$$\begin{aligned} Q_i : & \text{minimize} \sum_{j \in S_i - S_{i-1}} f_j(x_j) \\ \text{subject to} & \sum_{j \in S_i - S_{i-1}} x_j = r(S_i) - r(S_{i-1}), \\ & x_j : \text{nonnegative integer}, \quad j \in S_i - S_{i-1}. \end{aligned} \quad (43)$$

Proof (i) Immediate from the definition of S_i , $i = 1, \dots, p$.

(ii) Before S_i becomes saturated, it holds $j \notin \text{sat}(x)$ for all $j \in S_i - S_{i-1}$. Hence, $x + e(j) \in P(r)$. Thus, SM-INCREMENT selects the $j^* \in S_i - S_{i-1}$ such that

$$d_{j^*}(x_{j^*} + 1) = \min\{d_j(x_j + 1) \mid j \in S_i - S_{i-1}\} \quad (44)$$

in the succeeding situations. Since $x^*(S_i) = r(S_i)$ and $x^*(S_{i-1}) = r(S_{i-1})$ hold, it holds that $x^*(S_i - S_{i-1}) = r(S_i) - r(S_{i-1})$. Thus, what SM-INCREMENT does to the variable x_j for $j \in S_i - S_{i-1}$ is exactly the same as what procedure INCREMENT does if problem Q_i of (43) is input. The correctness of INCREMENT then proves property (ii). \square

Lemma 9 In the execution of SM-INCREMENT,

$$d_j(x_j^*) \leq \min\{d_k(x_k^* + 1) \mid k \in E - S_{i-1}\} \quad (45)$$

holds for all $i \in E_A$ and any $j \in S_i - S_{i-1}$.

Proof For a $j \in S_i - S_{i-1}$, let $\hat{x} = \{\hat{x}_k \mid k \in E\}$ denote the vector obtained just before $x_j = x_j^* - 1$ is increased to $x_j = x_j^*$. Then all $k \in E - S_{i-1}$ satisfy $\hat{x} + e(k) \in P(r)$ by the definition of S_i and S_{i-1} , and thus,

$$d_j(x_j^*) = d_j(\hat{x}_j + 1) = \min\{d_k(\hat{x}_k + 1) \mid k \in E - S_{i-1}\}$$

holds. This proves the lemma because $d_k(\hat{x}_k + 1) \leq d_k(x_k^* + 1)$ holds for all $k \in E - S_{i-1}$ by $\hat{x}_k \leq x_k^*$. \square

Theorem 5 SM-INCREMENT correctly computes an optimal solution of SC/SM/D in $O(r(E) \log n + (r(E) + n)\tau)$ time, where τ denotes the time required to perform the membership test of $x \in P(r)$.

Proof Let x^* be the solution output by SM-INCREMENT. This x^* is clearly a feasible solution of SC/SM/D. From [Theorem 4](#), it suffices to show that

$$d_j(x_j^* + 1) \geq d_i(x_i^*) \quad (46)$$

holds for all $i, j \in E$ with $x^* - e(i) + e(j) \in B_0(r)$. Let $x' = x^* - e(i) + e(j)$. Suppose $i \in S_k - S_{k-1}$. Then $j \in E - S_{k-1}$ must hold since otherwise $x'(S_{k-1}) > x^*(S_{k-1}) = r(S_{k-1})$ holds from $i \notin S_{k-1}$ and $j \in S_{k-1}$ (the equality is from Lemma 7), contradicting the feasibility of x' . Then (46) follows from Lemma 9.

As for the running time, it is needed to test whether $x + e(j^*) \in P(r)$. Once j^* is removed from E' , j^* is no more considered. Thus, the number of executions of such feasible test is at most $r(E) + n$. The other part of the procedure is analyzed in a manner similar to the analysis of procedure INCREMENT. This completes the proof. \square

Notice that the running time of the above procedure SM-INCREMENT is not polynomial but pseudo-polynomial if $r(E)$ is given as an input.

3.2.2 Polynomial-Time Algorithm

This section presents a polynomial algorithm for solving SC/SM/D. It first solves a problem of SC/Simple/D type, which is obtained from the original problem by considering only the simple constraint $x(E) = r(E)$ but disregarding the rest. If the obtained solution y is feasible, that is, $y \in P(r)$, then it is an optimal solution of the original problem. Otherwise, the problem is decomposed into subproblems using the information obtained from the vector y and the submodular constraints. For this, a maximal vector $v \in R^E$ satisfying below is first computed:

$$v \in P(r) \quad \text{and} \quad v \leq y. \quad (47)$$

If $v = y$, y is a feasible solution of SC/SM/D, that is, y is an optimal solution. Otherwise, let

$$E_1 = \text{sat}(v) \quad \text{and} \quad E_2 = E - E_1,$$

and define vectors $l^1, u^1 \in R^{E_1}$ and $l^2, u^2 \in R^{E_2}$ by

$$\begin{aligned} l_j^1 &= 0, & u_j^1 &= y_j \quad \text{for } j \in E_1, \\ l_j^2 &= y_j, & u_j^2 &= +\infty \quad \text{for } j \in E_2. \end{aligned} \quad (48)$$

As will be proved later, there exists an optimal solution x^* of SC/SM/D such that

$$\begin{aligned} l_j^1 &\leq x_j^* \leq u_j^1 \quad \text{for } j \in E_1, \\ l_j^2 &\leq x_j^* \leq u_j^2 \quad \text{for } j \in E_2, \\ x^*(E_1) &= r(E_1), \\ x^*(E_2) &= r(E) - r(E_1). \end{aligned} \quad (49)$$

This means that the original problem is equivalently solved by the following two subproblems, Q_1 and Q_2 :

$$\begin{aligned} Q_1 : & \text{minimize } \sum_{j \in E_1} f_j(x_j) \\ \text{subject to } & x(E_1) = r(E_1), \\ & x(X) \leq r(X), X \in 2^{E_1}, \\ & l_j^1 \leq x_j \leq u_j^1, j \in E_1, \\ & x_j : \text{nonnegative integer, } j \in E_1, \end{aligned} \quad (50)$$

$$\begin{aligned} Q_2 : & \text{minimize } \sum_{j \in E_2} f_j(x_j) \\ \text{subject to } & x(E_2) = r(E) - r(E_1), \\ & x(X) \leq r(X \cup E_1) - r(E_1), X \in 2^{E_2}, \\ & l_j^2 \leq x_j \leq u_j^2, j \in E_2, \\ & x_j : \text{nonnegative integer, } j \in E_2. \end{aligned} \quad (51)$$

Note that the constraint of problem Q_1 is to add constraints $x_j \leq y_j$, $j \in E_1$, to the original constraint $x \in B_0(r)$, and the constraint of problem Q_2 is to add constraints $x_j \geq y_j$, $j \in E_2$, to the original constraint $x \in B_0(r)$. The constraints of Q_1 and Q_2 are again submodular, because the former is equivalent to the restriction of $(2^{E_1}, r)$ by vector y (see Sect. 3.2), and the latter is equivalent to the contraction of $(2^{E_2}, r)$ by vector y (see Sect. 3.2). Thus, these problems can be solved by recursively executing the algorithm. In a general step of the recursion, it solves the following problem $SM(E', S, l, u)$ of SC/SM/D for some $E' \subset E$ and $l, u \in R^{E'}$, by first solving its relaxation, $SI(E', S, l, u)$:

$$\begin{aligned} SM(E', S, l, u) : & \text{minimize } \sum_{j \in E'} f_j(x_j) \\ \text{subject to } & x \in R^{E'}, \\ & x(E') = r(E' \cup S) - r(S), \\ & x(X) \leq r(X \cup S) - r(S), X \in 2^{E'}, \\ & l \leq x \leq u, \\ & x_j : \text{integer, } j \in E'. \end{aligned} \quad (52)$$

$$\begin{aligned} SI(E', S, l, u) : & \text{minimize } \sum_{j \in E'} f_j(x_j) \\ \text{subject to } & x \in R^{E'}, \\ & x(E') = r(E' \cup S) - r(S), \\ & l \leq x \leq u, \\ & x_j : \text{integer, } j \in E'. \end{aligned} \quad (53)$$

The entire procedure is called SM, in which subroutine $DA(E', S, l, u)$ solves the above problem $SM(E', S, l, u)$.

Procedure SM

Input: An instance of problem SC/SM/D.

Output: An optimal solution x^* .

Step 1: Let $l_j := 0$ and $u_j := +\infty$ for $j \in E$.

Step 2: Call procedure DA(E, \emptyset, l, u) to obtain a solution x^* .

Step 3: Output x^* and halt.

Procedure DA(E' , S , l , u)

Step 1: Compute an optimal solution y of SI(E' , S , l , u).

Step 2: Find a maximal vector $v \in P'(r)$ such that $v \leq y$, where $P'(r)$ is the submodular polyhedron of the underlying submodular system of problem SM(E' , S , l , u).

Step 3: If $v = y$, let $x^* := y$ and return x^* .

Step 4: Compute $\text{sat}(v)$ for $P'(r)$, and let $E'_1 := \text{sat}(v)$ and $E'_2 := E' - E'_1$.

Step 5: Define two vectors $l^1, u^1 \in Z^{E'_1}$ by $l_j^1 := l_j, u_j^1 := y_j$ for $j \in E'_1$, and call DA(E'_1, S, l^1, u^1) to obtain an optimal solution x^1 of $Q'_1 = \text{SM}(E'_1, S, l^1, u^1)$ (which is the above Q_1 in the case of the first call).

Step 6: Define two vectors $l^2, u^2 \in Z^{E'_2}$ by $l_j^2 := y_j, u_j^2 := u_j$ for $j \in E'_2$, and call DA($E'_2, S \cup E'_1, l^2, u^2$) to obtain an optimal solution x^2 of $Q'_2 = \text{SM}(E'_2, S \cup E'_1, l^2, u^2)$ (which is the above Q_2 in the first call).

Step 7: Return an optimal solution $x^* = (x_j^1, j \in E'_1; x_j^2, j \in E'_2)$.

Before proving the correctness of procedure SM, the following lemma is proved:

Lemma 10 *If DA(E' , S , l , u) returns x^* in Step 3, it is an optimal solution of problem SM(E' , S , l , u).*

Proof Step 1 of DA(E' , S , l , u) computes an optimal solution y of problem SI(E' , S , l , u), which belongs to class SC/LUB/D. Since the problem SI(E' , S , l , u) is a relaxation of problem SM(E' , S , l , u), the y is optimal to SM(E' , S , l , u) if it is feasible to SM(E' , S , l , u). \square

Theorem 6 *Procedure SM correctly computes an optimal solution of SC/SM/D.*

Proof Consider the computation of DA(E', \emptyset, l, u). If $v < y$, E' is partitioned into E'_1 and E'_2 , and the original problem is accordingly decomposed into two subproblems. This decomposition is recursively applied, if necessary, and the entire process is represented by a decomposition tree T_E , where $E = \{1, 2, \dots, n\}$. The proof is done by the induction on the height of T_E . At a leaf of T_E , the corresponding subset E' is no more decomposed because the condition of Step 3 holds. Thus, due to Lemma 10, the subproblem can be correctly solved at the leaf. Consider an intermediate node of T_E , and let SM(E' , S , l , u) denote the problem considered at the node. Let Q'_1 and Q'_2 denote the subproblems of SC/SM/D considered in Steps 5 and 6 of DA(E' , S , l , u), respectively. By induction hypothesis, assume that problems Q'_1 and Q'_2 are correctly solved, and let $\{x_j^* \mid j \in E'_1\}$ (resp.,

$\{x_j^* \mid j \in E'_2\}$) denote the obtained optimal solution of Q'_1 (resp., Q'_2). It will be proven that $\{x_j^* \mid j \in E' (= E'_1 \cup E'_2)\}$ is an optimal solution of $\text{SM}(E', S, l, u)$.

From [Theorem 4](#), it suffices to show

$$d_j(x_j^* + 1) \geq d_i(x_i^*) \quad (54)$$

for all $i, j \in E'$ with $x^* - e(i) + e(j) \in B_0(r)$. Let $x' = x^* - e(i) + e(j)$. If $i, j \in E'_1$ or $i, j \in E'_2$, the inequality (54) clearly holds from the induction hypothesis. If $i \in E'_2$ and $j \in E'_1$, it holds that

$$x'(E'_1) > x^*(E'_1) = r(E'_1) - r(S)$$

(the right equality follows from the constraint of (52)), violating the feasibility of Q'_2 . Thus, consider the case of $i \in E'_1$ and $j \in E'_2$. From the way of decomposition used in Steps 5 and 6,

$$x_i^* \leq y_i \text{ and } x_j^* \geq y_j \quad (55)$$

hold. Since y is an optimal solution of the simple resource allocation problem $\text{SI}(E', S, l, u)$,

$$d_i(y_i) \leq d_j(y_j + 1) \quad (56)$$

holds from [Theorem 1](#). Then from the convexity of f_i and f_j , and from (55), it follows that

$$d_i(x_i^*) \leq d_j(x_j^* + 1).$$

This completes the proof. \square

Theorem 7 *The running time of procedure SM is polynomial in $|E|$ and $\log r(E)$. The time complexity is $O(\tau_1|E| + \tau_2|E|^2 \log r(E) + \tau_3|E|)$ time, where τ_1 , τ_2 , and τ_3 denote the running times to solve $\text{SI}(E', S, l, u)$, to test $x \in P(r)$ for a given $x \in R^E$, and to compute $\text{sat}(X)$ for a given $X \subseteq E$, respectively.*

Proof The running time of each execution of procedure $\text{DA}(E', S, l, u)$ is first evaluated. Step 1 can be solved in τ_1 time. Computation of a maximal vector v in Step 2 is done by iteratively increasing the j -th component of v by d_j^{\max} , $j \in E$, where

$$d_j^{\max} = \max\{d \mid v + d \cdot e(j) \in P(r)\}.$$

The computation of this d_j^{\max} can be done by binary search (i.e., in $O(\log r(E'))$ iterations), and testing whether $v + d \cdot e(j) \in P(r)$ or not can be done in τ_2 time. Therefore, Step 2 requires $O(\tau_2|E'| \log r(E'))$ time. Finally, $\text{sat}(v)$ is computed in τ_3 time. These computations clearly dominate all the other parts of DA, showing that the time to execute all steps of $\text{DA}(E', S, l, u)$ once is $O(\tau_1 + \tau_2|E'| \log r(E') + \tau_3)$. Since the number of vertices in the decomposition tree T_E is $O(|E|)$, DA is called

$O(|E|)$ times. Also, by $|E'| \leq |E|$ and $r(E') \leq r(E)$, the stated time complexity of SM follows.

From [Theorem 3](#), τ_1 is polynomial in $|E|$ and $\log r(E)$. Also, from [Lemma 5](#), τ_2 and τ_3 are polynomial in $|E|$ and $\log r(E)$. Therefore, the running time of procedure SM is polynomial in $|E|$ and $\log r(E)$. \square

3.3 SC/GUB/D, SC/Nested/D, SC/Tree/D, and SC/Network/D

It shall be briefly explained how separable convex resource allocation problems under generalized upper bounds (GUB), nested (Nested), tree (Tree), and network (Network) constraints can be solved efficiently, when the decomposition algorithm SM in the previous subsection is specialized to these cases. Since GUB, Nested, and Tree are special cases of Network, only problem SC/Network/D shall be considered.

Call a vector $\{x_t(\varphi) | x \in T\}$ for a feasible flow φ of (11)–(15) an *inflow vector*. For $X \in T$, define

$$w(X) = \max \left\{ \sum_{t \in X} x_t(\varphi) \mid \{x_t(\varphi) | x \in T\} \text{ is an inflow vector} \right\}. \quad (57)$$

Then, it is easy to see from the well-known max-flow min-cut theorem [40] that

$$w(X) = \min\{c(U, V - U) \mid s \in U, X \subseteq V - U\} \quad (58)$$

holds, where $c(U, V - U) = \sum_{u \in U, v \in V - U} c(u, v)$ represents the capacity of a cut (i.e., a partition) $(U, V - U)$, separating X from the sources. It is also well known in the network theory (see [68]) that the submodular propFerty holds for $w(X)$, that is,

$$W(X) + W(Y) \geq W(X \cup Y) + W(X \cap Y), \quad \text{for } X, Y \in T.$$

Then, $\{x_t(\varphi) \mid x \in T\}$ is an inflow vector of some feasible flow φ if and only if

$$x(X) \leq w(X) \quad \text{for all } X \subseteq T,$$

and

$$x(T) = N.$$

(See, e.g., [69] for the proof.)

Now, the running time of procedure SM is analyzed when procedure SM is specialized to SC/Network/D. Step 1 of DA can be executed by solving a problem of SC/Simple/D. For the obtained optimal solution y , Step 2 computes a maximal vector $v \leq y$. In the case of SC/Network/D, this is done by introducing a supersink t^* as well as arcs (t, t^*) for all $t \in T$ with capacity $c(t, t^*) = y_t$ and finding a maximum flow φ^* from s to t^* in the modified network. (To be more precise, while constructing the modified network, the lower bound on the flow value of the arc

(t, t^*) should be introduced in order to reflect the constraints implied by a vector l .) Then a vector

$$\{v_t = \varphi^*(t, t^*) \mid t \in T\}$$

is obtained. Thus, the v can be computed by applying an appropriate max-flow algorithm. The time required for other steps is dominated by that of Steps 1 and 2. Thus, the following theorem is obtained.

Theorem 8 *Problem SC/Network/D can be solved in $O(|T|(\tau(n, m, C_{\max}) + |T| \log(N/|T|)))$ time, where $\tau(n, m, C_{\max})$ denotes the running time for the maximum flow algorithm for a network with n vertices, m arcs, and the maximum arc capacity C_{\max} .*

Proof Since SC/Network/D is a special case of SC/SM/D, the running time is analyzed by following the proof of [Theorem 7](#). Since a maximum flow algorithm requires $\Omega(n)$ time, $|T| \leq \tau(n, m, C_{\max})$ clearly holds. The computation of vector y of Step 1 in procedure DA reduces to solving problem SC/Simple/D, which can be done in $O(|T| \log(N/|T|))$ time by using Frederickson and Johnson's algorithm [42]. The computation of vector $v \leq y$ of Step 2 is done by computing a maximum flow, which requires $\tau(n, m, C_{\max})$ time. These computations clearly dominate all the rest of DA. Thus, the theorem follows from [Theorem 7](#) (recall that $|E| = |T|$ and $r(E) = N$ hold for this case). \square

Existing max-flow algorithms run in time $\tau(n, m, C_{\max}) = O(nm \log(n^2/m))$, $O(n^3/\log n)$, and $O(n^{2/3}m \log(n^2/m) \log C_{\max})$ [124]. Since the maximum flow for a tree network can be computed in $O(m)$ time (see [69]) and $m = O(n)$ holds for a tree, the following corollary holds.

Corollary 1 *Problems SC/GUB/D, SC/Nested/D, and SC/Tree/D can be solved in $O(n^2 \log(N/n))$ time.* \square

Faster algorithms have been developed for SC/GUB/D, SC/Nested/D, and SC/Tree/D. Hochbaum [61] showed that SC/GUB/D can be solved in the same running time as SC/Simple/D by using the observation that every instance of SC/GUB/D can be reduced to a family of *disjoint* instances of SC/Simple/D. This implies, in particular, that SC/GUB/D can be solved in $O(n \log(N/n))$ time by using the algorithm of Frederickson and Johnson [42] repeatedly.

For SC/Nested/D, Dyer and Walker's algorithm [35] runs in $O(n \log n \log^2(N/n))$ time, and for SC/Tree/D, Dyer and Frieze [34] developed an $O(n \log^2 n \log N)$ time algorithm. Hochbaum [61] further improved the running time of these two algorithms to $O(n \log n \log(N/n))$. The idea of the improvement is based on a general proximity theorem between SC/SM/D and its *scaled* version. Proximity theorems and the resulting efficient algorithms are described in [Sects. 4](#) and [5](#).

3.4 Minimax and Maximin Problems

It will be shown here that minimax and maximin resource allocation problems, Minimax/-/D and Maximin/-/D, are equivalently transformed into problems of SC/-/D, where \cdot denotes any type of constraints defined in Sect. 2.2. Therefore, equally efficient algorithms can be developed for minimax and maximin problems. It suffices to show this fact for the most general case, that is, Minimax/SM/D and Maximin/SM/D, which are described as follows:

$$\begin{aligned} \text{MINIMAX: } & \text{minimize } \max_{j \in E} f_j(x_j), \\ & \text{subject to } x : \text{an integral base of } B_0(r), \end{aligned} \quad (59)$$

$$\begin{aligned} \text{MAXIMIN: } & \text{maximize } \min_{j \in E} f_j(x_j), \\ & \text{subject to } x : \text{an integral base of } B_0(r). \end{aligned} \quad (60)$$

Here all f_j , $j \in E$, are assumed to be nondecreasing. When all f_j are nonincreasing, problems MINIMAX and MAXIMIN are mutually transformed into MAXIMIN and MINIMAX, respectively, by the following identities:

$$\begin{aligned} -\min_x \max_{j \in E} f_j(x_j) &= \max_x \min_{j \in E} -f_j(x_j), \\ -\max_x \min_{j \in E} f_j(x_j) &= \min_x \max_{j \in E} -f_j(x_j). \end{aligned}$$

Define for $j \in E$

$$\begin{aligned} g_j(x_j) &= \sum_{y=0}^{x_j} f_j(y), \quad x_j = 0, 1, 2, \dots, \\ h_j(x_j) &= \sum_{y=-1}^{x_j} f_j(y), \quad x_j = 0, 1, 2, \dots, \end{aligned} \quad (61)$$

where $f_j(-1) = f_j(0)$ is assumed. Note that

$$\begin{aligned} g_j(x_j) - g_j(x_j - 1) &= f_j(x_j), \\ h_j(x_j) - h_j(x_j - 1) &= f_j(x_j - 1) \end{aligned} \quad (62)$$

hold for each $x_j = 0, 1, \dots$. From the nondecreasingness of f_j , it follows that g_j and h_j are convex over the nonnegative integers. Now consider the following problems of SC/SM/D:

$$Q_g : \min \left\{ \sum_{j \in E} g_j(x_j) \mid x : \text{an integral base of } B_0(r) \right\}, \quad (63)$$

$$\mathcal{Q}_h : \min \left\{ \sum_{j \in E} h_j(x_j) \mid x : \text{an integral base of } B_0(r) \right\}. \quad (64)$$

Theorem 9 Every optimal solution of problem \mathcal{Q}_g (resp., \mathcal{Q}_h) is optimal to MINIMAX (resp., MAXMIN).

Proof Only the proof for \mathcal{Q}_g is given (the case of \mathcal{Q}_h can be similarly treated). Let x^g be an optimal solution of \mathcal{Q}_g . By Theorem 4 and property $f_j(x_j) = g_j(x_j) - g_j(x_j - 1)$ by (62), it holds

$$f_j(x_j^g + 1) \geq f_i(x_i^g) \quad (65)$$

for all $i, j \in E$ with $x^g - e(i) + e(j) \in B_0(r)$. Suppose that x^g is not optimal to MINIMAX, and let x^* be an optimal solution such that $\|x^g - x^*\| (= \sum_{j \in E} |x_j^g - x_j^*|)$ is minimum. By (39) with $x = x^g$ and $y = x^*$, it holds that

$$f_i(x_i^g) - f_i(x_i^* + 1) + f_j(x_j^*) - f_j(x_j^g + 1) \geq 0 \quad (66)$$

for any i, j with $x_i^g > x_i^*$, $x_j^g < x_j^*$ such that $x^g - e(i) + e(j), x^* + e(i) - e(j) \in B_0(r)$. Hence, together with (65), it holds that

$$f_j(x_j^*) - f_i(x_i^* + 1) \geq 0. \quad (67)$$

Let $\hat{x} = x^* + e(i) - e(j)$. Since $f_j(x_j)$ is nondecreasing, $f_j(\hat{x}_j) = f_j(x_j^* - 1) \leq f_j(x_j^*)$ holds. In addition, it holds that

$$f_j(x_j^*) \geq f_i(x_i^* + 1) = f_i(\hat{x}_i). \quad (68)$$

Since $f_k(\hat{x}_k) = f_k(x_k^*)$ for $k \neq i, j$, it follows

$$\max_{j \in E} f_j(x_j^*) \geq \max_{j \in E} f_j(\hat{x}_j).$$

This implies that \hat{x} is also an optimal solution to MINIMAX, contradicting the minimality of $\|x^* - x^g\|$. \square

3.5 Notes and References

Most of the proofs of fundamental properties of a submodular system can be found in [45, 69]. The proof of Lemma 4 (ii) is due to Murota [111] although this property has been known as a folklore among researchers in this field. Also, Murota [111]

has shown that the condition of [Lemma 4](#) (ii) is a necessary and sufficient condition that a set $B \subseteq R^E$ is a base polyhedron of a submodular system.

Incremental and decomposition algorithms of [Sects. 3.2.1](#) and [3.2.2](#) are due to Federgruen and Groenevelt [39] and Groenevelt [53]. The original idea of the decomposition algorithm is due to Fujishige [43] who considered a special case of SC/SM/C in which $f_j(x_j) = w_j x_j^2$ ($w_j > 0$) holds for each j . The correctness proof given here is based on [Theorem 4](#), which is due to Murota [109]. [Theorem 4](#) helps simplify the proofs given in the original papers. The proof of [Theorem 9](#) for MINIMAX is also based on the result of [109] for M -convex functions.

The incremental algorithm for SC/SM/D was extended to more general constraints, for example, to the separable convex resource allocation problem for a bisubmodular system and for a finite jump system by Ando, Fujishige, and Naitoh (see papers [4, 5, 44] for the details). Notice that a finite jump system is a generalization of a bisubmodular system. The existence of a polynomial-time algorithm similar to SM of [Sect. 3.2.2](#) was known for a bisubmodular system [44], and for a finite jump system, a polynomial-time algorithm was proposed by Shioura and Tanaka [131].

Resource allocation problem with continuous variables has also been extensively studied, although the details are omitted in this chapter.

The decomposition algorithm of [Sect. 3.2.2](#) works also for the case of continuous variables, that is, problem SC/SM/C, with a minor modification in Step 1 of procedure DA that problem SC/Simple/C is solved instead of SC/Simple/D (see the book by Fujishige [45]). Fujishige [43, 45] showed the equivalence between Lexico-Minimax/SM/C and SC/SM/C in a sense similar to [Theorem 9](#). Also, it has been shown in [43, 45] that an optimal solution of Minimax of (59) obtained through problem Q_g of (63) is lexicographically minimax.

For general S/Simple/D with nonconvex objective function, a parallel algorithm has been proposed by Shao and Rao [127], and a metaheuristic algorithm based on ant-colony optimization was proposed by Yin and Wang [146].

Minimax/Simple/C and Minimax/Simple/D have been further studied in [21, 22, 37, 75, 91, 100, 147] since the book by Ibaraki and Katoh [69] has been published. In particular, Luss [100] studied lexicographic minimax approach while mentioning several application fields including production planning and scheduling, workforce management, allocation of emergency services, distribution of strategic resource, and telecommunications network design.

Fujishige, Katoh, and Ichimori [46] proposed an efficient algorithm for Fair/SM/D by making use of the proximity result that relates an optimal solution of Fair/SM/D and optimal solutions of Minimax/SM/D and Maximin/SM/D. Namikawa and Ibaraki [112] also derived an efficient algorithm for Fair/SM/D using the continuous relaxation.

The separable convex quadratic resource allocation problem with continuous variables has been well studied, where, instead of the constraint $\sum_{j=1}^n x_j = N$, the following knapsack constraint is considered:

$$\sum_{j=1}^n a_j x_j \leq N, \quad (69)$$

where all a_j are nonnegative. This problem is called the *quadratic knapsack problem*. Notice that the problem with this constraint can be transformed into SQC/Simple/C because, due to continuous variables, introducing new variables $x'_j = a_j x_j$ and a slack variable s turns the above knapsack constraint into the equality constraint of the form $\sum_{j=1}^n x_j + s = N$ without increasing the computational difficulty. The LUB constraint can also be easily incorporated without increasing the difficulty. For this problem, Brucker [23] developed a linear-time algorithm. Later, Nielsen and Zenios [114], Pardalos and Kovoov [118], Pardalos, Ye, and Han [119], and Robinson, Jiang, and Lerme [123] further studied this problem. Problem SQC/GUB/C has been also studied by Brethauer and Shetty [15] who performed extensive computational experiments for various problem instances with up to hundred thousand variables and showed that their algorithm is extremely efficient compared with a general-purpose software for nonlinear programs. Megiddo and Tamir [105] developed a linear-time algorithm for the separable convex quadratic resource allocation problem with more general constraints. Problem SQC/-/C will be utilized to solve SQC/-/D in Sect. 5.3.

4 Proximity Theorems

Proximity theorem refers to a theoretical bound on the distance between two optimal solutions to an optimization problem and to its related (relaxed or approximated) problem. In this section, proximity theorems are presented for the two types of problems. The first theorem deals with SC/Linear/D, due to Hochbaum and Shanthikumar [65], where Linear is defined by linear inequalities $Ax \geq b$ for $m \times n$ integer matrix A , and the second deals with SC/SM/D, due to Hochbaum [61], Moriguchi and Shioura [107], and Moriguchi, Shioura, and Tsuchimura [108].

The first proximity result is described in terms of the maximum absolute value of the subdeterminants of the constraint matrix A , denoted by Δ . If $\Delta = 1$ (i.e., constraint matrix is *totally unimodular*), the theorem leads to a polynomial-time algorithm for the problem with integer variables. Thus, this result identifies a new class of resource allocation problems with integer variables for which a polynomial-time algorithm can be developed. Notice that a system of linear inequalities defined by a totally unimodular matrix is different from the one defined by submodular constraints, because the constraint matrix defined by submodular functions (i.e., (5)) is *totally dual integral* but is not totally unimodular (see, e.g., [36, 67]).

From the second proximity theorem for SC/SM/D, Hochbaum [61] developed efficient algorithms for SC/GUB/D, SC/Nested/D, and SC/Tree/D, improving the running time of the algorithms given in Sect. 3.2. The algorithms use the

so-called scaling techniques in which the scaled versions of incremental algorithms are iteratively applied. These algorithms will be described in [Sect. 5](#).

4.1 Proximity Theorem for General Linear Constraints

For simplicity, denote

$$f(x) = \sum_{j=1}^n f_j(x_j), \quad (70)$$

where all $f_j : R \rightarrow R$, $j = 1, \dots, n$ are convex. Consider the following problem,

$$\begin{aligned} \text{IP : minimize } & f(z) \\ \text{subject to } & Az \geq b, \\ & z \geq 0, \\ & z : \text{integer}, \end{aligned} \quad (71)$$

as well as its continuous version,

$$\begin{aligned} \text{RP : minimize } & f(x) \\ \text{subject to } & Ax \geq b, \\ & x \geq 0. \end{aligned} \quad (72)$$

Here, A is an $m \times n$ integer matrix and b is an m -dimensional integer vector. It is assumed that the polyhedron defined by $\{x \mid Ax \geq b, x \in R^n\}$ is bounded, and thus, there exists an optimal solution for each of IP and RP. For a scaling parameter s (a positive integer), let the scaled problem IP/ s be defined by

$$\begin{aligned} \text{IP}/s : \text{minimize } & f(sy) \\ \text{subject to } & Ay \geq b/s, \\ & y \geq 0, \\ & y : \text{integer}. \end{aligned} \quad (73)$$

In problem IP/ s , the solution $x = sy$ is an integer multiple of s . Although RP and a continuous version of IP/ s are the same, it is needed to define the linearized functions $f_j^{L:s}$ and $f^{L:s}$ for s .

$f_j^{L:s} : R \rightarrow R$, a piecewise linear convex function such that

$$f_j^{L:s}(sy_j) = f_j(sy_j) \text{ holds for all integers } y_j,$$

$$f^{L:s}(x) = \sum_{j=1}^n f_j^{L:s}(x_j). \quad (74)$$

Then an optimal solution to the following problem,

$$\begin{aligned} \text{IP}'/s : & \text{minimize } f^{L:s}(sy) \\ & \text{subject to } Ay \geq b/s, \\ & y \geq 0, \\ & y : \text{integer}, \end{aligned} \tag{75}$$

is optimal to IP/s, since $f^{L:s}(sy) = f(sy)$ holds for all integer vectors y . Define also the following continuous problem:

$$\begin{aligned} \text{LP}/s : & \text{minimize } f^{L:s}(x) \\ & \text{subject to } Ax \geq b, \\ & x \geq 0. \end{aligned} \tag{76}$$

Now assume, without loss of generality (see [117]), that lower and upper bounds on variables are available such that an optimal solution exists in the interval given by the bounds, that is,

$$l_j \leq x_j \leq u_j, \quad j = 1, 2, \dots, n.$$

Remark 1 LP/s can be formulated as a linear programming problem by introducing N_j continuous variables for each j corresponding to the line segments of the piecewise linear convex function $f_j^{L:s}(sy_j)$, where $N_j = (u_j - l_j)/s$ (see [33]).

Use the notation $x \vee y$ and $x \wedge y$ for $x, y \in R^n$ to denote

$$\begin{aligned} x \vee y &= (\max\{x_1, y_1\}, \dots, \max\{x_n, y_n\}), \\ x \wedge y &= (\min\{x_1, y_1\}, \dots, \min\{x_n, y_n\}). \end{aligned}$$

Lemma 11 *For the function f of (70) and for any $x, x', y, y' \in R^n$ satisfying*

- (i) $x \wedge x' \leq y \leq x \vee x'$,
 - (ii) $x \wedge x' \leq y' \leq x \vee x'$,
 - (iii) $x + x' = y + y'$,
- it holds that*

$$f(x) + f(x') \geq f(y) + f(y').$$

Proof Let $z = x \wedge x'$ and $z' = x \vee x'$. Since either $x_j = z_j$, $x'_j = z'_j$ or $x_j = z'_j$, $x'_j = z_j$ holds for all j from the definition of z and z' ,

$$z_j + z'_j = x_j + x'_j, \tag{77}$$

$$f_j(z_j) + f_j(z'_j) = f_j(x_j) + f_j(x'_j) \tag{78}$$

hold for all j . Then from (i), (ii), (iii), and (77), it follows that $z_j \leq y_j \leq z'_j$, $z_j \leq y'_j \leq z'_j$ and $z_j + z'_j = y_j + y'_j$ for all j . From the convexity of f_j , it is easy to see

$$f_j(z_j) + f_j(z'_j) \geq f_j(y_j) + f_j(y'_j),$$

and hence,

$$f(z) + f(z') \geq f(y) + f(y').$$

Since $f(z) + f(z') = f(x) + f(x')$ holds from (78), the lemma follows. \square

Now let Δ be defined as above, and

$$\|x\|_\infty = \max_{1 \leq j \leq n} |x_j|$$

be the L_∞ norm of $x \in R^n$. The proximity theorem between IP and RP is stated as follows.

Theorem 10 (i) For every optimal solution \hat{x} of RP, there exists an optimal solution z^* of IP such that $\|\hat{x} - z^*\|_\infty \leq n\Delta$.
(ii) For every optimal solution \hat{z} of IP, there exists an optimal solution x^* of RP such that $\|\hat{z} - x^*\|_\infty \leq n\Delta$.

Proof First note that both IP and RP have optimal solutions as assumed at the beginning of Sect. 4.1. First, a cone with respect to \hat{z} and \hat{x} is defined. Let (S_1, S_2) be the partition of $\{1, \dots, n\}$ such that $\hat{z}_j \geq \hat{x}_j$ for all $j \in S_1$ and $\hat{z}_j < \hat{x}_j$ for all $j \in S_2$. Also, partition the matrix A into submatrices

$$A = \begin{pmatrix} A_1 \\ A_2 \end{pmatrix}$$

such that $A_1\hat{z} < A_1\hat{x}$ and $A_2\hat{z} \geq A_2\hat{x}$. Define the cone $C = \{y \in R^n \mid A_1y \leq 0, A_2y > 0, y_j \geq 0, j \in S_1, y_j \leq 0, j \in S_2\}$. Let $U \subset C$ be a finite set of integer vectors that generate C . Then, because of the integrality of the components of A ,

$$\|u\|_\infty \leq \Delta$$

holds for all $u \in U$, and since $\hat{z} - \hat{x} \in C$, there exist t ($\leq n$) vectors $u^{(i)} \in U$ and $\alpha_i \geq 0$, $i = 1, \dots, t$ such that $\hat{z} - \hat{x} = \sum_{i=1}^t \alpha_i u^{(i)}$ (see [31]), that is,

$$\hat{z} = \hat{x} + \sum_{i=1}^t \alpha_i u^{(i)}. \quad (79)$$

Let

$$\beta_i = \alpha_i - \lfloor \alpha_i \rfloor, \quad i = 1, \dots, t$$

and define

$$z^* = \hat{x} + \sum_{i=1}^t \beta_i u^{(i)} \quad (80)$$

and

$$x^* = \hat{z} - \sum_{i=1}^t \beta_i u^{(i)}. \quad (81)$$

From (79), (80), and (81), it follows that

$$z^* = \hat{z} - \sum_{i=1}^t (\alpha_i - \beta_i) u^{(i)}, \quad (82)$$

$$x^* = \hat{x} + \sum_{i=1}^t (\alpha_i - \beta_i) u^{(i)}. \quad (83)$$

Now, it is shown that these z^* and x^* are feasible for IP and RP, respectively. Observe from (82) that

$$A_1 z^* = A_1 \hat{z} - \sum_{i=1}^t (\alpha_i - \beta_i) A_1 u^{(i)} \geq A_1 \hat{z}, \quad (84)$$

since $\alpha_i - \beta_i \geq 0$ and $u^{(i)} \in C$ (i.e., $A_1 u^{(i)} \leq 0, i = 1, \dots, t$). Similarly, from (80),

$$A_2 z^* = A_2 \hat{x} + \sum_{i=1}^t \beta_i A_2 u^{(i)} \geq A_2 \hat{x}. \quad (85)$$

Hence, $Az^* \geq b$ holds from $A\hat{z} \geq b$ and $A\hat{x} \geq b$. Since $\alpha_i - \beta_i = \lfloor \alpha_i \rfloor$ and $u^{(i)}$ are integral, the integrality of z^* follows from (82). Analogously,

$$A_1 x^* = A_1 \hat{z} - \sum_{i=1}^t \beta_i A_1 u^{(i)} \geq A_1 \hat{z}, \quad (86)$$

$$A_2 x^* = A_2 \hat{x} + \sum_{i=1}^t (\alpha_i - \beta_i) A_2 u^{(i)} \geq A_2 \hat{x}. \quad (87)$$

Hence, $Ax^* \geq b$. Since $u^{(i)} \in C$, it holds that $u_j^{(i)} \geq 0$ for $j \in S_1$ and $u_j^{(i)} \leq 0$ for $j \in S_2$. Note also that $\hat{z}_j \geq \hat{x}_j$ for $j \in S_1$ and $\hat{z}_j < \hat{x}_j$ for $j \in S_2$. Hence, it follows from (80) and (82) that

$$\begin{aligned} \hat{z}_j &\geq z_j^* \geq \hat{x}_j, \quad j \in S_1, \\ \hat{z}_j &\leq z_j^* \leq \hat{x}_j, \quad j \in S_2, \end{aligned} \quad (88)$$

and similarly from (81) and (83) that

$$\begin{aligned}\hat{z}_j &\geq x_j^* \geq \hat{x}_j, \quad j \in S_1, \\ \hat{z}_j &\leq x_j^* \leq \hat{x}_j, \quad j \in S_2.\end{aligned}\tag{89}$$

The inequalities (88) and (89) imply

$$\hat{z} \wedge \hat{x} \leq z^* \leq \hat{z} \vee \hat{x}\tag{90}$$

and

$$\hat{z} \wedge \hat{x} \leq x^* \leq \hat{z} \vee \hat{x}.\tag{91}$$

Furthermore, (80) and (81) imply

$$\hat{z} + \hat{x} = z^* + x^*.\tag{92}$$

It then follows from (90), (91), (92), and Lemma 11 that

$$f(\hat{z}) + f(\hat{x}) \geq f(z^*) + f(x^*).\tag{93}$$

Therefore,

$$f(z^*) \leq f(\hat{z}) + f(\hat{x}) - f(x^*) \leq f(\hat{z}),$$

since \hat{x} is an optimal solution of RP and x^* is feasible to RP. Hence, z^* is also optimal to IP and $f(z^*) = f(\hat{z})$ holds. Therefore, $f(\hat{x}) = f(x^*)$ follows, and x^* is also optimal to RP. Finally, by (80) and (81), it holds that

$$\begin{aligned}\|\hat{x} - z^*\| &= \left\| \sum_{i=1}^t \beta_i u^{(i)} \right\|_\infty \leq n\Delta, \\ \|\hat{z} - x^*\| &= \left\| \sum_{i=1}^t \beta_i u^{(i)} \right\|_\infty \leq n\Delta.\end{aligned}$$

□

The proofs for the following proximity theorems, between IP/s and IP, and between IP and LP/s, can also been done by using the arguments similar to the above theorem. These will be used to develop an algorithm in the next subsection.

- Theorem 11** (i) For every optimal solution \hat{y} of IP/s, there exists an optimal solution z^* of IP such that $\|s\hat{y} - z^*\|_\infty \leq ns\Delta$.
(ii) For every optimal solution \hat{z} of IP, there exists an optimal solution y^* of IP/s such that $\|\hat{z} - sy^*\|_\infty \leq ns\Delta$. □

- Theorem 12** For every optimal solution \hat{x} of LP/s, there exists an optimal solution z^* of IP such that

$$\|\hat{x} - z^*\|_\infty \leq 2ns\Delta. \quad (94)$$

Proof Since LP/s is a continuous relaxation of IP'/s with $x = sy$, it follows from [Theorem 10](#) that there exists an optimal solution y^* of IP'/s (and hence of IP/s) such that $\|\hat{x}/s - y^*\|_\infty \leq n\Delta$. From [Theorem 11](#), there exists an optimal solution z^* of IP such that $\|sy^* - z^*\|_\infty \leq ns\Delta$. Combining these proximity results implies (94). \square

4.2 Algorithm for Problem IP

As stated at the beginning of [Sect. 4.1](#), it is assumed that the polyhedron defined by the $\{x \mid Ax \geq b, x \in R^n\}$ is bounded. This implies that there exists a positive integer γ such that an optimal solution of the problem,

$$\begin{aligned} \text{IP}^{(1)} : & \text{minimize } f(z) \\ & \text{subject to } Az \geq b, \\ & \quad -2^{\gamma+1}n\Delta e \leq z \leq 2^{\gamma+1}n\Delta e, \\ & \quad z : \text{integer}, \end{aligned}$$

where $e = (1, \dots, 1)^T$, is also optimal to IP (see the book [117] for the proof of the existence of such γ). In particular, it can be chosen that

$$\gamma = \lceil \log_2((m/n)\|b\|_\infty) \rceil - 1.$$

Now the algorithm for IP is described as follows:

Algorithm SOLVE_IP

Input: An instance of problem IP.

Output: An optimal solution \hat{z} .

Step 1: Let $s_k := 2^{\gamma-k}$, $k = 0, \dots, \gamma$, and $\hat{x}^{(0)} := 0$.

Step 2: For each of $k = 1, \dots, \gamma$, compute an optimal solution $\hat{x}^{(k)}$ of the following problem:

$$\begin{aligned} \text{LP}^{(k)}/s_k : & \text{minimize } f^{L:s_k}(x) \\ & \text{subject to } Ax \geq b, \\ & \quad \hat{x}^{(k-1)} - 2ns_{k-1}\Delta e \leq x \leq \hat{x}^{(k-1)} + 2ns_{k-1}\Delta e. \end{aligned}$$

Step 3: Obtain an optimal solution \hat{z} by solving the following integer program with lower bound $L_j = x_j^{(\gamma)} - 2n\Delta$ and upper bound $U_j = x_j^{(\gamma)} + 2n\Delta$ on z_j :

$$\begin{aligned} \text{IP}^* : & \text{minimize } f(z) \\ & \text{subject to } Az \geq b, \\ & \quad \hat{x}^{(\gamma)} - 2n\Delta e \leq z \leq \hat{x}^{(\gamma)} + 2n\Delta e \\ & \quad z : \text{integer}. \end{aligned}$$

Output \hat{z} as an optimal solution of IP.

Let $T(n, m, \Delta)$ denote the running time of a linear programming algorithm for solving $\min\{cx \mid Ax \geq b, 0 \leq x_j \leq 1 \text{ for } j = 1, 2, \dots, n\}$, where Δ denotes the maximum absolute value of the subdeterminants of A , and let $TI(n, m, A)$ denote the running time to solve the integer linear programming problem $\min\{cx \mid Ax \geq b, 0 \leq x_j \leq 1 \text{ for } j = 1, 2, \dots, n, x : \text{integer}\}$. Let A^k denote the $m \times kn$ matrix in which each column of A appears k times.

Theorem 13 *The solution \hat{z} obtained by Algorithm SOLVE_IP is an optimal solution of problem IP. The running time of SOLVE_IP is*

$$\log_2((m/n)\|b\|_\infty) \cdot T(8n^2\Delta, m, \Delta) + TI(4n^2\Delta, m, A^{4n\Delta}).$$

Proof Consider the problem $LP^{(1)}/s_1$ with $s_1 = 2^{\gamma-1}$, which is solved in Step 1 for $k = 1$. This $LP^{(1)}/s_1$ is a relaxation of $IP^{(1)}$ since $f_j^{L,s_1}(x)$ is a piecewise linearization of the original function $f(x)$. By [Theorem 12](#), there exists an optimal solution $z^{(1)}$ of $IP^{(1)}$ such that

$$\|\hat{x}^{(1)} - z^{(1)}\|_\infty \leq 2ns_1\Delta = 2^\gamma n\Delta.$$

Therefore, an optimal solution of the integer program,

$$\begin{aligned} IP^{(2)} : & \text{minimize } f(z) \\ & \text{subject to } Az \geq b, \\ & \hat{x}^{(1)} - 2^\gamma n\Delta e \leq z \leq \hat{x}^{(1)} + 2^\gamma n\Delta e \\ & z : \text{integer}, \end{aligned}$$

is also optimal to $IP^{(1)}$ (and hence of IP). Observe that problem $LP^{(2)}/s_2$ with $s_2 = 2^{\gamma-2}$ is a linearized relaxation of $IP^{(2)}$. Hence, again from [Theorem 12](#), it follows that there exists an optimal solution $z^{(2)}$ of $IP^{(2)}$ (and hence of IP) such that

$$\|\hat{x}^{(2)} - z^{(2)}\|_\infty \leq 2ns_2\Delta = 2^{\gamma-1}n\Delta.$$

Repeating this argument, it can be seen that, for each $k = 1, \dots, \gamma$, there exists an optimal solution $z^{(k)}$ of IP such that

$$\|\hat{x}^{(k)} - z^{(k)}\|_\infty \leq 2^{\gamma+1-k}n\Delta.$$

Therefore, for each $k = 1, \dots, \gamma$, an optimal solution of $IP^{(k)}$ (defined similarly to $IP^{(2)}$) is also optimal to IP. Since [Theorem 12](#) tells that there exists an optimal solution \hat{z} of IP such that $\|\hat{x}^{(\gamma)} - \hat{z}\|_\infty \leq 2n\Delta$, the correctness of Algorithm SOLVE_IP follows.

As for the time complexity, Step 2 is repeated γ times. Here,

$$\gamma = \lceil \log_2((m/n)\|b\|_\infty) \rceil - 1 < \log_2((m/n)\|b\|_\infty).$$

At every iteration, each variable x_j is replaced by $8n\Delta$ variables (see Remark 1) because x_j is in an interval of length $4ns_{k-1}\Delta$ from definition of $\text{LP}^{(k)}/s_k$, and the number of variables used for linearization is $4ns_{k-1}\Delta/s_k = 8n\Delta$. Thus, the time complexity for solving the corresponding linear program is $T(8n^2\Delta, m, \Delta)$. In order to solve the problem IP^* in Step 3, it is transformed into an integer linear program first. For this transformation, $4n\Delta$ 0-1 variables are needed since x_j for all j is in an interval of length $4n\Delta$. Thus, the number of resulting 0-1 variables is $4n^2\Delta$, and the matrix A has each column duplicated $4n\Delta$ times. Hence, Step 3 requires $TI(4n^2\Delta, m, A^{4n\Delta})$ time. \square

Corollary 2 *If A is totally unimodular, problem IP can be solved in polynomial time. The time complexity is $\log_2((m/n)\|b\|_\infty) \cdot T(8n^2, m, 1)$.*

Proof If A is totally unimodular, problem IP^* can be solved by applying a polynomial-time algorithm for the linear program. The theorem then immediately follows from $\Delta = 1$. \square

4.3 Proximity Theorem for Submodular Constraints

As remarked at the beginning of this section, the constraint matrix defining the base polyhedron of a submodular system is not totally unimodular. Thus, Algorithm `SOLVE_IP` in the previous subsection cannot be applied directly to SC/SM/D in order to obtain a polynomial-time algorithm. However, as will be shown below, stronger proximity results for this case can be established.

Recall the formulation of the problem SC/SM/D.

$$\begin{aligned} Q : & \text{minimize } \sum_{j \in E} f_j(x_j), \\ & \text{subject to } x : \text{ an integer base of } B(r). \end{aligned} \tag{95}$$

Let x^* denote an optimal solution of Q . For a positive integer s , the following algorithm `SM-INCREMENT(s)` obtained by modifying an incremental algorithm of Sect. 3.2.1 produces a feasible solution $x^{(s)}$ of Q . This $x^{(s)}$ is then used to establish a strong proximity theorem. This algorithm will be used as a subroutine in the algorithm presented in Sect. 5.3. The description of the following algorithm reflects a correction of an error in the original version by Hochbaum [61] (fixed in Moriguchi and Shioura [107]). Recall the definition of the saturation capacity $\hat{c}(x, j)$ for $x \in P(r)$ and $j \in E$, which is given by (35). δ computed in the algorithm is used only for the proof of the proximity theorem (Theorem 14).

Procedure `SM-INCREMENT(s)`

Input: An instance Q of problem SC/SM/D and a positive integer s .

Output: A feasible solution $x^{(s)}$ of SC/SM/D.

Let $x_j := 0$ and $\delta_j := 0$ for all $j \in E$, $E' := E$ and $k := 0$.

```

while  $E' \neq \emptyset$  do
  begin
    Find  $j^* \in E'$  such that
     $d_{j^*}(x_{j^*} + 1) = \min\{d_j(x_j + 1) \mid j \in E'\};$ 
    if  $x + e(j^*) \notin P(r)$  then  $E' := E' - \{j^*\}$ 
    else if  $x + s \cdot e(j^*) \notin P(r)$  then  $E' := E' - \{j^*\}, \alpha := \hat{c}(x, j^*),$ 
       $x_{j^*} := x_{j^*} + \alpha, k := k + \alpha$  and  $\delta_{j^*} := \alpha$ 
    else  $x_{j^*} := x_{j^*} + s, k := k + s$ , and  $\delta_{j^*} := s$ 
  end;
  Output  $x^{(s)} := x$ .

```

Note that the output $x^{(s)}$ of SM-INCREMENT(s) satisfies $x^{(s)} + e(j) \notin P(r)$ for all $j \in E$, and therefore, $x^{(s)} \in B(r)$ holds; in particular, $\sum_{j \in E} x_j^{(s)} = r(E)$ holds.

A proximity theorem of the following form holds for SC/SMD. Notice that the vector δ records the last increments executed by SM-INCREMENT(s), that is, $\delta_j = \alpha$ implies that $x^{(s)}$ is equal to α modulo s .

Theorem 14 *For the solution $x^{(s)}$ and vector δ output by SM-INCREMENT(s), there exists an optimal solution x^* of problem Q such that $x^* \geq x^{(s)} - \delta \geq x^{(s)} - se$.*

This proximity theorem follows immediately from the next result by Girlich, Kovalev, and Zaporozhets [51]. Notice that the next result also gives an alternative proof for the validity of the incremental algorithm for SC/SMD presented in Sect. 3.2.1.

Theorem 15 *Let $x \in P(r)$ and $y \in \mathbb{Z}^E$ be a vector with $y \leq x$ such that there exists an optimal solution x^* of problem Q satisfying $x^* \geq y$. Suppose that $j^* \in E$ satisfies $x + e(j^*) \in P(r)$ and*

$$d_{j^*}(x_{j^*} + 1) = \min\{d_j(x_j + 1) \mid j \in E, x + e(j) \in P(r)\}.$$

Then, there exists an optimal solution \tilde{x} of problem Q satisfying both of $\tilde{x} \geq y$ and $\tilde{x}_{j^} > x_{j^*}$.*

Proof Let x^* be an optimal solution of problem Q with $x^* \geq y$ such that the value of $x_{j^*}^*$ is the maximum among all such vectors. To derive a contradiction, assume that $x_{j^*}^* \leq x_{j^*}$. Let $x' = x + e(j^*)$. Then, it holds that $x'_{j^*} = x_{j^*} + 1 > x_{j^*}^*$. Since x' and x^* are in the submodular polyhedron $P(r)$ and satisfy $\sum_{j \in E} x'_j \leq r(E) = \sum_{j \in E} x_j^*$, it can be shown in a similar way as in Lemmas 4 and 6 that there exists some $i \in E$ with $x'_i < x_i^*$ such that $x' - e(j_*) + e(i) \in P(r)$, $x^* + e(j_*) - e(i) \in P(r)$, and

$$f(x') + f(x^*) \geq f(x' - e(j_*) + e(i)) + f(x^* + e(j_*) - e(i)). \quad (96)$$

Notice that $x' - e(j_*) + e(i) = x + e(i)$, which implies that $f(x' - e(j_*) + e(i)) \geq f(x')$ due to the choice of j^* . It follows from this inequality and the inequality (96) that $f(x^*) \geq f(x^* + e(j_*) - e(i))$. Since $x^* + e(j_*) - e(i) \in B(r)$ holds, the vector $\tilde{x} \equiv x^* + e(j_*) - e(i)$ is also an optimal solution of problem Q , which satisfies $\tilde{x} \geq y$; recall that $\tilde{x}_i = x_i^* - 1 \geq x'_i \geq y_i$. In addition, \tilde{x} satisfies $\tilde{x}_{j_*} > x_{j_*}^*$, a contradiction to the choice of x^* . \square

A proximity theorem for SC/SM/D and its continuous relaxation, that is, SC/SM/C are now considered. The following statement is shown by Moriguchi, Shioura, and Tsuchimura [108], which corrects an error in the corresponding statement of Hochbaum [61].

Theorem 16 *For any optimal solution x^* of Q , there exists an optimal solution \tilde{x} of the continuous relaxation of Q such that*

$$\|\tilde{x} - x^*\|_1 \leq 2(n - 1), \quad (97)$$

and, vice versa, for any optimal solution \tilde{x} of the continuous relaxation of Q , there exists an optimal solution x^ of Q that satisfies (97). Here $\|y\|_1$ denotes the l_1 -norm $\sum_{j \in E} |y_j|$.* \square

The proof of this theorem is omitted. From Theorem 16, the following result can be obtained by using the fact that $\sum_{j \in E} x_j^* = \sum_{j \in E} \tilde{x}_j$.

Corollary 3 *For any optimal solution x^* of Q , there exists an optimal solution \tilde{x} of the continuous relaxation of Q such that*

$$\|\tilde{x} - x^*\|_\infty \leq n - 1, \quad (98)$$

and, vice versa, for any optimal solution \tilde{x} of the continuous relaxation of Q , there exists an optimal solution x^ of Q that satisfies (98).*

The bound in (98) is better than the one given in Theorem 10, which says $\|x^* - \tilde{x}\|_\infty \leq n\Delta$, since Δ for the submodular constraints is generally greater than one.

These proximity results shown in this section will be used to develop efficient algorithms for SC/-/D and SQC/-/D in the next section.

4.4 Notes

Proximity results between continuous and integer optimal solutions for some optimization problems have been known before. In Chap. 4 of the book by Ibaraki and Katoh [69], a proximity theorem between SC/Simple/C and SC/Simple/D was shown, based on which an efficient algorithm for SC/Simple/D was developed. An efficient algorithm for Fair/SM/D by Fujishige, Katoh, and Ichimori [46] is based on

the proximity theorem developed therein among Fair/SM/D, Minimax/SM/D, and Maximin/SM/D. Namikawa and Ibaraki [112] proved a similar theorem between Fair/SM/C and Fair/SM/D, to derive an efficient algorithm for Fair/SM/D.

These proximity results come from the special structures of objective functions and/or constraints. By extending this line of development, many other types of proximity results may be obtained.

Notice that Algorithm SOLVE.IP explained in Sect. 4.2 does not specify an algorithm that solves the linear program $\text{LP}^{(k)}/s_k$. When the constraint matrix represents a network, Hochbaum [60] proposed a network flow algorithm for this case which is an adaptation of the *successive shortest path method* for minimum-cost flow problems. For a general totally unimodular constraint matrix, Karzanov and McCormick [76] proposed another polynomial-time algorithm. The idea of their algorithm is a generalization of the *minimum mean cancellation method* developed for minimum-cost flow problems. Thus, the algorithm does not rely on linear programming, either. Karzanov and McCormick [76] further considered specializations and generalizations by changing the form of the objective functions and the constraints.

5 Lower Bounds on Time Complexity and Improved Algorithms

This section first explains an alternative, faster algorithm for SC/SM/D based on the proximity theorem (Theorem 14), which is developed by Hochbaum [61] and later fixed by Moriguchi and Shioura [107]. This algorithm, when specialized to problems SC/Nested/D and SC/Tree/D, gives better time bounds than previous algorithms. The running times of the resulting algorithms are $O(n \log n \log(N/n))$ for both of SC/Nested/D and SC/Tree/D. None of these algorithms, however, is strongly polynomial, where a polynomial-time algorithm is called *strongly polynomial* if its running time depends only on the dimension of the problem (i.e., the number of the input, e.g., n in the resource allocation problem), instead of the input size, and is called *weakly polynomial* otherwise. For instance, the $O(n \log(N/n))$ time bound of the SC/Simple/D is weakly polynomial because the number of the input is $O(n)$, but the running time depends on N .

Then, a lower bound result for SC/Simple/D obtained by Hochbaum [61] is shown (see also Hochbaum [63]), which says that, under a certain computation model, there cannot exist a strongly polynomial algorithm even for SC/Simple/D, if it is assumed that f_j 's are general convex functions (e.g., polynomials of degree at least 3). This is then contrasted with the cases of linear and quadratic objective functions. In the latter cases, there are strongly polynomial algorithms for SC/-/D, where \cdot denotes Simple, GUB, Nested, Tree, and Network, as demonstrated by Hochbaum and Hong [64] (see also Moriguchi, Shioura, and Tsuchimura [108]).

This section is mainly devoted to describing the underlying basic ideas of how the above results are derived.

5.1 Improved Algorithms for SC/SM/D and Its Special Cases

An algorithm for SC/SM/D is described below, which is based on the scaling technique and a proximity theorem ([Theorem 14](#)) and runs in $O(n(\log n + \tilde{\tau}) \log(r(E)/n))$ time, where $\tilde{\tau}$ denotes the time required to compute the saturation capacity $\hat{c}(x, j)$ for given $x \in P(r)$ and $j \in E$.

Procedure SCALING

Input: An instance of problem SC/SM/D.

Output: An optimal solution x^* .

```

Let  $s := \lceil r(E)/2n \rceil$  and  $l := x := (0, 0, \dots, 0)$ ;
while  $s > 1$  do
begin
    Call SM-INCREMENT( $s, l$ ), and let  $x^{(s)}$  be its output;
    Let  $l$  be defined by  $l_i := \max\{x_i^{(s)} - s, 0\}$  for each  $i \in E$ ;
    Let  $s := \lceil s/2 \rceil$ 
end;
Call SM-INCREMENT with  $x^{(s)}$  as an initial solution;
Output the obtained solution as  $x^*$ .

```

In the above procedure, $e = (1, 1, \dots, 1)$ and SM-INCREMENT(s, l) is the same as procedure SM-INCREMENT(s) of [Sect. 4.3](#) except that it starts with $x = l$ as an initial solution.

Theorem 17 *Given an instance of SC/SM/D, procedure SCALING correctly finds an optimal solution x^* in $O(n(\log n + \tilde{\tau}) \log(r(E)/n))$ time.*

Proof Since the vector $x^{(s)} - se$ is a lower bound of an optimal solution by [Theorem 14](#), addition of the constraint $x \geq x^{(s)} - se$ does not change the optimal value of the problem. Thus, the correctness of the algorithm follows immediately.

Then, the running time is analyzed. The algorithm calls procedure SM-INCREMENT(s, l) $O(\log \lceil r(E)/2n \rceil)$ times in the while loop and procedure SM-INCREMENT only once. In each call to SM-INCREMENT(s, l), at most $\lfloor (r(E) - \sum_{j \in E} l_j)/s \rfloor + n$ increments are executed. Let s' be the value of s in the last iteration in the while loop. Then, $s = \lceil s'/2 \rceil$ and $l = x^{(s')} - s'e$ hold. Since $\sum_{j \in E} x_j^{(s')} = r(E)$, it holds that

$$\sum_{j \in E} l_j = \sum_{j \in E} (x_j^{(s')} - s') = \sum_{j \in E} x_j^{(s')} - s'n \geq r(E) - 2sn.$$

Hence, the number of increments in SM-INCREMENT(s, l) is

$$\left\lfloor \frac{r(E) - \sum_{j \in E} l_j}{s} \right\rfloor + n \leq \left\lfloor \frac{2sn}{s} \right\rfloor + n = 3n = O(n).$$

The call to SM-INCREMENT after the while loop also requires $O(n)$ increments. Thus, it can be shown in a similar way as in [Theorem 5](#) that the running time of procedure SCALING is $O(n(\log n + \tilde{\tau}) \log(r(E)/n))$. \square

[Theorem 17](#) implies that when specialized to problems SC/Nested/D or SC/Tree/D, the algorithm SCALING runs in $O(n^2 \log(N/n))$ time since there exist $O(n)$ constraints, and hence, the following operations for $x \in P(r)$ and $i \in E$ can be done in $O(n)$ time:

- (a) Check the feasibility of $x + e(i)$, and if $x + e(i)$ is feasible, update x to $x + e(i)$.
- (b) For a given integer $s \geq 2$, compute the saturation capacity $\hat{c}(x, i)$, and update x to $x + \alpha e(i)$, where $\alpha = \min\{\hat{c}(x, i), s\}$.

That is, $\tilde{\tau} = O(n)$ holds if a naive implementation is used. In contrast, Hochbaum [61] improved upon this running time by using the special structure of the problems. The results obtained by Hochbaum [61] are summarized as follows:

Theorem 18 *Problems SC/Nested/D and SC/Tree/D can be solved in $O(n \log n \log (N/n))$ time.* \square

This improvement is attained by devising a systematic implementation of the operations (a) and (b) above, which makes it possible to perform the two operations in $O(1)$ time on the average. Instead of giving their details, a key idea is illustrated by briefly explaining how to implement the operation (a) (i.e., feasibility check of $x + e(i)$) for the case of problem SC/Nested/D.

Suppose that the following n nested constraints are given:

$$\sum_{j \in S_i} x_j \leq b_i, \quad i = 1, \dots, n, \quad (99)$$

where $S_i = \{1, 2, \dots, i\}$ ($i = 1, \dots, n$) are assumed for simplicity. Also, assume without loss of generality that $b_1 \leq b_2 \leq \dots \leq b_n$.

It is now explained how to check the feasibility of a vector $x + e(i)$ for given feasible vector x and $i \in E$. For this purpose, a nonnegative *slack* σ_i is associated with each variable x_i (or i -th inequality in (99)). The value of each slack σ_i is determined as follows by using the current feasible vector x :

$$\sigma_1 = \bar{b}_1, \quad \sigma_i = \bar{b}_i - \bar{b}_{i-1} \quad (i = 2, 3, \dots, n), \quad (100)$$

where \bar{b}_i is recursively defined by

$$\bar{b}_i = \begin{cases} b_n - \sum_{j=1}^n x_j & (i = n), \\ \min\{b_i - \sum_{j=1}^i x_j, \bar{b}_{i+1}\} & (i = n-1, n-2, \dots, 1). \end{cases} \quad (101)$$

For example, if $x = (0, 0, \dots, 0)$, then it holds that $\sigma_1 = b_1$ and $\sigma_i = b_i - b_{i-1}$ for $i = 2, 3, \dots, n$. Note that $\sigma_i \geq 0$ for all i since \bar{b}_i is monotone nondecreasing in i by definition and that the set of constraints (99) is equivalent to

$$\bar{b}_i = \sigma_1 + \sigma_2 + \dots + \sigma_i \geq 0, \quad i = 1, 2, \dots, n.$$

During the execution, the algorithm implicitly maintains the feasibility of constraints (99) through the slack vector $\sigma = (\sigma_1, \dots, \sigma_n)$.

Suppose that the current solution x is feasible and the vector σ of (100) is given. To check whether the increment of x_i by one unit is feasible or not, the value

$$k(i) := \max\{j \mid 1 \leq j \leq i, \sigma_j > 0\} \quad (102)$$

is computed, where it is understood that $k(i) = 0$ if there exists no j with $1 \leq j \leq i$ such that $\sigma_j > 0$. If $k(i) = 0$, then it holds that $\sigma_1 = \dots = \sigma_i = 0$, that is, $\bar{b}_i = 0$ holds, and therefore, the increment of x_i by one unit is clearly infeasible from definition of \bar{b} . Otherwise, $x + e(i)$ is feasible since $\bar{b}_i > 0$ holds. According to the update of x to $x + e(i)$, σ is also updated as

$$\sigma_{k(i)} := \sigma_{k(i)} - 1. \quad (103)$$

It is easy to see that this update correctly maintains the condition (100) for the new feasible solution $x + e(i)$; indeed, before the update $\bar{b}_{k(i)} = \dots = \bar{b}_i$ holds from the definition of $k(i)$, and updating σ by (103) implicitly decreases all $\bar{b}_{k(i)}, \dots, \bar{b}_i$ by one unit, which maintains the correct \bar{b} defined by (101) for the new feasible solution $x + e(i)$. It shall be explained later how this update of the vector σ can be done in $O(1)$ time on the average.

The feasibility check algorithm is summarized as follows. The input of the algorithm is a feasible vector x , the index i of the variable to be increased, the current slack vector σ , and a 0-1 labeling vector $label$ defined as

$$label_i = \begin{cases} 1 & \text{if } \sigma_i > 0, \\ 0 & \text{if } \sigma_i = 0. \end{cases} \quad (104)$$

As is made clear later, the vector $label$ plays an important role in efficient implementation of the algorithm.

Procedure FEASIBILITY-CHECK

Input: An instance of SC/Nested/D, a feasible solution x , an index i , a slack vector σ , and a 0-1 labeling vector $label$.

Output: “feasible” and the updated slack vector σ if $x + e(i)$ is feasible, and “infeasible” otherwise.

Compute $k(i)$ by (102);

if $k(i) > 0$ **then do**

begin

Let $\sigma_{k(i)} := \sigma_{k(i)} - 1$ and $label_{k(i)} := \min\{label_{k(i)}, \sigma_{k(i)}\}$;

Output “feasible” and $(\sigma_1, \dots, \sigma_n)$

end

else output “infeasible”

The implementation of FEASIBILITY-CHECK requires the labeling of $label_j$ for all $j \in E$ and the identification of index $k(i)$ for all $i \in E$. This can be done in linear time as follows. If the vector $label$ is regarded as a one-dimensional array, $label$ can be seen as the intervals of 0’s, separated by 1’s. Such intervals are maintained so that the interval containing a given index i can be identified efficiently. Left-end and right-end indices of the interval are associated with the interval ID, which makes it possible to find $k(i)$ efficiently. When $label_{k(i)}$ is updated from 1 to 0, the adjacent two intervals are merged. Hence, this can be seen a special case of a *union-find* problem, and the sequence of $O(n)$ such operations can be executed in $O(n)$ time using Gabow and Tarjan’s algorithm [47]. Thus, feasibility check of a vector $x + e(i)$ can be done in $O(1)$ time on the average.

In a similar way, the other operation (b) can be implemented so that it can be performed in $O(1)$ time on the average. Therefore, from [Theorem 17](#), the total complexity of algorithm SCALING for SC/Nested/D becomes $O((n \log n + n) \log(N/n)) = O(n \log n \log(N/n))$.

5.2 Lower Bounds

Two types of weakly polynomial lower bounds for SC/Simple/D are presented, which tell that no strongly polynomial algorithm exists for SC/Simple/D. The first one is based on a comparison model and the second on an algebraic tree model.

5.2.1 Lower Bound on a Comparison Model

A comparison computation model allows only the operations of comparisons and branchings. The lower bound proof establishes that no algorithm exists that solves SC/Simple/D in less than $\log_2 N$ comparisons. The proof relies on a result of information theory according to which there is no algorithm that finds a value in a monotone nondecreasing n -array that is the first to be smaller than some specified constant in less than $\log_2 n$ time. Consider first a lower bound result for SC/Simple/D in two variables, $Q(2)$:

$$Q(2) : \text{minimize } f_1(x_1) + c \cdot x_2,$$

$$\text{subject to } x_1 + x_2 = N,$$

$$x_j : \text{nonnegative integer, } j = 1, 2.$$

Let the function $f_1(x_1)$ be given as an array of N increments at the N integer points. Namely, if $f_1(i) = a_i$, the array of increments is $\{a_0, a_1 - a_0, a_2 - a_1, \dots, a_N - a_{N-1}\}$. Since the function is convex, the entries in the array are monotone nondecreasing, $a_{i+1} - a_i \geq a_i - a_{i-1}$. The optimal solution to this problem is $x_1 = j$ and $x_2 = N - j$, where j is the largest index such that $a_j - a_{j-1} \leq c$. Since the entries in the array are monotone nondecreasing, determining the index j can be done using binary search in $\log_2 N$ comparisons. The information theoretic lower bound is also $\log_2 N$ comparisons. This is because the comparison tree has N leaves so the path of comparisons leading from the root to a leaf could be as long as $\log_2 N$ (see Knuth [87]). Suppose the problem could be solved independently of N , then given a monotone nondecreasing array and a value c , it has a corresponding convex function f_1 such that the solution to the $Q(2)$ is independent of N . Consequently, the required entry in the vector could be found independently of N , which is a contradiction to the comparison tree lower bound.

The same arguments can be extended to prove that in the comparison model, the problem of SC/Simple/D on $n + 1$ variables has complexity $\Omega(n \log_2 \lfloor \frac{N}{n} \rfloor)$.

Consider the following problem $Q(n + 1)$ of SC/Simple/D, where $c < 0$ is a given constant:

$$\begin{aligned} Q(n + 1) : \text{minimize } & \sum_{j=1}^n f_j(x_j) + c \cdot x_{n+1}, \\ \text{subject to } & \sum_{j=1}^{n+1} x_j = N, \\ & x_j : \text{nonnegative integer, } j = 1, 2, \dots, n + 1. \end{aligned}$$

Let the functions f_j be monotone decreasing in interval $[0, \lfloor \frac{N}{n} \rfloor]$, and constant in $[\lfloor \frac{N}{n} \rfloor, N]$. Define a vector $\hat{x} = (\hat{x}_1, \hat{x}_2, \dots, \hat{x}_{n+1})$ as follows:

$$\begin{aligned} \hat{x}_j &= \max\{y \mid d_j(y) \leq c, y \in [1, \lfloor \frac{N}{n} \rfloor]\}, \\ \hat{x}_{n+1} &= N - \sum_{j=1}^n \hat{x}_j. \end{aligned} \tag{105}$$

It is claimed that \hat{x} is an optimal solution of $Q(n + 1)$. First note that \hat{x} is feasible to Q from (105). Since $d_{n+1}(y) = c$ holds for all y , condition (105) tells that \hat{x} satisfies the optimality condition of [Theorem 4](#), that is,

$$d_i(\hat{x}_i) \leq d_i(\hat{x}_j + 1) \tag{106}$$

holds for all i, j with $1 \leq i, j \leq n + 1$.

Thus, the above claim holds. Therefore, solving problem $Q(n + 1)$ is equivalent to determining in n arrays of length $\lfloor \frac{N}{n} \rfloor$ each, the largest entry of value $\leq c$. Since the arrays are independent, the information theory lower bound is $\Omega(n \log_2 \lfloor \frac{N}{n} \rfloor)$.

Theorem 19 *In a comparison model, a lower bound on the time complexity for SC/Simple/D is $\Omega(n \log \lfloor \frac{N}{n} \rfloor)$.* \square

5.2.2 Lower Bound on an Algebraic Tree Model

The comparison model may be considered too restrictive. If it is allowed to use arithmetic operations such as addition, subtraction, multiplication, and division, there may be a possibility of constructing a strongly polynomial algorithm for SC/Simple/D. In fact, if all f_j are quadratic, an $O(n)$ time algorithm can be developed for SQC/Simple/D (SQC means *separable quadratic convex*) by making use of a continuous optimal solution of SQC/Simple/C (see Sect. 4.6 of [69]), which can be obtained in $O(n)$ time by the algorithm for SQC/Simple/C of Brucker [23]. This approach, however, is denied in the general case, as will be shown below, even if f_j are polynomials of degree 3.

The lower bound proof is based on Renegar's result [122] saying that $\Omega(\log \log(R/\epsilon))$ is a lower bound for the time complexity of finding an ϵ -accurate single real root of a polynomial of a single variable of degree ≥ 2 in an interval $[0, R]$, even if the polynomial is monotone increasing in that interval. Here $\hat{x} \in R$ is called an ϵ -*accurate root* of an equation $p(x) = 0$ if \hat{x} satisfies $|\hat{x} - x^*| \leq \epsilon$ for an exact root x^* of $p(x) = 0$.

Let $p_1(x), \dots, p_n(x)$ be n monotone increasing polynomials, each with a single root in interval $[0, N/n]$ for the equation $p_j(x) = c$, where c is a fixed constant. Since the choice of these polynomials is arbitrary, the lower bound on finding the n roots of these n equations is $\Omega(n \log \log(N/n\epsilon))$. Let

$$f_j(x_j) = \int_0^{x_j} p_j(x) dx.$$

These f_j are then polynomials of degree ≥ 3 .

Now, consider the following problem Q_ϵ for $\epsilon > 0$ such that $1/\epsilon$ is an integer:

$$Q_\epsilon : \text{minimize } \sum_{j=1}^n f_j(\epsilon \cdot x_j) + c \cdot \epsilon \cdot x_{n+1},$$

$$\text{subject to } \sum_{j=1}^{n+1} x_j = \frac{N}{\epsilon}, \tag{107}$$

$$x_j : \text{nonnegative integer}, \quad j = 1, \dots, n+1.$$

Also, let R_ϵ be a continuous version of Q_ϵ . Problems Q_ϵ and R_ϵ are instances of SC/Simple/D and SC/Simple/C, respectively. It is claimed below that, for any

optimal solution x^* of Q_ϵ , $y = \epsilon \cdot x^*$ is an ϵ -accurate vector of roots for the following system of nonlinear equations:

$$\begin{cases} p_1(y_1) = c, \\ p_2(y_2) = c, \\ \vdots \\ p_n(y_n) = c. \end{cases} \quad (108)$$

This means that the computational complexity is not less than finding an ϵ -accurate vector for the above system of equations. Since it is assumed that for each j with $1 \leq j \leq n$ there exists a single root in interval $[0, N/n]$ for the equation $p_j(x) = c$, it follows from the Karush–Kuhn–Tucker condition that an optimal solution y^* of R_ϵ satisfies (108) with $y = y^*$.

It follows from [Theorem 4](#) that

$$d_j(x_j^* + 1) \geq d_{n+1}(x_{n+1}^*) \quad (= c \cdot \epsilon)$$

and $d_j(x_j^*) \leq d_{n+1}(x_{n+1}^* + 1) \quad (= c \cdot \epsilon)$

for all j , that is,

$$\int_{\epsilon x_j^*}^{\epsilon x_j^* + \epsilon} p_j(x) dx \geq c \cdot \epsilon \text{ and}$$

$$\int_{\epsilon x_j^* - \epsilon}^{\epsilon x_j^*} p_j(x) dx \leq c \cdot \epsilon,$$

for all j , implying that there are $y_j \in [\epsilon x_j^* - \epsilon, \epsilon x_j^* + \epsilon]$ such that $p_j(y_j) = c$ from the monotonicity of $p_j(y_j)$. This proves the above claim. Hence, a lower bound for the time complexity of solving Q_ϵ is $\Omega(n \log \log(N/n\epsilon))$. For $\epsilon = 1$, Q_ϵ is an instance of SC/Simple/D, and thus, the following result is obtained.

Theorem 20 *In the algebraic computation tree model, a lower bound on the computational complexity for SC/Simple/D is $\Omega(n \log \log(N/n))$. \square*

5.3 Strongly Polynomial Algorithms for Separable Quadratic Convex Objective Functions

Although no strongly polynomial-time algorithm for SC/Simple/D exists even for polynomials f_j of degree 3, as proved in [Sect. 5.2.2](#), there remains a possibility of a strongly polynomial algorithm for the case of a separable *quadratic* objective function. Indeed, SQC/Simple/D can be solved in $O(n)$ time, as mentioned in [Sect. 5.2.2](#). This result also implies the linear-time solvability of SQC/GUB/D (see [Sect. 3.3](#)).

In addition, Hochbaum and Hong [64] constructed such algorithms for several cases of constraints. Results are summarized as follows.

Theorem 21 *Let n be the number of variables.*

- (i) *SQC/Nested/D can be solved in $O(n^2 \log n)$ time.*
- (ii) *SQC/Tree/D can be solved in $O(n^2 \log n)$ time.*
- (iii) *SQC/Network/D can be solved in $O(n^2 M + NM \log(N^2/M))$ time, where N and M denote the numbers of nodes and arcs in a network.* \square

It is noted that the statements in [Theorem 21](#) are corrected version of the corresponding statements in Hochbaum and Hong [64], which rely on an incorrect proximity statement. However, [Theorem 21](#) can be obtained by using an alternative proximity theorem, as explained below (see [108, Sect. 2] for details).

The underlying idea to derive [Theorem 21](#) is now explained. Consider SQC/SM/D because all the problems listed in [Theorem 21](#) are special cases of SQC/SM/D. The first idea is to make use of an optimal solution of the corresponding continuous problem SQC/SM/C. It is here assumed that an optimal solution of SQC/SM/C is available; as shown below, the continuous versions of all the above three problems can be solved in strongly polynomial time if the objective function is quadratic. The continuous optimal solution can then be used to bound an integer optimal solution from below, based on the proximity theorem given in [Sect. 4](#). The algorithm then applies procedure SM-INCREMENT of [Sect. 3.2.1](#) in order to solve SQC/SM/D. This runs in strongly polynomial time since the lower bound obtained is sufficiently close to the integer optimal solution, as will be seen below.

Let \bar{x} be a continuous optimal solution of SQC/SM/C. From the proximity result in [Corollary 3](#), there exists an optimal solution x^* of SQC/SM/D such that

$$x^* \geq l, \quad \text{where } l_j = \lceil \bar{x}_j \rceil - (n-1) \text{ for } j \in E. \quad (109)$$

Notice that the vector l belongs to the submodular polyhedron $P(r)$. Then, procedure SM-INCREMENT of [Sect. 3.2.1](#) is applied, where the vector l is used as an initial solution. Procedure SM-INCREMENT terminates in $O(n^2)$ iterations since

$$r(E) - \sum_{j \in E} l_j = \sum_{j \in E} \bar{x}_j - \sum_{j \in E} \{\lceil \bar{x}_j \rceil - (n-1)\} \leq n(n-1).$$

Hence, [Theorem 5](#) implies the following lemma. Recall that feasibility check of a vector $x + e(i)$ for $x \in P(r)$ and $i \in E$ can be done in $O(1)$ time on the average for SQC/Nested/D and for SQC/Tree/D (see [Sect. 5.1](#)).

Lemma 12 *Suppose that an optimal solution of SQC/Nested/C (resp., SQC/Nested/C) is given. Then SQC/Nest/D (resp., SQC/Tree/D) can be solved in $O(n^2 \log n)$ time.* \square

In case of SQC/Network/D, feasibility check of a vector $x + e(i)$ can be done in $O(M)$ time, as is well known in the network flow theory. Hence, the next lemma follows.

Lemma 13 *Given an optimal solution of SQC/Network/C, problem SQC/Network/D can be solved in $O(n^2M)$ time, where M is the number of arcs in a network.* \square

In order to efficiently compute a continuous optimal solution for the three problems under consideration, it is possible to use a technique based on the Karush–Kuhn–Tucker condition involving the original variables and Lagrange multipliers. Since the objective function is quadratic, the Karush–Kuhn–Tucker condition contains only linear terms with respect to variables, and optimal Lagrange multipliers can be efficiently computed using the special structure of the constraints. In particular, Hochbaum and Hong [64] showed that optimal Lagrange multipliers for SQC/Network/C can be computed by reduction to the parametric flow problem, which is solved by a generalization of the algorithm given by Gallo, Grigoriadis, and Tarjan [49] (The generalization is necessary since the latter algorithm is applicable only to the case in which each quadratic function $f_j(x_j)$ does not contain a linear term. In addition, Hochbaum and Hong [64] found a flaw in the algorithm of [49] and fixed it).

Further details about how this task can be done efficiently are omitted and only the results are stated here (see [64] for details).

Theorem 22 *Let n be the number of variables.*

- (i) *SQC/Nested/C can be solved in $O(n \log n)$ time.*
- (ii) *SQC/Tree/C can be solved in $O(n \log n)$ time.*
- (iii) *SQC/Network/C can be solved in $O(NM \log(N^2/M))$ time, where N and M denote the numbers of nodes and arcs in a network, respectively.* \square

Theorem 21 can be obtained by combining Theorem 22 with Lemmas 12 and 13.

Finally, some improved results for SQC/Nested/D, SQC/Tree/D, and SQC/Network/D will be explained which were obtained by Moriguchi, Shioura, and Tsuchimura [108]. The results are summarized as follows.

Theorem 23 *Let n be the number of variables.*

- (i) *SQC/Nested/D can be solved in $O(n^2)$ time.*
- (ii) *SQC/Tree/D can be solved in $O(n^2)$ time.*
- (iii) *SQC/Network/D can be solved in $O(NM \log(N^2/M))$ time, where N and M denote the numbers of nodes and arcs in a network.* \square

As in the approach by Hochbaum and Hong [64], the approach in [108] also uses a continuous optimal solution and a proximity theorem, but the approach in [108] uses Theorem 16 rather than Corollary 3; in particular, it uses neither of upper

nor lower bounds for an integer optimal solution. Their approach firstly transforms a continuous optimal solution $\bar{x} \in B(r) \cap R^E$ into an integer feasible solution $x \in B(r) \cap Z^E$ which is sufficiently close to \bar{x} . Then, the vector x is iteratively updated by incrementing some x_i by one unit and decrementing some x_k by one unit until an integer optimal solution is found. It can be shown that the number of iterations required by this algorithm is proportional to the L_1 distance between integer and continuous optimal solutions. Hence, the algorithm terminates in $O(n)$ iterations by [Theorem 16](#). For more details, see [108].

5.4 Notes and References

Strongly polynomial algorithms have also been developed for problem SQC/Linear/C(or D) which includes special constraints other than submodular constraints, for example, the transportation problem with a fixed number of sources (or sinks) [32] and its extension [105] and the minimum-cost flow in a series-parallel network with a single source and sink [133]. In these cases, the constraint matrix is totally unimodular, and the problems can be viewed as separable convex cost flow problems. A strongly polynomial algorithm has also been developed for the transportation problem with a certain type of nonseparable quadratic convex objective function [66].

6 Nonseparable Convex Resource Allocation

In this section, a class of nonseparable convex resource allocation problems is considered. Recall that a separable convex function f defined over a base polyhedron $B(r)$ satisfies [Lemma 6](#), that is,

$$f(x) + f(y) \geq f(x - e(i) + e(j)) + f(y + e(i) - e(j))$$

for any bases $x, y \in B(r)$ and any $i, j \in E$ with $x_i > y_i$ and $x_j < y_j$ such that $x - e(i) + e(j), y + e(i) - e(j) \in B(r)$. The class of functions f (which is not separable in general) that satisfy this property is defined as an *M-convex function*, which was introduced by Murota [109]. There are several beautiful theorems concerning an *M-convex* function that can be viewed as a discrete analogue of theorems in classical convex analysis. Since the class of *M-convex* functions provides a potentially much wider class of problems than the separable convex functions, it is interesting to ask whether there exists an efficient general algorithm for minimizing an *M-convex* function over a base polyhedron of a submodular system. Shioura [129] answers this question affirmatively by giving a polynomial-time algorithm for this problem, which will be explained in this section after preparing some notions and properties in the next subsection.

6.1 M -Convex Functions

Let $E = \{1, 2, \dots, n\}$. A function $f : Z^E \rightarrow R \cup \{\infty\}$ is said to be M -convex if it satisfies the following property:

(M-EXC): For any $x, y \in \text{dom } f$, and for any $i \in \text{supp}^+(x - y)$, there exists $j \in \text{supp}^-(x - y)$ such that

$$f(x) + f(y) \geq f(x - e(i) + e(j)) + f(y + e(i) - e(j)), \quad (110)$$

where

$$\begin{aligned}\text{dom } f &= \{x \in Z^E \mid f(x) < +\infty\}, \\ \text{supp}^+(x - y) &= \{k \in E \mid x_k > y_k\}, \\ \text{supp}^-(x - y) &= \{k \in E \mid x_k < y_k\}.\end{aligned}$$

Minimizing an M -convex function f over $\text{dom } f$ is called MC/SM/D. The property (M-EXC) implies that $\text{dom } f$ is an integral base polyhedron as shown by Murota [109] because $B \subseteq Z^E$ is an integral base polyhedron if and only if B satisfies the following property (see Lemma 4 (ii)):

(B-EXC): For any $x, y \in \text{dom } f$, and for any $i \in \text{supp}^+(x - y)$, there exists $j \in \text{supp}^-(x - y)$ such that $x - e(i) + e(j), y + e(i) - e(j) \in B$.

Before describing an algorithm for minimizing an M -convex function, the following results are first shown. A vector $x \in Z^E$ that minimizes an M -convex function f is called a *minimizer* of f , which is assumed to exist in the following discussion. Let the underlying base polyhedron be denoted by B . Also, assume that B is bounded.

Lemma 14 *Given an $x \in \text{dom } f$, it holds $f(x) \leq f(y)$ for all $y \in \text{dom } f$ if and only if $f(x) \leq f(x - e(i) + e(j))$ for all $i, j \in E$.*

Proof The proof is done essentially in the same manner as the proof of Theorem 4. \square

Lemma 15 *Let $f : Z^E \rightarrow R \cup \{\infty\}$ be an M -convex function.*

(i) *Given an $x \in \text{dom } f$ and a $j \in E$, let $i \in E$ satisfy*

$$f(x - e(i) + e(j)) = \min_{h \in E} f(x - e(h) + e(j)).$$

Then, for the vector $x' = x - e(i) + e(j)$, there exists a minimizer x^ of f that satisfies $x_i^* \leq x'_i$.*

(ii) *Given an $x \in \text{dom } f$ and an $i \in E$, let $j \in E$ satisfy*

$$f(x - e(i) + e(j)) = \min_{l \in E} f(x - e(i) + e(l)).$$

Then, for the vector $x' = x - e(i) + e(j)$, there exists a minimizer x^ of f that satisfies $x_j^* \geq x'_j$.*

Proof Only (i) is proved. Let x^* be a minimizer of f such that x_i^* is minimum among all minimizers of f . Suppose $x_i^* > x'_i$. From (M-EXC), there exists some $k \in \text{supp}^-(x^* - x')$ such that

$$f(x^*) + f(x') \geq f(x^* - e(i) + e(k)) + f(x' + e(i) - e(k)). \quad (111)$$

From the assumption on x' , it holds that

$$f(x' + e(i) - e(k)) = f(x - e(k) + e(j)) \geq f(x - e(i) + e(j)).$$

This, combined with (111), implies that $f(x^* - e(i) + e(k)) \leq f(x^*)$, from which it follows that $x^* - e(i) + e(k)$ is also a minimizer of f . This contradicts the assumption on x^* . \square

Corollary 4 *Let $x \in \text{dom } f$ be not a minimizer of an M -convex function f , for which $i, j \in E$ satisfy*

$$f(x - e(i) + e(j)) = \min_{h,l \in E} f(x - e(h) + e(l)).$$

Then, there exists a minimizer x^ of f satisfying $x_i^* \leq x_i - 1$ and $x_j^* \geq x_j + 1$.* \square

6.2 A Polynomial Algorithm for Minimizing an M -Convex Function

Lemma 14 suggests a simple algorithm for finding a minimizer of f in a manner similar to the *steepest-descent* method for minimizing a convex function over continuous variables. That is, starting from $x \in B$, the algorithm checks whether

$$f(x) = \min_{h,l \in E} f(x - e(h) + e(l))$$

holds or not. If so, x is a minimizer of f by **Lemma 14**. Otherwise, repeat the above procedure after updating $x := x - e(i) + e(j)$, where the $i, j \in E$ satisfy $f(x - e(i) + e(j)) = \min_{h,l \in E} f(x - e(h) + e(l))$. Since the value of $f(x)$ strictly decreases in every iteration, a minimizer of f can be eventually found. This simple approach, however, cannot guarantee the convergence in polynomial time, and a more sophisticated method is needed.

For this, the *peeled base polyhedron* $B_{\text{peeled}} \subseteq B$ is defined as follows. For each $j \in E$, define

$$l_j = \min_{x \in B} x_j, \quad u_j = \max_{x \in B} x_j, \quad (112)$$

and then

$$l'_j = \lfloor (1 - 1/n)l_j + (1/n)u_j \rfloor, \quad u'_j = \lceil (1/n)l_j + (1 - 1/n)u_j \rceil. \quad (113)$$

Then, B_{peeled} is defined as

$$B_{\text{peeled}} = \{x \in B \mid l'_j \leq x_j \leq u'_j, \quad j \in E\}.$$

In other words, B_{peeled} is the base polyhedron obtained from B by performing the restriction by $u' = (u'_1, \dots, u'_n)$ and the contraction by $l' = (l'_1, \dots, l'_n)$ to B .

Theorem 24 *For a base polyhedron B ($\neq \emptyset$), the peeled base polyhedron B_{peeled} satisfies $B_{\text{peeled}} \neq \emptyset$.*

Proof Let $r: 2^E \rightarrow Z$ be a submodular function such that $B = B(r)$. Note that $l_j = r(E) - r(E - \{j\})$ and $u_j = r(j)$ hold for all $j \in E$ (see [45]). It suffices to show the following (see [45]):

- (i) $l'_j(X) \leq r(X)$ for all $X \subseteq E$.
- (ii) $u'_j(X) \geq r(E) - r(E - X)$ for all $X \subseteq E$.

Since (ii) can be proved similarly, only (i) is proved. Let $|X| = k$. It is claimed that

$$k \cdot r(X) + k \sum_{j \in X} (r(E - \{j\}) - r(E)) \geq \sum_{j \in X} (r(j) + r(E - \{j\}) - r(E)). \quad (114)$$

Indeed, by the submodularity of r , it holds that

(the left-hand side of (114))

$$\begin{aligned} &= k \cdot r(X) + \sum_{j \in X} \sum_{k \in X - \{j\}} (r(E - \{k\}) - r(E)) + \sum_{j \in X} (r(E - \{j\}) - r(E)) \\ &\geq k \cdot r(X) + \sum_{j \in X} (r(E - (X - \{j\})) - r(E)) + \sum_{j \in X} (r(E - \{j\}) - r(E)) \\ &\geq (\text{the right-hand side of (114)}). \end{aligned}$$

Since the right-hand side of (114) is nonnegative, the k in (114) can be replaced by n ($\geq k$). Thus, it holds that

$$\begin{aligned} r(X) &\geq (1 - 1/n) \sum_{j \in X} [r(E - \{j\}) - r(E)] + \sum_{j \in X} r(j) \\ &\geq l'_j(X). \end{aligned}$$

□

The following algorithm for finding a minimizer x^* of f reduces B iteratively, until B contains a single base.

Procedure REDUCTION

Input: M -convex function f .

Output: A minimizer x^* of f .

Let $B := \text{dom } f$, and compute vectors l and u by (112);

while $u_j - l_j \geq 1$ for some j **do**

begin

Compute vectors l' and u' of (113) to define B_{peeled} ;

Find a vector $x \in B_{peeled}$;

Let $f(x - e(i) + e(j)) := \min_{h,l \in E} f(x - e(h) + e(l))$;

if $f(x) = f(x - e(i) + e(j))$ **then** output $x^* := x$ and halt

else let $u_i := x_i - 1$, $l_j := y_j + 1$, and

$B := B \cup \{y \in Z^E \mid y_i \leq u_i, y_j \geq l_j\}$;

end.

Output the unique vector in B .

The correctness immediately follows from Corollary 4 and Theorem 24. The running time is analyzed below.

Lemma 16 Let B^k , l^k , and u^k denote the set B , l , and u at the beginning of the k -th iteration of the while loop of REDUCTION, respectively. Then $u_h^{k+1} - l_h^{k+1} < (1 - 1/n)(u_h^k - l_h^k)$ holds for $h = i$ and j , where $i, j \in E$ are the elements found in the k -th execution of the while loop.

Proof Only the case of $h = i$ is considered (the case of $h = j$ is similar), and let $x \in B_{peeled}^k$ be the vector chosen in the while loop. Then,

$$\begin{aligned} u_i^{k+1} - l_i^{k+1} &\leq x_i - 1 - l_i^k \\ &\leq \lceil (1/n)l_i^k + (1 - 1/n)u_i^k \rceil - 1 - l_i^k \\ &< (1 - 1/n)(u_i^k - l_i^k). \end{aligned}$$

□

Lemma 17 Procedure REDUCTION halts in $O(n^2 \log L)$ iterations, where

$$L = \max_{j \in E} (u_j^1 - l_j^1). \quad (115)$$

Proof Since $u_j^k - l_j^k$ is a nonnegative integer for every $j \in E$, the procedure halts if $u_j^k - l_j^k < 1$ holds for all $j \in E$. Let k be the minimum integer such that $(1 - 1/n)^k (u_j^1 - l_j^1) < 1$. Then,

$$\begin{aligned} k &\leq -\ln(u_j^1 - l_j^1)/\ln(1 - 1/n) + 1 \\ &\leq n \ln(u_j^1 - l_j^1) + 1 \leq n \ln L + 1 \end{aligned}$$

by the inequality $\ln z \leq z - 1$ for $z > 0$. Thus, the lemma follows. \square

The most time-consuming part of the above procedure is the computation of $x \in B_{peeled}$. It is assumed that a subroutine to test whether a vector x belongs to the submodular polyhedron P or not is available. Notice that this test can be done in polynomial time by Lemma 5. So, the l and u satisfying (112) can be computed by applying the subroutine $O(n^2 \log L)$ times, because l_j and u_j for each j can be computed by $O(n \log L)$ applications of the subroutine. The computation of $x \in B_{peeled}$ is done by starting from $x \in B$ and iteratively updating x as $x + \alpha(e(i) - e(j))$ for appropriately chosen i, j , and α (see [45] for details of this procedure). Therefore, $x \in B_{peeled}$ can be computed by applying the subroutine $O(n^2 \log L)$ times. Hence, the following theorem follows from Lemma 17.

Theorem 25 *A minimizer of an M -convex function f with n variables can be computed in $O(n^4(\log L)^2 F)$ time, where L is given by (115) and F is the time required to evaluate the function value of f .* \square

7 Applications

As mentioned in Introduction, the resource allocation problem has a wide range of applications. Here, several interesting applications will be explained, to supplement standard ones (see, e.g., [69]).

7.1 Computer Science Applications

1. Optimal Batching Policies for Video-on-Demand Storage Server (Aggarwal, Wolf and Yu [1])

In a video-on-demand environment, *batching* of video requests is often used to reduce I/O demand and improve throughput. The basic idea of batching is to delay the requests of some videos for a certain amount of time so that more requests for the same video arriving during the current *batching interval* may be serviced using the same stream. Thus, when a stream becomes available at the server end, a question arises as to which video is best to schedule at that particular time moment.

There may be several scheduling policies for implementing the batching. Since viewers may defect if they experience long waits, a good video scheduling policy needs to consider not only the batch size but also the viewer defection probabilities and wait times. Two conventional scheduling policies for batching are the *first-come-first-served* (FCFS) policy that always schedules the video with the longest waiting request and the *maximum queue length* (MQL) policy which selects the video with the maximum number of waiting requests. Neither of these policies lead to entirely satisfactory results. MQL tends to be too aggressive in scheduling popular videos, while FCFS has the opposite effect by completely ignoring the queue length.

The problem of determining a best batching policy is formulated as an optimization problem after introducing the following performance measure: Suppose that the server contains a database of n different videos from which the clients may make requests.

- *Average Latency Time:* The latency of a viewer is the period that elapses between the arrival of the video request and the time when the service to the display device is actually initiated.

Assume that the frequency of requests for the j -th video is known and is denoted by f_j . If L_j denotes the length of video j , then $L = \left(\sum_{j=1}^n f_j \cdot L_j \right) / \left(\sum_{j=1}^n f_j \right)$ is the average video length. Assume that the server capacity (in terms of the number of streams) is S . Consequently, the average number of streams which are scheduled by the server every minute at full capacity is S/L . Suppose that t_1, t_2, \dots, t_n are the average time intervals at which the videos $1, 2, \dots, n$ are batched. Then the average latency for a video of type j is equal to $t_j/2$. The objective in this model is to minimize the average latency of the viewers. Thus, modulo a constant that can be ignored, it is desired to minimize the sum of the expected latency times of all the requests which arrive in a unit interval of time: $\sum_{j=1}^n f_j \cdot t_j/2$.

A constraint is needed that limits the number of video streams which can be scheduled at any moment of time. On average, the number of streams for video j scheduled per unit of time is approximately equal to $1/t_j$. (This is not entirely rigorous because $E[1/X] \neq 1/E[X]$ holds for a random variable X , in general. However, if X has a relatively small deviation, the approximation $E[1/X] \approx 1/E[X]$ is fairly accurate.) Thus, the total number of streams of all video types scheduled per unit of time at full capacity is $\sum_{j=1}^n 1/t_j$, which must be equal to S/L . Thus, the following constrained nonlinear program can be obtained:

$$\begin{aligned} & \text{minimize} \quad \sum_{j=1}^n f_j \cdot t_j, \\ & \text{subject to} \quad \sum_{j=1}^n 1/t_j = S/L, \\ & \quad t_j \geq 0, \quad j = 1, \dots, n. \end{aligned}$$

This is a typical problem of SC/Simple/C. There exists the unique optimal solution, which satisfies

$$t_1 \cdot \sqrt{f_1} = t_2 \cdot \sqrt{f_2} = \cdots = t_n \cdot \sqrt{f_n}.$$

In the absence of any defections from the system, the average queue length q_j of the j -th video at the time of batching is equal to $q_j = t_j \cdot f_j$. Thus, from the above equations, it holds the following relationship for the queue lengths at the time of batching:

$$\frac{q_1}{\sqrt{f_1}} = \frac{q_2}{\sqrt{f_2}} = \cdots = \frac{q_n}{\sqrt{f_n}}.$$

In other words, the following intuitive result can be obtained.

Theorem 26 *In order to achieve the best average latency time at the above video-on-demand server, the queue lengths q_j at the time of batching should be approximately proportional to $\sqrt{f_j}$.* \square

Theorem 26 suggests the following greedy scheduling policy, called *maximum factored queue length policy*, or *MFQ policy*, for the video-on-demand problem.

Whenever the server capacity becomes available for scheduling a stream, choose the video with the largest $q_j / \sqrt{f_j}$.

Aggarwal, Wolf, and Yu [1] performed a simulation study to establish the effectiveness of the proposed MFQ policy against existing MQL and FCFS policies from several points of view. Empirical simulations indicate that MFQ yields excellent empirical results in terms of standard performance measures such as average latency time, defection rates, and fairness.

2. Optimal Buffer Partition of the Nested Block Join Algorithm (Wolf, Iyer, Pattipati and Yu [143])

Nested loop is the well-known method for query processing in a relational database, when queries require complex join predicates. There are two alternatives for efficient execution of join operations: *sort merge join* and *nested loop join*. It is said that nested loop join is preferable when only a small amount of main memory is available. Nested loop join is executed as follows: for every row of the outer relation, the inner relation is examined in order to seek for a match. The inner relation is looped over once for every row of the outer relation. This generalizes to the case of more than two relations. If no relation fits into main memory, it is required to fetch each row of the inner relation from disk for each row of the outer relation. This requires too much I/O access.

In order to reduce the number of I/O accesses, nested block join has been proposed by Kim [80]. Suppose that a block (which is usually called a page) is employed as the unit of I/O access. Each relation is partitioned into consecutive blocks of rows of the same size so that the sum of block sizes of two relations does not exceed memory size. One block of each relation is brought into memory. A naive loop join is performed among the rows contained within the blocks in

memory. Suppose that there exist R relations and a total buffer size in memory is B . Let p_i and x_i denote the size of relation i and its block size, respectively, that is, relation i is divided into $\lceil p_i/x_i \rceil$ blocks. Let us assume that relation 1 is outermost, and so on. Since relation 1 is fetched into memory once, the number of I/Os for relation 1 is p_1 . For each block of relation 1, it is needed to fetch relation 2 into memory once. Thus, the number of I/Os for relation 2 is $p_2 \lceil p_1/x_1 \rceil$. Similarly, the number of I/Os for relation 3 is thus $p_3 \lceil p_2/x_2 \rceil \lceil p_1/x_1 \rceil$, and so forth. Thus, the total number of I/Os is given by

$$\sum_{i=1}^R p_i \prod_{j=1}^{i-1} \lceil p_j/x_j \rceil. \quad (116)$$

It is desired to minimize this objective function under the buffer size B . It is easy to see from the form of the objective function (116) that x_R can be set to 1. Thus, the problem is formulated as follows:

$$Q : \text{minimize } \sum_{i=1}^R p_i \prod_{j=1}^{i-1} \lceil p_j/x_j \rceil \quad (117)$$

$$\text{subject to } \sum_{i=1}^{R-1} x_i = B - 1, \quad (118)$$

$$x_i : \text{positive integer, } i = 1, \dots, n. \quad (119)$$

It is assumed here for simplicity that the ordering of relations is fixed. Since the objective function of Q is not separable, it needed a general algorithm such as a dynamic programming algorithm of an $O(RB^2)$ time bound [69], which can be improved to $O(RB^{1.5})$ by using a clever analysis based on the number theory [143]. Here, instead of the original problem, consider the following approximate problem:

$$Q' : \text{minimize } \sum_{i=1}^R p_i \prod_{j=1}^{i-1} p_j/x_j \quad (120)$$

$$\text{subject to } \sum_{i=1}^{R-1} x_i = B - 1, \quad (121)$$

$$x_i : \text{positive integer, } i = 1, \dots, n. \quad (122)$$

Although the objective function is still nonseparable, surprisingly, the incremental algorithm of Sect. 3.1 works for this problem, as will be seen below. Thus, this is another class of problems for which an incremental algorithm works.

Now a class of problems shall be described, including problem Q' , for which the incremental algorithm works. Let a_1, \dots, a_n and b_1, \dots, b_n be integers satisfying

$a_i \leq b_i$ for all i . Let $F(x_1, \dots, x_n)$ be a function defined on $\{a_1, a_1 + 1, \dots, b_1\} \times \{a_2, a_2 + 1, \dots, b_2\} \times \dots \times \{a_n, a_n + 1, \dots, b_n\}$, and let K be an integer satisfying $\sum_{i=1}^n a_i \leq K \leq \sum_{i=1}^n b_i$. Consider the problem R_K of minimizing

$$R_K : \text{minimize } F(x_1, \dots, x_n) \quad (123)$$

$$\text{subject to } \sum_{i=1}^n x_i = K, \quad (124)$$

$$x_i \in \{a_i, a_i + 1, \dots, b_i\}, \quad i = 1, \dots, n. \quad (125)$$

An incremental algorithm for problem R_K starts from $(x_1, \dots, x_n) = (a_1, \dots, a_n)$ and, in each iteration, increments the variable x_{i^*} by one, where i^* is chosen so that the cost increase incurred by the increment of x_{i^*} is minimum among all variables x_i with $x_i < b_i$. This process is repeated until $\sum_{i=1}^n x_i = K$ is satisfied.

Definition 1 Given a function $F(x_1, \dots, x_n)$ with the domain as described above, define, for each K with $\sum_{i=1}^n a_i \leq K \leq \sum_{i=1}^n b_i$, the expression $\hat{F}(K)$ to be equal to the optimal objective value of problem R_K . Thus, $\hat{F}(K)$ is a single-variable function and is called the *surrogate function* of F .

The following theorem can be viewed as describing how to glue together those functions which can be solved by incremental algorithms into a new function which can again be solved by an incremental algorithm.

Theorem 27 (i) For each $i = 1, \dots, M$, let $F_i(x_{i,1}, \dots, x_{i,n_i})$ be a function for which an incremental algorithm can be applied, and suppose that each of the resulting surrogate function $\hat{F}_i(K)$ is convex in K . Then, an incremental algorithm can also be applied to

$$F_\Sigma(\{x_{ij}\}) = \sum_{i=1}^M F_i(x_{i,1}, \dots, x_{i,n_i}),$$

and the surrogate function \hat{F}_Σ of F_Σ is also convex.

(ii) For each $i = 1, \dots, M$, let $F_i(x_{i,1}, \dots, x_{i,n_i})$ be a positive-valued function for which an incremental algorithm can be applied, and suppose that each of the resulting surrogate function \hat{F}_i is logarithmic convex, that is, $\log \hat{F}_i(K)$ is convex in K . Then an incremental algorithm can be applied to

$$F_\Pi(\{x_{ij}\}) = \prod_{i=1}^M F_i(x_{i,1}, \dots, x_{i,n_i}),$$

and the surrogate function \hat{F}_Π is also logarithmic convex.

Proof (i) The fact that an incremental algorithm can be applied is evident by applying [Theorem 2](#) to the objective function, which can be rewritten in convex, separable form as $\sum_{i=1}^M \hat{F}_i(y_i)$, where $y_i = \sum_{j=1}^{n_i} x_{ij}$. To show the convexity of \hat{F}_Σ , let us look at the values of the surrogate function \hat{F}_Σ at three consecutive integers, say K , $K + 1$, and $K + 2$. Suppose

$$\hat{F}_\Sigma(K) = \sum_{j=1}^M \hat{F}_i(y_i)$$

for some choice (y_1, \dots, y_M) whose sum satisfies $\sum_{i=1}^M y_i = K$. Since an incremental algorithm can be applied to the right-hand side, there exists an index $i_1 \in \{1, \dots, M\}$ for which $\hat{F}_\Sigma(K + 1) = \hat{F}_1(y_1) + \dots + \hat{F}_{i_1}(y_{i_1} + 1) + \dots + \hat{F}_M(y_M)$. Similarly, there will exist an index $i_2 \in \{1, \dots, M\}$ which corresponds to the value of $\hat{F}_\Sigma(K + 2)$ when incremented by one more from $(y_1, \dots, y_{i_1} + 1, \dots, y_M)$. There are two cases: either $i_1 = i_2$ or $i_1 \neq i_2$. In the first case, it holds that

$$\begin{aligned} & \hat{F}_\Sigma(K + 2) - \hat{F}_\Sigma(K + 1) \\ &= \hat{F}_1(y_1) + \dots + \hat{F}_{i_1}(y_{i_1} + 2) + \dots + \hat{F}_M(y_M) \\ &\quad - [\hat{F}_1(y_1) + \dots + \hat{F}_{i_1}(y_{i_1} + 1) + \dots + \hat{F}_M(y_M)] \\ &= \hat{F}_{i_1}(y_{i_1} + 2) - \hat{F}_{i_1}(y_{i_1} + 1) \\ &\geq \hat{F}_{i_1}(y_{i_1} + 1) - \hat{F}_{i_1}(y_{i_1}) \\ &= [\hat{F}_1(y_1) + \dots + \hat{F}_{i_1}(y_{i_1} + 1) + \dots + \hat{F}_M(y_M)] \\ &\quad - [\hat{F}_1(y_1) + \dots + \hat{F}_{i_1}(y_{i_1}) + \dots + \hat{F}_M(y_M)] \\ &= \hat{F}_\Sigma(K + 1) - \hat{F}_\Sigma(K). \end{aligned} \tag{126}$$

Here, the inequality at the center is due to the convexity of \hat{F}_{i_1} . In the second case, analogously,

$$\begin{aligned} & \hat{F}_\Sigma(K + 2) - \hat{F}_\Sigma(K + 1) \\ &= [\hat{F}_1(y_1) + \dots + \hat{F}_{i_1}(y_{i_1} + 1) + \dots + \hat{F}_{i_2}(y_{i_2} + 1) + \dots + \hat{F}_M(y_M)] \\ &\quad - [\hat{F}_1(y_1) + \dots + \hat{F}_{i_1}(y_{i_1} + 1) + \dots + \hat{F}_{i_2}(y_{i_2}) + \dots + \hat{F}_M(y_M)] \\ &= \hat{F}_{i_2}(y_{i_2} + 1) - \hat{F}_{i_2}(y_{i_2}) \\ &\geq \hat{F}_{i_1}(y_{i_1} + 1) - \hat{F}_{i_1}(y_{i_1}) \\ &= [\hat{F}_1(y_1) + \dots + \hat{F}_{i_1}(y_{i_1} + 1) + \dots + \hat{F}_M(y_M)] \\ &\quad - [\hat{F}_1(y_1) + \dots + \hat{F}_{i_1}(y_{i_1}) + \dots + \hat{F}_M(y_M)] \\ &= \hat{F}_\Sigma(K + 1) - \hat{F}_\Sigma(K). \end{aligned} \tag{127}$$

Here, the inequality at the center is due to the rule of the incremental algorithm.

The results (126) and (127) tell that $\hat{F}_\Sigma(K)$ is convex in K .

- (ii) Note that minimizing a function amounts to minimizing the logarithm of the function. Since

$$\log \prod_{i=1}^M \hat{F}_i(y_i) = \sum_{i=1}^M \log \hat{F}_i(y_i), \quad (128)$$

and $\log \hat{F}_i(y_i)$ is convex by assumption, part (ii) follows from part (i). \square

A positive logarithmic convex function over the integers can be shown to be convex. This follows easily from the fact that the arithmetic mean of two numbers exceeds the geometric mean. But the converse is not true. So the convexity condition in part (ii) of [Theorem 27](#) is slightly stronger than that of part (i). Note that, functions of the form p/K , where K is a positive integer, are logarithmic convex. Furthermore, adding a positive constant to a logarithmic convex function yields a new logarithmic convex function. Hence the following theorem is established.

Theorem 28 *An incremental algorithm of [Sect. 3.1](#) correctly solves problem Q' of (120).*

Proof Rewrite the objective function of problem Q' of (120) as

$$p_1 + \frac{p_1}{x_1} \{ p_2 + \frac{p_2}{x_2} \{ p_3 + \frac{p_3}{x_3} \{ p_4 + \cdots + \frac{p_{R-2}}{x_{R-2}} \{ p_{R-1} + \frac{p_{R-1}}{x_{R-1}} p_R \} \cdots \} \} \cdots \}. \quad (129)$$

Notice that a function $f(x) = a/x + b$ for constants $a > 0$ and $b \geq 0$ is logarithmic convex and that the product of two such functions is also logarithmic convex. Thus, applying this argument from the innermost terms of (129) out to the outermost, it follows that the function of (129) is logarithmic convex. Thus, from [Theorem 27](#) (ii), the theorem follows.

The computational complexity of this procedure is $O(RB)$ since employing [Theorem 27](#) (ii) at one stage takes $O(R)$ time, and there are $O(B)$ such stages.

Notice that the polynomial algorithm of [Sect. 3.1.2](#) for SC/Simple/D cannot be applied to problem Q' and it is not known yet whether Q' can be solved in polynomial time or not. However, to the authors' knowledge, Q' is the first nonseparable convex resource allocation problem that has been shown to be solvable by an incremental algorithm.

7.2 Reliability Applications

1. Optimal Allocation for Software-Testing Resources (Ohtera and Yamada [115])

During the module testing stage in the software development process, the manager has to determine an optimal allocation of resources such as manpower,

CPU hours, test cases to be executed, and so forth, so that the software quality and reliability are maximized. This problem is modeled as a resource allocation problem on the basis of the software reliability growth model developed by Kubat and Koch [90], which describes the relationship between the applied resource and the detected software errors. In the model of [90], the average of the cumulative number of software errors $m(t)$ detected in the time interval $(0, t]$ is expressed in terms of $W(t)$, the cumulative resource expenditures used until time t , that is,

$$m(t) = a(1 - \exp[-rW(t)]), \quad (130)$$

where a denotes the mean number of initial errors and r (> 0) denotes the error detection rate per unit resource expenditure.

Based on this model, a resource allocation problem can be defined, which minimizes software errors under the following assumptions:

1. The software system is composed of M independent modules. The number of software errors remaining in each module can be estimated by the model of [90].
2. The manager has to allocate the total amount of testing-resource R to each software module to minimize the number of software errors remaining in the system.

From (130), the number of software errors remaining in module j is estimated as:

$$z_j = a_j \cdot \exp[-r_j q_j], \quad j = 1, 2, \dots, M, \quad (131)$$

where a_j and r_j denote the average of initial number of errors in module j and the error detection rate per unit resource expenditure for module j , respectively.

Thus, the testing-resource allocation problem is formulated as

$$\text{minimize} \sum_{j=1}^M v_j a_j \cdot \exp[-r_j q_j] \quad (132)$$

$$\text{subject to} \sum_{j=1}^M q_j = R, \quad (133)$$

$$q_j \geq 0, \quad j = 1, 2, \dots, M, \quad (134)$$

where v_j stands for the relative importance of module j . This problem is a special case of SC/Simple/C.

7.3 Production Planning Applications

To illustrate rich applications in production planning as mentioned in [69], a new application is mentioned below.

1. Service-Constrained Optimal Policy for Spare Parts (Cohen, Kleindorfer and Lee [30])

The problem is to determine the optimal policy for a facility that stocks various spare parts for repairs to satisfy an overall service level requirement.

Suppose that a product is made up of n field replaceable units (FRUs for short), denoted by subscripts $i \in N = \{1, 2, \dots, n\}$. Demands for parts in any given period are represented by nonnegative integer-valued independent random variables $\{D_i \mid i \in N\}$ whose probability density function and cumulative distribution function are denoted by f_i and F_i , respectively. It is asked to determine the amounts of stocks $S = \{S_i \mid i \in N\}$ at the beginning of a period, where S_i are nonnegative integers, so as to minimize the expected holding and ordering costs while meeting the specified service levels for products and customers. Stock replenishment occurs instantaneously (i.e., zero lead time) at the end of each period to restore the stock levels depleted through the period demands.

The objective is to minimize the expected total cost per period:

$$\text{minimize } G(S) = \sum_{i \in N} G_i(S_i), \quad (135)$$

where $G_i(S_i)$ is the expected cost of FRU $_i$ per period defined by

$$\begin{aligned} G_i(S_i) = & E\{K_i \delta(D_i)\} && \text{ordering cost} \\ & + (C_{ih}/2)[S_i + (S_i - D_i)^+] && \text{holding cost} \\ & + C_{it} \min[S_i, D_i] && \text{transportation cost} \\ & + C_{is}(D_i - S_i)^+\}. && \text{shortage cost} \end{aligned} \quad (136)$$

Here, $x^+ = \max(x, 0)$ and $\delta(x) = 0$ (respectively, 1) if $x \leq 0$ (respectively, if $x > 0$). In (136), K_i is a fixed order cost, which will be neglected since it is independent of the stock policy S_i . The holding cost is the average of the initial inventory S_i and the final inventory $(S_i - D_i)^+$ times the holding cost per unit C_{ih} . Transportation cost per unit C_{it} denotes the cost of issuing an FRU, if available, and transporting it to the customer. Finally, the shortage cost C_{is} is associated with the incremental cost of meeting the demand from a remote location. It is assumed that

$$C_{is} \geq C_{it} > 0 \text{ and } C_{ih} > 0 \quad (137)$$

hold for all i . It is desired to minimize (135) subject to the following service constraints:

$$Pr\left\{\sum_{i \in N}(D_i - S_i)^+ > 0\right\} \leq \beta. \quad (138)$$

This tells that, in the long run, the excess demand occurs for at most a fraction β of the period. This type of constraint is often used in this field. Now note that the event $\{\sum_{i \in N}(D_i - S_i)^+ > 0\}$ is equivalent to the event $\{\cup_{i \in N}[D_i > S_i]\}$. Moreover, $Pr\{\sum_{i \in N} D_i > 0\} = 1 - \prod_{i \in N} F_i(0)$. Thus, (138) can be expressed as

$$1 - \prod_{i \in N} F_i(S_i) \leq \beta[1 - \prod_{i \in N} F_i(0)].$$

Assuming that $\alpha = 1 - \beta[1 - \prod_{i \in N} F_i(0)]$ is nonzero, the following equivalent, separable constraint can be obtained:

$$\sum_{i \in N} \log(F_i(S_i)) \geq \log \alpha. \quad (139)$$

Therefore, the above problem has a separable objective function and a separable nonlinear constraint. Since the derivative of $G_i(S_i)$ is shown to be

$$(C_{is} - C_{it} + C_{ih}/2)F_i(S_i) - (C_{is} - C_{it} - C_{ih}/2),$$

it follows that $G_i(S_i)$ is convex because $C_{is} - C_{it} + C_{ih}/2 > 0$ from (137) and $F_i(S_i)$ is nondecreasing in S_i .

Efficient solution algorithm similar to the incremental algorithm has been developed by Cohen et al. [30] although the constraint (139) is nonlinear.

7.4 Other Applications

7.4.1 An Optimal Scheduling of the Mass Screening Tests

The policy maker is faced with designing the mass screening programs for contagious diseases by taking into account the trade-off between the frequency of test applications and the types of tests used (as different technologies may have different reliability characteristics and costs), against the benefits to be achieved from detecting the defect in an earlier stage of development. Moreover, because different subpopulations may have different susceptibility to the disease, the problem of optimal allocation of a fixed testing budget among subpopulations must be considered [93]. This problem will be formulated as SC/Simple/C under the assumptions stated below:

1. The latent period of the disease is negligible.
2. The infectious period of the disease is exponentially distributed. Note that the termination of the infectious period can be a result of natural deaths.
3. The size of the population is large enough so that the number of susceptibles is relatively constant.
4. The incidence rates and the rates of transmission of the disease are stationary over time and are independent of each other.
5. The probability of an increase in the number of infected units at time t is directly proportional to the number of units in the infectious period of the disease at time t .
6. Once an infected unit is identified as having the disease after a mass screening test, it will be removed from the population and subsequently treated. As a result, it is assumed to be no longer infectious.

The assumption that the infectious periods are exponentially distributed is common in most of the related models. Assumption 5 is also generally used in epidemics. The following notation is used:

λ : natural incidence rate of the disease for the unit

γ : rate of transmission of the disease from a contagious unit to a susceptible

μ : rate of infected units ending the infectious period

In the time interval $[t, t']$ consisting of two consecutive mass screening tests, the number of contagious units is considered to be a stochastic process described by

$$X(t + \Delta t) = \lambda \Delta t + \gamma X(t) \Delta t - \mu X(t) \Delta t.$$

From this equation and the above assumptions, a closed-form expression can be obtained for the average number of infected units over $[t, t']$. Now suppose that it is required to perform M mass screening tests over the planning time horizon $[0, T]$. In [93], it is shown that the best scheduling policy for M tests is to perform the tests with equal interval lengths. Then, it has been shown that the average number of infected units in the population over a planning horizon of T time units can be written as

$$[\lambda/(\gamma - \mu)^2](M/T)\{\exp[(\gamma - \mu)(T/M)] - 1\} - [\lambda/(\gamma - \mu)], \quad (140)$$

where M is the number of mass screening tests performed over the planning time horizon $[0, T]$. As easily verified, given T , (140) is decreasing in M .

Now, suppose that each mass screening costs C , and B is the amount that the society can afford or is willing to pay per unit time for mass screening. Then, given a budget, the society would try to increase M as much as possible. For argument's sake, suppose M is increased so that $M/T = B/C$ holds. The average number of infected units in the population under the optimal screening schedule becomes as follows:

$$\psi(B) = [\lambda/(\gamma - \mu)^2](B/C)\{\exp[(\gamma - \mu)(C/B)] - 1\} - [\lambda/(\gamma - \mu)]. \quad (141)$$

As $T \rightarrow \infty$, (141) can be viewed as the long-range average number of infected units in the population under the optimal mass screening schedule. Notice that $\psi(B)$ is convex in B .

Suppose that there are J subpopulations, where there is little or no interaction among the subpopulations as far as the transmission of the disease is concerned. Thus, each subpopulation may be viewed as an independent population in terms of the etiology of the disease under screening. Let $D_j(\cdot)$ be the respective utility function for subpopulations j . Suppose B_j and C_j are the amount per unit time allotted to mass screening and the cost of each mass screening for subpopulation j , respectively. Let B be the amount per unit time available to all the subpopulations.

Thus, the problem facing the policy maker is to determine the B_j 's by solving the following resource allocation problem of type SC/Simple/C to maximize the objective function $f(B_1, B_2, \dots, B_J)$ under the assumption that $D_j(y)$ is concave in y (i.e., to minimize a convex function $-f(B_1, B_2, \dots, B_J)$):

$$\begin{aligned} & \text{maximize } f(B_1, B_2, \dots, B_J) \\ &= \sum_{j=1}^J D_j \left(\frac{\lambda_j}{(\gamma_j - \mu_j)^2} \left(\frac{B_j}{C_j} \right) \cdot \left[\exp \left\{ (\gamma_j - \mu_j) \left(\frac{C_j}{B_j} \right) \right\} - 1 \right] - \frac{\lambda_j}{\gamma_j - \mu_j} \right) \\ & \text{subject to } \sum_{j=1}^J B_j = B, \\ & \quad B_j \geq 0; \quad j = 1, \dots, J. \end{aligned}$$

7.4.2 Minimum Entropy Orientation Problem

Most of the resource allocation problems discussed so far mainly deal with separable *convex* functions as objective functions, which are to be minimized. In contrast, the application explained below gives an interesting example of a resource allocation problem, where a separable *concave* function is minimized.

Let $G = (V, E)$ be an undirected graph which may have parallel edges but no self loop. A directed graph $D_G = (V, A)$ is called an *orientation* of G if D_G is obtained from G by orienting each edge $(u, v) \in E$ as a (directed) arc (u, v) or (v, u) . For the directed graph D_G and a vertex $v \in V$, denote by $\rho_{D_G}(v)$ the in-degree of v in D_G , that is, the number of arcs in D_G which enter the vertex v . A vector $p \in R^V$ given by $p_v = \rho_{D_G}(v)/|E|$ for $v \in E$ is called the *in-degree distribution* of D_G .

The *minimum entropy orientation* problem (MINEO) is the problem of finding an orientation of G for which the in-degree distribution is as unbalanced as possible. More formally, the objective function of MINEO is given by

$$f(D_G) = - \sum_{v \in V} \frac{\rho_{D_G}(v)}{|E|} \log \frac{\rho_{D_G}(v)}{|E|},$$

which is minimized among all orientations D_G of G . Notice that $g(\alpha) = -(\alpha/|E|) \log(\alpha/|E|)$ is a concave function in α .

The problem MINEO is firstly considered by Cardinal et al. [25] as a special case of a problem called the minimum entropy set cover problem (MINESC). The input of MINESC is a ground set U and a family $\mathcal{S} = \{S_1, S_2, \dots, S_q\}$ of subsets of U . The output is an assignment (or a function) $\pi : U \rightarrow \{1, \dots, q\}$, which minimizes the *entropy*

$$-\sum_{i=1}^q \frac{|U_i|}{|U|} \log \frac{|U_i|}{|U|},$$

where $S_i = \{v \in S \mid \pi(v) = i\}$ ($i = 1, \dots, q$). It is not difficult to see that MINEO is a special case of MINESC by setting $U = E$ and $\mathcal{S} = \{S_v \mid v \in V\}$, where $S_v = \{e \in E \mid e \text{ is incident to } v\}$ for $v \in V$.

MINESC is introduced by Halperin and Karp [59], due to a motivation to solve a certain haplotyping problem, which is of importance in computational biology. The haplotyping problem involves covering a set U of *partial haplotypes* of length d , defined as words in the set $\{0, 1, *\}^d$, by *complete haplotypes*, defined as words in $\{0, 1\}^d$. Each subset S_i in \mathcal{S} corresponds to a complete haplotype $a \in \{0, 1\}^d$ and is given as the set of partial haplotypes b in U that are *compatible* with a , that is, $b_j = a_j$ for all $j = 1, \dots, d$ such that $b_j \neq *$. It is shown that, under some probabilistic assumptions, minimizing the entropy amounts to maximizing its likelihood [59].

In this context, MINEO corresponds to a special case of the haplotyping problem, where each partial haplotype has exactly one “*” in it. In this case, partial haplotypes correspond to edges of a d -dimensional hypercube, and the subsets U_i correspond to vertices of the hypercube. That is, this special case of the haplotyping problem is a minimum entropy orientation problem in a partial hypercube.

Cardinal et al. [25] show that MINEO is NP-hard by using the reduction of the 1-in-3 satisfiability problem. On the other hand, it is shown that an approximate solution with additive error of one (i.e., the objective function value is at most [the optimal value of MINEO] + 1) can be computed in linear time by a simple algorithm. In addition, it is presented in [25] that MINEO can be formulated as the minimization of a separable *concave* function on a base polyhedron, as explained below.

Consider an undirected graph $G = (V, E)$ which is an instance of MINEO. For $S \subseteq V$, let $r(S)$ be the number of edges in E incident to S . Then, $r : 2^V \rightarrow \mathbb{Z}$ is a nondecreasing submodular function. The set of orientations of G is deeply related to the base polyhedron $B(r)$ of the submodular system $(2^V, r)$, and it is known that an integral vector $x \in \mathbb{Z}^V$ is in $B(r)$ (i.e., x is an integral base of $B(r)$) if and only if there exists an orientation D_G of G such that $\rho_{D_G}(v) = x_v$ for all $v \in V$ (see, e.g., [124, Chap. 61]). Hence, MINEO can be formulated as follows:

$$\begin{aligned} & \text{minimize} \sum_{v \in V} (-1) \cdot \frac{x_v}{|E|} \log \frac{x_v}{|E|} \\ & \text{subject to } x : \text{ an integral base of } B(r), \end{aligned}$$

which is the minimization of a separable concave function under submodular constraints. It should be noted that the maximization version of MINEO is a special case of SC/SM/D and therefore can be solved in polynomial time by using the results in Sect. 4.

7.5 Notes and References

There are many other applications of the resource allocation problem. Among them, applications to computer science are found in [2, 28, 95, 101, 136–141, 144, 150].

Biller et al. [10] considered an optimal dynamic pricing problem which can be formulated as a problem of SC/SM/D.

Baldick and Wu [7] considered the problem of an optimal design of coordination of capacitors and regulators in which they applied the algorithm by Hochbaum and Shanthikumar [65].

Carrizosa and Morales [26] studied the sample allocation problem for stratified simple random sampling that is to determine sample sizes drawn from each stratum. The paper considered two objectives: the total sampling cost and the variance of the so-called Horvitz–Thompson estimator. It then proposed a method to compute a set of Pareto optimal solutions.

A biobjective method for sample allocation in stratified sampling, Eu [38] considered an optimal allocation of sample sizes in a real-time monitoring system to detect errors of digital signals in telecommunication systems, by sampling, so as to minimize the sum of the so-called bit error ratios of multiple signals. He formulated the problem as SC/LUB/C.

Li and Haimes [94] considered an optimization problem that arises in designing a high-reliability large-scale system that is also viewed as a variant of the resource allocation problem.

Shanthikumar and Yao [126] considered the optimal control problem for a class of multi-class queueing systems. They found a certain submodular structure of performance vectors that allows us to efficiently compute an optimal performance vector.

Shanthikumar and Yao [125] studied the resource allocation problem in queueing networks, which models certain types of manufacturing systems where each node represents a machine or a workstation. It seeks to find an optimal allocation of servers to the stations in order to maximize the throughput, under the constraint that the total number of servers to be allocated is fixed.

Bitran and Tirupati [12, 13] studied a manufacturing capacity planning problem in manufacturing systems that are also regarded as queueing networks (see also Buzacott and Shanthikumar [24]). The problem involves the minimum-cost selection of the service rate (or capacity) at each workstation, subject to an upper limit on the total dollar value of work in process in the system. Under certain assumptions, they have formulated the problem as the separable convex resource allocation problem under a separable convex constraint. They presented efficient heuristic algorithms for the continuous variable case [12] and for the discrete variable case [13].

Resource allocation problems with nonlinear constraints in production planning under uncertainty are often encountered. One such application is found in [145]. This topic will be discussed again in Sect. 8.3.

The quickest flow problem on a grid network which arises in determining an optimal evacuation planning in cities was studied by Kamiyama, Katoh, and Takizawa [73]. The paper formulated the problem to find the optimal allocation of evacuees to paths to a safety place as Minimax/Simple/D and gave a polynomial-time algorithm.

See also [9, 18, 27, 29, 121, 132, 134] for other applications of resource allocation problems.

8 Further Topics

This section deals with some extensions and generalizations of resource allocation problems not discussed so far.

The first topic is on the multiple resource allocation problem in which each activity requires more than one type of resource. The modeling capability is substantially enhanced by this generalization. An application of this problem is typically found in production planning to find an optimal allocation of many types of resources such as raw materials, machines, and manpower among competing production lines so as to meet the demands. This problem has been well studied [82–86, 97–99, 102, 104, 135]. For most of multiple resource allocation problems discussed in the literature, the performance of each activity (the production level of a certain product in the context of production planning) is measured by the deviation of the planned activity level (the amount of products to be produced) from a given demand. Minimax objective is usually adopted because minimizing the maximum deviation among all activities balances deviations over all activities and is thus intuitively appealing to practitioners engaged in production planning. Also, decision variables can be usually regarded as continuous. Efficient algorithms for such problems have been developed. Among them two algorithms proposed by Luss [97, 98] shall be reviewed in the next subsection.

The second topic is on the multiperiod resource allocation problem. A typical application is also found in production planning. For each activity, a cumulative target level is prespecified. Each decision variable represents the cumulative level selected for an activity up to some period. Similarly to the multiple resource allocation problem, this type of problem is usually formulated as the one with minimax objective function and continuous variables. This will be discussed in Sect. 8.2.

The third topic deals with the resource allocation problem under a single nonlinear constraint. An application of this problem is mentioned in Sect. 7.3, and, as pointed out in the survey paper [17] by Brethauer and Shetty, this type of problem has many applications in various fields. This topic will be dealt with in Sect. 8.3.

Finally, in Sect. 8.4 miscellaneous problems related to resource allocation shall be discussed, including (1) multiple resource allocation problem with smoothing objectives and (2) minimum variance resource allocation problem.

8.1 Multiple Resource Allocation

As remarked above, the multiple resource allocation problem usually has a minimax objective function and continuous variables. A problem formulation is given first, and then two algorithms are explained briefly. The following notation is used:

- i : index for resources, $i = 1, 2, \dots, m$
- j : index for activities, $j = 1, 2, \dots, n$
- a_{ij} : amount of resource i used by one unit of activity j ; $a_{ij} \geq 0$
- b_i : amount of available resource i ; $b_i > 0$
- x_j : activity level to be chosen for j ; $x_j \geq 0$
- $f_j(x_j)$: cost function associated with activity j

The problem is formulated as follows:

$$\begin{aligned} MRP : \quad & \text{minimize} \quad \max_{1 \leq j \leq n} f_j(x_j) \\ & \text{subject to} \quad \sum_{j=1}^n a_{ij} x_j \leq b_i, \quad i = 1, 2, \dots, m, \\ & \quad x_j \geq 0, \quad j = 1, 2, \dots, n. \end{aligned} \tag{142}$$

It is assumed that $f_j(x_j)$ is strictly decreasing and continuous. Denote the inverse function of $f_j(x_j)$ by $f_j^{-1}(\cdot)$, that is, $f_j(x_j) = y$ implies $f_j^{-1}(y) = x_j$. Note that $f_j^{-1}(y)$ is also strictly decreasing and continuous. Let the indices j be reordered so that

$$f_1(0) \leq f_2(0) \leq \dots \leq f_n(0)$$

holds. In the following, denote the optimal objective value by V^* .

Theorem 29 *There exists an optimal solution x^* of MRP with the objective value V^* , such that there exists a set $J^* = \{j^*, j^* + 1, \dots, n\}$ satisfying*

$$x_j^* > 0, \quad j \in J^*, \tag{143}$$

$$x_j^* = 0, \quad j \notin J^*, \tag{144}$$

and

$$f_j(x_j^*) = V^*, \quad j \in J^*, \tag{145}$$

$$f_j(0) \leq V^*, \quad j \notin J^*. \tag{146}$$

Proof Suppose there is an optimal solution x^* of problem MRP with $x_{j_1}^* = 0$ and $x_j^* > 0$ for some $j < j_1$. Since $f_j(0) \leq f_{j_1}(0) \leq V^*$ for all $j \leq j_1$ and all a_{ij} are nonnegative, reducing x_j^* to zero for all $j < j_1$ preserves feasibility and optimality; so (143) and (144) hold for some J^* . Now, suppose $f_j(x_j^*) < V^*$ for some $j \in J^*$. Reducing each such x_j^* until $f_j(x_j^*) = V^*$ or until x_j^* reaches zero,

whichever occurs first, preserves feasibility and optimality; so (145) holds. (Note that if $x_{j_1}^*$ is reduced to zero, then all x_j^* 's for $j \leq j_1$ are also reduced to zero, so that (143) and (144) holds.) Since $f_j(x_j^*) \leq V^*$ for all j , (144) implies (146). \square

An optimal solution for MRP is not necessarily unique. However, for an optimal solution that satisfies (143)–(146) none of the x_j^* 's can be reduced without violating the nonnegativity constraints or optimality. Thus, there is a unique optimal set J^* that satisfies (143)–(146). Since $f_j(x_j)$ is strictly decreasing, (143)–(146) also imply

$$f_{j^*}(0) > V^*, \quad (147)$$

$$f_{j^*-1}(0) \leq V^*. \quad (148)$$

If $j^* = 1$ holds here, only (147) is relevant. Note that the following property holds by definition of J^* :

$$f_{j^*}(0) = \min_{j \in J^*} f_j(0) \text{ and } f_{j^*-1}(0) = \max_{j \notin J^*} f_j(0).$$

The first algorithm solves the problem by identifying the above set J^* , by considering a sequence of relaxed versions MRP_h , $h = 1, 2, \dots, n$, each obtained by removing nonnegativity constraints $x_j \geq 0$. That is, MRP_h is defined on set $J_h = \{h, h+1, \dots, n\}$ of activities as follows:

$$\text{MRP}_h : \text{ minimize } \max_{j \in J_h} f_j(x_j) \quad (149)$$

$$\text{subject to } \sum_{j \in J_h} a_{ij} x_j \leq b_i, \quad i = 1, 2, \dots, m. \quad (150)$$

Since all f_j are decreasing and all a_{ij} are nonnegative, at least one of the constraints (150) holds with equality for an optimal solution of MRP_h . Thus, from (145), in order to solve MRP_h , values k_i ($i = 1, 2, \dots, m$) are first computed such that

$$\sum_{j \in J_h} a_{ij} f_j^{-1}(k_i) = b_i, \quad i = 1, 2, \dots, m. \quad (151)$$

The optimal objective value V_h^* of MRP_h is then obtained by

$$V_h^* = \max_i k_i.$$

If

$$f_h(0) > V_h^* \text{ and } f_{h-1}(0) \leq V_h^* \quad (152)$$

hold for $J_h = \{h, h+1, \dots, n\}$, then this J_h gives the optimal set J^* . Furthermore, the optimal objective value V^* of MRP is equal to V_h^* , and the positive x_j^* 's are

given by $x_j^* = f_j^{-1}(V_h^*)$. By [Theorem 29](#), there exists an h satisfying (152), thus yielding an algorithm to compute J^* .

As shown in [97], for certain nonlinear functions, the k_i 's are given as closed-form expressions. For example, this is possible if

$$f_j(x_j) = \beta_j(x_j + \gamma_j)^{-\delta} \text{ for all } j,$$

where $\beta_j > 0$, $\gamma_j \geq 0$ and $\delta > 0$. However, in general (e.g., the above δ is replaced by δ_j), solving equation (151) requires numerical methods such as Newton method.

Another algorithm is now explained that facilitates the search for J^* without explicitly solving equations of the type (151). Some properties used for this purpose are presented below.

Theorem 30 *The optimal set $J^* = \{j^*, j^* + 1, \dots, n\}$ of problem MRP satisfies the following conditions:*

$$\sum_{j \in J^*} a_{ij} f_j^{-1}(f_{j^*}(0)) < b_i \text{ for } i = 1, 2, \dots, m. \quad (153)$$

Furthermore, if $j^* > 1$, it holds that

$$\sum_{j \in J^*} a_{ij} f_j^{-1}(f_{j^*-1}(0)) \geq b_i \text{ for some } i. \quad (154)$$

Proof By (142) and (145) and the nonnegativity of a_{ij} , it holds that

$$\sum_{j \in J^*} a_{ij} x_j^* = \sum_{j \in J^*} a_{ij} f_j^{-1}(V^*) \leq b_i$$

for all i . Since $f_{j^*}(0) > V^*$ holds by (147), $f_j^{-1}(y)$ is strictly decreasing, and all a_{ij} 's are nonnegative, it follows

$$\sum_{j \in J^*} a_{ij} f_j^{-1}(f_{j^*}(0)) < \sum_{j \in J^*} a_{ij} f_j^{-1}(V^*) \leq b_i,$$

which then implies (153). To prove (154), note that there is some i , say i' , such that

$$\sum_{j \in J^*} a_{i'j} x_j^* = b_{i'}.$$

Furthermore, since (148) implies $f_{j^*-1}(0) \leq V^*$, it holds that

$$f_j^{-1}(f_{j^*-1}(0)) \geq f_j^{-1}(V^*).$$

Therefore,

$$\begin{aligned} \sum_{j \in J^*} a_{i'j} f_j^{-1}(f_{j^*-1}(0)) &\geq \sum_{j \in J^*} a_{i'j} f_j^{-1}(V^*) \\ &= \sum_{j \in J^*} a_{i'j} x_j^* = b_{i'} \end{aligned}$$

follows. \square

Remark 2 If $J^* = \{n\}$, condition (153) is always satisfied since $b_i > 0$ for all i and $f_{j^*}^{-1}(f_{j^*}(0)) = 0$.

Theorem 31 For problem MRP, if a set $J_h = \{h, h+1, \dots, n\}$ does not satisfy (153) (i.e., $\sum_{j \in J_h} a_{ij} f_j^{-1}(f_h(0)) \geq b_i$ for some i), it holds that

$$J^* \subset J_h.$$

Proof Let $J_l = \{l, l+1, \dots, n\}$ be any set such that $J_l \supset J_h$ (i.e., $l < h$) and suppose that $J_l = J^*$, that is, J_l satisfies (153) (i.e., $\sum_{j \in J_l} a_{ij} f_j^{-1}(f_l(0)) < b_i$ for all i). This implies that

$$\begin{aligned} \sum_{j \in J_h} a_{ij} f_j^{-1}(f_h(0)) &\leq \sum_{j \in J_h} a_{ij} f_j^{-1}(f_l(0)) \\ &\leq \sum_{j \in J_l} a_{ij} f_j^{-1}(f_l(0)) < b_i \end{aligned}$$

holds for all i . The first inequality follows since $l < h$ implies $f_l(0) \leq f_h(0)$ and $f_i^{-1}(\cdot)$ is strictly decreasing. The second inequality follows since

$$f_j^{-1}(f_l(0)) \geq 0 \text{ for all } j \geq l$$

holds from $f_j^{-1}(f_j(0)) = 0$, $f_j(0) \geq f_l(0)$ for $j \geq l$ and the monotone decreasingness of $f_i^{-1}(\cdot)$. These inequalities tell that J_h also satisfies (153), which is a contradiction.

Hence, $J^* \neq J_l$ holds for all $l < h$, from which $J^* \subset J_h$ follows since $J^* \neq J_h$. \square

Theorem 32 For problem MRP, if a set $J_h = \{h, h+1, \dots, n\}$ (for $h \geq 2$) does not satisfy condition (154) (i.e., $\sum_{j \in J_h} a_{ij} f_j^{-1}(f_{h-1}(0)) < b_i$ for all i), then it holds that

$$J^* \supset J_h.$$

Proof Let $J_l = \{l, l+1, \dots, n\}$ satisfy $J_l \subset J_h$ (i.e., $l > h$). Then

$$\begin{aligned} \sum_{j \in J_l} a_{ij} f_j^{-1}(f_{l-1}(0)) &\leq \sum_{j \in J_l} a_{ij} f_j^{-1}(f_{h-1}(0)) \\ &\leq \sum_{j \in J_h} a_{ij} f_j^{-1}(f_{h-1}(0)) < b_i \end{aligned}$$

holds for all i . The first inequality is from $f_{h-1}(0) \leq f_{l-1}(0)$. The second inequality holds since

$$f_j^{-1}(f_{h-1}(0)) \geq 0 \text{ for } j \geq h$$

by assumption $f_j^{-1}(f_j(0)) = 0$, $f_{h-1}(0) \leq f_j(0)$ for $j \geq h$ and the monotone decreasingness of $f_j^{-1}(\cdot)$. Hence, J_l does not satisfy (154), implying that $J^* \supset J_h$. \square

As a direct consequence of [Theorems 31](#) and [32](#), J^* can be computed efficiently by applying the binary search over the index set $\{1, 2, \dots, n\}$ using (153) and (154). It should be remarked here that, unlike conditions (147) and (148), testing whether a set J^* satisfies (153) and (154) does not require the costly computation of V_h^* , which is obtained by solving nonlinear equations (151) as in the first algorithm. Instead, it suffices to solve equations (151) only once, in order to determine V^* after the J^* is found. This will greatly reduce the computation time.

8.2 Multiperiod Resource Allocation

Consider the multiperiod resource allocation problem that seeks to find an optimal allocation of resources over multiple periods so as to minimize the cost incurred by the resulting allocation.

As in the problem discussed in the previous subsection, activities may require more than one resource type. It is assumed that all resources are storable, that is, excess resources in one period can be used in the subsequent periods.

As mentioned at the beginning of this section, a cumulative target level is prespecified for each activity. This means that each decision variable represents the cumulative level selected for the corresponding activity up to some period, implying that there exists an ordering constraint on the decision variables for each activity telling that the cumulative activity levels are nondecreasing over time. All variables are assumed to be continuous. The objective is again Minimax, as in the previous subsection, that is, the maximum among all costs of activities is minimized.

Suppose that a set of resources I and a set of activities A are given. Resources in I are represented by index i , and activities in A are represented by index j . The model considers discrete time periods $t = 1, 2, \dots, \tau$ and $T = \{1, 2, \dots, \tau\}$. Activity i at time t is represented by two indices (j, t) for $j \in A$ and $t \in T$. The set of all activity-period pairs is denoted by AP . The following additional notations are used:

- a_{ijt} : amount of resource i used by one unit of activity (j, t) ; $a_{ijt} \geq 0$
- b_i : amount available of resource i ; $b_i > 0$

- x_{jt} : cumulative level selected for activity (j, t)
 l_{jt} : lower bound on the level selected for activity (j, t) ; $l_{jt} \geq 0$
 u_{jt} : upper bound on the level selected for activity (j, t) ; $u_{jt} \geq 0$
 $f_{jt}(x_{jt})$: performance function associated with activity (j, t)

The multiperiod minimax resource allocation problem is formulated as follows:

$$\text{MPMRP : minimize } \max_{(j,t) \in AP} f_{jt}(x_{jt}) \quad (155)$$

$$\text{subject to } \sum_{(j,t) \in AP} a_{ijt} x_{jt} \leq b_i, \quad i \in I, \quad (156)$$

$$x_{jt} \geq x_{j,t-1}, \quad (j, t) \in AP, \quad (157)$$

$$l_{jt} \leq x_{jt} \leq u_{jt}, \quad (j, t) \in AP, \quad (158)$$

where $x_{j0} = 0$ is assumed for all $j \in A$ by convention. Denote the optimal objective value by V^* and assume that $f_{jt}(x_{jt})$ is strictly decreasing and continuous in x_{jt} . The inverse function of f_{jt} is denoted by f_{jt}^{-1} .

Betts, Brown, and Luss [8] has developed an efficient algorithm for this problem, based on the following theorem (the proof is omitted here; see [8] for its proof). For a given constant $V \in R$, we call V *feasible* if there exists a feasible solution x of MPMRP such that the objective value is less than or equal to V .

Theorem 33 *Given a $V \in R$ for problem MPMRP, let $x(V) = \{x_{jt}(V) \mid (j, t) \in AP\}$ satisfy the following:*

$$x_{jt}(V) = \max\{l_{jt}, x_{j,t-1}(V), f_{jt}^{-1}(V)\}, \quad (j, t) \in AP. \quad (159)$$

(This $x(V)$ can be obtained by executing (159) in the increasing order of t , starting from $x_{j0}(V) = 0$, $j \in A$.) Then

- (i) *V is feasible to problem MPMRP if and only if $x(V)$ satisfies constraints (156)–(158).*
- (ii) *If $V = V^1$ is feasible to problem MPMRP and $V = V^2$ is not, then $V^2 < V^1$ holds.* \square

Theorem 33 immediately suggests a binary search method to find an optimal solution of MPMRP. Since we can compute $x(V)$ using the recursive formula (159), the entire algorithm is efficient.

8.3 Minimizing a Separable Convex Function Under a Nonlinear Constraint

The problem considered here has a single nonlinear constraint together with lower and upper bounds on all variables:

$$\text{SC/NLP/D : } \underset{\mathbf{x}}{\text{minimize}} \quad \sum_{j=1}^n f_j(x_j) \quad (160)$$

$$\text{subject to} \quad \sum_{j=1}^n g_j(x_j) \leq b, \quad (161)$$

$$l_j \leq x_j \leq u_j, \quad j = 1, \dots, n, \quad (162)$$

$$x_j : \text{integer}, \quad j = 1, \dots, n, \quad (163)$$

where $f_j(x_j)$ and $g_j(x_j)$, $j = 1, \dots, n$ are differentiable convex functions over R , b is a constant, and l_j and u_j ($l_j < u_j$), $j = 1, \dots, n$ are lower and upper bounds on the integer variables. We assume that the feasible region is nonempty and bounded. Note that the assumptions on $f_j(x_j)$ and $g_j(x_j)$ imply that the continuous relaxation of SC/NLP/D (denoted by SC/NLP/C) is a convex program.

Bretthauer and Shetty [14, 17] pointed out that both problems SC/NLP/D and SC/NLP/C have a wide variety of applications, including production planning, capital budgeting, capacity planning in manufacturing networks, capacity planning in computer networks, stratified sampling, and marketing. They proposed a branch-and-bound algorithm based on the continuous relaxation and reported that the proposed algorithm could solve problem instances with up to 200 variables, all of which were taken from the real applications as mentioned above.

Kodialam and Luss [88] studied SC/NLP/C and developed an algorithm by generalizing the algorithms for SC/LUB/C developed by Bitran and Hax [11] and Zipkin [151]. They carried out computational experiments for problem instances taken from production planning applications and showed that the proposed algorithms are practically efficient.

Hochbaum [62] proposed a fully polynomial-time approximation scheme for SC/NLP/D with running time $O(\frac{1}{\epsilon^2}(n \log N + \log \frac{1}{\epsilon} \log n + \frac{1}{\epsilon^2} \log \frac{1}{\epsilon}))$. She also proposed an $O(n \log(N/\epsilon))$ time algorithm that computes an ϵ -accurate solution for SC/NLP/C. Both algorithms assume that g_j are nondecreasing.

See also [16, 20] for other results related to the problem SC/NLP/D.

8.4 Other Variants of Resource Allocation Problems

8.4.1 Resource Allocation Problem with Smoothing Objectives

This problem is a variant of the multiperiod resource allocation problem discussed in Sect. 8.2. For simplicity, let us assume that we have a single resource type.

The objective is to allocate the resource as smoothly as possible over the T periods while satisfying the demands in all periods. More specifically, we attempt to minimize the sum of the absolute values of the changes in resource allocation in adjacent periods. A perfectly smooth allocation of the resource implies that the same amount of resource is made available in each period. However, this ideal situation is, in general, infeasible, as it may incur temporary shortages or require additional resources that will become surplus at the end of the planning horizon. There are two models. The first model assumes that the allocation decisions are continuous variables, and the second model considers discrete variables. Both models have been studied by Luss and Rosenwein [102].

As indicated in [102], an application of such smoothing problems can be found, for example, in a manufacture-to-order environment, where the orders are known for a finite planning horizon. Consider a complex product like a communication switching system. Each system is custom-made and requires a different amount of many subassemblies. The sequence of systems assembled in the final assembly shop during the planning horizon imposes varying demands on each feeder shop that manufactures a subassembly for that system. The question then arises how smooth can the production of each subassembly be, subject to meeting the demands in all periods without having unnecessary inventory.

Here a problem formulation in the simplest case is presented in which the following notations are used:

T : the planning horizon

t, τ : indices for time periods; $t, \tau = 1, 2, \dots, T$

d_t : demand for the product in period t ; $d_t \geq 0$

x_t : amount of resource made available in period t

In production planning applications, d_t is the demand for the product (sub-assembly or component) at period t , and x_t is the amount of the product produced in period t . The model assumes that resource allocations and demands occur instantaneously and simultaneously at the beginning of each period. Further, no resources are available prior to the first period, and the resource made available in period t is storable. That is, it can be used to satisfy the demand of period t or of later periods. Demands must be met on time, that is, the demand of period t must be satisfied by resources made available in period t or earlier. The objective is to allocate the resource as smoothly as possible among successive periods. More precisely, the objective is to minimize the sum of the absolute value of the changes in the amounts of resource made available in adjacent periods. The formulation of this model is as follows:

$$\text{minimize} \quad \sum_{t=2}^T |x_{t-1} - x_t| \quad (164)$$

$$\text{subject to} \quad \sum_{\tau=1}^t x_{\tau} \geq \sum_{\tau=1}^t d_{\tau}, \quad t = 1, 2, \dots, T-1, \quad (165)$$

$$\sum_{\tau=1}^T x_\tau = \sum_{\tau=1}^T d_\tau, \quad (166)$$

$$x_t \geq 0, \quad t = 1, 2, \dots, T. \quad (167)$$

The case for discrete variables is similarly defined. Luss and Rosenwein [102] proposed an $O(T^2)$ time algorithm for the continuous case. For the discrete case, they proposed an algorithm with the same running time that converts a continuous optimal solution to the discrete one with an extra postprocessing time of $O(T)$.

8.4.2 Minimum Variance Resource Allocation Problem

All the objectives of Minimax, Maximin, Lexico-Minimax, Lexico-Maximin, and Fair may be viewed as those seeking for a *fair* allocation of resources to activities. However, in an allocation of discrete resources, the *perfect fairness* may not be attained in general. Consider here *variance* as an alternative measure to express the degree of the *unfairness* or *imbalance* of the resulting allocation. Suppose that function $f_j(x_j)$ represents the profit resulting from allocating x_j amount of resources to activity j . Then the variance of the profit vector $(f_1(x_1), f_2(x_2), \dots, f_n(x_n))$ for an allocation vector $x = (x_1, x_2, \dots, x_n)$ is defined as

$$\text{Var}(x) = \sum_{j=1}^n \frac{1}{n} [f_j(x_j) - \frac{1}{n} \sum_{k=1}^n f_k(x_k)]^2. \quad (168)$$

Then, the minimum variance resource allocation problem under a simple constraint is formulated as follows:

$$\begin{aligned} Q : & \text{minimize } \text{Var}(x) \\ & \text{subject to } \sum_{j=1}^n x_j = N, \\ & x_j \geq 0, \quad \text{integer } j = 1, \dots, n. \end{aligned}$$

This problem has been studied by Katoh [77] and a pseudo-polynomial-time algorithm was presented. The proposed algorithm is based on the technique that transforms the problem into an equivalent parametric problem where the objective function becomes separable, that is,

$$\begin{aligned} Q(\lambda) : & \text{minimize } \sum_{j=1}^n ([f_j(x_j)]^2 - \lambda f_j(x_j)) \\ & \text{subject to } \sum_{j=1}^n x_j = N, \\ & x_j \geq 0, \quad \text{integer } j = 1, \dots, n. \end{aligned}$$

Katoh [77] showed that there exists a parameter $\lambda = \lambda^*$ such that $Q(\lambda^*)$ is optimal to Q . Notice here that each term $[f_j(x_j)]^2 - \lambda f_j(x_j)$ in the objective function may not be convex even if $f_j(x_j)$ is convex. Because of this, no efficient method to search for λ^* has been developed. Thus, it is necessary to solve $Q(\lambda)$ for all λ in a certain range. It was shown in [69] that, in continuously changing the parameter λ , the number of different optimal solutions for $Q(\lambda)$ is $O(n^2 N^2)$. Therefore, all optimal solutions in the range can be obtained in $O(n^2 N^2 \cdot \tau)$ time, where τ denotes the time to solve $Q(\lambda)$ for a fixed λ . Although τ is not polynomial in general, we can apply dynamic programming to solve $Q(\lambda)$ in $O(nN^2)$ time (see, e.g., [69]). (This is possible even if the objective function is not convex.) Thus, problem Q can be solved in a pseudo-polynomial time. This idea can be generalized to the problems with more general constraints such as submodular constraints.

Ichimori and Katoh [72] (see also [71]) studied a special case of Q where each $f_j(x_j)$ is x_j/s_j ($s_j > 0$). In this case, $[f_j(x_j)]^2 - \lambda f_j(x_j)$ is convex, and hence, $Q(\lambda)$ reduces to problem SC/Simple/D. They proposed a very efficient algorithm for this case by devising a technique similar to branch-and-bound procedures. They exhibited its efficiency through computational experiments.

8.5 Notes and References

We give here some additional references not mentioned in the previous sections. We start with multiple resource allocation problem MRP. King [81] developed an interactive software tool for solving problem MRP with linear objective function in support of manufacturing resource planning (MRP II) systems. Ichimori [70] developed a polynomial-time algorithm for a special class of two-resource allocation problem with quadratic convex objective function. Klein and Luss [82] and Klein, Luss, and Rothblum [84] considered an extension of problem MRP in which certain substitutions among resources are possible. They proposed efficient algorithms for the problem. It was mentioned in [82, 84] that such substitution is an important function in the manufacturing of high-tech electronic products because shortage of parts is often incurred due to rapid changes in technology. Nguyen and Stone [113] and Pang and Yu [116] considered similar minimax resource allocation problems with substitutional resources.

A special case of problem MPMRP was examined by Luss and Smith [103] and Klein, Luss, and Smith [83], where $f_{jt}(x_{jt})$ is linear in x_{jt} . In [83], the objective is Lexico-Minimax, and efficient algorithms have been developed for this case in [83, 103]. The algorithms in [83, 103] first solve a relaxed problem obtained by neglecting the constraints (157) and (158). When variables \hat{x}_{jt} in the optimal solution \hat{x} of the relaxed problem violate the constraint (157) or the lower bound constraint of (158), x_{jt} is fixed to $x_{jt} = \max\{l_{jt}, x_{j,t-1}\}$ or $x_{jt} = l_{jt}$, respectively. We then repeat this process by solving the relaxed problem with the above additional equality constraints until all variables are fixed. It was shown in [83, 103] that this algorithm produces an optimal solution. This algorithm can be viewed in a certain sense as a generalization of the algorithm for problem SC/LUB/C by Bitran and

Hax [11] and Zipkin [151] (see also Chap. 2 of [69]). Luss [99] developed post-optimization schemes and parametric analysis, which may be employed once an optimal solution of the problem is obtained.

Klein, Luss, and Rothblum [85] have developed a general methodology to solve multiple resource minimax problems including MRP and MPMRP discussed in this section, based on the so-called relaxation method.

Betts, Brown, and Luss [8] considered minimax resource allocation problems with ordering constraints by generalizing the constraints (157) of problem MPMRP and proposed a practically efficient algorithm that solves a sequence of problems without ordering constraints.

Hackman and Platzman [58] considered another generalization of MRP in which a set of resources required by an activity is not fixed, but such allocation of resource types to an activity is also a decision variable. This problem is formulated as a nonlinear mixed-integer program, which may be solved by a branch-and-bound algorithm. This was motivated by positioning stock problem in a large distribution center (see [57] for the details).

Karabati, Kouvelis, and Yu [74, 75] considered the so-called min-max-sum resource allocation problem with discrete variables that include as special cases both SC/Simple/D and Minimax/Simple/D. Yüceer [149] proposed a variant of the incremental algorithm for the resource allocation problem with a nonseparable objective function and a single knapsack constraint (69), which produces a non-dominated solution. He discussed an application of this problem to a spare-kit problem. Moré and Vavasis [106] considered a separable concave discrete minimization with a simple constraint $\sum_{j=1}^n x_j = N$ and developed an algorithm for the problem.

Recently, a decentralized algorithm to solve SC/Simple/C was proposed [92] in which it is assumed that agents communicate through a network of dynamic topology in order to solve the problem. The proposed algorithm is shown to converge under a mild condition on the objective function (e.g., $f_j(x_j)$ has bounded subgradients).

Also, a parallel algorithm for S/Simple/D was proposed by Shao and Rao [127]. See also [3, 6, 19, 50, 56, 79, 148] for other results related to resource allocation problems.

9 Conclusion

This chapter reviewed the state of the art in the theory and algorithms of the resource allocation problems, mainly with integer variables. In addition, various applications of the resource allocation problems as well as related problems were presented.

The resource allocation problem is one of the most fundamental problem in nonlinear integer programming. Due to the recent advances in the research of nonlinear integer programming, the resource allocation problem has still been studied extensively, although it is a classical problem which dates back to the 1950s. Indeed, applications and generalizations of resource allocation problems

often appear in the literature, as mentioned in this chapter. Therefore, a further advance is desired in the research on the resource allocation problem.

One important open problem is to detect a general class of resource allocation problems which can be solved in polynomial time. One such class is the nonseparable convex resource allocation problem with an M-convex objective functions discussed in Sect. 6. This generalization, however, is not sufficient from the viewpoint of application since it does not fully cover interesting applications of resource allocation problems. Some attempts in this research direction are done by one of the present authors [130, 131], but further investigation is still required.

As mentioned in Sects. 7 and 8, there are many applications and generalizations of resource allocation problems which are known to be NP-hard. Another important open problem is to devise approximation algorithms with theoretical approximation guarantee for such NP-hard problems. For example, Hochbaum [62] proposed a fully polynomial-time approximation scheme for SC/NLP/D (see Sect. 8.3). However, there are only a few results in this research direction so far. From this viewpoint, an interesting (possibly NP-hard) problem is the maximization of a separable convex quadratic function under submodular constraints considered in Goemans et al. [52], where they devise a $1/O(\log n)$ -approximation algorithm. This problem arises as a subproblem for the approximation of a monotone submodular function, and an approximation algorithm for the subproblem with a better approximation ratio would provide a better approximation of a monotone submodular function.

Abstract

This chapter discusses rollout algorithms, a sequential approach to optimization problems, whereby the optimization variables are optimized one after the other. A rollout algorithm starts from some given heuristic and constructs another heuristic with better performance than the original. The method is particularly simple to implement and is often surprisingly effective. This chapter explains the method and its properties for discrete deterministic optimization problems.

1 Introduction

Rollout is a form of sequential optimization that originated in dynamic programming (DP for short). It may be viewed as a single iteration of the fundamental method of policy iteration. The starting point is a given policy (called the base policy), whose performance is evaluated in some way, possibly by simulation. Based on the evaluation, an improved policy is obtained by one-step lookahead. When the problem is discrete and deterministic, as will be assumed in this chapter, the

D.P. Bertsekas (✉)

e-mail: dimitrib@mit.edu

method is very simple to implement: the base policy is just some heuristic, and the rollout policy consists of repeated application of this heuristic. The rollout policy is guaranteed to improve the performance of the base policy, often very substantially in practice. In this chapter, rather than using the dynamic programming formalism, the method is explained starting from first principles.

Consider the minimization of a function

$$g(x_1, \dots, x_N)$$

of the discrete variables x_1, \dots, x_N , assumed to take values in some finite set. This can be done (at least conceptually) by minimizing over x_1 the result of minimization of g over the remaining variables x_2, \dots, x_N , with x_1 held fixed, that is, finding

$$x_1^* \in \arg \min_{x_1} J_1(x_1)$$

where the function J_1 is defined by

$$J_1(x_1) = \min_{x_2, \dots, x_N} g(x_1, x_2, \dots, x_N).$$

Leaving aside for the moment the difficulty of calculating $J_1(x_1)$, given the optimal value x_1^* , the optimal value of x_2 can be found by the minimization

$$x_2^* \in \arg \min_{x_2} J_2(x_1^*, x_2),$$

where the function J_2 is defined by

$$J_2(x_1, x_2) = \min_{x_3, \dots, x_N} g(x_1, x_2, x_3, \dots, x_N).$$

Similarly, for every $k = 1, \dots, n$, given the optimal values x_1^*, \dots, x_{k-1}^* , the optimal value of x_k can be found by the minimization

$$x_k^* \in \arg \min_{x_k} J_k(x_1^*, \dots, x_{k-1}^*, x_k), \quad k = 1, \dots, N, \quad (1)$$

where the function J_k is defined by

$$J_k(x_1, \dots, x_k) = \min_{x_{k+1}, \dots, x_N} g(x_1, \dots, x_k, x_{k+1}, \dots, x_N). \quad (2)$$

This is a calculation that is typical of DP, where the functions J_k are called the *optimal cost-to-go functions*, and are defined by the recursion

$$J_k(x_1, \dots, x_k) = \min_{x_{k+1}} J_{k+1}(x_1, \dots, x_k, x_{k+1}),$$

starting from the boundary condition

$$J_N(x_1, \dots, x_N) = g(x_1, \dots, x_N).$$

[The validity of this recursion can be seen from the definition of J_k .]

Unfortunately, there is a serious difficulty with the preceding approach: calculating numerically and storing the functions J_k in tables is impossible in practice (except for very special problems; if each of the variables x_1, \dots, x_k may take m distinct values, the storage of J_k requires a table of size m^k). In DP this is known as *the curse of dimensionality*.

In the rollout approach, J_k is *approximated* by a function that is more easily calculated and does not require excessive storage. In particular, for any given x_1, \dots, x_k , an easily implementable heuristic (called *base heuristic*) is used to approximate the minimization (2). If $H_k(x_1, \dots, x_k)$ denotes the corresponding approximately optimal value, the *rollout algorithm* obtains a suboptimal solution by replacing J_k with H_k in Eq. (1):

$$x_k \in \arg \min_{x_k} H_k(\tilde{x}_1, \dots, \tilde{x}_{k-1}, x_k), \quad k = 1, \dots, N.$$

These minimizations are carried out in sequence, first obtaining $\tilde{x}_1 \in \arg \min_{x_1} H_1(x_1)$, then obtaining $\tilde{x}_2 \in \arg \min_{x_2} H_2(\tilde{x}_1, x_2)$, and proceeding with $\tilde{x}_3, \dots, \tilde{x}_N$ in that order.

With some analysis and algorithmic refinement, it can be shown that rollout results in no performance deterioration over just applying the base heuristic once to the original problem. Most importantly, experimentation has shown that rollout typically results in significant and often dramatic improvement over the common approach of just applying the base heuristic. This improvement comes at the expense of a substantial but often tractable (polynomial) increase in computational requirements. The following example provides some insight into the nature of cost improvement.

Example 1 (The Breakthrough Problem) Consider a binary tree with N stages as shown in Fig. 1. Stage k of the tree has 2^k nodes. There are two types of tree arcs: *free* and *blocked*. A free (or blocked) arc can (cannot, respectively) be traversed in the direction from the root to the leaves. The objective is to break through the graph with a sequence of free arcs (a free path) starting from the root and ending at one of the leaves.

One may use a DP-like algorithm to discover a free path (if one exists) by starting from the last stage and by proceeding backward to the root node. The k th step of the algorithm determines for each node of stage $N - k$ whether there is a free path from that node to some leaf node, by using the results of the preceding step. The amount of calculation at the k th step is $O(2^{N-k})$. Adding the calculations for the N stages, it can be seen that the total amount of calculation is $O(N2^N)$, so it increases exponentially with the number of stages.

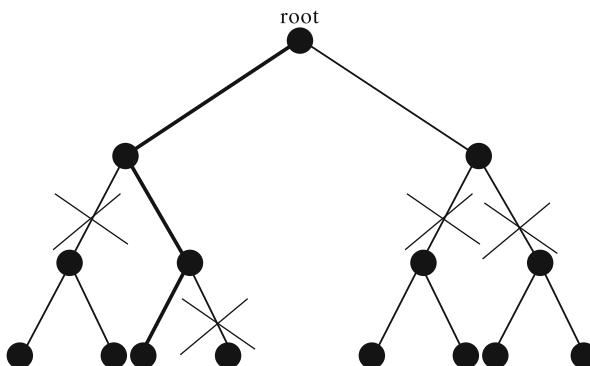

Fig. 1 Binary tree with N stages for the breakthrough problem. Each arc is either free or is blocked (crossed out in the figure). The problem is to find a path from the root to one of the leaves, which is free (such as the one shown with *thick lines*)

As an alternative, one may suboptimally use a *greedy* algorithm, which starts at the root node, selects a free outgoing arc (if one is available), and tries to construct a free path by adding successively nodes to the path. Generally, at the current node, if one of the outgoing arcs is free and the other is blocked, the greedy algorithm selects the free arc. Otherwise, it selects one of the two outgoing arcs according to some fixed rule that depends only on the current node (and not on the status of other arcs). Clearly, the greedy algorithm may fail to find a free path even if such a path exists, as can be seen from Fig. 1 (e.g., if the choice at the root node is the right-hand side arc). On the other hand the amount of computation associated with the greedy algorithm is $O(N)$, which is much faster than the $O(N2^N)$ computation of the optimal algorithm. Thus, one may view the greedy algorithm as a fast heuristic, which is suboptimal in the sense that there are problem instances where it fails while the DP algorithm succeeds.

Consider also the rollout algorithm that uses the greedy algorithm as the base heuristic. This algorithm starts at the root and tries to construct a free path by exploring alternative paths constructed by the greedy algorithm. At the current node, it proceeds according to the following two cases:

- (a) If at least one of the two outgoing arcs of the current node is blocked, the rollout algorithm adds to the current path the arc that the greedy algorithm would select at the current node.
 - (b) If both outgoing arcs of the current node are free, the rollout algorithm considers the two end nodes of these arcs, and from each of them it runs the greedy algorithm. If the greedy algorithm succeeds in finding a free path that starts from at least one of these nodes, the rollout algorithm stops with a free path having been found; otherwise, the rollout algorithm moves to the node that the greedy algorithm would select at the current node.

Thus, when both outgoing arcs are free, the rollout algorithm explores further the suitability of these arcs, as in case (b) above. Because of this additional

discriminatory capability, the rollout algorithm always does at least as well as the greedy (it always finds a free path when the greedy algorithm does, and it also finds a free path in some cases where the greedy algorithm does not). This is consistent with our earlier discussion of the generic cost improvement property of the rollout algorithm over the base heuristic. On the other hand, the rollout algorithm applies the greedy heuristic as many as $2N$ times, so that it requires $O(N^2)$ amount of computation – this is intermediate between the $O(N)$ computation of the greedy and the $O(N2^N)$ computation of the DP algorithm.

The greedy and the rollout algorithms may be evaluated by calculating the probabilities that they will find a free path given a randomly chosen breakthrough problem. In particular, the graph of the problem may be generated randomly, by selecting each of its arcs to be free with probability p , independently of the other arcs. If the corresponding probabilities of success for the greedy and the rollout algorithms are calculated, it follows that the rollout algorithm has an $O(N)$ times larger probability of finding a free path than the greedy algorithm, while requiring $O(N)$ times more computation (see [3], Example 6.4.2). This type of tradeoff is qualitatively typical: the rollout algorithm achieves a substantial performance improvement over the base heuristic at the expense of extra computation that is equal to the computation time of the base heuristic times a factor that is a low order polynomial of the problem size.

2 The Basic Rollout Algorithm for Discrete Optimization

The rollout algorithm will now be formalized by introducing a graph search problem that can serve as a general model for discrete optimization. A graph is given that has a finite set of nodes \mathcal{N} , a finite set of arcs \mathcal{A} , and a special node s , called the *origin*. The arcs are directed in the sense that arc (i, j) is distinct from arc (j, i) . A subset $\bar{\mathcal{N}}$ of nodes is also given, called *destinations* and a cost $g(i)$ for each destination i . The destination nodes are terminal in the sense that they have no outgoing arcs. The problem is to find a path that starts at the origin s , ends at one of the destination nodes $i \in \bar{\mathcal{N}}$, and is such that the cost $g(i)$ is minimized.

In our terminology, a path is a sequence of arcs

$$(i_1, i_2), (i_2, i_3), \dots, (i_{m-1}, i_m),$$

all of which are oriented in the forward direction. The nodes i_1 and i_m are called the *start node* and the *end node* of the path, respectively. For convenience, and without loss of generality,¹ it will be assumed that given an ordered pair of nodes (i, j) , there is at most one arc with start node i and end node j , which (if it exists) will be

¹In the case where there are multiple arcs connecting a node pair, all these arcs can be merged to a single arc, since the set of destination nodes that can be reached from any non-destination node will not be affected.

denoted by (i, j) . In this way, a path consisting of arcs $(i_1, i_2), (i_2, i_3), \dots, (i_{m-1}, i_m)$ is unambiguously specified as the sequence of nodes (i_1, i_2, \dots, i_m) .

Let us assume the availability of a heuristic path construction algorithm, denoted \mathcal{H} , which given a non-destination node $i \notin \bar{\mathcal{N}}$, constructs a path $(i, i_1, \dots, i_m, \bar{i})$ starting at i and ending at one of the destination nodes \bar{i} . Implicit in this assumption is that for every non-destination node, there exists at least one path starting at that node and ending at some destination node. The algorithm \mathcal{H} is referred to as the *base heuristic* and will be used as the basic building block for constructing the rollout algorithm to be introduced shortly.

The end node \bar{i} of the path constructed by the base heuristic \mathcal{H} is completely specified by the start node i . The node \bar{i} is called the *projection of i under \mathcal{H}* and is denoted by $p(i)$. The corresponding cost is denoted by $H(i)$,

$$H(i) = g(p(i)).$$

The projection of a destination node is the node itself by convention, so that $i = p(i)$ and $H(i) = g(i)$ for all $i \in \bar{\mathcal{N}}$. Note that while the base heuristic \mathcal{H} will generally yield a suboptimal solution, the path that it constructs may involve a fairly sophisticated suboptimization. For example, \mathcal{H} may construct several paths ending at destination nodes according to some heuristics and then select the path that yields minimal cost.

One possibility for suboptimal solution of the problem is to start at the origin s and use the base heuristic \mathcal{H} to obtain the projection $p(s)$. It is instead proposed to use \mathcal{H} to construct a path to a destination node sequentially. At the typical step, a path that starts at s and ends at a node i is available, the base heuristic \mathcal{H} is run starting from each of the downstream neighbors j of i , and the corresponding projections and costs are obtained. The neighbor that gives the best projection is chosen as the next node in the current path. This sequential version of \mathcal{H} is called the *rollout algorithm based on \mathcal{H}* and is denoted by \mathcal{RH} .

Formally, let $N(i)$ denote the set of downstream neighbors of a non-destination node i ,

$$N(i) = \{j \mid (i, j) \text{ is an arc}\}.$$

The rollout algorithm \mathcal{RH} starts with the origin node s . At the typical step, given a node sequence (s, i_1, \dots, i_m) , where i_m is not a destination, \mathcal{RH} adds to the sequence a node i_{m+1} such that

$$i_{m+1} \in \arg \min_{j \in N(i_m)} H(j). \quad (3)$$

If i_{m+1} is a destination node, \mathcal{RH} terminates. Otherwise, the process is repeated with the sequence $(s, i_1, \dots, i_m, i_{m+1})$ replacing (s, i_1, \dots, i_m) ; see Fig. 2.

Once \mathcal{RH} has terminated with a path (s, i_1, \dots, i_m) , the projection $p(i_k)$ of each of the nodes i_k , $k = 1, \dots, m$, will have been obtained. The best of these projections yields a cost

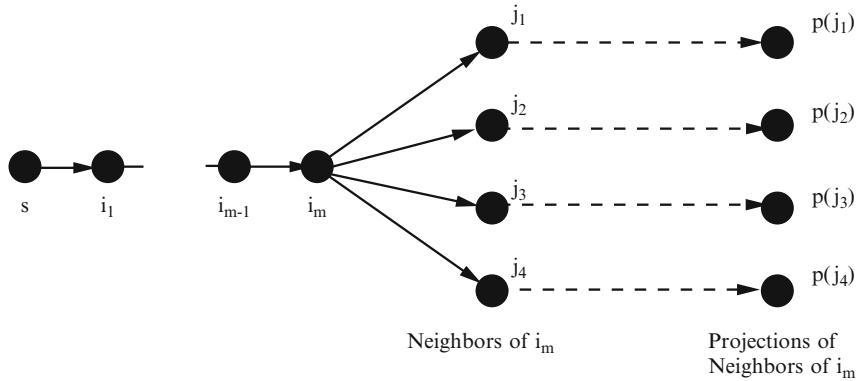

Fig. 2 Illustration of the rollout algorithm. After m steps, the algorithm has constructed the path (s, i_1, \dots, i_m) . To extend this path at the next step, the set $N(i_m)$ of neighbors of the terminal node i_m is generated, and the neighbor that has the best projection is selected from this set, that is, $i_{m+1} \in \arg \min_{j \in N(i_m)} H(j) \in \arg \min_{j \in N(i_m)} g(p(j))$

$$\min_{k=1,\dots,m} H(i_k) = \min_{k=1,\dots,m} g(p(i_k)),$$

and the projection that corresponds to the minimum above may be taken as the final (suboptimal) solution produced by the rollout algorithm. The above minimal cost may also be compared with the cost $g(p(s))$ of the projection $p(s)$ of the origin, so that $p(s)$ is used as the final solution if it produces a smaller cost. This will ensure that the rollout algorithm will produce a solution that is no worse than the one produced by the base heuristic. Note that while the best neighbor of i_m is i_{m+1} according to Eq. (3), it does not necessarily follow that i_{m+1} has a better projection than i_m under \mathcal{H} , that is, that

$$H(i_{m+1}) \leq H(i_m). \quad (4)$$

The reason is that if the path constructed by \mathcal{H} starting from i_m is $(i_m, j_1, \dots, j_k, \bar{i})$, it is not necessarily true that the path constructed by \mathcal{H} starting from j_1 is $(j_1, \dots, j_k, \bar{i})$. If this were so, then Eq. (4) would hold, since i_{m+1} would have no worse projection than j_1 according to Eq. (3). This argument will be the basis for further analysis to be given later (see Proposition 1).

Example 2 (Traveling Salesman Problem) Let us consider the traveling salesman problem, whereby a salesman wants to find a minimum mileage/cost tour that visits each of N given cities exactly once and returns to the city he started from. With each city $i = 1, \dots, N$, a node is associated and an arc (i, j) with traversal cost a_{ij} is introduced for each ordered pair of nodes i and j . Note that the graph is assumed complete; that is, there exists an arc for each ordered pair of nodes. There is no loss of generality in doing so because a very high cost a_{ij} can be assigned to an arc

(i, j) that is precluded from participation in the solution. The problem is to find a cycle that goes through all the nodes exactly once and whose sum of arc costs is minimum.

There are many heuristic approaches for solving the traveling salesman problem. For illustration purposes, consider a simple *nearest neighbor* heuristic. It starts from a path consisting of just a single node i_1 , and at each iteration, it enlarges the path with a node that does not close a cycle and minimizes the cost of the enlargement. In particular, after k iterations, a path $\{i_1, \dots, i_k\}$ consisting of distinct nodes has been constructed, and at the next iteration, an arc (i_k, i_{k+1}) that minimizes $a_{i_k i}$ over all arcs (i_k, i) with $i \neq i_1, \dots, i_k$, is added. After $N - 1$ iterations, all nodes are included in the path, which is then converted to a tour by adding the final arc (i_N, i_1) .

The traveling salesman problem can be formulated as a graph search problem as follows: A starting city, say i_1 , is chosen corresponding to the origin of the graph search problem. Each node of the graph search problem corresponds to a path (i_1, i_2, \dots, i_k) , where i_1, i_2, \dots, i_k are distinct cities. The neighbor nodes of the path (i_1, i_2, \dots, i_k) are paths of the form $(i_1, i_2, \dots, i_k, i_{k+1})$ that correspond to adding one more unvisited city $i_{k+1} \neq i_1, i_2, \dots, i_k$ at the end of the path. The destinations are the cycles of the form (i_1, i_2, \dots, i_N) , and the cost of a destination in the graph search problem is the cost of the corresponding cycle. Thus, a path from the origin to a destination in the graph search problem corresponds to constructing a cycle in $N - 1$ arc addition steps and at the end incurring the cost of the cycle.

Let us now use as base heuristic the nearest neighbor method. The corresponding rollout algorithm operates as follows: After k iterations, a path $\{i_1, \dots, i_k\}$ consisting of distinct nodes has been constructed. At the next iteration, the nearest neighbor heuristic is run starting from each of the paths of the form $\{i_1, \dots, i_k, i\}$ where $i \neq i_1, \dots, i_k$, and a corresponding cycle is obtained. The node i_{k+1} of the path is selected to be the node i that corresponds to the best cycle thus obtained.

2.1 Termination and Sequential Consistency

The rollout algorithm \mathcal{RH} is said to be *terminating* if it is guaranteed to terminate finitely starting from any node. Contrary to the base heuristic \mathcal{H} , which by definition, has the property that it yields a path terminating at a destination starting from any node, the rollout algorithm \mathcal{RH} need not have this property in the absence of additional conditions. The termination question can usually be resolved quite easily, and a few different methods by which this can be done will now be discussed.

One important case where \mathcal{RH} is terminating is when the graph is acyclic, since then the nodes of the path generated by \mathcal{RH} cannot be repeated within the path, and their number is bounded by the number of nodes in \mathcal{N} . As a first step toward developing another case where \mathcal{RH} is terminating, consider the following definition, which will also set the stage for further analysis of the properties of \mathcal{RH} .

Definition 1 The base heuristic \mathcal{H} is said to be *sequentially consistent* if for every node i , it has the following property: If \mathcal{H} generates the path $(i, i_1, \dots, i_m, \bar{i})$ when it starts at i , it generates the path $(i_1, \dots, i_m, \bar{i})$ when it starts at the node i_1 .

Thus, \mathcal{H} is sequentially consistent if all the nodes of a path that it generates have the same projection. There are many examples of sequentially consistent algorithms that are used as heuristics in combinatorial optimization, including the following.

Example 3 (Greedy Algorithms as Base Heuristics) Consider a function F , which for each node i , provides a scalar estimate $F(i)$ of the optimal cost starting from i , that is, the minimal cost $g(\bar{i})$, that can be obtained with a path that starts at i and ends at one of the destination nodes $\bar{i} \in \bar{\mathcal{N}}$. Then, F can be used to define a base heuristic, called the *greedy algorithm with respect to F* , as follows:

The greedy algorithm starts at a node i with the (degenerate) path that consists of just node i . At the typical step, given a path (i, i_1, \dots, i_m) , where i_m is not a destination, the algorithm adds to the path a node i_{m+1} such that

$$i_{m+1} \in \arg \min_{j \in N(i_m)} F(j). \quad (5)$$

If i_{m+1} is a destination, the algorithm terminates with the path $(i, i_1, \dots, i_m, i_{m+1})$. Otherwise, the process is repeated with the path $(i, i_1, \dots, i_m, i_{m+1})$ replacing (i, i_1, \dots, i_m) .

An example of a greedy algorithm is the nearest neighbor heuristic for the traveling salesman problem (cf. [Example 2](#)). Recall from that example that nodes of the graph search problem correspond to paths (sequences of distinct cities), and a transition to a neighbor node corresponds to adding one more unvisited city to the end of the current path. The function F in the nearest neighbor heuristic specifies the cost of the addition of the new city.

It is also interesting to note that by viewing F as a cost-to-go approximation, the greedy algorithm may be considered to be a special type of one-step lookahead policy. Furthermore, if $F(j)$ is chosen to be the cost obtained by some base heuristic starting from j , then the greedy algorithm becomes the corresponding rollout algorithm. Thus, it may be said that the rollout algorithm is a special case of a greedy algorithm. However, the particular choice of F used in the rollout algorithm is responsible for special properties that are not shared by other types of greedy algorithms.

Let us denote by \mathcal{H} the greedy algorithm described above and assume that it terminates starting from every node (this has to be verified independently). Let us also assume that whenever there is a tie in the minimization of Eq. (5), \mathcal{H} resolves the tie in a manner that is fixed and independent of the starting node i of the path, for example, by resolving the tie in favor of the numerically smallest node j that attains the minimum in Eq. (5). Then, it can be seen that \mathcal{H} is sequentially consistent, since by construction, every node on a path generated by \mathcal{H} has the same projection.

For a sequentially consistent base heuristic \mathcal{H} , a restriction will be imposed in the way the rollout algorithm \mathcal{RH} resolves ties in selecting the next node on its path; this restriction will guarantee that \mathcal{RH} is terminating. In particular, suppose that after m steps, \mathcal{RH} has produced the node sequence (s, i_1, \dots, i_m) , and that the path generated by \mathcal{H} starting from i_m is $(i_m, i_{m+1}, i_{m+2}, \dots, \bar{i})$. Suppose that among the neighbor set $N(i_m)$, the node i_{m+1} attains the minimum in the selection test

$$\min_{j \in N(i_m)} H(j), \quad (6)$$

but there are also some other nodes, in addition to i_{m+1} , that attain this minimum. Then, the tie is broken in favor of i_{m+1} , that is, the next node added to the current sequence (s, i_1, \dots, i_m) is i_{m+1} . Under this convention for tie-breaking, the following proposition shows that the rollout algorithm \mathcal{RH} terminates at a destination and yields a cost that is no larger than the cost yielded by the base heuristic \mathcal{H} .²

Proposition 1 *Let the base heuristic \mathcal{H} be sequentially consistent. Then, the rollout algorithm \mathcal{RH} is terminating. Furthermore, if $(i_1, \dots, i_{\tilde{m}})$ is the path generated by \mathcal{RH} starting from a non-destination node i_1 and ending at a destination node $i_{\tilde{m}}$, the cost of \mathcal{RH} starting from i_1 is less or equal to the cost of \mathcal{H} starting from i_1 . In particular,*

$$H(i_1) \geq H(i_2) \geq \dots \geq H(i_{\tilde{m}-1}) \geq H(i_{\tilde{m}}). \quad (7)$$

Furthermore, for all $m = 1, \dots, \tilde{m}$,

$$H(i_m) = \min \left\{ H(i_1), \min_{j \in N(i_1)} H(j), \dots, \min_{j \in N(i_{m-1})} H(j) \right\}. \quad (8)$$

Proof Let i_m and i_{m+1} be two successive nodes generated by \mathcal{RH} , and let $(i_m, i'_{m+1}, i'_{m+2}, \dots, \bar{i}_m)$ be the path generated by \mathcal{H} starting from i_m , where \bar{i}_m is the projection of i_m . Then, since \mathcal{H} is sequentially consistent,

$$H(i_m) = H(i'_{m+1}) = g(\bar{i}_m).$$

Furthermore, since $i'_{m+1} \in N(i_m)$, using the definition of \mathcal{RH} [cf. Eq. (3)],

²For an example where this convention for tie-breaking is not observed and as a consequence \mathcal{RH} does not terminate, assume that there is a single destination d and that all other nodes are arranged in a cycle. Each non-destination node i has two outgoing arcs: one arc that belongs to the cycle and another arc which is (i, d) . Let \mathcal{H} be the (sequentially consistent) base heuristic that, starting from a node $i \neq d$, generates the path (i, d) . When the terminal node of the path is node i , the rollout algorithm \mathcal{RH} compares the two neighbors of i , which are d and the node next to i on the cycle, call it j . Both neighbors have d as their projection, so there is tie in Eq. (6). It can be seen that if \mathcal{RH} breaks ties in favor of the neighbor j that lies on the cycle, then \mathcal{RH} continually repeats the cycle and never terminates.

$$H(i'_{m+1}) \geq \min_{j \in N(i_m)} H(j) = H(i_{m+1}).$$

Combining the last two relations,

$$H(i_m) \geq H(i_{m+1}) = \min_{j \in N(i_m)} H(j). \quad (9)$$

To show that \mathcal{RH} is terminating, note that in view of Eq. (9), either $H(i_m) > H(i_{m+1})$ or else $H(i_m) = H(i_{m+1})$. In the latter case, in view of the convention for breaking ties that occur in Eq. (6) and the sequential consistency of \mathcal{H} , the path generated by \mathcal{H} starting from i_{m+1} is the tail portion of the path generated by \mathcal{H} starting from i_m and has one arc less. Thus, the number of nodes generated by \mathcal{RH} between successive times that the inequality $H(i_m) > H(i_{m+1})$ holds is finite. On the other hand, the inequality $H(i_m) > H(i_{m+1})$ can occur only a finite number of times, since the number of destination nodes is finite, and the destination node of the path generated by \mathcal{H} starting from i_m cannot be repeated if the inequality $H(i_m) > H(i_{m+1})$ holds. Therefore, \mathcal{RH} is terminating.

Finally, if $(i_1, \dots, i_{\tilde{m}})$ is the path generated by \mathcal{RH} , the relation (9) implies the desired relations (7) and (8). **Q. E. D.**

Proposition 1 shows that in the sequentially consistent case, the rollout algorithm \mathcal{RH} has an important “automatic cost sorting” property, whereby it follows the best path generated by the base heuristic \mathcal{H} . In particular, when \mathcal{RH} generates a path $(i_1, \dots, i_{\tilde{m}})$, it does so by using \mathcal{H} to generate a collection of other paths and corresponding projections starting from all the successor nodes of the intermediate nodes $i_1, \dots, i_{\tilde{m}-1}$. However, $(i_1, \dots, i_{\tilde{m}})$ is guaranteed to be the best among this path collection, and $i_{\tilde{m}}$ has minimal cost among all generated projections [cf. Eq. (8)]. Of course, this does not guarantee that the path generated by \mathcal{RH} will be a near-optimal path, because the collection of paths generated by \mathcal{H} may be “poor.” Still, the property whereby \mathcal{RH} at all times follows the best path found so far is intuitively reassuring.

The following example illustrates the preceding concepts.

Example 4 (One-Dimensional Walk) Consider a person who walks on a straight line and at each time period takes either a unit step to the left or a unit step to the right. There is a cost function assigning cost $g(i)$ to each integer i . Given an integer starting point on the line, the person wants to minimize the cost of the point where he will end up after a given and fixed number N of steps.

This problem can be formulated as a graph search problem of the type discussed in the preceding section. In particular, without loss of generality, assume that the starting point is the origin, so that the person’s position after n steps will be some integer in the interval $[-n, n]$. The nodes of the graph are identified with pairs (k, m) , where k is the number of steps taken so far ($k = 1, \dots, N$) and m is the person’s position ($m \in [-k, k]$). A node (k, m) with $k < N$ has two outgoing arcs

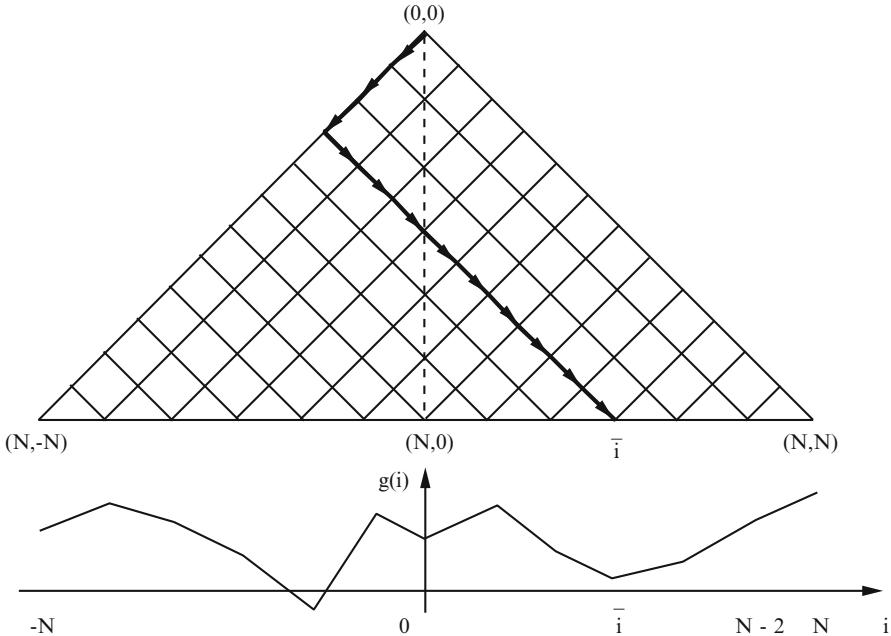

Fig. 3 Illustration of the path generated by the rollout algorithm \mathcal{RH} in [Example 4](#). The algorithm keeps moving to the *left* up to the time where the base heuristic \mathcal{H} generates two destinations (N, \bar{i}) and $(N, \bar{i} - 2)$ with $g(\bar{i}) \leq g(\bar{i} - 2)$. Then it continues to move to the *right* ending at the destination (N, \bar{i}) , which corresponds to the local minimum closest to N

with end nodes $(k+1, m-1)$ (corresponding to a left step) and $(k+1, m+1)$ (corresponding to a right step). The starting state is $(0, 0)$ and the terminating states are of the form (N, m) , where m is of the form $N-2l$ and $l \in [0, N]$ is the number of left steps taken.

Let the base heuristic \mathcal{H} be defined as the algorithm, which, starting at a node (k, m) , takes $N-k$ successive steps to the right and terminates at the node $(N, m+N-k)$. Note that \mathcal{H} is sequentially consistent. The rollout algorithm \mathcal{RH} , at node (k, m) , compares the cost of the destination node $(N, m+N-k)$ (corresponding to taking a step to the right and then following \mathcal{H}) and the cost of the destination node $(N, m+N-k-2)$ (corresponding to taking a step to the left and then following \mathcal{H}).

Let us say that an integer $i \in [-N+2, N-2]$ is a *local minimum* if $g(i-2) \geq g(i)$ and $g(i) \leq g(i+2)$. Let us also say that N (or $-N$) is a local minimum if $g(N-2) \leq g(N)$ [or $g(-N) \leq g(-N+2)$, respectively]. Then, it can be seen that starting from the origin $(0, 0)$, \mathcal{RH} obtains the local minimum that is closest to N (see [Fig. 3](#)). This is no worse (and typically better) than the integer N obtained by \mathcal{H} . This example illustrates how \mathcal{RH} may exhibit “intelligence” that is totally lacking from \mathcal{H} and is in agreement with the result of [Proposition 1](#).

2.1.1 Sequential Improvement

It is possible to show that the rollout algorithm improves on the base heuristic (cf. [Proposition 1](#)) under weaker conditions. To this end the following definition is introduced.

Definition 2 The base heuristic \mathcal{H} is said to be *sequentially improving* if for every non-destination node i ,

$$H(i) \geq \min_{j \in N(i)} H(j). \quad (10)$$

It can be seen that a sequentially consistent \mathcal{H} is also sequentially improving, since sequential consistency implies that $H(i)$ is equal to one of the values $H(j)$, $j \in N(i)$. The following proposition generalizes [Proposition 1](#).

Proposition 2 Let the base heuristic \mathcal{H} be sequentially improving and assume that the rollout algorithm \mathcal{RH} is terminating. Let $(i_1, \dots, i_{\tilde{m}})$ be the path generated by \mathcal{RH} starting from a non-destination node i_1 and ending at a destination node $i_{\tilde{m}}$. Then, the cost of \mathcal{RH} starting from i_1 is less or equal to the cost of \mathcal{H} starting from i_1 . In particular, for all $m = 1, \dots, \tilde{m}$,

$$H(i_m) = \min \left\{ H(i_1), \min_{j \in N(i_1)} H(j), \dots, \min_{j \in N(i_{m-1})} H(j) \right\}. \quad (11)$$

Proof For each $m = 1, \dots, \tilde{m} - 1$,

$$H(i_m) \geq \min_{j \in N(i_m)} H(j),$$

by the sequential improvement assumption, while

$$\min_{j \in N(i_m)} H(j) = H(i_{m+1}),$$

by the definition of the rollout algorithm. These two relations imply Eq. (11). Since the cost of \mathcal{RH} starting from i_1 is $H(i_{\tilde{m}})$, the result follows. **Q. E. D.**

Example 5 (One-Dimensional Walk: Continued) Consider the one-dimensional walk problem of [Example 4](#), and let \mathcal{H} be defined as the algorithm that, starting at a node (k, m) , compares the cost $g(m + N - k)$ (corresponding to taking all of the remaining $N - k$ steps to the right) and the cost $g(m - N + k)$ (corresponding to taking all of the remaining $N - k$ steps to the left) and accordingly moves to node

$$(N, m + N - k) \quad \text{if} \quad g(m + N - k) \leq g(m - N + k),$$

or to node

$$(N, m - N + k) \quad \text{if} \quad g(m - N + k) < g(m + N - k).$$

It can be seen that \mathcal{H} is not sequentially consistent, but is instead sequentially improving. Using Eq. (11), it follows that starting from the origin $(0, 0)$, \mathcal{RH} obtains the global minimum of g in the interval $[-N, N]$, while \mathcal{H} obtains the better of the two points $-N$ and N .

Proposition 2 actually follows from a general equation for the cost of the path generated by the rollout algorithm, which holds for any base heuristic (not necessarily one that is sequentially improving). This is given in the following proposition.

Proposition 3 Assume that the rollout algorithm \mathcal{RH} is terminating. Let $(i_1, \dots, i_{\tilde{m}})$ be the path generated by \mathcal{RH} starting from a non-destination node i_1 and ending at a destination node $i_{\tilde{m}}$. Then, the cost of \mathcal{RH} starting from i_1 is equal to

$$H(i_1) + \delta_{i_1} + \dots + \delta_{i_{\tilde{m}-1}},$$

where for every non-destination node i ,

$$\delta_i = \min_{j \in N(i)} H(j) - H(i).$$

Proof By the definition of the rollout algorithm

$$H(i_m) + \delta_{i_m} = \min_{j \in N(i_m)} H(j) = H(i_{m+1}), \quad m = 1, \dots, \tilde{m} - 1.$$

By adding these equations over m ,

$$H(i_1) + \delta_{i_1} + \dots + \delta_{i_{\tilde{m}-1}} = H(i_{\tilde{m}}).$$

Since the cost of \mathcal{RH} starting from i_1 is $H(i_{\tilde{m}})$, the result follows. **Q. E. D.**

If the base heuristic is sequentially improving, there holds $\delta_i \leq 0$ for all non-destination nodes i , so it follows from **Proposition 3** that the cost of the rollout algorithm is less or equal to the cost of the base heuristic (cf. **Proposition 2**).

2.1.2 The Fortified Rollout Algorithm

A variant of the rollout algorithm will now be described, which implicitly uses a sequentially improving base heuristic, so that it has the cost improvement property of **Proposition 2**. This variant, called the *fortified rollout algorithm*, and denoted by \mathcal{RH} , starts at the origin s , and after m steps, maintains, in addition to the current sequence of nodes (s, i_1, \dots, i_m) , a path

$$P(i_m) = (i_m, i'_{m+1}, \dots, i'_k),$$

ending at a destination i'_k . Roughly speaking, the path $P(i_m)$ is the tail portion of the best path found after the first m steps of the algorithm, in the sense that the destination i'_k has minimal cost over all the projections of nodes calculated thus far.

In particular, initially $P(s)$ is the path generated by the base heuristic \mathcal{H} starting from s . At the typical step of the fortified rollout algorithm \mathcal{RH} , a node sequence (s, i_1, \dots, i_m) has been constructed and the path $P(i_m) = (i_m, i'_{m+1}, \dots, i'_k)$ is available, where i_m is not a destination. Then, if

$$\min_{j \in N(i_m)} H(j) < g(i'_k), \quad (12)$$

\mathcal{RH} adds to the node sequence (s, i_1, \dots, i_m) the node

$$i_{m+1} \in \arg \min_{j \in N(i_m)} H(j)$$

and sets $P(i_{m+1})$ to the path generated by \mathcal{H} , starting from i_{m+1} . On the other hand, if

$$\min_{j \in N(i_m)} H(j) \geq g(i'_k), \quad (13)$$

\mathcal{RH} adds to the node sequence (s, i_1, \dots, i_m) the node

$$i_{m+1} = i'_{m+1}$$

and sets $P(i_{m+1})$ to the path $(i_{m+1}, i'_{m+2}, \dots, i'_k)$. If i_{m+1} is a destination, \mathcal{RH} terminates, and otherwise, \mathcal{RH} repeats the process with (s, i_1, \dots, i_{m+1}) replacing (s, i_1, \dots, i_m) and $P(i_{m+1})$ replacing $P(i_m)$, respectively.

The idea behind the construction of \mathcal{RH} is to follow the path $P(i_m)$ unless a path of lower cost is discovered through Eq. (12). It can be shown that \mathcal{RH} may be viewed as the rollout algorithm \mathcal{RH} corresponding to a modified version of \mathcal{H} , called *fortified* \mathcal{H} , and denoted $\bar{\mathcal{H}}$. This algorithm is applied to a slightly modified version of the original problem, which involves an additional downstream neighbor for each node i_m that is generated in the course of the algorithm \mathcal{RH} and for which the condition (13) holds. For every such node i_m , the additional neighbor is a copy of i'_{m+1} , and the path generated by $\bar{\mathcal{H}}$ starting from this copy is (i'_{m+1}, \dots, i'_k) . From every other node, the path generated by $\bar{\mathcal{H}}$ is the same as the path generated by \mathcal{H} .

It can be seen that $\bar{\mathcal{H}}$ is sequentially improving, so that \mathcal{RH} is terminating and has the automatic cost sorting property of [Proposition 2](#); that is,

$$H(i_m) = \min \left\{ H(i_1), \min_{j \in N(i_1)} H(j), \dots, \min_{j \in N(i_{m-1})} H(j) \right\}.$$

The above property can also be easily verified directly, using the definition of \mathcal{RH} . Finally, it can be seen that when \mathcal{H} is sequentially consistent, the rollout algorithm \mathcal{RH} and its fortified version \mathcal{RH} coincide.

2.1.3 Using Multiple Base Heuristics: Parallel Rollout

In many problems, several promising path construction heuristics may be available. It is then possible to use all of these heuristics in parallel within the rollout framework, essentially by combining them into a single “superheuristic.” In particular, let us assume that K algorithms $\mathcal{H}_1, \dots, \mathcal{H}_K$ are available. The k th of these algorithms, given a non-destination node i , produces a path $(i, i_1, \dots, i_m, \bar{i})$ that ends at a destination node \bar{i} , and the corresponding cost is denoted by $H_k(i) = g(\bar{i})$. The K algorithms can be incorporated in a generalized version of the rollout algorithm, which uses the minimal cost

$$H(i) = \min_{k=1, \dots, K} H_k(i), \quad (14)$$

in place of the cost obtained by any one of the K algorithms $\mathcal{H}_1, \dots, \mathcal{H}_K$.

In particular, the algorithm starts with the origin node s . At the typical step, given a node sequence (s, i_1, \dots, i_m) , where i_m is not a destination, the algorithm adds to the sequence a node i_{m+1} such that

$$i_{m+1} \in \arg \min_{j \in N(i_m)} H(j).$$

If i_{m+1} is a destination node, the algorithm terminates, and otherwise, the process is repeated with the sequence $(s, i_1, \dots, i_m, i_{m+1})$ replacing (s, i_1, \dots, i_m) .

An interesting property, which can be readily verified by using the definitions, is that if all the algorithms $\mathcal{H}_1, \dots, \mathcal{H}_K$ are sequentially improving, the same is true for \mathcal{H} . This is evident from the fact that the heuristics run in parallel from a given node may be viewed as a single heuristic, which has the cost improvement property of [Definition 2](#). The fortified version of the rollout algorithm \mathcal{RH} easily generalizes for the case of Eq. (14), by defining the path generated starting from a node i as the path generated by the path construction algorithm, which attains the minimum in Eq. (14).

In an alternative version of the rollout algorithm that uses multiple path construction heuristics, the results of the K algorithms $\mathcal{H}_1, \dots, \mathcal{H}_K$ are weighted with some fixed scalar weights r_k to compute $H(i)$ for use in Eq. (3):

$$H(i) = \sum_{k=1}^K r_k H_k(i). \quad (15)$$

The weights r_k may be adjusted by trial and error or more sophisticated techniques which may be found in the literature (see e.g., [6]).

2.1.4 Extension for Intermediate Arc Costs

Let us consider a variant of the graph search problem where in addition to the terminal cost $g(i)$, there is a cost $c(i, j)$ for a path to traverse an arc (i, j) . Within this context, the cost of a path (i_1, i_2, \dots, i_n) that starts at i_1 and ends at a destination node i_n is redefined to be

$$g(i_n) + \sum_{k=1}^{n-1} c(i_k, i_{k+1}). \quad (16)$$

Note that when the cost $g(i)$ is zero for all destination nodes i , this is the problem of finding a shortest path from the origin node s to one of the destination nodes, with $c(i, j)$ viewed as the length of arc (i, j) . However, here we are interested in problems where the number of nodes is very large, and the use of the shortest path algorithms is impractical.

One way to transform the problem with arc costs into one involving a terminal cost only is to redefine the graph of the problem so that nodes correspond to sequences of nodes in the original problem graph. Thus, having arrived at node i_k using path (i_1, \dots, i_k) , the choice of i_{k+1} as the next node is viewed as a transition from (i_1, \dots, i_k) to $(i_1, \dots, i_k, i_{k+1})$. Both nodes (i_1, \dots, i_k) and $(i_1, \dots, i_k, i_{k+1})$ are viewed as nodes of a redefined graph. Furthermore, in this redefined graph, a destination node has the form (i_1, i_2, \dots, i_n) , where i_n is a destination node of the original graph, and has a cost given by Eq. (16).

After the details are worked out, it can be seen that to recover our earlier algorithms and analysis, the cost of the heuristic algorithm \mathcal{H} needs to be modified as follows: If the path (i_1, \dots, i_n) is generated by \mathcal{H} starting at i_1 , then

$$H(i_1) = g(i_n) + \sum_{k=1}^{n-1} c(i_k, i_{k+1}).$$

Furthermore, the rollout algorithm \mathcal{RH} at node i_m selects as next node i_{m+1} the node

$$i_{m+1} \in \arg \min_{j \in N(i_m)} [c(i_m, j) + H(j)];$$

[cf. Eq. (3)]. The definition of a sequentially consistent algorithm remains unchanged. Furthermore, [Proposition 1](#) remains unchanged except that Eqs. (7) and (8) are modified to read

$$H(i_k) \geq c(i_k, i_{k+1}) + H(i_{k+1}) = \min_{j \in N(i_k)} [c(i_k, j) + H(j)], \quad k = 1, \dots, m-1.$$

A sequentially improving algorithm should now be characterized by the property

$$H(i_k) \geq c(i_k, i_{k+1}) + H(i_{k+1}),$$

where i_{k+1} is the next node on the path generated by \mathcal{H} starting from i_k . Furthermore, [Proposition 2](#) remains unchanged, except that Eq. (11) is modified to read

$$H(i_k) \geq \min_{j \in N(i_k)} [c(i_k, j) + H(j)], \quad k = 1, \dots, m-1.$$

Finally, the criterion $\min_{j \in N(i_m)} H(j) < g(i'_k)$ [cf. Eq. (12)] used in the fortified rollout algorithm, given the sequence (s, i_1, \dots, i_m) , where $i_m \notin \bar{\mathcal{N}}$, and the path $P(i_m) = (i_m, i'_{m+1}, \dots, i'_k)$, should be replaced by

$$\min_{j \in N(i_m)} [c(i_m, j) + H(j)] < g(i'_k) + c(i_m, i'_{m+1}) + \sum_{l=m+1}^{k-1} c(i'_l, i'_{l+1}).$$

2.1.5 Rollout Algorithms with Multistep Lookahead

It is possible to incorporate *multistep lookahead* into the rollout framework. To describe the case of 2-step lookahead, suppose that after m steps of the rollout algorithm, the current node sequence is (s, i_1, \dots, i_m) . Then, the set of all 2-step-ahead neighbors of i_m is considered, defined as

$$N_2(i_m) = \{j \in \mathcal{N} \mid j \in N(i_m) \text{ and } j \in \bar{\mathcal{N}}, \text{ or } j \in N(n) \text{ for some } n \in N(i_m)\}.$$

The base heuristic \mathcal{H} is then run starting from each $j \in N_2(i_m)$, and the node $\bar{j} \in N_2(i_m)$ that has projection of minimum cost is found. Let $i_{m+1} \in N(i_m)$ be the node next to i_m on the (one- or two-arc) path from i_m to \bar{j} . If i_{m+1} is a destination node, the algorithm terminates. Otherwise, the process is repeated with the sequence $(s, i_1, \dots, i_m, i_{m+1})$ replacing (s, i_1, \dots, i_m) .

Note that a fortified version of the rollout algorithm described above is possible along the lines described earlier. Also, it is possible to eliminate from the set $N_2(i_m)$ some of the 2-step neighbors of i_m that are judged less promising according to some heuristic criterion, in order to limit the number of applications of the base heuristic. This may be viewed as *selective depth lookahead*. Finally, the extension of the algorithm to look ahead more than two steps is straightforward: The 2-step-ahead neighbor set $N_2(i_m)$ is simply replaced with a suitably defined k -step-ahead neighbor set $N_k(i_m)$.

2.1.6 Interpretation in Terms of DP

Let us now reinterpret the graph-based rollout algorithm within the context of deterministic DP. The base heuristic will be viewed as a suboptimal policy, and the rollout algorithm will be viewed as a policy obtained by a process of policy improvement, provided the base heuristic is sequentially consistent.

To this end, the graph search problem is cast as a sequential decision problem, where each node corresponds to a state of a dynamic system. At each non-destination node/state i , a node j must be selected from the set of neighbors $N(i)$; then, if j is a destination, the process terminates with cost $g(j)$, and otherwise, the process is repeated with j becoming the new state. The DP algorithm calculates for every node i , the minimal cost that can be achieved starting from i , that is, the smallest value of $g(\bar{i})$ that can be obtained using paths that start from i and end at destination nodes \bar{i} . This value, denoted $J^*(i)$, is the optimal cost-to-go starting at node i . Once $J^*(i)$ is computed for all nodes i , an optimal path (i_1, i_2, \dots, i_m)

can be constructed starting from any initial node/state i_1 by successively generating nodes using the relation

$$i_{k+1} \in \arg \min_{j \in N(i_k)} J^*(j), \quad k = 1, \dots, m-1, \quad (17)$$

up to the point where a destination node i_m is encountered.³

A base heuristic \mathcal{H} defines a policy π , that is, an assignment of a successor node to any non-destination node. However, starting from a given node i , the cost of π need not be equal to $H(i)$ because if a path $(i_1, i_2, i_3, \dots, i_m)$ is generated by \mathcal{H} starting from node i_1 , it is not necessarily true that the path (i_2, i_3, \dots, i_m) is generated by the base heuristic starting from i_2 . Thus, the successor node chosen at node i_2 by policy π may be different than the one used in the calculation of $H(i_1)$. On the other hand, if \mathcal{H} is sequentially consistent, the cost of policy π starting from a node i is $H(i)$, since sequential consistency implies that the path that the base heuristic generates starting at the successor node is part of the path it generates at the predecessor node. It turns out that the cost improvement property of the rollout algorithm in the sequentially consistent case is a special case of a cost improvement property for rollout algorithms that holds for more general DP contexts, including stochastic ones.

Generally, in the DP context the rollout algorithm \mathcal{RH} is viewed as a one-step lookahead policy that uses $H(j)$ as a cost-to-go approximation from state j . In some cases, $H(j)$ is the cost of some policy (in the DP sense), such as when \mathcal{H} is sequentially consistent, as explained above. In general, however, this need not be so, in which case $H(j)$ can be viewed as a convenient cost-to-go approximation that is derived from the base heuristic. Still, the rollout algorithm \mathcal{RH} may improve on the cost of the base heuristic (e.g., when \mathcal{H} is sequentially improving, cf. [Proposition 2](#)).

3 Applications in Discrete Optimization

Finally, to provide some perspective on the rollout methodology, let us explore the connections with some important discrete optimization problems and methods. In particular, let us consider the generic discrete optimization problem of minimizing a cost function $g(x)$ over a finite set X of feasible solutions. This problem will be reformulated as a graph search problem. It may be noted that several reformulations are possible, and different choices of the underlying graph give rise to different rollout algorithms. Thus, it is important to select a reformulation that matches the type of rollout algorithm one wishes to develop. Some reformulations and corresponding rollout algorithms will be discussed in what follows, and these algorithms will be related to some general computational methods.

³It is assumed here that there are no termination/cycling difficulties of the type illustrated in the footnote following [Example 3](#).

Suppose that each solution x has N components; that is, it has the form $x = (x_1, \dots, x_N)$, where N is a positive integer. For example, in a 0-1 integer programming problem, each component x_k may correspond to a single variable that can take the values 0 or 1, or alternatively, it may correspond to a multidimensional vector involving several variables each taking the values 0 or 1. In a network optimization problem, each component x_k may correspond to a vector involving the flows of several arcs of the network. One way to reformulate the problem

$$\begin{aligned} & \text{minimize } g(x) \\ & \text{subject to } x \in X \end{aligned}$$

into the framework of the search problem is to introduce an acyclic graph involving an artificial origin node s and N subsets of nodes I_1, \dots, I_N . In particular, for each feasible solution $x \in X$ and each $k = 1, \dots, N$, the node set I_k contains a node $(x(k), k)$, where $x(k)$ consists of the first k components of x [two feasible solutions $x, x' \in X$ whose first k components are identical are mapped onto the same node $(x(k), k)$ of I_k]. Each node $(x(N), N) \in I_N$ is viewed as a destination node of the graph and has cost $g(x)$, where x is the feasible solution mapping onto $x(N)$. The origin node is connected with an arc to each node $(x(1), 1) \in I_1$. Furthermore, for every $k = 1, \dots, N-1$, each node $(x(k), k) \in I_k$ is connected with an arc to each node $(x(k+1), k+1) \in I_{k+1}$ such that the components x_1, \dots, x_k of $x(k)$ and the first k components $x(k+1)$ are identical. A few observations may be made:

- (a) Selecting one neighbor out of the set of neighbors of the origin node amounts to selecting the first component x_1 of x , while selecting one neighbor out of the set of neighbors of a node $(x(k), k) \in I_k$ amounts to selecting the $(k+1)$ st component x_{k+1} of x .
- (b) Choosing a path that starts at s and ends at a destination node $(x(N), N)$ amounts to a sequential choice of the components of x : The first component is chosen when the arc connecting s to a node $(x(1), 1) \in I_1$ is selected, and the k th component is chosen ($k = 2, \dots, N$) when the arc connecting a node $(x(k-1), k-1) \in I_{k-1}$ to a node $(x(k), k) \in I_k$ is selected. For each $k = 2, \dots, N$, the first $k-1$ components of $x(k-1)$ and $x(k)$ are identical.
- (c) Any base heuristic that starts at node s amounts to a sequential choice of the components x_k , $k = 1, \dots, N$, so that the final result (x_1, \dots, x_N) is feasible (belongs to X). Any base heuristic that starts at a non-destination node $(x(k), k) \in I_k$ amounts to a sequential choice of the components x_{k+1}, \dots, x_N , so that after they are added to the k components x_1, \dots, x_k specified by $x(k)$, the final result (x_1, \dots, x_N) is feasible.

Given a base heuristic \mathcal{H} , as described in (c) above, the k th step of the rollout algorithm \mathcal{RH} minimizes g with respect to the k th component x_k , while keeping the preceding components x_1, \dots, x_{k-1} at the values selected at the preceding steps, and using the base heuristic \mathcal{H} to supply the remaining components x_{k+1}, \dots, x_N .

Here is an example where the base heuristic is trivial, and the rollout algorithm leads to a well-known method.

Example 6 (Coordinate Descent) Assume that the set X has the (Cartesian product) form

$$\{(x_1, \dots, x_N) \mid x_k \in X_k, k = 1, \dots, N\}, \quad (18)$$

where $X_k, k = 1, \dots, N$, are some given finite sets. In principle, there is no loss of generality in this assumption since sets X_k such that the set (18) contains X can always be found, and the cost $g(x)$ can be set to a very high value for every $x \notin X$ that belongs to the set (18).

Let \bar{x} be some given feasible solution. Consider the base heuristic that operates as follows:

- (a) Starting from the origin s , it generates the solution \bar{x} .
- (b) Starting from $(x(k), k) \in I_k, k = 1, \dots, N_1$, it generates the solution that has the first k components equal to the corresponding k components of $x(k)$ and the last $N - k$ components equal to the corresponding last $N - k$ components of \bar{x} .

Then, it can be seen that the rollout algorithm is equivalent to a coordinate descent method that starts from \bar{x} and yields $(\tilde{x}_1, \dots, \tilde{x}_N)$ according to

$$\begin{aligned} \tilde{x}_1 &\in \arg \min_{x_1 \in X_1} g(x_1, \bar{x}_2, \dots, \bar{x}_N), \\ \tilde{x}_k &\in \arg \min_{x_k \in X_k} g(\tilde{x}_1, \dots, \tilde{x}_{k-1}, x_k, \bar{x}_{k+1}, \dots, \bar{x}_N), \quad k = 2, \dots, N. \end{aligned}$$

Note that a more general version of coordinate descent is obtained by using a base heuristic similarly defined by multiple solutions $\bar{x}^1, \dots, \bar{x}^m$ in place of \bar{x} . Then, the preceding equation is replaced by

$$\begin{aligned} \tilde{x}_1 &\in \arg \min_{x_1 \in X_1} \min \{g(x_1, \bar{x}_2^1, \dots, \bar{x}_N^1), \dots, g(x_1, \bar{x}_2^m, \dots, \bar{x}_N^m)\}, \\ \tilde{x}_k &\in \arg \min_{x_k \in X_k} \min \{g(\tilde{x}_1, \dots, \tilde{x}_{k-1}, x_k, \bar{x}_{k+1}^1, \dots, \bar{x}_N^1), \dots, \\ &\quad g(\tilde{x}_1, \dots, \tilde{x}_{k-1}, x_k, \bar{x}_{k+1}^m, \dots, \bar{x}_N^m)\}, \quad k = 2, \dots, N. \end{aligned}$$

The preceding example provides a baseline. It shows what can be achieved in a coordinate-based formulation of the rollout algorithm, even with a very trivial base heuristic. One can expect much better performance with more sophisticated base heuristics.

There are interesting variations of the coordinate-based reformulation of the generic discrete optimization problem into a graph search problem. In particular, the problem has been reformulated so that the components of x_1, \dots, x_N are selected in a specific order. Alternative orders are possible, and in fact an attempt to optimize the choice of order may be effected through the rollout algorithm. This can be done by introducing the index of the component of x as part of the specification of a node. In particular, the nodes in the “layer” I_k of the graph may have the form $(x(k), k, n)$ where n specifies the next component to be chosen by the rollout algorithm.

Let us also explore the relation between rollout algorithms and local search methods, which are a broad and important class of heuristics for the generic discrete optimization problem of minimizing $g(x)$ over the finite set X . A local search method uses the notion of a *neighborhood* $N(x)$ of a feasible solution $x \in X$, which is a (usually small) subset of X , containing solutions that are “close” to x in some sense.

In particular, given a solution x , the method selects among the solutions in the neighborhood $N(x)$ a successor solution x' , according to some rule. The process is then repeated with x' replacing x (or stops when some termination criterion is met). Thus, a local search method is characterized by:

- (a) The method for choosing a starting solution
- (b) The definition of the neighborhood $N(x)$ of a solution x
- (c) The rule for selecting a successor solution from within $N(x)$
- (d) The termination criterion

The definition of a neighborhood often involves intricate calculations and suboptimizations that aim to bring to consideration promising neighbors. While the definition of neighborhood is typically problem dependent, some general classes of procedures for generating neighborhoods have been developed. An example of such a class is the well-known *genetic algorithms*.

The criterion for selecting a solution from within a neighborhood is usually the cost of the solution, so that a neighbor of minimum cost is selected. Then, by assuming that each $x \in X$ belongs to its own neighborhood $N(x)$, the local search is *cost improving* and effectively stops at a *local minimum*, that is, a solution that is no worse than all other solutions within its neighborhood. Attention will be restricted to such methods, but there are important alternatives, such as in the methods of *tabu search* and *simulated annealing*, which will not be discussed here.

Consider a cost-improving local search method, as described above, and let $N(x)$ and \bar{x} be the neighborhood definition and the starting point of the method, respectively. Let us assume that there is a given limit M to the number of iterations, so that the method terminates when it reaches this limit (if it encounters a local minimum before M iterations are performed, it may be assumed that it simply repeats the local minimum, until the limit M is reached). We will provide a reformulation of the problem into the framework of the search problem of the preceding section, so that the rollout algorithm becomes identical to the local search method described above.

To this end, an acyclic graph is introduced, which consists of an origin node that corresponds to the starting solution \bar{x} , and M subsets of nodes I_1, I_2, \dots, I_M , which may be viewed as replicas of the feasible set X . In particular, for each feasible solution $x \in X$ and each $k = 1, \dots, M$, the node set I_k contains a node (x, k) . Each node $(x, M) \in I_M$ is viewed as a destination node of the graph and has cost $g(x)$. The origin node is connected with an arc to each node $(x, 1)$ such that $x \in N(\bar{x})$, while for every $k = 1, \dots, M - 1$, each node $(x, k) \in I_k$ is connected with an arc to each node $(x', k + 1) \in I_{k+1}$ such that $x' \in N(x)$.

Consider now the base heuristic that, starting from a node $(x, k) \in I_k$, generates the destination (x, N) with cost $g(x)$. Then, it can be seen that the rollout algorithm

reduces to the local search method. In particular, the rollout algorithm, given x after k steps [i.e., when at node (x, k)], it considers all x' in the neighborhood $N(x)$ and runs the base heuristic starting at x' and yielding the cost $g(x')$. It then selects $x' \in N(x)$ that yields the minimum cost. This is exactly what the local search method also does.

The preceding reformulation suggests that rollout algorithms can provide an additional dimension to local search methods, whereby intermediate infeasible solutions may be generated, and these solutions are evaluated through their projections, which are obtained through a base heuristic. Thus, while local search methods rely on a single construct, namely, neighborhoods, for selecting successive solutions, rollout algorithms bring to bear two independent constructs, neighborhoods *and* base heuristics. It should be mentioned also that rollout algorithms embody some additional important methodological ideas, namely, DP and policy iteration. For this reason, rollout algorithms admit natural extensions to stochastic control problems, for which there is no known analog of a local search method.

4 Further Reading

The main idea of rollout algorithms, obtaining an improved policy starting from some other suboptimal policy using a one-time policy improvement, has appeared in several DP application contexts. In the context of game-playing computer programs, it has been proposed by Abramson [1] and by Tesauro and Galperin [24]. The name “rollout” was coined by Tesauro in specific reference to rolling the dice in the game of backgammon. In Tesauro’s proposal, a given backgammon position is evaluated by “rolling out” many games starting from that position, using a simulator, and the results are averaged to provide a “score” for the position. The internet contains a lot of material on computer backgammon and the use of rollout, in some cases in conjunction with multistep lookahead and cost-to-go approximation.

The application of rollout algorithms to discrete optimization problems has its origin in the neuro-dynamic programming work of the author and J. Tsitsiklis [6]. The formalization as a path construction algorithm, including the notions of sequential consistency, sequential improvement, and fortified and parallel rollout, was given in the paper by Bertsekas, Tsitsiklis, and Wu [7]. The subsequent paper by Bertsekas and Castanon [5] considered its application to stochastic DP and stochastic scheduling. The analysis of the breakthrough problem ([Example 1](#)) is given in the DP book by Bertsekas [3] and is based on unpublished work by Bertsekas, Castanon, and Tsitsiklis. An analysis of the optimal policy and some suboptimal policies for this problem is given by Pearl [18]. A discussion of rollout algorithms as applied to network optimization problems may be found in the author’s network optimization book [2].

For applications of rollout algorithms, see Christodouleas [11], Duin and Voss [12], Secomandi [20–22], Ferris and Voelker [13, 14], McGovern, Moss, and Barto [16], Savagaonkar, Givan, and Chong [19], Bertsimas and Popescu [8], Guerriero and Mancini [15], Tu and Pattipati [25], Wu, Chong, and Givan [26],

Chang, Givan, and Chong [10], Meloni, Pacciarelli, and Pranzo [17], Yan, Diaconis, Rusmevichientong, and Van Roy [27], Besse and Chaib-draa [9], and Sun, Zhao, Lun, and Tomastik [23]. These works discuss a broad variety of applications and case studies and generally report positive computational experience. The survey [4] discusses rollout algorithms from a control theory point of view and explores its close connection with model predictive control (MPC).

Abstract

Simplicial methods were originated by Scarf for approximating fixed points of continuous mappings. They have many applications in economics and science. With regard to its geometric structure, a simplicial method can be classified as either a variable dimension simplicial method or a homotopy simplicial method. A variable dimension simplicial method works directly on the interested space,

whereas a simplicial homotopy method needs to introduce an extra dimension. It is well known that integer programming is equivalent to determining whether there is an integer point in a polytope. Simplicial methods were extended to computing an integer point in a polytope. There is a significant difference between simplicial methods for approximating fixed points and simplicial methods for integer programming, though they both have the same foundation. Two most important components of simplicial methods are labeling rules and triangulations. Efficiency of simplicial methods depends critically on the underlying triangulations. Three simplest triangulations of R^n are the K_1 -triangulation, the J_1 -triangulation, and the D_1 -triangulation. This chapter presents a brief introduction to these developments of simplicial methods.

1 Introduction

Brouwer's fixed point theorem (Brouwer 1912) asserts that a continuous mapping from a convex and compact nonempty set of R^n to itself has a fixed point. This theorem and its generalizations in Kakutani [83] have many applications in economics and engineering. However, the nonconstructive proofs of these fixed point theorems limited their further applications. To overcome this shortcoming, Scarf presented in his seminal paper [144] the first method for constructively proving Brouwer's fixed point theorem on S^n (here S^n denotes the unit simplex that is a subset of R^n in which all the components of every point are nonnegative and sum up to one). Since then the substantial developments have been made on approximating fixed points.

Scarf's method subdivides the unit simplex in a large number of the so-called primitive sets. Starting at a corner of the unit simplex, the method generates a sequence of adjacent primitive sets until it meets a primitive set that yields an approximate fixed point. However, operating with the primitive sets consumes an extremely large amount of computer storage. To address this difficulty, a systematic procedure was proposed in Hansen [74] for choosing a primitive set. It was found later that the pivot steps for moving from one primitive set to an adjacent one in the procedure are identical to those of a regular triangulation of S^n given in Freudenthal [52], which was applied in Kuhn [97] to approximate fixed points. Although Scarf's method introduces the primitive sets, the subsequential developments are based on triangulations.

Two methods were proposed in Kuhn [97], one of which is an artificial start method and the other a variable dimension method. The artificial start method starts at an artificial simplex outside the unit simplex and generates a sequence of adjacent full-dimensional simplices, and the variable dimension method starts at one of the vertices of the unit simplex and generates a sequence of adjacent simplices of varying dimension. Both of Kuhn's methods terminate within a finite of iterations with

a simplex that yields an approximate fixed point. The accuracy of approximation is completely determined by grid size of the triangulation underlying a simplicial method. When the accuracy is not good enough, one could restart the method with a triangulation of smaller grid size. However, Scarf's method and Kuhn's method both have a deficiency in that they discard all the relevant information about the location of a fixed point obtained in the previous implementation.

To deal with this deficiency, a homotopy method with continuous refinement of grid size and a restart homotopy method were developed in Eaves [33] and Merrill [114], respectively. Both Eaves's and Merrill's homotopy methods can start anywhere, but they need to introduce an extra dimension. A variable dimension method without an extra dimension was invented in van der Laan and Talman [176], which directly works on S^n and can also start anywhere. After this result, several variable dimension methods were proposed in the literature such as Kojima and Yamamoto [94, 95], Wright [192], and Yamamoto [193].

It is well known that integer programming is equivalent to determining whether there is an integer point in a polytope. To compute an integer point in P , a variable dimension simplicial method and a homotopy-like simplicial method were developed in Dang [17], Dang and Maaren [18–20], and Dang and Ye [21]. These simplicial methods can be considered as an extension of Eaves's and Merrill's homotopy methods and van der Laan and Talman's $(n + 1)$ -ray variable dimension method to integer programming. However, there is a significant difference between simplicial methods for integer programming and simplicial methods for approximating fixed points. A simplicial method for approximating fixed points terminates as soon as a complete full-dimensional simplex is met, whereas a simplicial method for integer programming terminates only when it either yields an integer point in a polytope or proves no such point exists. Therefore, a simplicial method for integer programming has to go one step further, which makes it significantly different from simplicial methods for approximating fixed points.

The two most important components of simplicial methods are labeling rules and triangulations. Efficiency of simplicial methods depends critically on the underlying triangulations. The three simplest triangulations of R^n are the K_1 -triangulation in Freudenthal [52], the J_1 -triangulation in Todd [159], and the D_1 -triangulation in Dang [13]. Measures of efficiency for triangulations were defined in Todd [157], which include the number of simplices in a unit cube, the diameter of a triangulation, and the average directional density. According to these measures, the D_1 -triangulation is superior to both the K_1 -triangulation and the J_1 -triangulation.

The rest of this chapter is organized as follows: Several simple triangulations are given in Sect. 2. Scarf's simplicial method is presented in Sect. 3. Kuhn's simplicial methods are discussed in Sect. 4. Eaves's simplicial homotopy method is given in Sect. 5. van der Laan and Talman's variable dimension simplicial method is introduced in Sect. 6. A variable dimension simplicial method for integer programming is described in Sect. 7. A homotopy-like simplicial method for integer programming is presented in Sect. 8. The chapter is concluded in Sect. 9.

2 Several Simple Triangulations

Triangulations play an important role in the developments of simplicial methods. Given $k + 1$ vectors in R^n , y^0, y^1, \dots, y^k , they are affinely independent if

$$\sum_{i=0}^k \alpha_i y^i = 0 \text{ and } \sum_{i=0}^k \alpha_i = 0$$

imply that $\alpha_i = 0$ for all i . The convex hull of $k + 1$ affinely independent vectors in R^n , y^0, y^1, \dots, y^k , is called a k -dimensional simplex or a k -simplex. The vectors, y^0, y^1, \dots, y^k , are called vertices of the simplex. Let σ denote a k -simplex. A face of σ is a simplex that is the convex hull of some vertices of σ . A facet of σ is a $(k - 1)$ -dimensional facet of σ .

Definition 1 Let C be a convex subset of R^n with $\dim(C) = m$. G is a triangulation or simplicial subdivision of C if:

1. G is a collection of m -dimensional simplices.
2. C is equal to the union of all the simplices in G .
3. For any σ^1 and σ^2 in G , $\sigma^1 \cap \sigma^2$ is either empty or a common facet of both of them.
4. Every $x \in C$ has a neighborhood that meets only a finite number of simplices in G .

Many triangulations have been constructed in the literature, but only several simple triangulations are given in this section.

2.1 The $K_2(m)$ -Triangulation of S^n

Let $S^n = \{x \in R_+^{n+1} \mid \sum_{i=0}^n x_i = 1\}$, which is the n -dimensional unit simplex. Let Q be an $(n + 1) \times n$ matrix given by

$$Q = \begin{pmatrix} -1 & & & \\ 1 & -1 & & \\ & 1 & \ddots & \\ & & \ddots & -1 \\ & & & 1 \end{pmatrix},$$

and q^i denote the i th column of Q for $i = 1, 2, \dots, n$. Let $N = \{1, 2, \dots, n\}$ and $\Pi(N) = \{\pi \mid \pi = (\pi(1), \pi(2), \dots, \pi(n))\}$ is a permutation of elements of N . For any given positive integer m , let

$$K_2^0(m) = \{y \in S^n \mid my_i \text{ is an integer for } i = 0, 1, \dots, n\}.$$

Table 1 Pivot rules of the $K_2(m)$ -triangulation of S^n

i	\bar{y}	$\bar{\pi}$
0	$y + \frac{1}{m}q^{\pi(1)}$	$(\pi(2), \dots, \pi(n), \pi(1))$
$1 \leq i < n$	y	$(\pi(1), \dots, \pi(i+1), \pi(i), \dots, \pi(n))$
n	$y - \frac{1}{m}q^{\pi(n)}$	$(\pi(n), \pi(1), \dots, \pi(n-1))$

Table 2 Pivot rules of the K_1 -triangulation of R^n

i	\bar{y}	$\bar{\pi}$
0	$y + u^{\pi(1)}$	$(\pi(2), \dots, \pi(n), \pi(1))$
$1 \leq i < n$	y	$(\pi(1), \dots, \pi(i+1), \pi(i), \dots, \pi(n))$
n	$y - u^{\pi(n)}$	$(\pi(n), \pi(1), \dots, \pi(n-1))$

Given any $y \in K_2^0(m)$ and $\pi \in \Pi(N)$, let $y^0 = y$ and

$$y^k = y^{k-1} + \frac{1}{m}q^{\pi(k)}, \quad k = 1, 2, \dots, n,$$

and $\sigma = \langle y^0, y^1, \dots, y^n \rangle$ be the convex hull of y^0, y^1, \dots, y^n . If $\sigma \subseteq S^n$, it is written that $\sigma = K_2(y, \pi)$. Let $K_2(m)$ be the collection of all such $\sigma = K_2(y, \pi)$. Then, $K_2(m)$ forms a triangulation of S^n [52].

Two simplices of $K_2(m)$ are adjacent if they share a common facet. For any given simplex $\sigma = K_2(y, \pi)$ with vertices y^0, y^1, \dots, y^n , its adjacent simplex opposite to a vertex, say y^i , is given by $K_2(\bar{y}, \bar{\pi})$, where \bar{y} and $\bar{\pi}$ are generated according to the pivot rules in [Table 1](#).

2.2 The K_1 -Triangulation of R^n

For $j \in N$, let u^j denote the j th unit vector of R^n . A simplex of the K_1 -triangulation is the convex hull of $n+1$ vectors, y^0, y^1, \dots, y^n , given by $y^0 = y$ and $y^k = y^{k-1} + u^{\pi(k)}$, $k = 1, 2, \dots, n$, where y is an integer point in R^n and $\pi = (\pi(1), \pi(2), \dots, \pi(n))$ is a permutation of elements of N . Let K_1 be the set of all such simplices. Then, K_1 forms a triangulation of R^n [52]. Since a simplex of the K_1 -triangulation is uniquely determined by y and π , it is denoted by $K_1(y, \pi)$.

Two simplices of K_1 are adjacent if they share a common facet. For any given simplex $\sigma = K_1(y, \pi)$ with vertices y^0, y^1, \dots, y^n , its adjacent simplex opposite to a vertex, say y^i , is given by $K_1(\bar{y}, \bar{\pi})$, where \bar{y} and $\bar{\pi}$ are generated according to the pivot rules in [Table 2](#).

2.3 The D_1 -Triangulation of R^n

A simplex of the D_1 -triangulation is the convex hull of $n+1$ vectors, y^0, y^1, \dots, y^n , given by: If $p = 0$, $y^0 = y$ and $y^k = y + s_{\pi(k)}u^{\pi(k)}$, $k = 1, 2, \dots, n$, and if $p > 0$, $y^0 = y + s$ and

Table 3 Pivot rules of the D_1 -triangulation of R^n

i		\bar{y}	\bar{s}	$\bar{\pi}$	\bar{p}
0	$n = 1$	$y + 2s_{\pi(1)}u^{\pi(1)}$	$s - 2s_{\pi(1)}u^{\pi(1)}$	π	p
	$n \geq 2$	y	s	π	$1-p$
	$2 \leq p \leq n-1$	y	$s - 2s_{\pi(1)}u^{\pi(1)}$	π	p
$1 \leq i$	$p = 0$	y	$s - 2s_{\pi(i)}u^{\pi(i)}$	π	p
	$i < p-1$	y	s	π^1	p
	$i = p-1$	y	s	π	$p-1$
	$p-1 < i$	$1 \leq p < n-1$	y	π^2	$p+1$
	$i = n-1$	$1 \leq p = n-1$	$y + 2s_{\pi(n)}u^{\pi(n)}$	$s - 2s_{\pi(n)}u^{\pi(n)}$	π
	$i = n$	$1 \leq p = n-1$	$y + 2s_{\pi(n-1)}u^{\pi(n-1)}$	$s - 2s_{\pi(n-1)}u^{\pi(n-1)}$	π

$$\pi^1 = (\pi(1), \dots, \pi(i+1), \pi(i), \dots, \pi(n))$$

$$\pi^2 = (\pi(1), \dots, \pi(p-1), \pi(p), \pi(p), \dots, \pi(i-1), \pi(i+1), \dots, \pi(n))$$

$$y^k = \begin{cases} y^{k-1} - s_{\pi(k)}u^{\pi(k)} & \text{if } 1 \leq k \leq p-1, \\ y + s_{\pi(k)}u^{\pi(k)} & \text{otherwise,} \end{cases}$$

$k = 1, 2, \dots, n$, where $y = (y_1, y_2, \dots, y_n)^\top$ with each component being an even integer, $\pi = (\pi(1), \pi(2), \dots, \pi(n))$ is a permutation of elements of N , $s = (s_1, s_2, \dots, s_n)^\top$ is a sign vector with each component being either -1 or 1 , and p is an integer with $0 \leq p \leq n-1$. Let D_1 be the set of all such simplices. Then, D_1 forms a triangulation of R^n [13]. Since a simplex of the D_1 -triangulation is determined by y, π, s , and p , it is denoted by $D_1(y, \pi, s, p)$.

Two simplices of D_1 are adjacent if they share a common facet. For any given simplex $\sigma = D_1(y, \pi, s, p)$ with vertices y^0, y^1, \dots, y^n , its adjacent simplex opposite to a vertex, say y^i , is given by $D_1(\bar{y}, \bar{\pi}, \bar{s}, \bar{p})$, where $\bar{y}, \bar{\pi}, \bar{s}$, and \bar{p} are generated according to the pivot rules in Table 3.

3 Scarf's Simplicial Method for Approximating Fixed Points on the Unit Simplex

Let $N_0 = \{0, 1, \dots, n\}$. Let f be a continuous mapping from S^n to itself. Let

$$\tilde{S}^n = \{x \in R^{n+1} \mid e^\top x = 1 \text{ and } x \leq 2e\},$$

where $e = (1, 1, \dots, 1)^\top \in R^{n+1}$. Then, $\tilde{v}^i = 2e - (2n+1)v^i$ is a vertex of \tilde{S}^n with v^i being the i th unit vector of R^{n+1} for $i = 0, 1, \dots, n$.

Definition 2 (An Integer Labeling Rule) For $i = 0, 1, \dots, n$,

$$l(\tilde{v}^i) = \mod(i - 1, n + 1),$$

and for $y \in S^n$,

$$l(y) = \min\{j \mid f_j(y) \leq y_j > 0\}.$$

With this integer labeling rule, it is ready to introduce the following definitions on completeness and almost completeness.

Definition 3 (Completeness and Almost Completeness)

- A q -dimensional simplex $\sigma = \langle y^0, y^1, \dots, y^q \rangle$ of $\mathcal{K}_1(m)$ is complete if $l(y^i) \neq l(y^j)$ for any $i \neq j$.
- A q -dimensional simplex $\sigma = \langle y^0, y^1, \dots, y^q \rangle$ of $\mathcal{K}_1(m)$ is almost complete if σ carries exactly q different labels.

As a direct result of this definition, one can easily obtain

Lemma 1 $\sigma^0 = \langle \tilde{v}^1, \tilde{v}^2, \dots, \tilde{v}^n, v^0 \rangle$ is an almost complete simplex.

With these notations and results, Scarf's method can be described as follows.

Initialization: Let $k = 0$ and $y^- = \tilde{v}^1$. Go to Step 1.

Step 1: Let τ^k be the facet of σ^k opposite to y^- and σ^{k+1} the unique n -dimensional simplex that shares τ^k with σ^k . Let y^+ be the vertex of σ^{k+1} opposite to τ^k and $k = k + 1$. Go to Step 2.

Step 2: If $l(y^+) = n$, the method terminates and an approximate fixed point has been found. Otherwise, let y^- be the vertex of σ^k that is different from y^+ and carries the same label as y^+ . Go to Step 1.

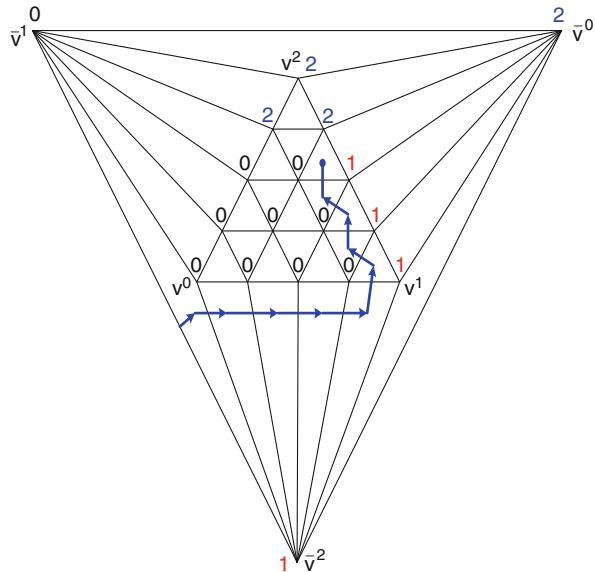

Theorem 1 (Scarf 1967) Within a finite number of iterations, the method terminates with a complete n -dimensional simplex that yields an approximate fixed point.

Example 1 (Todd 1979) Consider

$$f(x) = \begin{pmatrix} 0.2 & 0.1 & 0.3 \\ 0.3 & 0.4 & 0.3 \\ 0.5 & 0.5 & 0.4 \end{pmatrix} x.$$

f has just one fixed point, which is $x^* = (7, 11, 15)^\top / 33$. An illustration of how Scarf's method works can be found in [Fig. 1](#).

Fig. 1 An illustration of Scarf's simplicial method

4 Kuhn's Simplicial Methods for Approximating Fixed Points on the Unit Simplex

After Scarf's work, two simplicial methods were proposed in Kuhn [97]. One is an artificial start simplicial method and the other is a variable dimension simplicial method. They are presented in the following two subsections, respectively.

4.1 Kuhn's Artificial Start Simplicial Method

Let

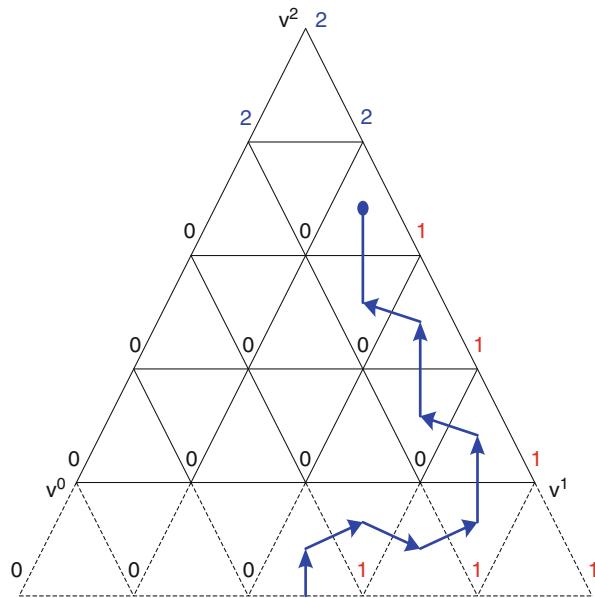

$$\tilde{S}^n = \left\{ x \in R^{n+1} \mid e^\top x = 1, x_i \geq 0, i = 0, 1, \dots, n-1, x_n \geq -\frac{1}{m} \right\}$$

and $\tilde{S}_n^n = \{x \in \tilde{S}^n \mid x_n = -\frac{1}{m}\}$.

Definition 4 (An Integer Labeling Rule) For $y \in \tilde{S}^n$,

$$l(y) = \begin{cases} \min\{j \mid f_j(y) \leq y_j > 0\} & \text{if } y \in S^n, \\ \min\{j \mid y_j = \max_{k \in N_0} y_k\} & \text{otherwise.} \end{cases}$$

Fig. 2 An illustration of Kuhn's artificial start simplicial method

With this labeling rule and [Definition 3](#), one can readily derive the following result.

Lemma 2 ([97]) *For any given triangulation of \tilde{S}^n , there is a unique complete $(n - 1)$ -dimensional simplex in \tilde{S}^n .*

With these notations and results, Kuhn's artificial start simplicial method can be described as follows.

Initialization: Let τ^0 be the unique complete $(n - 1)$ -dimensional simplex in \tilde{S}^n , σ^0 the unique n -dimensional simplex with τ^0 as a facet, y^+ the vertex of σ^0 opposite to τ^0 , and $k = 0$. Go to *Step 1*.

Step 1: If $l(y^+) = n$, the method terminates and an approximate fixed point has been found. Otherwise, let y^- be the vertex of σ^k that is different from y^+ and carries the same label as y^+ . Go to *Step 2*.

Step 2: Let τ^k be the facet of σ^k opposite to y^- and σ^{k+1} the unique n -dimensional simplex that shares τ^k with σ^k . Let y^+ be the vertex of σ^{k+1} opposite to τ^k and $k = k + 1$. Go to *Step 1*.

Theorem 2 ([97]) *Within a finite number of iterations, the artificial start simplicial method terminates with a complete n -dimensional simplex that yields an approximate fixed point.*

Example 2 Consider f the same as that in [Example 1](#). An illustration of how Kuhn's artificial start simplicial method works can be found in [Fig. 2](#).

4.2 Kuhn's Variable Dimension Simplicial Method

To avoid the introduction of an extra layer in the artificial start simplicial method, a variable dimension simplicial method was developed in Kuhn [97], which works directly on S^n and can start at any given vertex of S^n . For any given vertex v^p of S^n and $K \subset N_0$ with $p \notin K$, let

$$S^n(v^p, K) = \{x \in S^n \mid x = v^p + \sum_{j \in K} \lambda_j (v^j - v^p), \lambda_j \geq 0, j \in K\}.$$

Initialization: Let $y^+ = v^p$, $h = (h(1), h(2), \dots, h(n))$ be a given permutation of elements of $N_0 \setminus \{p\}$, $K = \emptyset$, $L = \emptyset$, and $\sigma^0 = \langle y^+ \rangle$, $q = 0$, and $k = 0$. Go to *Step 1*.

- Step 1: If $l(y^+) \notin L$, let $L = L \cup \{l(y^+)\}$ and $q = q + 1$, and go to *Step 2*. Otherwise, let y^- be the vertex of σ^k that is different from y^+ and carries the same label as y^+ and τ^{k+1} the facet of σ^k opposite to y^- , and go to *Step 3*.
- Step 2: If $q = n + 1$, the method terminates and an approximate fixed point has been found. Otherwise, let $K = K \cup \{h(q)\}$, $\tau^{k+1} = \sigma^k$, σ^{k+1} be the unique q -dimensional simplex in $S^n(v^p, K)$ with τ^{k+1} as a facet, y^+ the vertex of σ^{k+1} opposite to τ^{k+1} , and $k = k + 1$, and go to *Step 1*.
- Step 3: If $\tau^{k+1} \subseteq S^n(v^p, K \setminus \{h(q)\})$, let $K = K \setminus \{h(q)\}$ and go to *Step 4*. Otherwise, let σ^{k+1} be the unique q -dimensional simplex in $S^n(v^p, K)$ sharing with σ^k the facet τ^{k+1} , y^+ be the vertex of σ^{k+1} opposite to τ^{k+1} , and $k = k + 1$, and go to *Step 1*.

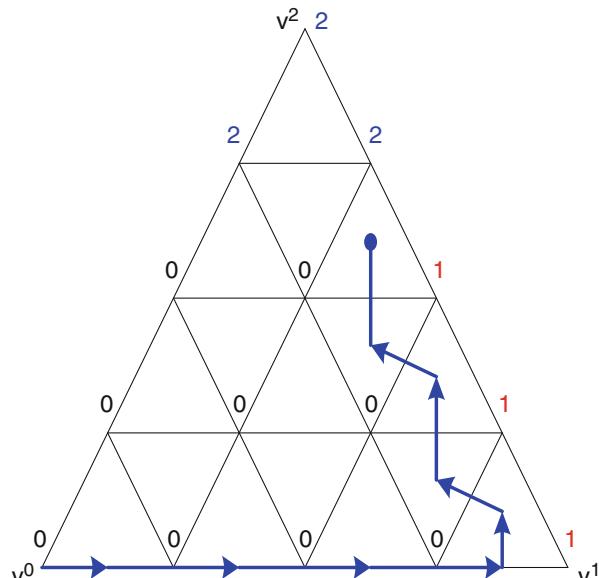

Fig. 3 An illustration of Kuhn's variable dimension simplicial method

Step 4: Let $q = q - 1$, $L = L \setminus \{h(q)\}$, $\sigma^{k+1} = \tau^{k+1}$, y^- be the vertex of σ^{k+1} with label $h(q)$, τ^{k+2} the facet of σ^{k+1} opposite to y^- , and $k = k + 1$, and go to Step 3.

Theorem 3 ([97]) Within a finite number of iterations, the variable dimension simplicial method terminates with a complete n -dimensional simplex that yields an approximate fixed point.

Example 3 Consider f the same as that in [Example 1](#). An illustration of how Kuhn's variable dimension simplicial method works can be found in [Fig. 3](#).

5 Eaves's Simplicial Homotopy Method for Approximating Fixed Points on the Unit Simplex

Scarf's and Kuhn's simplicial methods all have a deficiency that they discard all the relevant information about the location of a fixed point obtained in the previous implementation when restarting. To address this issue, a simplicial homotopy method with continuous refinement and a restart simplicial homotopy method were proposed by introducing an extra dimension in Eaves [33] and Merrill [114], respectively. Let x^0 be any given interior point of S^n . Let T be a triangulation of $S^n \times [0, 1]$ with continuous refinement of grid size.

Definition 5 (A Vector Labeling Rule) For any given point $(y, t) \in S^n \times [0, 1]$,

$$l(y, t) = \begin{cases} y - f(y) & \text{if } t > 0, \\ y - x^0 & \text{otherwise.} \end{cases}$$

With this vector labeling rule, a complete simplex can be defined as follows.

Definition 6 A simplex $\sigma = \langle y^0, y^1, \dots, y^k \rangle$ is complete if

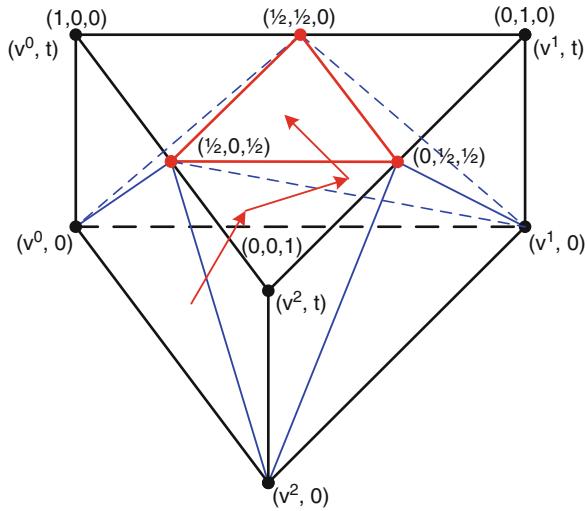

$$\sum_{i=0}^k \lambda_i \binom{1}{l(y^i)} = \binom{1}{0} \quad (1)$$

has a nonnegative solution $\lambda = (\lambda_0, \lambda_1, \dots, \lambda_k)^\top$.

Lemma 3 If $(x^0, 0)$ is an interior point of an n -simplex $\tau^0 \subseteq S^n \times \{0\}$, then τ^0 is a unique complete n -dimensional simplex in $S^n \times \{0\}$.

With these notations and results, Eaves's simplicial homotopy method of continuous refinement can be described as follows.

Fig. 4 An illustration of Eaves's simplicial homotopy method

Initialization: Let σ^0 be the unique $(n + 1)$ -dimensional simplex in $S^n \times [0, 1]$ with τ_0 as a facet, y^+ be the vertex of σ^0 opposite to τ_0 , and $k = 0$. Go to *Step 1*.

Step 1: Perform a pivoting step of linear programming on the system (Eq. 1) to determine the vertex y^- of σ^k that is replaced by y^+ . Let τ^{k+1} be the facet of σ^k opposite to y^- . If $\tau^{k+1} \subseteq S^n \times \{t\}$ with $t > 0$ yields a satisfactory approximate fixed point, the method terminates. Otherwise, go to *Step 2*.

Step 2: Let σ^{k+1} be the unique $(n + 1)$ -dimensional simplex that shares τ^{k+1} with σ^k , y^+ the vertex of σ^{k+1} opposite to τ^{k+1} , and $k = k + 1$. Go to *Step 1*.

Theorem 4 ([33]) *Under the nondegeneracy condition, Eaves's simplicial homotopy method terminates within a finite number of iterations with a satisfactory approximate fixed point.*

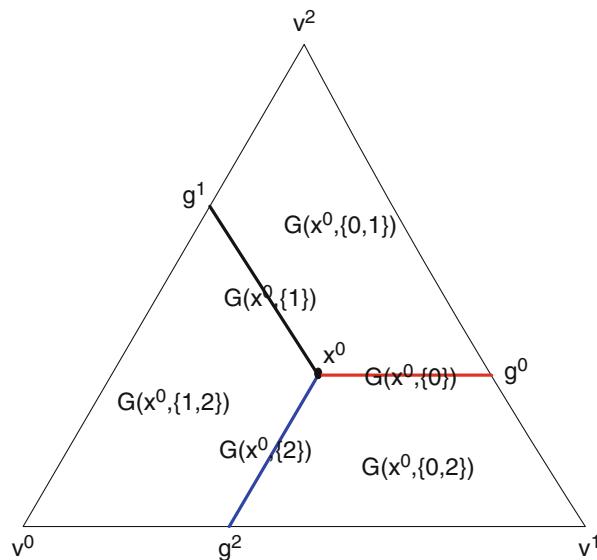

Example 4 Consider f the same as that in [Example 1](#). An illustration of how Eaves's simplicial homotopy method works can be found in [Fig. 4](#).

Merrill's simplicial homotopy method is the same as Eaves's but without the continuous refinement.

6 van der Laan and Talman's Variable Dimension Simplicial Method for Approximating Fixed Points on the Unit Simplex

Eaves's and Merrill's simplicial homotopy methods can start anywhere and are more efficient than Scarf's and Kuhn's simplicial methods, but they need to introduce an extra dimension. To get rid of this extra dimension, a variable dimension simplicial

Fig. 5 An illustration of $G(x^0, K)$

method was developed in van der Laan and Talman [176] to approximate fixed points on the unit simplex, which works directly on S^n and can also start anywhere.

Definition 7 (An Integer Labeling Rule) For $y \in S^n$,

$$l(y) = \min\{j \mid f_j(y) \leq y_j > 0\}.$$

Let Q_0 be an $(n + 1) \times (n + 1)$ matrix given by

$$Q_0 = \begin{pmatrix} -1 & & & & 1 \\ 1 & -1 & & & \\ & 1 & \ddots & & \\ & & \ddots & -1 & \\ & & & 1 & -1 \end{pmatrix}.$$

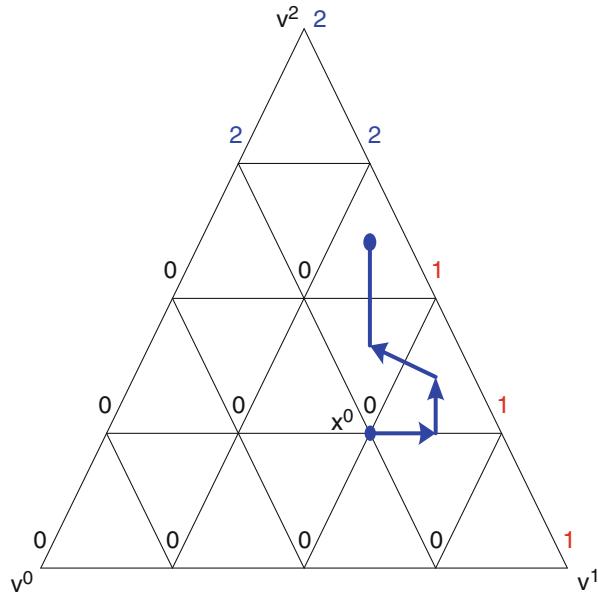

For $i \in N_0$, let g^i denote the $(i + 1)$ th column of Q_0 . Given any $x^0 \in S^n$ and $K \subset N_0$, let

$$G(x^0, K) = \{x \in S^n \mid x = x^0 + \sum_{i \in K} \lambda_i g^i, \lambda_i \geq 0, i \in K\}.$$

An illustration of $G(x^0, K)$ can be found in Fig. 5.

With these notations and results, van der Laan and Talman's variable dimension simplicial method can be described as follows.

Fig. 6 An illustration of van der Laan and Talman's variable dimension simplicial method

Initialization: Let $y^+ = x^0$, $K = \emptyset$, $\sigma^0 = \langle y^+ \rangle$, and $k = 0$. Go to *Step 1*.

- Step 1: If $l(y^+) \notin K$, let $K = K \cup \{l(y^+)\}$ and go to *Step 2*. Otherwise, let y^- be the vertex of σ^k that is different from y^+ and carries the same label as y^+ and τ^{k+1} the facet of σ^k opposite to y^- , and go to *Step 3*.
- Step 2: If $|K| = n + 1$, the method terminates and an approximate fixed point has been found. Otherwise, let $\tau^{k+1} = \sigma^k$, σ^{k+1} be the unique $|K|$ -dimensional simplex in $G(x^0, K)$ with τ^{k+1} as a facet, y^+ the vertex of σ^{k+1} opposite to τ^{k+1} , and $k = k + 1$, and go to *Step 1*.
- Step 3: If $\tau^{k+1} \subseteq G(x^0, K \setminus \{j\})$ for some $j \in K$, go to *Step 4*. Otherwise, let σ^{k+1} be the unique $|K|$ -dimensional simplex in $G(x^0, K)$ sharing with σ^k the facet τ^{k+1} , y^+ the vertex of σ^{k+1} opposite to τ^{k+1} , and $k = k + 1$, and go to *Step 1*.
- Step 4: Let $\sigma^{k+1} = \tau^{k+1}$, y^- be the vertex of σ^{k+1} with label j , τ^{k+2} the facet of σ^{k+1} opposite to y^- , and $k = k + 1$, and go to *Step 3*.

Theorem 5 [176] Within a finite number of iterations, the variable dimension simplicial method terminates with a complete n -dimensional simplex that yields an approximate fixed point.

Example 5 Consider f the same as that in [Example 1](#). An illustration of how van der Laan and Talman's variable dimension simplicial method works can be found in [Fig. 6](#).

7 A Variable Dimension Simplicial Method for Integer Programming

It is well known that integer programming is equivalent to determining whether there is an integer point in a polytope. To compute an integer point in a polytope, simplicial methods have been developed in Dang and Maaren [18–20], Dang [17] and Dang and Ye [21], which can be considered as extensions of simplicial methods for approximating fixed points. The problem is as follows: Determine whether there is an integer point in a polytope given by $P = \{x \in R^n \mid Ax \leq b\}$, where

$$A = \begin{pmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{pmatrix}$$

is a rational matrix satisfying that each row of A has at most one positive entry and $b = (b_1, b_2, \dots, b_m)^\top$ is a rational vector. It has been shown in Lagarias [103] that

Theorem 6 *Determining whether there is an integer point in P is an NP-complete problem.*

Let $M = \{1, 2, \dots, m\}$, $N = \{1, 2, \dots, n\}$, and $N_0 = \{1, 2, \dots, n+1\}$. For $i \in M$, let a_i^\top denote the i th row of A . Then, $A = (a_1, a_2, \dots, a_m)^\top$. Without loss of generality, assume that P is bounded and full dimensional. As a result of the property of A , it follows that

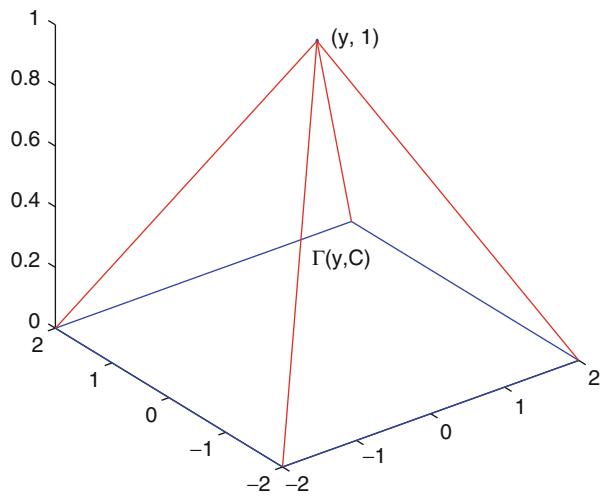

Lemma 4 *If $x^1 = (x_1^1, x_2^1, \dots, x_n^1)^\top \in P$ and $x^2 = (x_1^2, x_2^2, \dots, x_n^2)^\top \in P$, then $\bar{x} = \max(x^1, x^2) = (\max\{x_1^1, x_1^2\}, \max\{x_2^1, x_2^2\}, \dots, \max\{x_n^1, x_n^2\})^\top \in P$.*

Let $e = (1, 1, \dots, 1)^\top \in R^n$. Lemma 4 implies that $\max_{x \in P} e^\top x$ has a unique solution, which is denoted by $x^{\max} = (x_1^{\max}, x_2^{\max}, \dots, x_n^{\max})^\top$. Let $x^{\min} = (x_1^{\min}, x_2^{\min}, \dots, x_n^{\min})^\top$ with $x_j^{\min} = \min_{x \in P} x_j$, $j = 1, 2, \dots, n$. Clearly, $x^{\min} \leq x \leq x^{\max}$ for all $x \in P$. For any real number α , let $\lfloor \alpha \rfloor$ denote the greatest integer less than or equal to α and $\lceil \alpha \rceil$ the smallest integer greater than or equal to α . Let

$$D(P) = \{x \in R^n \mid x^l \leq x \leq x^u\},$$

where $x^u = \lfloor x^{\max} \rfloor = (\lfloor x_1^{\max} \rfloor, \lfloor x_2^{\max} \rfloor, \dots, \lfloor x_n^{\max} \rfloor)^\top$ and $x^l = \lceil x^{\min} \rceil = (\lceil x_1^{\min} \rceil, \lceil x_2^{\min} \rceil, \dots, \lceil x_n^{\min} \rceil)^\top$. Thus, $D(P)$ contains all integer points in P . Without loss of generality, assume that $x^l \leq x^u$ since otherwise there is no integer point in P .

Fig. 7 An illustration of $\Gamma(y, C)$

For $x \in R^n$, let

$$f(x) = \begin{cases} 0 \in R^n & \text{if } x \in P, \\ \sum_{i \in I(x)} \frac{a_i^\top x - b_i}{a_i^\top a_i} a_i & \text{otherwise,} \end{cases}$$

where $I(x) = \{i \in M \mid a_i^\top x - b_i > 0\}$.

Let $x^0 = (x_1^0, x_2^0, \dots, x_n^0)^\top$ be any given integer point of $D(P)$. For $y \in R^n$ and $C \subseteq R^n$, let $\Gamma(y, C)$ be an augmented set in R^{n+1} given by

$$\Gamma(y, C) = \{t(x, 0) + (1-t)(y, 1) \mid x \in C \text{ and } 0 \leq t \leq 1\}.$$

An illustration of $\Gamma(y, C)$ can be found in [Fig. 7](#).

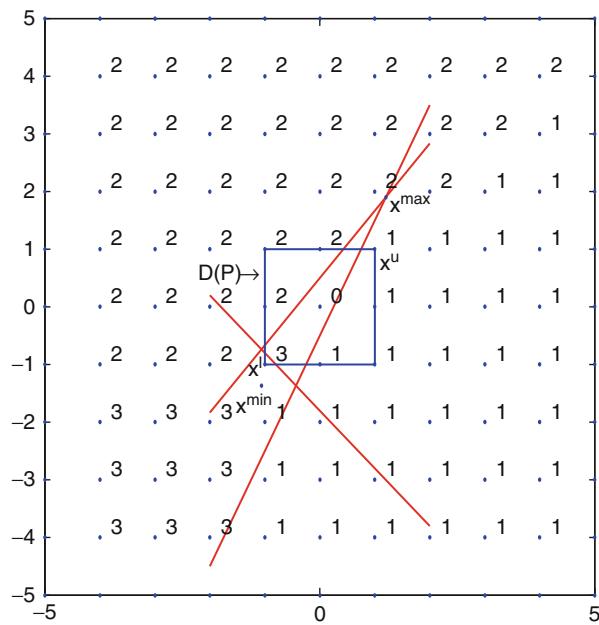

Definition 8 (An Integer Labeling Rule) For each integer point $(x, \gamma) \in \Gamma(x^0, R^n)$, assign to (x, γ) an integer label $l(x, \gamma) \in N_0 \cup \{0\}$ as follows:

1. $l(x^0, 1) = n + 1$.
2. For $(x, 0)$ with $x \in D(P)$,

$$l(x, 0) = \begin{cases} 0 & \text{if } x \in P, \\ \max\{k \mid f_k(x) = \max_{j \in N} f_j(x)\} & \text{if } f_j(x) > 0 \text{ for some } j \in N, \\ n + 1 & \text{if } f(x) \leq 0 \text{ and } f(x) \neq 0. \end{cases}$$

3. For $(x, 0)$ with $x_j > x_j^u$ for some $j \in N$,

Fig. 8 An illustration of the labeling rule on $R^2 \times \{0\}$ for Example 6

$$l(x, 0) = \max\{k \mid x_k - x_k^u = \max_{j \in N} x_j - x_j^u\}.$$

4. For $(x, 0)$ with $x \leq x^u$ and $x_j < x_j^l$ for some $j \in N$,

$$l(x, 0) = \begin{cases} n+1 & \text{if } x < x^l, \\ \max\{k \mid x_k - x_k^l = \max_{j \in N} x_j - x_j^l\} & \text{otherwise.} \end{cases}$$

Example 6 Consider

$$P = \{x = (x_1, x_2)^\top \mid 2x_1 - x_2 \leq \frac{1}{2}, -\frac{7}{6}x_1 + x_2 \leq \frac{1}{2}, -x_1 - x_2 \leq \frac{9}{5}\},$$

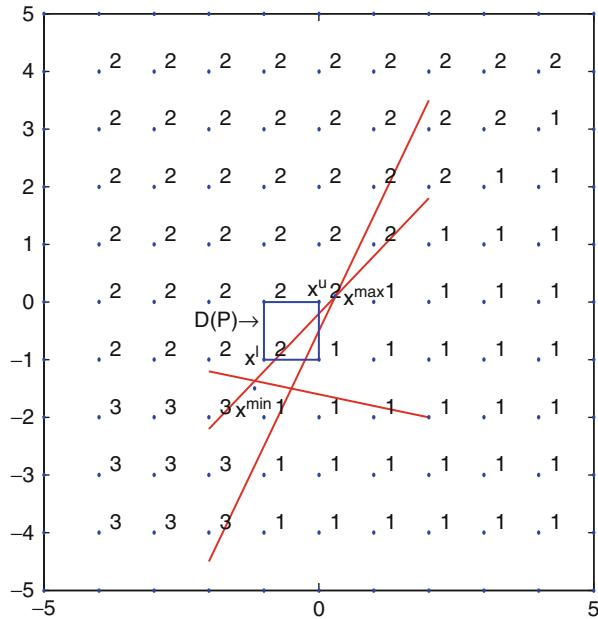

which has an integer point. **Figure 8** illustrates the labeling rule on $R^2 \times \{0\}$ for this polytope.

Example 7 Consider

$$P = \{x = (x_1, x_2)^\top \mid 2x_1 - x_2 \leq \frac{1}{2}, -x_1 + x_2 \leq -\frac{1}{5}, -\frac{1}{5}x_1 - x_2 \leq \frac{8}{5}\},$$

which has no integer point. **Figure 9** illustrates the labeling rule on $R^2 \times \{0\}$ for this polytope.

Fig. 9 An illustration of the labeling rule on $R^2 \times \{0\}$ for Example 7

Let $h(n+1) = (1, 1, \dots, 1, 0)^\top \in R^{n+1}$ and $h(j) = -u^j$, $j = 1, 2, \dots, n$. Let $G(x^0, \emptyset) = \{(x^0, 0)\}$ and $G(x^0, N_0) = \Gamma(x^0, R^n)$. For any $K \subset N_0$ with $K \neq \emptyset$, let

$$G(x^0, K) = \{(x^0, 0) + \sum_{j \in K} \lambda_j h(j) \mid 0 \leq \lambda_j, j \in K\}.$$

Clearly, $\cup_{j \in N_0} G(x^0, N_0 \setminus \{j\}) = R^n \times \{0\}$ and, for any two subsets $K^1 \subset N_0$ and $K^2 \subset N_0$, the intersection of $G(x^0, K^1)$ and $G(x^0, K^2)$, $G(x^0, K^1) \cap G(x^0, K^2)$, is a common facet of both of them. Thus, $\{G(x^0, K) \mid K \subset N_0\}$ forms a subdivision of $R^n \times \{0\}$. An illustration of $G(x^0, K)$ is given in Fig. 10.

For further developments, a cubic triangulation is needed, whose restriction on $G(x^0, K)$ is a triangulation of $G(x^0, K)$ for each $K \subseteq N_0$. For simplicity, the K_1 -triangulation in Freudenthal [52] is adopted, which is as follows.

For $j \in N_0$, let u^j denote the j th unit vector of R^{n+1} . A simplex of the K_1 -triangulation of $\Gamma(x^0, R^n)$ is the convex hull of $n+2$ vectors, y^0, y^1, \dots, y^{n+1} , given by $y^0 = y$, $y^k = y^{k-1} + u^{\pi(k)}$, $k = 1, 2, \dots, n$, and $y^{n+1} = (x^0, 1)$, where $y = (y_1, y_2, \dots, y_{n+1})^\top$ is an integer point in $R^n \times \{0\}$ and $\pi = (\pi(1), \pi(2), \dots, \pi(n), \pi(n+1))$ is a permutation of elements of N_0 with $\pi(n+1) = n+1$. Let K_1 be the set of all such simplices. Then, K_1 forms a triangulation of $\Gamma(x^0, R^n)$. Since a simplex of the K_1 -triangulation is uniquely determined by y and π , it is denoted by $K_1(y, \pi)$. An illustration of the K_1 -triangulation can be found in Fig. 11.

Fig. 10 An illustration of $G(x^0, K)$

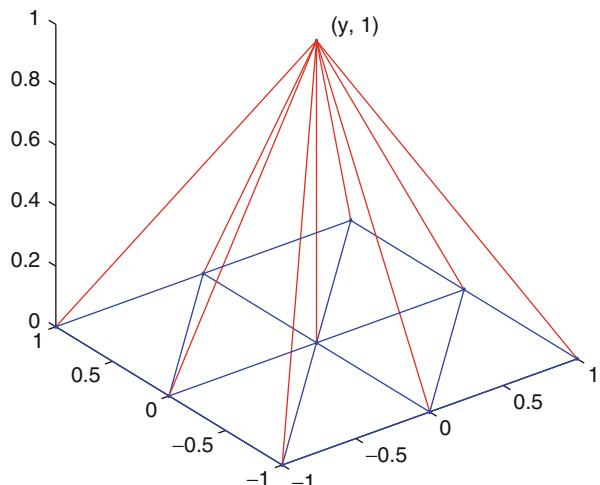

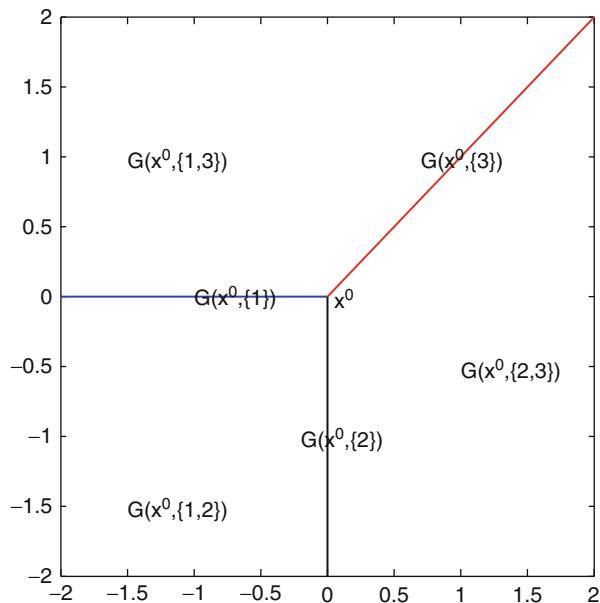

Fig. 11 An illustration of the K_1 -triangulation

Two simplices of K_1 are adjacent if they share a common facet. For any given simplex $\sigma = K_1(y, \pi)$ with vertices y^0, y^1, \dots, y^{n+1} , its adjacent simplex opposite to a vertex, say y^i , is given by $K_1(\bar{y}, \bar{\pi})$, where \bar{y} and $\bar{\pi}$ are generated according to the pivot rules in Table 4.

Let \mathcal{K}_1 be the set of faces of simplices of K_1 . A q -dimensional simplex of \mathcal{K}_1 with vertices y^0, y^1, \dots, y^q is denoted by $\langle y^0, y^1, \dots, y^q \rangle$. For $\sigma \in \mathcal{K}_1$ with $\sigma \subset R^n \times \{0\}$, let $\text{grid}(\sigma) = \max\{\|x-y\| \mid (x, 0) \in \sigma \text{ and } (y, 0) \in \sigma\}$, where $\|\cdot\|$ denotes

Table 4 Pivot rules of the K_1 -triangulation of $\Gamma(x^0, R^n)$

i	\bar{y}	$\bar{\pi}$
0	$y + u^{\pi(1)}$	$(\pi(2), \dots, \pi(n), \pi(1), \pi(n+1))$
$1 \leq i < n$	y	$(\pi(1), \dots, \pi(i+1), \pi(i), \dots, \pi(n+1))$
n	$y - u^{\pi(n)}$	$(\pi(n), \pi(1), \dots, \pi(n-1), \pi(n+1))$

the infinity norm. It is defined that $\text{mesh}(K_1) = \max\{\text{grid}(\sigma) \mid \sigma \in \mathcal{K}_1 \text{ and } \sigma \subset R^n \times \{0\}\}$. Then, $\text{mesh}(K_1) = 1$.

For $K \subset N_0$, the restriction of \mathcal{K}_1 on $G(x^0, K)$ is given by

$$\mathcal{K}_1|G(x^0, K) = \{\sigma \in \mathcal{K}_1 \mid \sigma \subset G(x^0, K) \text{ and } \dim(\sigma) = |K|\},$$

where $|\cdot|$ denotes the cardinality of a set and $\dim(\cdot)$ the dimension of a set. Obviously, $\mathcal{K}_1|G(x^0, K)$ is a triangulation of $G(x^0, K)$.

With the labeling rule and the K_1 -triangulation, a variable dimension simplicial method has been developed for computing an integer point in P , which is as follows.

Initialization: Let $K = \emptyset$, $y^0 = (x^0, 0)$, $\sigma_0 = \langle y^0 \rangle$, $y^+ = y^0$, and $k = 0$. Go to *Step 1*.

Step 1: If $l(y^+) = 0$, the method terminates, and an integer point of P has been found. If $K = N_0$ and $y^+ \geq (x^u, 0)$ with $y_{n+1}^+ = 0$, the method terminates, and P has no integer point. If $l(y^+) \in K$, let y^- be the vertex of σ_k other than y^+ and carrying integer label $l(y^+)$, and τ_{k+1} the facet of σ_k opposite to y^- , and go to *Step 2*. If $l(y^+) \notin K$, go to *Step 3*.

Step 2: If $\tau_{k+1} \subset G(x^0, K \setminus \{j\})$ for some $j \in K$, let $K = K \setminus \{j\}$ and go to *Step 4*. Otherwise, proceed as follows: Let σ_{k+1} be the unique simplex that is adjacent to σ_k and has τ_{k+1} as a facet. Let y^+ be the vertex of σ_{k+1} opposite to τ_{k+1} and $k = k + 1$. Go to *Step 1*.

Step 3: Let $K = K \cup \{l(y^+)\}$ and $\tau_{k+1} = \sigma_k$. Let σ_{k+1} be the unique $|K|$ -dimensional simplex in $G(x^0, K)$ having τ_{k+1} as a facet and y^+ the vertex of σ_{k+1} opposite to τ_{k+1} . Let $k = k + 1$, and go to *Step 1*.

Step 4: Let $\sigma_{k+1} = \tau_{k+1}$, y^- be the vertex of σ_{k+1} carrying integer label j , and τ_{k+2} the facet of σ_{k+1} opposite to y^- . Let $k = k + 1$, and go to *Step 2*.

Theorem 7 Within a finite number of iterations, the method either yields an integer point in P or proves no such point exists.

The following example illustrates how the method works when $n = 2$.

Example 8 Find an integer point in

$$P = \left\{ x = (x_1, x_2)^\top \mid -x_1 + x_2 \leq \frac{1}{2}, x_1 - x_2 \leq \frac{1}{2}, x_1 \leq \frac{4}{5}, -x_1 \leq \frac{4}{5} \right\}.$$

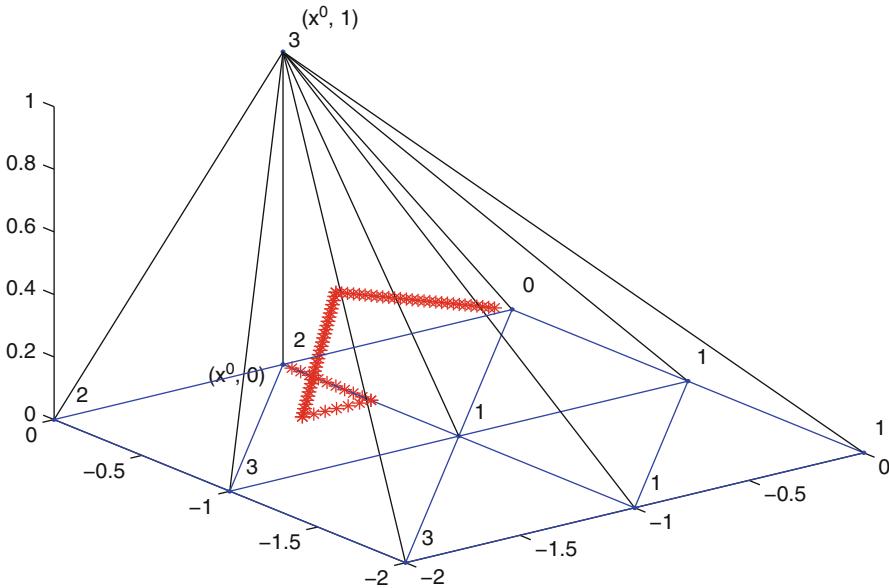

Fig. 12 An illustration of the method

Given this polytope, it is obtained that $x^u = (1, 0)^T$ and $x^l = (-1, 0)^T$. Let $x^0 = (-1, 0)^T$, $K = \emptyset$, $y^0 = (x^0, 0)$, $\sigma_0 = \langle y^0 \rangle$, and $y^+ = y^0$.

Iteration 1: $l(y^+) = 2 \notin K$. Let $K = K \cup \{2\} = \{2\}$, $\tau_1 = \sigma_0$, $y^1 = (-1, -1, 0)^T$, $\sigma_1 = \langle y^0, y^1 \rangle$, and $y^+ = y^1$.

Iteration 2: $l(y^+) = 1 \notin K$. Let $K = K \cup \{1\} = \{1, 2\}$, $\tau_2 = \sigma_1$, $y^2 = (-2, -1, 0)^T$, $\sigma_2 = \langle y^0, y^1, y^2 \rangle$, and $y^+ = y^2$.

Iteration 3: $l(y^+) = 3 \notin K$. Let $K = K \cup \{l(y^+)\} = \{1, 2, 3\} = N_0$, $\tau_3 = \sigma_2$, $y^3 = (-1, 0, 1)^T$, $\sigma_3 = \langle y^0, y^1, y^2, y^3 \rangle$, and $y^+ = y^3$.

Iteration 4: $l(y^+) = 3 = l(y^2) \in K$. Let $\tau_4 = \langle y^0, y^1, y^3 \rangle$, $y^2 = (0, 0, 0)^T$, $\sigma_4 = \langle y^0, y^1, y^2, y^3 \rangle$, and $y^+ = y^2$.

Iteration 5: $l(y^+) = 0$. An integer point of P has been found.

Figure 12 illustrates how the method moves along a simplicial path starting from $(x^0, 0)$ and ending at a feasible integer point in P .

In the remaining of this section, a proof to [Theorem 7](#) is given.

Lemma 5 *For any $x \in R^n$, $f(x) = 0$ if and only if $x \in P$.*

Proof It suffices to prove the “only if” part. Suppose that there is some $x \in R^n$ with $f(x) = 0$ and $x \notin P$. Then, $I(x) \neq \emptyset$. Thus, for any $y \in P$ (i.e., $b_i - a_i^T y \geq 0$ for all $i \in M$),

$$\begin{aligned}
0 &= (x - y)^\top f(x) = (x - y)^\top \sum_{i \in I(x)} \frac{a_i^\top x - b_i}{a_i^\top a_i} a_i = \sum_{i \in I(x)} \frac{a_i^\top x - b_i}{a_i^\top a_i} a_i^\top (x - y) \\
&= \sum_{i \in I(x)} \frac{a_i^\top x - b_i}{a_i^\top a_i} (a_i^\top x - b_i + b_i - a_i^\top y) \geq \sum_{i \in I(x)} \frac{a_i^\top x - b_i}{a_i^\top a_i} (a_i^\top x - b_i) \\
&= \sum_{i \in I(x)} \frac{(a_i^\top x - b_i)^2}{a_i^\top a_i} > 0.
\end{aligned}$$

Therefore, a contradiction occurs. This completes the proof. \square

Lemma 6 *If $f(x) \leq 0$ and $f(x) \neq 0$, then, for any $y \in P$, there is some $k \in N$ satisfying that $x_k - y_k < 0$.*

Proof Since $f(x) \neq 0$, hence, $I(x) \neq \emptyset$. Let y be an arbitrary point in P . Suppose that $x - y \geq 0$. Then, similar to that in the proof of [Lemma 5](#), one can obtain that $0 \geq (x - y)^\top f(x) > 0$. Thus, a contradiction occurs. The lemma follows immediately. \square

Definition 9

- A q -dimensional simplex $\sigma = \langle y^0, y^1, \dots, y^q \rangle$ of \mathcal{K}_1 is complete if $l(y^i) \neq l(y^j)$ for $0 \leq i < j \leq q$, and $l(y^k) \neq 0$, $k = 0, 1, \dots, q$.
- A q -dimensional simplex $\sigma = \langle y^0, y^1, \dots, y^q \rangle$ of \mathcal{K}_1 is 0-complete if $l(y^i) \neq l(y^j)$ for $0 \leq i < j \leq q$, and there is some k satisfying that $l(y^k) = 0$.
- A q -dimensional simplex $\sigma = \langle y^0, y^1, \dots, y^q \rangle$ of \mathcal{K}_1 is almost complete if labels of $q + 1$ vertices of σ consist of q different nonzero integers.

An illustration of this definition can be found in [Fig. 13](#). From [Definition 9](#), it is easy to see that an almost complete simplex has exactly two complete facets both carrying the same set of integer labels.

For $y \in R^n$ and $K \subseteq N$, let $H(y, K)$ be the “higher”-level cone originated at y along certain directions given in K , that is,

$$H(y, K) = \{y + h \in R^n \mid 0 \leq h_j, j \in K, \text{ and } h_j = 0, j \notin K\}.$$

Lemma 7 *If P has an integer point, then, for any integer point $z^0 \in P$ and any nonempty $K \subseteq N$, each integer point of $H(z^0, K) \times \{0\}$ carries either integer label 0 or an integer label in K .*

Proof Let $(x, 0)$ be an integer point of $H(z^0, K) \times \{0\}$. Consider that $x \in D(P)$. From [Lemma 6](#), it is known that $l(x, 0) \neq n + 1$ since $x \geq z^0$, which is equivalent to that $f(x) = 0$ or $f_j(x) > 0$ for some $j \in N$.

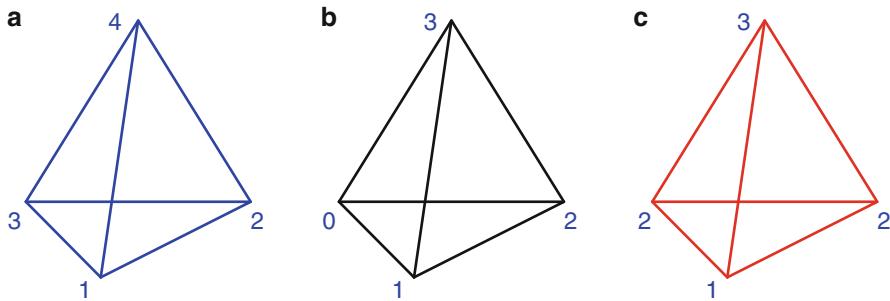

Fig. 13 An illustration of a complete simplex, a 0-complete simplex, and an almost complete simplex

Let $\lambda = x - z^0$. Then, $\lambda_j \geq 0$, $j \in K$, and $\lambda_j = 0$, $j \notin K$. Thus, for any constraint i with $a_{ij} \leq 0$ for all $j \in K$,

$$a_i^\top x = a_i^\top z^0 + a_i^\top \lambda \leq b_i + a_i^\top \lambda = b_i + \sum_{j \in K} a_{ij} \lambda_j \leq b_i.$$

This implies that, for every violated constraint $i \in I(x)$ (if exists), $a_{ij} > 0$ for some $j \in K$. Since at most one of a_{kj} , $j = 1, 2, \dots, n$, is positive for any $k \in M$; hence, $a_{ij} \leq 0$ for all $j \notin K$ and for every violated constraint i . Therefore, if $f_j(x) > 0$, one must have $j \in K$, that is, $l(x, 0) \in K$ from the labeling rule.

Consider $x \notin D(P)$. Since $x^l \leq z^0 \leq x$, hence, $x_j > x_j^u$ for some $j \in N$. From $x \in H(z^0, K)$, it is known that $x_j = z_j^0 \leq x_j^u$ for all $j \notin K$. Therefore, according to the labeling rule, $l(x, 0) \in K$. This completes the proof. \square

This lemma plays an essential role in the development. An illustration of labels of integer points in $H(z^0, K)$ can be found in Fig. 14. As a corollary of Lemma 7, it is obtained that

Corollary 1 If z^0 is an integer point of P , there is no complete n -dimensional simplex in $H(z^0, N) \times \{0\}$ carrying all integer labels in N_0 , and, for any $j \in N$ and $k \in N_0$, there is no complete $(n-1)$ -dimensional simplex in $H(z^0, N \setminus \{j\}) \times \{0\}$ carrying all integer labels in $N_0 \setminus \{k\}$.

Let

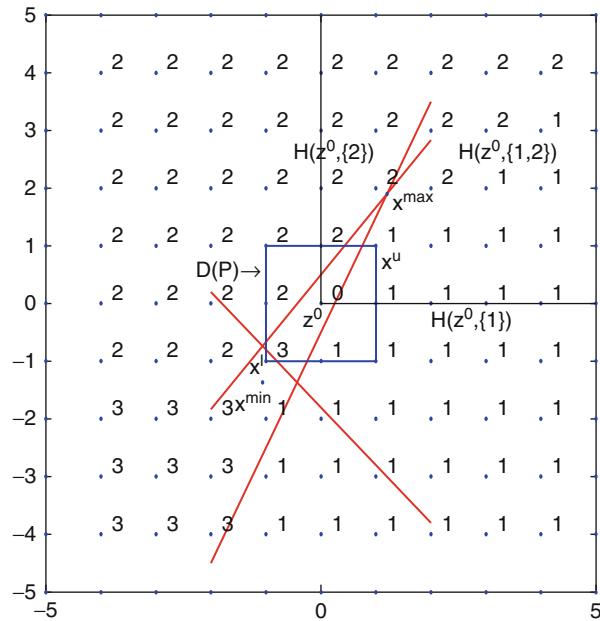

$$\Omega = \{x \in R^n \mid x^l - e \leq x \leq x^u + e\}$$

and $\partial\Omega$ denote the boundary of Ω . Clearly, $D(P) \subset \Omega$. Let $C(x^u)$ be a unit cube given by

$$C(x^u) = \{x \mid x^u \leq x \leq x^u + e\}.$$

Then, $C(x^u) = H(x^u, N) \cap \Omega$.

Fig. 14 An illustration of labels of integer points in $H(z^0, K)$

Lemma 8 $C(x^u) \times \{0\}$ contains all the complete $(n-1)$ -dimensional simplices in $\partial\Omega \times \{0\}$ carrying all integer labels in N .

Proof Let $\tau = \langle (y^1, 0), (y^2, 0), \dots, (y^n, 0) \rangle$ be a complete $(n-1)$ -dimensional simplex in $\partial\Omega \times \{0\}$ carrying all integer labels in N . Without loss of generality, it is assumed that $l(y^i, 0) = i$, $i = 1, 2, \dots, n$.

Since τ is an $(n-1)$ -dimensional simplex in the boundary of $\Omega \times \{0\}$, there must be an index $h \in N$ such that $y_h^1 = y_h^2 = \dots = y_h^n$. Suppose that

$$\tau \subset \{x \in \Omega \mid x_h = x_h^l - 1\} \times \{0\},$$

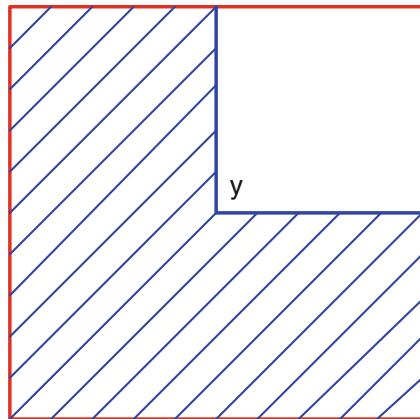

that is, this common entry hits the lower bound side of Ω . But, for any integer point $(x, 0) \in R^n \times \{0\}$, from (4) of the labeling rule, it follows that $l(x, 0) = n+1$ if $x < x^l$. Hence, $y^i \not< x^l$ for every vertex $(y^i, 0)$ of τ . In particular,

$$y_h^h - x_h^l = \max_{j \in N} y_j^h - x_j^l \geq 0.$$

This contradicts with $y_h^h = x_h^l - 1 < x_h^l$. Thus, the common entry of τ must hit the upper bound side of Ω , or

$$\tau \subset \{x \in \Omega \mid x_h = x_h^u + 1\} \times \{0\}.$$

Fig. 15 An illustration of $L(y, C)$ (shaded area)

For all $i \in N$, from $y_h^i = x_h^u + 1$, $y^i \leq x^u + e$, and

$$l(y^i, 0) = i = \max\{k \mid y_k^i - x_k^u = \max_{j \in N} y_j^i - x_j^u\},$$

it is derived that

$$y_i^i - x_i^u = \max_{j \in N} y_j^i - x_j^u = 1.$$

Therefore, as a result of $\text{mesh}(K_1) = 1$, it follows that $\tau \subset C(x^u) \times \{0\}$. This completes the proof. \square

For $y \in R^n$ and $C \subseteq R^n$, let

$$L(y, C) = \{x \in C \mid x_i \leq y_i \text{ for some } i \in N\}$$

and $\partial L(y, C)$ denote the boundary of $L(y, C)$. An illustration of $L(y, C)$ can be found in Fig. 15. As a result of Corollary 1 and Lemma 8, it is obtained that

Corollary 2 If z^0 is an integer point of P , there is no complete n -dimensional simplex in $\Gamma(x^0, \partial L(z^0, \Omega))$ carrying all integer labels in N_0 .

Lemma 9 For $K \subset N_0$ with $K \neq \emptyset$, there is no complete $(|K| - 1)$ -dimensional simplex in $G(x^0, K) \cap (\partial \Omega \times \{0\})$ carrying all integer labels in K .

Proof Suppose that $\tau = \langle (y^1, 0), (y^2, 0), \dots, (y^{|K|}, 0) \rangle$ is a complete $(|K| - 1)$ -dimensional simplex in $G(x^0, K) \cap (\partial \Omega \times \{0\})$ carrying all integer labels in K . Consider the case of $n + 1 \notin K$. Without loss of generality, it is assumed that $K = \{1, 2, \dots, k_0\}$ and $l(y^i, 0) = i$, $i = 1, 2, \dots, k_0$. Since $x^0 \leq x^u$ and $n + 1 \notin K$, there is some $h \in K$ such that

$$\tau \subset \{x \in \Omega \mid x \leq x^u \text{ and } x_h = x_h^l - 1\} \times \{0\}.$$

For any integer point $(x, 0) \in R^n \times \{0\}$, from (4) of the labeling rule, it is known that $l(x, 0) = n + 1$ if $\max_{j \in N} x_j - x_j^l < 0$. Thus, for every $i \in K$, from $x^0 \leq x^u$, $l(y^i, 0) = i$ and (4) of the labeling rule, it follows that

$$y_i^i - x_i^l = \max_{j \in N} y_j^i - x_j^l \geq 0.$$

This contradicts with $y_h^h = x_h^l - 1$.

Consider the case of $n + 1 \in K$. Since $|K| \leq n$, there is some $k \in N$ with $k \notin K$. Let $(y, 0)$ be the vertex of τ with $l(y, 0) = n + 1$. Then, from $y \in \partial\Omega$ and the labeling rule, one can get that $y = x^l - e$ since $x^l - e$ is a unique integer point in $\partial\Omega$ carrying integer label $n + 1$. However, from $(y, 0) \in G(x^0, K)$ and $k \in N$ with $k \notin K$, it holds that $y_k \geq x_k^0 \geq x_k^l$. This contradicts with $y_k = x_k^l - 1$. The lemma follows immediately. \square

[Corollaries 1, 2](#), and [Lemma 9](#) together imply the following conclusion.

Corollary 3 *All the simplices generated by the method are contained in $\Gamma(x^0, \Omega)$.*

To prove [Theorem 7](#), one needs to show first that the method does not cycle. To accomplish this task, one can rely on an undirected graph. For convenience of further discussions, several shorthand notations are introduced in the following:

1. An AC(K)S stands for an almost complete $|K|$ -dimensional simplex, which carries only integer labels in K and is contained in $G(x^0, K) \cap \Gamma(x^0, \Omega)$.
2. A C(K)S stands for a complete $|K|$ -dimensional simplex, which carries all integer labels in K and is contained in $G(x^0, K) \cap \Gamma(x^0, \Omega)$.
3. A ZC(K)S stands for a 0-complete $|K|$ -dimensional simplex, which carries all integer labels in K and is contained in $G(x^0, K) \cap \Gamma(x^0, \Omega)$.
4. A C($K, -1$)S stands for a complete $(|K| - 1)$ -dimensional simplex, which carries all integer labels in K and is contained in $\cup_{j \in K} (G(x^0, K \setminus \{j\}) \cap \Gamma(x^0, \Omega))$.
5. A C(n)S stands for a complete n -dimensional simplex in $\Gamma(x^0, \partial\Omega)$.

For $K \subset N_0$, a graph $\Xi(K)$ is defined as follows:

- Nodes of $\Xi(K)$ consist of:
 1. All AC(K)Ss
 2. All C(K)Ss
 3. All ZC(K)Ss
 4. All C($K, -1$)Ss
 - There is an edge between two nodes of $\Xi(K)$ if one is a complete facet of the other or they have a common complete facet that carries all integer labels in K .
- For $K = N_0$, a graph $\Xi(N_0)$ is defined as follows:
- Nodes of $\Xi(N_0)$ consist of:
 1. All AC(N_0)Ss
 2. All ZC(N_0)Ss
 3. All C($N_0, -1$)Ss
 4. All C(n)Ss

- There is an edge between two nodes of $\Xi(N_0)$ if one is a complete facet of the other or they have a common complete facet that carries all integer labels in N_0 .

Let Ξ be a graph formed by taking the union of the graphs $\Xi(K)$ over all the subsets K of N_0 in such a way that all the nodes given by the same complete simplex become one node of Ξ .

Two nodes of a graph are adjacent if there is an edge between them. The degree of a node of a graph is equal to the number of nodes adjacent to it.

Let us first determine the degree of each node of Ξ .

1. Consider node σ of an $AC(K)S$. From the definition of Ξ , one can obtain that node σ is only adjacent to a pair of nodes given by one of the following pairs:

- a. Two $AC(K)S$ s
- b. An $AC(K)S$ and a $C(K)S$
- c. An $AC(K)S$ and a $ZC(K)S$
- d. An $AC(K)S$ and a $C(K, -1)S$
- e. Two $C(K)S$ s
- f. A $C(K)S$ and a $ZC(K)S$
- g. A $C(K)S$ and a $C(K, -1)S$
- h. Two $ZC(K)S$ s
- i. A $ZC(K)S$ and a $C(K, -1)S$
- j. Two $C(K, -1)S$ s

Thus, node σ has degree 2 (a balanced node).

2. Consider node σ of a $C(K)S$ with $0 < |K| \leq n$. Let h denote the unique integer label that is carried by σ and does not belong to K . From the definition of Ξ , one can obtain that node σ is only adjacent to a pair of nodes given by one of the following pairs:

- a. An $AC(K)S$ and an $AC(K \cup \{h\})S$
- b. An $AC(K)S$ and a $C(K \cup \{h\})S$
- c. An $AC(K)S$ and a $ZC(K \cup \{h\})S$
- d. A $C(K)S$ and an $AC(K \cup \{h\})S$
- e. A $C(K)S$ and a $C(K \cup \{h\})S$
- f. A $C(K)S$ and a $ZC(K \cup \{h\})S$
- g. A $ZC(K)S$ and an $AC(K \cup \{h\})S$
- h. A $ZC(K)S$ and a $C(K \cup \{h\})S$
- i. A $ZC(K)S$ and a $ZC(K \cup \{h\})S$
- j. A $C(K, -1)S$ and an $AC(K \cup \{h\})S$
- k. A $C(K, -1)S$ and a $C(K \cup \{h\})S$
- l. A $C(K, -1)S$ and a $ZC(K \cup \{h\})S$

Thus, node σ has degree 2 (a balanced node).

3. Consider node σ of a $C(K)S$ with $|K| = 0$. Then, $\sigma = (x^0, 0)$. From the definition of Ξ , one can obtain that node σ is only adjacent to the node given by one of the following:

- a. An $AC(\{l(x^0, 0)\})S$
- b. A $C(\{l(x^0, 0)\})S$
- c. A $ZC(\{l(x^0, 0)\})S$

Thus, node σ has degree 1 when $|K| = 0$ (an unbalanced node).

4. Consider node σ of a $ZC(K)S$. From the definition of Ξ , one can obtain that node σ is only adjacent to the node given by one of the following:

- a. An $AC(K)S$
- b. A $C(K)S$
- c. A $ZC(K)S$
- d. A $C(K, -1)S$

Thus, node σ has degree 1 (a balanced node).

5. Consider node σ of a $C(n)S$. From the definition of Ξ , one can obtain that node σ is only adjacent to the node given by one of the following:

- a. An $AC(N_0)S$
- b. A $ZC(N_0)S$

Thus, node σ has degree 1 (an unbalanced node).

From the construction of Ξ , one can see that each node of Ξ belongs uniquely to one of these five categories. The above results show that the degree of each node of Ξ is at most two and that $(x^0, 0)$, $C(n)S$ s, and $ZC(K)S$ s are the only nodes that have degree 1. Therefore, it follows that

Lemma 10 *Each connected component of Ξ has one of the following forms:*

- *A simple circuit, in which each of nodes has degree 2.*
- *A simple path, in which each of end nodes has degree 1 and is given by one of the following:*
 1. $(x^0, 0)$
 2. A $C(n)S$
 3. A $ZC(K)S$

Clearly, the starting point of the method, $(x^0, 0)$, is a node of Ξ with degree 1. Thus, $(x^0, 0)$ is a starting node of a simple path of Ξ . Let P_{x^0} denote the simple path of Ξ starting from $(x^0, 0)$. From the method, one can see that all the simplices generated by the method are nodes of P_{x^0} . In fact, the method exactly follows P_{x^0} by moving from one node to another. Therefore, the method does not cycle.

Proof of Theorem 7

1. Assume that P has an integer point. Let z^0 be an integer point of P . Suppose that $x^0 \geq z^0$. Then, from [Lemma 7](#) and [Corollary 1](#), it is derived that all the simplices generated by the method are contained in the bounded set $\{x \in R^n \mid z^0 \leq x \leq x^0\} \times \{0\}$. Thus, within a finite number of iterations, the method terminates with a $ZC(K)S$.

Suppose that $x^0 \not\geq z^0$. Then, $x^0 \in \mathcal{L}(z^0, D(P)) \subseteq L(z^0, \Omega)$. Thus, from [Lemma 7](#), [Corollaries 1, 2](#), and [Lemma 9](#), it is derived that all the simplices generated by the method are contained in the bounded set $\Gamma(x^0, L(z^0, \Omega))$. Since $z^0 \leq x^u$, hence, within a finite number of iterations, the method terminates with a $ZC(K)S$.

2. Assume that P has no integer point. As a result of [Corollary 3](#), one can obtain that, within a finite number of iterations, the method terminates with $K = N_0$ and a vertex $(y, 0)$ such that $y \geq x^u$. This completes the proof. \square

8 A Homotopy-Like Simplicial Method for Integer Programming

Let $x^0 = (x_1^0, x_2^0, \dots, x_n^0)^\top$ be an arbitrary integer point in $D(P)$.

Definition 10 (An Integer Labeling Rule) For each integer point $(x, \gamma) \in (R^n \times [-1, 0]) \cup \Gamma(x^0, R^n)$, assign to (x, γ) an integer label $l(x, \gamma) \in N_0 \cup \{0\}$ as follows:

1. $l(x^0, 1) = n + 1$.
2. For $(x, 0)$ with $x \in D(P)$,

$$l(x, 0) = \begin{cases} 0 & \text{if } f(x) = 0, \\ \max\{k \mid f_k(x) = \max_{j \in N} f_j(x)\} & \text{if } f_j(x) > 0 \text{ for some } j \in N, \\ n + 1 & \text{if } f(x) \leq 0 \text{ and } f(x) \neq 0. \end{cases}$$

3. For $(x, 0)$ with $x \geq x^l$ and $x_j > x_j^u$ for some $j \in N$,

$$l(x, 0) = \max\{k \mid x_k - x_k^u = \max_{j \in N} x_j - x_j^u\}.$$

4. For $(x, 0)$ with $x_j < x_j^l$ for some $j \in N$, $l(x, 0) = n + 1$.

5. For $(x, -1)$ with $x \geq x^0$ and $x_j > x_j^0$ for some $j \in N$,

$$l(x, -1) = \max\{k \mid x_k - x_k^0 = \max_{j \in N} x_j - x_j^0\}.$$

6. For $(x, -1)$ with $x = x^0$ or $x_j < x_j^0$ for some $j \in N$, $l(x, -1) = n + 1$.

For further discussions, one needs a triangulation of $(R^n \times [-1, 0]) \cup \Gamma(x^0, R^n)$ that subdivides both $R^n \times [-1, 0]$ and $\Gamma(x^0, R^n)$ into simplices in such a way that every integer point of $(R^n \times [-1, 0]) \cup \Gamma(x^0, R^n)$ is a vertex of some simplex of the triangulation and every such vertex is an integer point of $(R^n \times [-1, 0]) \cup \Gamma(x^0, R^n)$. Any cubic triangulation of R^n can be an underlying triangulation of the method. For simplicity, one can choose the K_1 -triangulation in Freudenthal [52], which is as follows.

For $k = 1, 2, \dots, n + 1$, let u^k be the k th unit vector of R^{n+1} . A simplex of the K_1 -triangulation of $(R^n \times [-1, 0]) \cup \Gamma(x^0, R^n)$ is the convex hull of $n + 2$ vectors, $y^0, y^1, \dots, y^n, y^{n+1}$, given by $y^0 = y$, $y^k = y^{k-1} + u^{\pi(k)}$, $k = 1, 2, \dots, n$, and

$$y^{n+1} = \begin{cases} y^n + u^{\pi(n+1)} & \text{if } y_{n+1} = -1, \\ (x^0, 1) & \text{otherwise,} \end{cases}$$

where $y = (y_1, y_2, \dots, y_{n+1})^\top$ is an integer point in $R^n \times [-1, 0]$ and $\pi = (\pi(1), \pi(2), \dots, \pi(n+1))$ is a permutation of elements of N_0 such that $\pi(n+1) =$

Table 5 Pivot rules of the K_1 -triangulation of $(R^n \times [-1, 0]) \cup \Gamma(x^0, R^n)$

i		\bar{y}	$\bar{\pi}$
0	$y_{n+1} = -1$	$y + u^{\pi(1)}$	$(\pi(2), \dots, \pi(n+1), \pi(1))$
	$y_{n+1} = 0$	$y + u^{\pi(1)}$	$(\pi(2), \dots, \pi(n), \pi(1), \pi(n+1))$
$1 \leq i < n$		y	$(\pi(1), \dots, \pi(i+1), \pi(i), \dots, \pi(n+1))$
n	$y_{n+1} = -1$	y	$(\pi(1), \dots, \pi(n-1), \pi(n+1), \pi(n))$
	$y_{n+1} = 0$	$y - u^{\pi(n)}$	$(\pi(n), \pi(1), \dots, \pi(n-1), \pi(n+1))$
$n+1$		$y - u^{\pi(n+1)}$	$(\pi(n+1), \pi(1), \dots, \pi(n))$

$n+1$ if $y_{n+1} = 0$. Let K_1 be the set of all such simplices. Then, K_1 is a triangulation of $(R^n \times [-1, 0]) \cup \Gamma(x^0, R^n)$. Since a simplex of the K_1 -triangulation is uniquely determined by y and π , it is denoted as $K_1(y, \pi)$. Two simplices of K_1 are adjacent if they share a common facet. For a given simplex $\sigma = K_1(y, \pi)$ with vertices y^0, y^1, \dots, y^{n+1} , its adjacent simplex opposite to a vertex, say y^i , is given by $K_1(\bar{y}, \bar{\pi})$, where \bar{y} and $\bar{\pi}$ are generated according to the pivot rules given in [Table 5](#).

Let \mathcal{K}_1 be the set of faces of simplices of K_1 . A q -dimensional simplex of \mathcal{K}_1 with vertices y^0, y^1, \dots, y^q is denoted by $\langle y^0, y^1, \dots, y^q \rangle$. For $\sigma \in \mathcal{K}_1$ with $\sigma \subset R^n \times [-1, 0]$, let $\text{grid}(\sigma) = \max\{\|x - y\| \mid (x, \gamma_x) \in \sigma \text{ and } (y, \gamma_y) \in \sigma\}$, where $\|\cdot\|$ denotes the infinity norm. It is defined that

$$\text{mesh}(K_1) = \max\{\text{grid}(\sigma) \mid \sigma \in \mathcal{K}_1 \text{ and } \sigma \subset R^n \times [-1, 0]\}.$$

Then, $\text{mesh}(K_1) = 1$.

With the integer labeling rule in [Definition 10](#) and the K_1 -triangulation of $(R^n \times [-1, 0]) \cup \Gamma(x^0, R^n)$, a homotopy-like simplicial method is developed to determine whether there is an integer point in P , which is as follows.

Initialization: Let $y = (x^0, -1)$ and $\pi = (1, 2, \dots, n+1)$. Then, $\sigma_0 = K_1(y, \pi) = \langle y^0, y^1, \dots, y^{n+1} \rangle$ is a unique $(n+1)$ -dimensional simplex of K_1 in $R^n \times [-1, 0]$ having τ_0 as a facet. Let y^+ be the vertex of σ_0 opposite to τ_0 and $k = 0$. Go to *Step 1*.

Step 1: Compute $l(y^+)$. If $l(y^+) = 0$, the method terminates and an integer point of P has been found. If $\sigma_k \subset \Gamma(x^0, R^n)$ and $y^+ \geq (x^u, 0)$ with $y_{n+1}^+ = 0$, the method terminates and P has no integer point. Otherwise, let y^- be the vertex of σ_k other than y^+ and carrying integer label $l(y^+)$ and τ_{k+1} the facet of σ_k opposite to y^- , and go to *Step 2*.

Step 2: Let σ_{k+1} be the unique $(n+1)$ -dimensional simplex that is adjacent to σ_k and has τ_{k+1} as a facet, y^+ the vertex of σ_{k+1} opposite to τ_{k+1} , and $k = k + 1$, and go to *Step 1*.

Theorem 8 Within a finite number of iterations, the method either yields an integer point in P or proves that no such point exists.

The following example illustrates how the method works when $n = 2$.

Example 9 Consider

$$P = \left\{ x = (x_1, x_2)^\top \middle| \begin{array}{l} -x_1 + x_2 \leq 1/2, \\ x_1 - x_2 \leq 1/2, \\ x_1 \leq 4/5, \\ -x_1 \leq 4/5 \end{array} \right\}.$$

[Figure 16](#) illustrates how the method moves along a simplicial path starting from τ_0 and ending at a feasible integer point in P .

In the following, a proof of [Theorem 8](#) is given.

For $y \in R^n$ and $K \subseteq N$, let

$$H(y, K) = \{y + x \mid 0 \leq x_i, i \in K, \text{ and } x_i = 0, i \notin K\}.$$

Let $y = (x^0, -1)$, $\pi = (1, 2, \dots, n+1)$, $y^0 = y$, $y^k = y^{k-1} + u^k$, $k = 1, 2, \dots, n+1$, $\tau_0 = \langle y^0, y^1, \dots, y^n \rangle$, and $\sigma_0 = \langle y^0, y^1, \dots, y^{n+1} \rangle$. Then, from [Definition 10](#), it holds that $l(y^0) = n+1$ and $l(y^k) = k$, $k = 1, 2, \dots, n$. Thus, τ_0 is a complete n -dimensional simplex in $R^n \times \{-1\}$.

Lemma 11 τ_0 is a unique complete n -dimensional simplex of \mathcal{K}_1 in $R^n \times \{-1\}$.

Proof Let $\tau = \langle \bar{y}^0, \bar{y}^1, \dots, \bar{y}^n \rangle$ be a complete n -dimensional simplex of \mathcal{K}_1 in $R^n \times \{-1\}$. Without loss of generality, it is assumed that $l(\bar{y}^0) = n+1$ and $l(\bar{y}^i) = i$, $i = 1, 2, \dots, n$. Then, from [Definition 10](#), it holds that $\bar{y}^i \geq (x^0, -1)$ and $\bar{y}_i^i \geq x_i^0 + 1$, $i = 1, 2, \dots, n$. Thus, as a result of $\text{mesh}(\mathcal{K}_1) = 1$, it follows that $\tau \subset H(x^0, N) \times \{-1\}$. Since $(x^0, -1)$ is a unique point of $H(x^0, N) \times \{-1\}$ carrying integer label $n+1$, hence, $\bar{y}^0 = (x^0, -1)$. Therefore, according to [Definition 10](#) and the definition of the \mathcal{K}_1 -triangulation of $(R^n \times [-1, 0]) \cup \Gamma(x^0, R^n)$, one must have that $\bar{y}^i = \bar{y}^{i-1} + u^i$, $i = 1, 2, \dots, n$. So, $\tau = \tau_0$. This completes the proof. \square

Lemma 12 There is no complete n -dimensional simplex of \mathcal{K}_1 in $\partial\Omega \times [-1, 0]$.

Proof Suppose that

$$\sigma = \langle (y^0, \gamma), (y^1, -1), \dots, (y^h, -1), (y^{h+1}, 0), \dots, (y^n, 0) \rangle$$

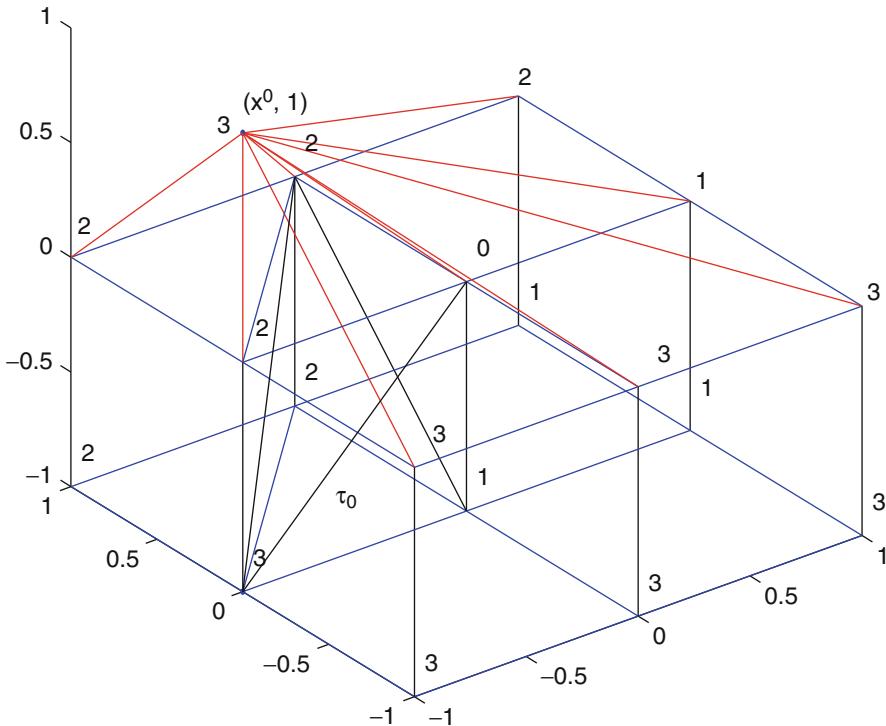

Fig. 16 An illustration of the method

with $\gamma \in \{-1, 0\}$ a complete n -dimensional simplex of \mathcal{K}_1 in $\partial\Omega \times [-1, 0]$. Without loss of generality, it is assumed that $l(y^0, \gamma) = n + 1$, $l(y^i, -1) = i$, $i = 1, 2, \dots, h$, and $l(y^i, 0) = i$, $i = h + 1, h + 2, \dots, n$. Then, from [Definition 10](#), it holds that for some $k \in N$,

$$y_k^0 \leq x_k^0 - 1 \text{ if } \gamma = -1, \text{ and } y_k^0 \leq x_k^l - 1 \text{ if } \gamma = 0,$$

and that

$$y_i^i \geq x_i^0 + 1, \quad i = 1, \dots, h,$$

$$y_i^i \geq x_i^u + 1, \quad i = h + 1, \dots, n.$$

Thus, when $\gamma = -1$, if $k \leq h$, then

$$y_k^k - y_k^0 \geq x_k^0 + 1 - x_k^0 + 1 = 2,$$

and if $k > h$, then

$$y_k^k - y_k^0 \geq x_k^u + 1 - x_k^0 + 1 \geq 2;$$

and, when $\gamma = 0$, if $k \leq h$, then

$$y_k^k - y_k^0 \geq x_k^0 + 1 - x_k^l + 1 \geq 2,$$

and if $k > h$, then

$$y_k^k - y_k^0 \geq x_k^u + 1 - x_k^l + 1 \geq 2.$$

Therefore, $\text{grid}(\sigma) \geq 2$, which contradicts with $\text{mesh}(K_1) = 1$. This completes the proof. \square

Lemma 13 $\Gamma(x^0, H(x^u, N) \cap \Omega)$ contains all the complete n -dimensional simplices in $\Gamma(x^0, \partial\Omega)$.

Proof Let $\tau = \{(y^1, 0), (y^2, 0), \dots, (y^n, 0)\}$ be a complete $(n-1)$ -dimensional simplex in $\partial\Omega \times \{0\}$ carrying all integer labels in N . Without loss of generality, it is assumed that $l(y^i, 0) = i$, $i = 1, 2, \dots, n$. Then, from [Definition 10](#), it holds that there is some $k \in N$ satisfying that $\tau \subset \{x \mid x \geq x^l \text{ and } x_k = x_k^u + 1\}$. Thus, for any $i \in N$, from $l(y^i, 0) = i$, it is derived that $y_i^i - x_i^u \geq 1$. Therefore, as a result of $\text{mesh}(K_1) = 1$, it follows that $\tau \subset (H(x^u, N) \cap \Omega) \times \{0\}$. This completes the proof. \square

[Lemmas 11, 12](#), [Corollary 1](#), [Lemma 13](#), and [Corollary 2](#) together imply the following conclusion.

Corollary 4 All the simplices generated by the method are contained in $(\Omega \times [-1, 0]) \cup \Gamma(x^0, \Omega)$.

To prove [Theorem 8](#), one needs to show first that the method does not cycle. To accomplish this task, one can rely on an undirected graph. In the following discussions,

1. A C(n)S stands for a complete n -dimensional simplex in the boundary of $(\Omega \times [-1, 0]) \cup \Gamma(x^0, \Omega)$.
2. An AC($n+1$)S stands for an almost complete $(n+1)$ -dimensional simplex in $(\Omega \times [-1, 0]) \cup \Gamma(x^0, \Omega)$.
3. A C($n+1$)S stands for a 0-complete $(n+1)$ -dimensional simplex in $(\Omega \times [-1, 0]) \cup \Gamma(x^0, \Omega)$.

Let Φ be a graph defined as follows. Nodes of Φ consist of:

1. All C(n)Ss.
2. All AC($n+1$)Ss.
3. All C($n+1$)Ss.

There is an edge between two nodes of Φ if one is a complete facet of the other or they have a common complete facet carrying all integer labels in N_0 .

Let us first determine the degree of each node of Φ :

1. Consider node σ of a $C(n)S$. From the definition of Φ , one can obtain that node σ is only adjacent to a node given by one of the following:
 - a. An $AC(n+1)S$
 - b. A $C(n+1)S$
 Thus, node σ has degree 1 (which is called an unbalanced node).
2. Consider node σ of an $AC(n+1)S$. From the definition of Φ , one can obtain that node σ is only adjacent to a pair of nodes given by one of the following pairs:
 - a. Two $C(n)S$ s
 - b. A $C(n)S$ and an $AC(n+1)S$
 - c. A $C(n)S$ and a $C(n+1)S$
 - d. Two $AC(n+1)S$ s
 - e. An $AC(n+1)S$ and a $C(n+1)S$
 - f. Two $C(n+1)S$ s
 Thus, node σ has degree 2 (which is called a balanced node).

3. Consider node σ of a $C(n+1)S$. From the definition of Φ , one can obtain that node σ is only adjacent to a node given by one of the following:
 - a. A $C(n)S$
 - b. An $AC(n+1)S$
 - c. A $C(n+1)S$

Thus, node σ has degree 1 (an unbalanced node).

From the construction of Φ , one can see that each node of Φ belongs uniquely to one of these three categories. The above results show that the degree of each node of Φ is at most two and that $C(n+1)S$ s and $C(n)S$ s are only nodes that have degree 1. Therefore, it follows that

Lemma 14 *Each connected component of Φ has one of the following forms:*

- *A simple circuit, in which each of nodes has degree 2*
- *A simple path, in which each of end nodes has degree 1 and is given by one of the following:*
 1. A $C(n)S$
 2. A $C(n+1)S$

Clearly, the starting simplex of the method, τ_0 , is a node of Φ with degree 1. Thus, τ_0 is a starting node of a simple path of Φ . Let P_{τ_0} denote the simple path of Φ starting from τ_0 . From the method, one can see that all the simplices generated by the method are nodes of P_{τ_0} . In fact, the method exactly follows P_{τ_0} by moving from one node to another. Therefore, the method does not cycle.

Proof of Theorem 8

1. Assume that P has an integer point. As a result of Corollaries 2 and 4, one can obtain that, within a finite number of iterations, the method terminates with a $C(n+1)S$.

2. Assume that P has no integer point. As a result of [Lemma 13](#) and [Corollary 4](#), it follows that, within a finite number of iterations, the method terminates with a vertex $(y, 0)$ such that $y \geq x^u$. This completes the proof. \square

9 Conclusion

In this chapter, a brief introduction to simplicial methods has been presented for approximating fixed points and computing integer points in polytopes. As a powerful mechanism for constructive proofs and numerical solutions of many important scientific and engineering problems, simplicial methods have been substantially developed in the literature. However, due to space limitation, only some representative results have been included here. The major developments of simplicial methods and their applications might be found in the recommended reading.

Abstract

Interest in network sciences has greatly increased over the last decades. Network models were recognized as a crucial tool in analyzing dynamics of complex systems. Small-world networks are apparently ubiquitous in nature and possess some special properties which make them highly suitable to model the brain. In this survey the theory of small-world networks and their applications in computational neuroscience is reviewed. First formal definitions and properties of small-world networks and how different network characteristics relate to each other are discussed. An overview of brain network models including anatomical network models and functional network models is given, and general steps of building these models are discussed. Different techniques of brain data acquisition are considered and a brief overview of computational methods of analysis these data is given. Finally, research works that have been done on neural data and reported existence of small-world networks in brain are reviewed.

1 Introduction

Over the last decades, network models have been widely appreciated as an essential part in studying complex systems [4, 16, 97]. Networks provide information on which system components interact with each other putting aside the mechanisms of these interactions. The dynamics of the system is tightly connected to the structure of underlying network. In many cases it is easy to describe the behavior of tiny system components on a microscopic level, but much more challenging to understand complex macroscopic system processes. Studying the topological properties of system networks can provide an insight about the system's high-level structure and function.

The human brain is probably one of the most complex objects in nature. Although the basic mechanisms and function principles on single neuron level are understood, not much progress has been achieved in understanding global brain processes and function. Its ability to gather and integrate information from numerous sources and generate responses is tightly connected to the complicated structure of neural connections network [18, 98]. Studying neural activity on the high level of interaction patterns between large neuron populations and segregated anatomical regions may help to understand fundamental laws of brain function.

It has been found that many complex networks in physics and biology follow common organizational principles [5, 9, 87]. These networks are densely connected on the local (neighborhood) level, but at the same time have certain number of “long-range” connections linking nodes, which otherwise would be far apart. Watts and Strogatz in their seminal paper [104] called such networks small worlds, by analogy with small-world phenomenon described by Milgram in 1960s. After this first paper numerous studies have reported small-world properties in different kinds of networks, in particular, brain networks.

Small-world networks are attractive models of the brain, since they tend to optimize the efficiency of parallel information transfer through the network, and at the same time remain fault tolerant, that is, resilient to damage of single nodes or connections [10, 46, 53, 55, 61]. The local density of brain connections is rather intuitively expected, since long wiring connections are expensive from material and energy points of view [21, 23, 25, 50]. However, computational studies showed that brain does not exhibit purely local connectivity structure, having certain number of consistent “long-range” connections between distant areas. This suggests that brain networks possess neither random nor completely regular structure. Multiple studies have shown that topology of brain networks at all scales has small-world attributes, and it is the main topic of this survey.

This chapter is organized as following. In Sect. 2 the quantitative definition of small-world networks and review of their properties are given. Two main approaches to quantify the small-world property of the network exist. These approaches were introduced by Watts et al. and Latora et al., which are fundamental in small-world networks theory, and therefore they will be reviewed in high details. In Sect. 3 brain anatomical and functional networks are reviewed, consider common approaches of constructing brain network models, and discuss some computational methods of processing real brain data. A review of studies reported small-world networks in brain is provided. In Sect. 4 the concluding remarks regarding small-world networks and their place in modern neuroscience are provided.

2 Small-World Networks: Models and Properties

The small-world phenomenon first was defined in social sciences an area where such networks naturally arise. In 1960 psychologist from Yale University Stanley Milgram has conducted series of experiments, where he tried to estimate average distance through the acquaintances between pairs of people in the world [63]. Results of his experiments were rather striking. He has found that average distance through the acquaintances between any two people is close to 6. Keeping in mind the total size of world’s population, this incredibly low number indicates that the social network of acquaintances has some very special structure. Milgram has called this finding a small-world phenomenon. Such short sequences of acquaintances between pairs of people are especially surprising, because social networks are known to have locally high-dense high-clustered structure, and most of the pairwise distances between people from different clusters are expected to be long.

Mathematically, Milgram’s findings can be formulated as low value of the average shortest path length between nodes in the dense, highly clustered network. Since in considered social network the connections are simply binary, two nodes are either connected or not; it is the topology of the network that makes it small world. Similar properties later were found in numerous social, economic, and biological networks. This gave rise to an interest in studying the properties and topology of small-world networks.

There are two main approaches in quantifying small-world network properties. One comprises evaluation of network characteristic path length and clustering coefficient, another focuses on quantifying network efficiency properties. Small-world networks have been shown to have low values of characteristic path length while maintaining high clustering coefficient. These properties can be reformulated in terms of one integrated measure of network efficiency: small-world networks have high values of network efficiency on both global and local levels. Below the formal definitions to these measures are given, and the relationships between them are discussed. Also, a review of models of network topology which give rise to small-world attributes is provided.

2.1 Characteristic Path Length and Clustering Coefficient

Consider a network $G = \{N, E\}$, where N is set of nodes, and E is a set of edges. Let d_{ij} be the length of the shortest path between nodes i and j through the connections in the network. This length computationally can be determined by variety of simple algorithms, like breadth-first search, or Dijkstra's algorithm. The characteristic path length L of the network G is defined as

$$L = \frac{1}{n(n-1)} \sum_{(i,j) \in E} d_{ij},$$

where n is a size of set N (number of nodes in the network).

Consider an arbitrary node i of the network G . Let G_i be a subgraph of G , containing nodes, adjacent to i . The local clustering coefficient C_i is defined as

$$C_i = \frac{\# \text{ of arcs in } G_i}{k_i(k_i - 1)},$$

where k_i is a number of nodes in G_i . Therefore, C_i is a fraction of arcs in subgraph G_i divided by maximum possible number of arcs, when G_i is a complete graph. The global clustering coefficient C is defined as a mean of local clustering coefficients:

$$C = \frac{1}{n} \sum_{i \in N} C_i.$$

The characteristic path length measures the typical distance between pairs of nodes, which is the global property of the network, while clustering coefficient measures the average “cliquishness,” or local connectedness of neighborhoods in the network, which is a local property. Characteristic path length and clustering coefficient are applicable to the connected binary networks. Two typical families of binary networks with simply expressed topology are regular networks or lattices and random networks. Regular networks can be thought of as networks, where nodes are placed on a grid and the neighboring nodes are connected by an edge.

Random networks, on the other hand, are the networks, where connections are thrown between nodes randomly according to uniform distribution. The topology of small-world networks lies somewhere between these two extreme cases. A simple model of binary networks exhibiting small-world topology was proposed by Watts and Strogatz [104]. The networks were generated from regular networks by random rewiring some of the edges, introducing degree of disorder into network topology. By changing the number of rewired edges, the networks can be tuned between regular and random states, passing through the range of intermediate topologies. For certain range of rewiring probability p , the resulting networks were highly clustered, like regular lattices, yet had small characteristic path lengths, like random graphs. Watts and Strogatz called these networks small worlds by analogy with the small-world phenomenon [104].

It turns out that these features are present in many real world networks. First such results were obtained by Watts and Strogatz in the same work [104], where they considered collaboration network of actors in films, the electrical power grid of the western United States, and the neural network of the nematode worm *C. elegans*. All three real networks of completely different nature exhibited small-world properties, having low characteristic path length and high clustering coefficients. This indicates that the small-world phenomenon is not merely a curiosity of social networks nor an artifact of an idealized model, but is common in networks found in nature.

2.2 Network Efficiency and Cost

Characteristic path length and clustering coefficient are useful only when studying unweighted (binary) connected networks with relatively small number of edges. Clearly, it does not cover whole variety of real networks. In most cases the information whether there is or there is not a connection between two nodes is poor and not sufficient in order to describe the network with suitable precision. Back to the network examples, considered above, in the case of films actors, the binary approximation only provides knowledge whether actors participated in some movie together, or not, and does not take into account the fact that two actors that have done ten movies together are in a much stronger relation than two actors that have acted together only once. In the case of the neural network, the number of junctions connecting a couple of neurons can vary a lot. A weighted network is more suitable to describe such system and can be built by setting the length of the connection proportional to the inverse number of junctions between nodes. The electrical power grid network is clearly a network where the geographical distances play a fundamental role.

The generalization on arbitrary networks can be made by using measure of so-called network efficiency. Network efficiency was introduced by Latora and Marchiori in [54, 55], where they proposed to express small-world properties of networks through its information transfer capabilities. The efficiency of transmitting information between two nodes in the network is inversely proportional to the distance between them (length of shortest path between given nodes). It turns out that small-world properties of the network can be formulated in terms of

the efficiency, which plays the role of characteristic path length L and clustering coefficient C . The formal definition follows.

Consider a network G as a weighted and possibly non-connected and non-sparse network. Let $(a)_{ij}$ be the adjacency matrix, containing the information about the existence of edges between nodes, and defined as for the topological network as a set of numbers $a_{ij} = 1$ for pairs of nodes (i, j) , connected by an edge, and $a_{ij} = 0$ for all other pairs. Let $(l)_{ij}$ be the matrix of weights associated with each connection, where element l_{ij} contains information about the weight of edge between nodes i and j . For the weighted network, the shortest path length d_{ij} between nodes i and j is defined as a minimum sum of weights of edges over all the possible paths in the graph from i to j . Suppose that every node in the graph sends information through the edges. One can assume that the efficiency e_{ij} of information transfer between nodes i and j is proportional to the inverse of the shortest path length from i to j , that is, $e_{ij} \sim \frac{1}{d_{ij}} \forall i \neq j$. In general this is a reasonable approximation, although in particular cases other relations can be used [55]. The average efficiency of the graph is defined as

$$E(G) = \frac{1}{N(N-1)} \sum_{i \neq j \in G} \frac{1}{d_{ij}}.$$

The value of E given by this formula may vary in the range $[0; \infty)$. The value of 0 is achieved in a completely disconnected network or in the network where lengths of all paths tend to infinity. The value of E tends to ∞ in weighted networks where lengths of shortest paths tend to 0. It is possible to normalize it by considering the extreme case of complete graph which has all $\frac{N(N-1)}{2}$ edges. In this case the information is being transferred in the most efficient way, and $d_{ij} = l_{ij} \forall i \neq j$. If one will divide actual E by E_{complete} of the complete graph, one will obtain a value from $[0; 1]$ range. Although the value 1 can be reached only when every pair of nodes in the network are connected with an edge, real networks often possess high values of normalized efficiency E [55].

The network efficiency can be measured on both local and global levels. The global meaning is defined as

$$E_{\text{global}} = \frac{E(G)}{E(G_{\text{complete}})},$$

where the normalization term $E(G_{\text{complete}})$ is an efficiency of the extreme case of complete graph. Arguably, E_{global} plays role similar to characteristic path length L , and it tells us how efficient is network in parallel information transferring [55]. In the case of disconnected graph, $L = \infty$, while E_{global} always remains finite value.

Let G_i be a subgraph of nodes, adjacent to node i , not including i itself. The local network efficiency is defined as mean of global efficiencies for subgraphs G_i over all $i \in V$:

$$E_{\text{loc}} = \frac{1}{N} \sum_{i \in G} \frac{E(G_i)}{E(G_i^{\text{complete}})},$$

where G_i^{complete} is a complete graph containing same vertices as G_i . E_{loc} is a mean of local efficiencies in the graph, and therefore it plays a role similar to the clustering coefficient. The local efficiency E_{local} tells how fault tolerant the system is, that is, how efficient is the communication between neighbors of i , when i is removed. High values of E_{local} mean that if one will randomly delete nodes from the network, the connectivity of the network will not be affected strongly.

The generalized definition of small world built in terms of the characteristics of information flow at global and local level is following: a small-world network is a network with high E_{global} and E_{loc} , that is, very efficient both in global and local communication [55]. This definition can be applied both for unweighted and for weighted networks, as well as to disconnected and/or nonsparse networks.

In order to understand the relation of two approaches to describe small-world networks, it is necessary to study the correspondence between E and L, C . Although both of measures L and E are related to the efficiency of flow transferring through the network, one should note that $1/L$ measures the efficiency of sequential system, like a system where there is only one path of information going along the network, whereas E is a measure of parallel systems, where information is being transferred through all the edges in the network [55].

In certain cases measure L works reasonably: it can be shown that $1/L$ is a reasonable approximation of E_{glob} when there are not significant differences among the distances in the graph [55]. However, it fails, like every approximation, to properly deal with all cases. Consider the limit case, where a node is isolated from the system. For neural network, this can be interpreted, for example, as the death of a neuron. In this case, $1/L$ drops to zero, since ($L = +\infty$), but the overall efficiency of the system is not affected that strongly: in fact, the brain continues to work, as all the other neurons continue to exchange information; only, the efficiency is just slightly decreased, since there is one neuron less. This slight change is properly taken into account using E_{glob} .

Similar relationship exists between clustering coefficient C and local efficiency E_{loc} . It can be shown that clustering coefficient C , in the case of undirected binary graphs, is always a reasonable approximation of E_{loc} [55]. It can be concluded therefore that there are no two different kinds of characteristics to consider when describing a network on the local and global levels. Exists just one general concept: the efficiency of information transfer [55].

Another important property of a network is its cost [55]. This measure comes into play particularly when dealing with real systems, modeled by weighted networks. Intuitively clear that the more edges there are in the network, the higher is the network's efficiency. On the other hand, in real situations there is a price to pay for number and length (weight) of edges. In particular the rewired edges that cause the fast drop of characteristic path length value L in the Watts and Strogatz model connect at no cost nodes that would otherwise be far apart. In realistic model, such connections would be expensive to create, and in certain cases this cost could overcome the gain in network efficiency, provided by adding these connections.

Therefore, it is necessary to consider weighted networks, where weights would allow us to differentiate between different edges in the network and to introduce a measure to quantify the cost of a network.

Formally, the cost of a network G is defined as

$$\text{Cost}(G) = \frac{\sum_{i \neq j \in G} a_{ij}\gamma(l_{ij})}{\sum_{i \neq j \in G} \gamma(l_{ij})}.$$

The function γ here identifies the cost needed to create a connection of a given length l_{ij} . Note that the value of total cost is normalized by dividing it by the cost of the complete graph, which contains all the possible edges. Because of such a normalization, the γ function needs only to be defined up to a multiplicative constant, and the measure $\text{Cost}(G)$ takes values from the interval $[0, 1]$, the maximum value 1 is reached for G_{complete} , that is, when all the edges are present in the graph [55]. $\text{Cost}(G)$ is nothing, but the normalized number of edges $2K/N(N - 1)$ in the case of an unweighted graph. In many cases it is reasonable to take γ function as the identity function: $\gamma(x) = x$. In fact such function is applied in case of unweighted networks and in many cases of the real networks, where the cost of a connection is proportional to its length (e.g., Euclidian distance). In such cases the definition of the cost reduces to

$$\text{Cost}(G) = \frac{\sum_{i \neq j \in G} a_{ij}l_{ij}}{\sum_{i \neq j \in G} l_{ij}}.$$

Now, an economic small-world network can be defined as a network with high local and global efficiencies and low cost [55]. In order to illustrate the use of new quantities in some abstract and practical examples, Latora and Marchiori [55] have studied several models of real and randomly generated networks, starting from the original Watts and Strogatz model, and proceeding to the models of weighted networks. These models will be briefly reviewed here, since they are good illustrations to the discussed measures of small worlds.

The Watts and Strogatz [104] network model is binary, that is, weight of every edge is equal to 1. An initial regular network was rewired with certain probability p , giving rise to a range of networks with a certain degree of randomness, depending on value of p , in particular, small-world networks. Since the total cost of a network is proportional to the number of connections, the cost of rewired networks does not change. Latora and Marchiori [55] have found that for $p = 0$ (regular network), the global efficiency E_{global} was low, while the local efficiency E_{local} possessed high values. This means that regular networks are inefficient in global information transferring, but efficient on a local level. The situation was reverted for $p = 1$, which corresponds to a completely random networks. The local efficiency E_{local} was close to 0, and the global efficiency E_{global} assumed a maximum value. The economic small-world behavior appeared for the intermediate values of p . As in case with characteristic path length L and clustering coefficient C , introduction

of several long-range connections significantly increased global efficiency E_{global} , while the local efficiency E_{local} remained almost unaffected. Moreover, the behavior of functions $E_{\text{local}}(p)/E_{\text{local}}(0)$ and $E_{\text{global}}(0)/E_{\text{global}}(0)$ was very similar to the behavior of $L(p)$ and $C(p)$.

In the second model Latora and Marchiori [55] have proposed different from reported in [104] approach to generate artificial small-world networks. Starting from a set of nodes N and empty set of edges, the edges were randomly added to the network, until the network became connected. These networks were binary, like networks in the first model, but unlike those, the cost of the given networks was not constant and was growing monotonically with increasing of number of added connections. The given procedure was giving rise to small-world networks for values of cost $\sim 0.5\text{--}0.6$, but it failed to generate economic small-world networks, which are networks with small-world properties and small number of connections.

While in previous models the long-range connections (or short cuts) have been rewired at no change in cost, which is unrealistic approach in relation to real world networks, in this third model Latora and Marchiori [55] have introduced lengths of connections in order to address this limitation. They have used the same random rewiring procedure, but after each rewiring, the length of a rewired edge has been changed from 1 to 3, and in this way the total cost of the network was increasing. The network in this model therefore was weighted, with weights of connections representing lengths of edges between nodes. The small-world behavior in these networks was still present. For small values of p , the global efficiency E_{global} grew rapidly, while local efficiency E_{local} did not change much. However, unlike the previous two models, the function $E_{\text{global}}(p)$ was not simply monotonically increasing. Contrary to it, the cost of the network was monotonically increasing with rewiring probability p . At the range of p , where generated networks possessed small-world properties, the cost of these networks was low, which means the networks were not only small worlds but also efficient. In contrast to the second model, this generalized rewiring approach was able to create economical small-world networks, by only rewiring of the edges. Therefore, the structure (topology) of the network plays a relevant role not only in its efficiency but also in economical properties.

In order to build a more realistic model, Latora and Marchiori [55] took in consideration geometrical distances between nodes. In this fourth model, they have placed the nodes of the network around the circle on the plane and they have defined the length of the connection as a Euclidian distance between corresponding nodes. For the points on the circle, this distance is equal to

$$l_{ij} = \frac{2\sin(|i - j|\pi/n)}{2\sin(\pi/n)},$$

if one will assume that the nodes are placed around the circle according to their indices i and that the length of the arc between neighbor points is equal to 1. The results of analyses of networks generated by this procedure were consistent with the results from the previous model. There was a range of values of p , where global efficiency E_{global} and local efficiency E_{local} attained high values, while the cost was relatively low, indicating economic small-world properties of the network.

As a conclusion, results derived from last two models imply that the economic small-world properties are not only an attribute of the topological abstractions, but are also present in the weighted networks, where the physical distance plays role and the rewiring of connections has a cost [55].

Latora and Marchiori [55] have applied their measures to the networks of cortico-cortical connections in macaque and cat. The databases they have considered contained only information about existence of connections between cortical areas, therefore the networks were unweighted (binary). Both the macaque and cat networks turned out to be economical small worlds. They had high global efficiency, high local efficiency, and low cost, where cost was calculated using identity cost function $\gamma(x) \equiv x$. In both networks, the global efficiency E_{global} was similar to that in random network of the same size, and the local efficiency E_{local} was much higher than that in random networks, indicating high fault tolerance of the network. In fact, in both networks, the local efficiency was greater than the global one, meaning that the fault tolerance in these systems was privileged with respect to information transmission efficiency.

Latora and Marchiori [55] studied weighted network of neural connections of *C. elegans*, the only case of a nervous system completely mapped at the level of neurons and synapses. The neural system of *C. elegans* is a system with multiple connections, that is, two neurons can be connected with more than one edges (up to 72). Latora and Marchiori [55] modeled the presence of multiple edges as weights of connections. The weight of edge between nodes i and j in the network they have defined as inverse to the number of connections between corresponding nodes. In this case the cost of the connection could not be computed anymore with identity cost evaluating function. Instead, Latora and Marchiori [55] have set the cost of the connection equal to the number of edges between corresponding pair of nodes in initial neural system.

For comparison purposes Latora and Marchiori [55] first considered obtained network as a binary one, setting the weight of the connection to 1, whenever exists at least one edge between corresponding neurons, and 0 otherwise. The unweighted *C. elegans* network, similar to the cortical networks of macaque and cat, was an economic small world. Unlike the cat and macaque networks, the values of local and global efficiencies in this case were similar to each other, showing that in *C. elegans* neural system, no privilege is given to fault tolerance with respect to efficiency.

Finally, for complete weighted *C. elegans* network, Latora and Marchiori [55] also found economic small-world properties, with almost equal values of global and local efficiencies, and low value of cost.

3 Brain Networks

Earlier studies of the brain function have focused mainly either on local or distributed properties. Modern works shifted the attention to the structure and dynamics of large-scale neuronal networks [37, 86]. In this section several characteristics of brain networks are described, in particular their small-world properties.

With a few exceptions, most part of communication between nerve cells is performed through the physical connections. Sometimes, these connections may link cells separated by long distances. Signals generated by neurons and transmitted through these connections comprise a series of action potentials or spikes. The reception of an action potential at a synaptic junction launches numerous biochemical and biophysical processes, resulting in generating an output spike, transmitted along the neuron's axon. Neurons in the cerebral cortex form a dense network with thousands of input and output connections [86]. By quantitative estimations, the human cerebral cortex contains roughly 8×10^9 neurons and 7×10^{13} connections [65]. The total length of all connections in the human brain is estimated between 10^5 and 10^7 km. However, having this tremendous number of connections, brain networks remain very sparse with a fraction of present connections of around 10^{-6} . It turns out that these sparse brain networks are not random, but have special structure patterns. Neurons tend to connect mainly to the neighbor neurons forming local groups, and thus local connectivity in neural network is much higher than it would be expected in random network [12, 86, 91].

Neural brain networks can be analyzed at different level of scale [89]. At microscopic scale, neurons form special sets of connections called local circuits. At a higher level of scale, populations of neurons communicate through the bundles of connections, forming networks within single cortical areas. Connection patterns formed by these local networks are defined by specific task each area is responsible for. Finally, at an entire brain level, the large-scale networks are formed by interconnections linking different brain areas [86].

So far neural connectivity has been discussed, that is, structural (anatomical) brain networks formed by physical connections between neurons. Another important aspect of brain function is neural activity and dynamics of brain processes. Neural activity also can be modeled by a network, the so-called functional connectivity brain network [39, 85]. The connections in functional network are defined not by physical paths in the brain but by dependencies between neural signals in different parts of the brain. If two populations of neurons exchange information, the signal patterns produced by these populations are likely to be statistically dependent, for example, correlated in time. It is commonly recognized that in resting human brain exists consistent functional network between cortical brain regions (so-called default mode network) [14, 30, 38, 73, 75, 103]. It has been proposed that functional networks form a physiological basis for information processing and mental cognition [17, 18, 20, 62]. One of the questions arising here is how do structural and functional networks relate to each other? No doubts that patterns of neural activity are defined and shaped by neural connectivity, and functional networks in large part resemble structural brain networks [45, 84]. But sometimes functional networks can tell us more about processes in the brain than just map of physical neural connections. Certain brain areas, which are not connected directly, communicate with each other through other areas, and these communications are reflected in the functional network. Therefore, functional network comprises structural network, but also contains connections between those areas which are

not connected in structural network, but link to each other dynamically, exhibiting related neural activity.

It is natural to assume that if structural networks in large part define functional network, they should have similar topological properties. And in fact this was confirmed by multiple studies, which reported small-world topology in both groups of networks. Historically, first studies on brain network properties were performed on structural networks, in particular those of mammalian brain. Further in this section studies on structural and functional brain networks will be reviewed in separate subsections, since the approaches are different in these cases.

3.1 Structural Brain Networks

As was mentioned above, structural connectivity refers to the set of physical connections linking neurons in the brain. Analysis of structural connectivity patterns can be done at different levels of spatial scale, from local circuit level with focus on the patterns of synaptic connections between individual neurons to large-scale connection patterns with pathways linking different areas of brain. Such pathways may contain thousands of individual fibers [86]. Anatomical connectivity data is available mostly for large-scale pathways in mammalian species, which has been catalogued in several surveys [29, 35, 79–81, 107]. There were also created several online databases [24, 51, 95]. Recent advances in diffusion imaging and tractography methods provided data sets of human brain cortico-cortical connections at high spatial resolution [26, 41, 42, 56, 82].

On the single neuron level, Humphries et al. [47] have shown that neural system of the medial reticular formation of the brain stem is a small world.

The neural system of a worm *C. elegans* is the only neural system which was mapped completely at the level of neurons and synapses [1]. By computing clustering coefficient and characteristic path length, Watts and Strogatz [104] have shown that this network exhibits small-world topology. Latora and Marchiori [55] have confirmed this result by analyzing more general case of weighted network, where weights of connections corresponded to the number of physical links between neurons.

A compelling small-world effect was found in macaque cortex, macaque visual cortex, and cat cortex by Sporns and Zwi [88]. They have considered binary networks built based on structural connectivity matrices. For macaque visual cortex the network consisted of $N = 30$ vertices and $K = 311$ edges; for macaque cortex, $N = 71$ and $K = 746$; and for cat cortex, $N = 52$ and $K = 820$. For all three networks they have computed clustering coefficient C and mean shortest path length L . In addition, for every case, they have constructed random and regular networks with the same number of nodes and edges and computed scaled measures C_{scl} and L_{scl} by formulas

$$C_{\text{scl}} = \frac{C_{\text{original}} - C_{\text{random}}}{C_{\text{lattice}} - C_{\text{random}}};$$

$$L_{\text{scl}} = \frac{L_{\text{original}} - L_{\text{random}}}{L_{\text{lattice}} - L_{\text{random}}}.$$

For all three networks they have obtained high values of C_{scl} , like in regular lattices, and low values of L_{scl} like in random networks. Therefore, all three networks had low average path length between any two nodes while maintained high connectivity on local level. Sporns et al. [88] compared C_{scl} and L_{scl} to those of random and regular networks of the same in- and out-degree distribution for all nodes, and again found that C_{scl} was close to regular networks and L_{scl} was close to random networks. This showed that small-world properties of the network cannot be explained by degree distribution of the nodes. It is the global topology of connections what makes it a small world.

Sporns and Zwi [88] have reported a series of experiments on simulated neural networks. They have generated three types of networks, where for given set of nodes, they introduced intra-areal and inter-areal connections according to the specific probability distributions. More precisely, they generated “all local” network, where all connections were assigned according to Gaussian probability; “local plus uniform network,” where part of the connections was generated again by Gaussian probability and another part distributed uniformly among randomly chosen nodes; and “local plus long-range” network, obtained from “all local” network by relinking part of the connections according to another Gaussian profile. Generated “all local” networks did not possess small-world properties. At the same time, both “local plus uniform network” and “local plus long-range” networks were small world, especially “small worldness” was strongly expressed in the latter ones. In both cases, introduction of a few long-range connections drastically dropped the mean shortest path length, while clustering coefficient remained almost unchanged.

Another research on mammalian structural neural networks was performed by Hilgetag et al. [44]. They have applied clustering techniques in order to find groups of densely connected areas in macaque cortex, macaque visual system, macaque somatosensory-motor system, and cat cortex. The two approaches used in order to find clusters were evolutionary algorithm (OSA) and nonparametric cluster analysis with multidimensional scaling of data matrix (NPCA). Both approaches gave consistent results, indicating that considered neural data is shaped by several dense clusters connected by few long-range connections. The evolutionary algorithm was generating partitions of the data into clusters via minimization of certain cost function. Different trials of algorithm started from different random initial partitions, but produced very close final “optimal” partitions, which indicate existence of well-expressed clusters in the data. The comparison between clusters obtained by this algorithm and NPCA showed high level of consistency, the similar analysis they have conducted on random matrices, generated by shuffling the entries of initial data connectivity matrices. In this way, the overall number of connections and degree distribution were preserved, but the topology of the network changed. The consistency between clustering analysis results by OSA and NPCA was much lesser in this case. Also, the clustering coefficients for all four considered networks were much greater in initial data than in randomly shuffled ones.

An interesting and insightful view on small-world neural networks was proposed by Sporns et al. [89]. In this study, Sporns et al. considered brain activity as multidimensional stochastic process, which can be characterized by statistical measures such as entropy, mutual information, and statistical complexity. Mainly, they have focused on measures of entropy and integration, which capture overall degree of statistical independence and dependence, respectively, and complexity, which measures the presence of functional segregation and functional integration in the system. First part of the study consisted in investigation of artificially created networks, which possess high values of certain network measures. The structural properties of such networks were studied, and apparent similarities were found with real neural networks. More detailed, the pseudo-evolutionary procedure was applied, which from initial random networks generated networks with higher value of entropy, integration, or complexity by certain rewiring or “mutations.” The network with highest value of correspondent measure was stored during the procedure. The number of nodes n and number of edges k were preserved during this procedure. Also, at each step, the network was required to be strongly connected; if mutation procedure was partitioning network into several components, such networks were discarded from the procedure. Therefore, in some sense, this procedure is similar to approximate optimization algorithms, like local search algorithms, and genetic algorithm. The solution space here is a set of possible networks of n nodes and k edges, and the objective function is either entropy, integration, or complexity. If one will assume that activity in n brain regions can be described as a Gaussian multidimensional stationary stochastic process, then the global measures of network dynamics can be derived from the network’s covariance matrix COV. The formal definitions of these measures are following. For a given system X , the entropy of the system $H(x)$ is defined as

$$H(X) = 0.5 \ln((2\pi e)^n |\text{COV}(X)|),$$

the integration of the system $I(X)$ is defined as

$$I(X) = \sum_i H(x_i) - H(x),$$

and the complexity of the system $C(X)$ is defined as

$$C(X) = H(X) - \sum_i H(x_i | X - x_i).$$

Here, $\{x_i\}$ is a set of individual components of the system X , and $|\cdot|$ denotes matrix determinant.

For all three measures the procedure of network selection converged fast for low rewiring rates, starting from random initial network. The patterns observed in the resulting networks were robust in relation to the procedure parameters and initial network characteristics n and k . Each simulation of network selection for

each network measure gave networks with different fine structure details, but with common structural motifs. In contrast, the selected networks were structurally completely different for different network measures. While all the networks had constant n and k and were strongly connected, even casual visual inspection showed that their connection patterns differed significantly. Random network apparently did not have any topological order. Networks selected by maximizing entropy $H(X)$ contained mostly connections linking nodes spread out without any evident local grouping (clustering). This structure is in consistence with network dynamics, characterized by high statistical independence of units. Networks with high integration $I(X)$ consisted of a central cluster of dense connections with a few outsiders, connected to the main cluster, and weakly connected to each other. This pattern is consistent high value of statistical dependence of the entire system. Increasing the number of connections k increased the size of main cluster, without changing the overall pattern. Finally, networks obtained by maximizing complexity $C(X)$ consisted of several clusters of densely connected nodes, with a few number of reciprocal bridges between clusters. This networks are characterized by presence of functional segregation and functional integration at the same time.

In order to investigate the relation between generated by evolutionary procedure networks and classical small-world networks, Sporns et al. [89] computed characteristic path length, clustering coefficient, and cost of these networks and compared them to random networks, which were used as a starting point for the generating procedure. The cost was estimated as a summation of weights of all connections, where weight of the connection between nodes A and B was defined to be proportional to the distance between corresponding to A and B columns in network adjacency matrix. In some sense this function of cost is similar to the one computed as a summation of Euclidian lengths of all connections, when nodes are placed around the circle according to their indices (node 1 is placed next to nodes 2 and n , node 2 is placed next to node 1 and node 3, and so on).

As expected, random networks were characterized by small value of characteristic path length L and small value of clustering coefficient C . Networks with high entropy $H(X)$ had similar characteristic path length as random networks, but even lower values of clustering coefficient C . In contrast, networks with high integration $I(X)$ had high values of characteristic path length and very high values of clustering coefficient C . Finally, networks with high values of complexity $C(X)$ possessed small values of characteristic path length and high values of clustering coefficient C and surprisingly low values of cost, even lower, than those in random networks. Therefore, networks generated by maximizing the complexity $C(X)$ were economical small worlds.

The characteristic path length, clustering coefficient, and cost of neural networks of cortical connections in macaque monkey and cat turned out to be very similar to those in generated networks with high complexity. Both network of macaque visual cortex connections and network of cat cortex connections appeared to be economic small worlds. The structure of these networks also resembled greatly the structure of artificial networks with high complexity. Finally, the complexity of both networks,

when they were modeled as dynamic systems, turned out to be high. This is due to their anatomic organization into distinct groups of areas.

Sporns et al. [89] produced several modified networks, by random rewiring of some part of connections of neural networks. In all cases resulting networks had significantly decreased value of complexity. This suggests that configurations of neural networks are close to the optimal with respect to network complexity. Therefore, the complexity is another quantifier of network small-world properties.

Human structural networks were studied by He et al. [43], where they have used diffusion MRI to measure brain cortical thickness. Cortical thickness reflects the size, density, and arrangement of neuron cells, and interregional associations in cortical thickness reflect connectivity patterns in the human brain [43, 58, 105]. The entire cerebral cortex was divided into 54 areas, and regional cortical thickness was measured in every region. The pairwise correlations in regional thickness across 124 subjects were estimated and correlation matrix was created. The values of correlation were further thresholded, and resulting binary matrix was considered as an adjacency matrix of an undirected network. The resulting network exhibited small-world properties with clustering coefficient more than twice greater than the one of random network with corresponding number of nodes and connections.

At a finer scale the human brain structure was studied by Hagmann et al. [42] via diffusion MRI tractography. Their approach, based on constructing of three-dimensional curves of maximal diffusion coherence, allowed to construct networks with 500–4,000 nodes; each node corresponded to a region of brain of millimeters scale. These regions were connected with a number of fibers, which were modeled by a weight of corresponding connection in the network. In order to examine topological properties of resulting network, Hagmann et al. have studied binary network of the same size in which two nodes were connected, if they had a connection with positive weight in the original network. As in previous study on large-scale anatomical network, this network was a small world with high clustering coefficient and low characteristic path length.

Taken together discussed studies indicate that small-world topology is an inherent property of a structural organization of neural connections at different levels of scale. Consistent findings in different mammalian species and human suggest that small-world structure comprises fundamental principles in organization and evolving of neural networks. Economical properties of small-world networks may give an explanation to this fact. As it was discussed in previous sections, small-world networks are efficient in information transfer at both global and local levels and at the same time are resilient to errors and damages. In light of this one can argue that neural networks may have developed small-world topology during evolution process. Although small-world topology is relatively general property of a network and many networks with different structural patterns may have similar small-world characteristics, it gives an understanding of how is brain organized on global level which in turn provides an insight about brain functional properties.

3.2 Functional Brain Networks

Functional connectivity refers to the patterns of temporal statistical dependencies, such as correlation, that exist between distinct groups of neurons. Such temporal dependencies are assumed to be the result of neuronal interaction along anatomical connections. There are different ways to estimate the level of dependence between neural elements. Although temporal correlation is most widely used, other measures can also be applied [22, 86]. A consistent functional network has been revealed in human brain in resting state. This network was called a default mode network [73], and later was confirmed by multiple studies [27, 28, 32, 60, 106].

There are several techniques of measuring neural activity in the brain, and resulting functional networks depend highly on which technique was used. However, the general steps in constructing functional networks are rather common [87]. First, it is necessary to define nodes of the network. Often nodes are chosen as distinct anatomical regions of brain or electrodes (sensors). Then, the measure of association between nodes should be estimated. In most cases the measure of similarity between corresponding signal time series is used (in case of anatomical regions parcellation, averaged time series in each region is computed). Often, a threshold is applied to similarity values in order to produce binary matrix of associations between each pair of nodes. This matrix is then treated as adjacency matrix of a functional connectivity network, and the network properties are further studied.

Another step in data analysis, shared by nearly all brain network studies, is the decomposition of signals into components at different frequency bands. In fact, all brain monitoring technique measurements contain significant portion of nonneural sources of fluctuations. Patient's head movements during recording session, respiratory and heart rhythms, etc. may affect significantly the data quality and the results of the study [19]. In order to localize and discard these effects, frequency analysis is applied. The signal is being decomposed into several components, and the components containing most portion of noise are being removed.

This frequency analysis can be performed by applying either Fourier transform or wavelet transform. These techniques are very common in neural data studies, and therefore each of them will be discussed in a little more details.

The Fourier transform images a signal from time space into frequency space. If the original signal depends on time, its Fourier transform depends on frequency and thus is called the frequency domain representation of the signal. In fact, the Fourier transform decomposes a signal into oscillatory functions (sines and cosines). Mathematically, for every real number ξ , a Fourier transform of a function f is defined as

$$A(\xi) = \int_{-\infty}^{+\infty} f(x)e^{-2\pi i x \xi} dx.$$

When the variable x represents time, the variable ξ represents frequency [70].

However, this classical definition of continuous Fourier transform is not very practical when dealing with real data. Real observations are always discrete, and the number of observations is finite. Therefore, continuous transform is not directly applicable. In practice, discrete Fourier transform (DFT) is used. Consider a sequence $a_t, t = (0, \dots, N - 1)$ of N variables. Its DFT is defined as a sequence:

$$A_k = \sum_{t=0}^{N-1} a_t e^{-i2\pi tk/N}, \quad k = 0, \dots, N - 1.$$

Here A_k is associated with frequency $f_k = k/N$. There was developed group of algorithms called fast Fourier transform (FFT) for fast computing Fourier transform of real sequences. These algorithms will not be discussed here; interested reader is referred to [66, 69] for further information.

To the certain degree wavelet analysis is a generalization of the Fourier analysis, where instead of sines and cosines so-called wavelet functions are used. Essentially, a wavelet is a “small wave,” that is, a function, which grows and decays in a limited time period. Strictly speaking, a wavelet is any function ψ defined over the $(-\infty, \infty)$ which satisfies following two conditions:

$$\int_{-\infty}^{+\infty} \psi(u) du = 0;$$

$$\int_{-\infty}^{+\infty} \psi^2(u) du = 1.$$

A continuous wavelet transform of a function f is defined as

$$W(\lambda, t) = \int_{-\infty}^{+\infty} \psi_{\lambda,t}(u) du,$$

where $\psi_{\lambda,t}(u) = 1/\sqrt{\lambda}\psi(\frac{u-t}{\lambda})$. Here t refers to time, and λ is associated with frequency [70].

For a discrete signal, a partial discrete wavelet transform (DWT) is defined as following. Let X be a vector of N components $X_t : t = 0, \dots, N - 1$, where the sample size N is an integer multiple of 2^{J_0} . The DWT of level J_0 of X is an orthonormal transform given by $W = WX$, where W is an N dimensional vector of DWT coefficients, and W is an $N \times N$ real matrix defining the DWT. In case when $N = 2^J$ and $J_0 = J$, we obtain a full DWT. The DWT coefficients and matrix W can be partitioned, such that $W = (W_1, \dots, W_{J_0}, V_{J_0})$, where W_j is a vector of wavelet coefficients corresponding to the scale $\tau_j = 2^{j-1}$. The vector X can be obtained from W as

$$X = W^T W = \sum_{j=1}^{J_0} W_j^T W_j + V_{J_0}^T = \sum_{j=1}^{J_0} D_j + S_{J_0},$$

which defines a multiresolution analysis (MRA) of X , that is, an additive decomposition by N -dimensional vectors $D_j = W_j^T W_j$, each of which corresponds to a particular frequency band [70]. A scale-dependent (or frequency-dependent) ANOVA can be computed based on decomposition:

$$\|X\|^2 = \sum_{j=1}^{J_0} \|W_j\|^2 + \|V_{J_0}\|^2.$$

Wavelet coefficients at all scales are also localized in time. In contrast, coefficients of DFT are not localized in time in any meaningful sense [70]. This is an advantage of wavelet analysis compared with Fourier analysis when dealing with nonstationary, non-smooth time series, which cannot be precisely represented by global transform, such as DFT.

For practical needs, like in case with discrete Fourier transform, fast computational algorithms were developed for obtaining wavelet coefficients. For further details, reader is referenced to [70].

3.2.1 Networks Derived from Electrophysiological Brain Data

Electrophysiological brain monitoring techniques (electroencephalogram (EEG) and magnetoencephalogram (MEG)) record electromagnetic potentials generated by large neuronal populations. EEG and MEG directly record signals generated by neural activity and have high temporal resolution. Their spatial resolution, however, is relatively low, and neither of these techniques allows precise reconstruction of location of sources of recorded signals. Therefore, EEG and MEG signals in most cases are not being associated with anatomical brain regions [87]. Depending on the location depth of the EEG electrodes, EEG signals may record neural activities on the scalp, cortex, or in the brain. Scalp EEG is widely used in research and clinical practice because of its portability, cost-efficiency, and easy setup.

EEG is used to study a variety of brain-related physiological phenomena including sleep [33, 36, 48], traumatic brain injury [100], brain machine interface [96], epilepsy [6, 57, 108, 109], anesthesia [49], cognition [11], Alzheimer's disease [31], and schizophrenia [67]. One of the salient characteristics of EEG data is the rhythmic oscillation. Therefore, frequency analysis is commonly used to preprocess EEG signals. It is broadly appreciated that different strengths of frequency components reveal different brain states [31, 34, 40, 68, 71]. During EEG signal analysis, filtering is usually implemented to remove artifacts or focus on the frequency bands of interest. Prior to network analysis based on EEG data, the artifacts removal procedures should be applied. The common input from artifact would likely result in the existence of spurious association among channels. In order to obtain EEG signals within a certain range of frequencies, apart from conventional fast Fourier transform-based filtering techniques, some studies implemented wavelet

transform to extract components with more specific time-frequency resolution. For example, Palva et al. [68] used Morlet wavelets [70] to filter EEG data into 36 frequency bands before constructing the oscillatory phase synchronized network.

At the network construction step, it is natural to designate EEG channels as vertices of a network and edges between vertices to associate with functional connections between corresponding groups of neurons (brain areas around electrodes). One would expect a larger correlation between two EEG channels when there is an edge between them. Most of the studies using network theoretic analysis on EEG data assume that statistical interdependencies between EEG time series reflect functional interactions between neurons of brain regions [34]. There are many statistical metrics computing the degree of association between time series. Some of the most used metrics in EEG functional connectivity studies are introduced below.

Phase-Locking Value

Phase-locking value (PLV) is a statistic which measures the frequency-specific synchronization between two neuroelectric signals [52]. This is a method focusing on the phase information of time series and is different from coherence, which gives the interrelation of both amplitude and phase between signals. The PLV is calculated by first extract the instantaneous phase information of signals through either wavelet transform [52] or Hilbert transform [64]. Both methods lead to similar result on real world EEG data [72]. When doing the wavelet transform on a signal $x(t)$, a wavelet function, $\psi(t)$, is firstly chosen. Gabor and Morlet wavelet function both have been applied on EEG data [59]. Then, the wavelet coefficient time series, $W_x(t)$, can be computed as a convolution of $x(t)$ and $W_x(t)$:

$$W_x(t) = (\psi \circ x)(t) = \int \psi(t')x(t' - t)dt' = A_x^W(t) \cdot e^{\phi^{W_x(t)}}.$$

The phase of time series, $\Phi(t)$, can be computed as follows:

$$\Phi^{X_i}(n, s) = \arctan \frac{\text{imag}(W^{X_i}(n, s))}{\text{real}(W^{X_i}(n, s))}.$$

When doing the Hilbert transform, the phase information $\Phi(t)$ of a signal $s(t)$ is

$$\Phi(t) = \arctan \frac{s(\tilde{t})}{s(t)},$$

where

$$s(\tilde{t}) = \frac{1}{\pi} \text{p.v.} \int_{-\infty}^{+\infty} \frac{s(\tau)}{t - \tau} d\tau$$

is the Hilbert transform, and p.v. denotes the Cauchy principal value. The relative phase, $\phi 1, 1(t)$, can be calculated as

$$\phi_{1,1}(t) = \phi_a(t) - \phi_b(t) = \arctan \frac{\tilde{s}_a(t)s_b(t) - s_a(t)\tilde{s}_b(t)}{s_a(t)s_b(t) + \tilde{s}_a(t)\tilde{s}_b(t)}.$$

The subscript 1, 1 signifies that the relative phase relationship $n\phi_a(t) - m\phi_b(t)$ considers only the case where $n = m = 1$. Finally, one can define the PLV as following:

$$\text{PLV} = \left| \frac{1}{N} \sum_{j=0}^{N-1} e^{\phi_{1,1}(j\delta t)} \right|.$$

PLV was used in a study by Dimitriadis et al. [34] to construct the functional connectivity networks from 30-electrode EEG data. They utilized surrogate data to generate baseline distribution of random PLVs and then determined the functional connections (edges) if there was a significantly different ($p < 0.001$) PLV of a specific pair [34]. The surrogate data is generated by permuting the order of trials of one signal for many times [59].

Synchronization Likelihood

Synchronization likelihood (SL) is a statistic measuring the nonlinear similarity between time series. SL offers an extended perspective of correlation and is not limited by linear relationship only, like, for example, coherence, which renders only the linear correlation as a function of frequency [92]. Consider a time series $X_{k,i}$ with $k = 1, \dots, M$ denoting a channel number and $i = 1, \dots, N$ denoting time index. The computation of SL first requires reconstructing $X_{k,i}$ using the method of delays [99]:

$$X_{k,i} = (x_{k,i}, x_{k,i+1}, x_{k,i+2l}, \dots, x_{k,i+(m-1)l}),$$

where l is the lag and m is embedding dimension. A measure $H_{(i,j)}$ is then defined to measure the number of channels $X_{k,i}$ and $X_{k,j}$ that are closer than a threshold $\varepsilon_{k,i}$:

$$H_{i,j} = \sum_{k=1}^M \theta(\varepsilon_{k,i} - |X_{k,i} - X_{k,j}|).$$

Finally, SL is obtained as

$$S_{k,i} = \frac{1}{2N} \sum_{j=1}^N S_{k,i,j},$$

$$S_{k,i,j} = \frac{H_{i,j} - 1}{M - 1}, \text{ when } |X_{k,i} - X_{k,j}| < \varepsilon_{k,i}, S_{k,i,j} = 0 \text{ otherwise.}$$

One can see that $S_{(k,i)}$ is a measure describing how well channel k at time i is correlated to all other $M - 1$ channels. Ponten et al. [71] used SL measure as the connectivity metric in their study on epilepsy.

Nonlinear Independence

Nonlinear independence (NIM) estimates strength of functional coupling between two time series embedded in their respective phase spaces [7, 72]. Consider time series $x(t)$ and $y(t)$. One can reconstruct the delay vectors $x_n = (x_n, \dots, x_{n-(m-1)\tau})$ and $y_n = (y_n, \dots, y_{n-(m-1)\tau})$, where m is the embedding dimension and τ is a time lag. Let $r_{n,j}$ and $s_{n,j}$, $j = 1, \dots, k$ be time indices of the k nearest neighbors of x_n and y_n correspondingly. For each x_n the mean square Euclidian distance to its k neighbors is computed,

$$R_n^{(k)}(X) = \frac{1}{k} \sum_{j=1}^k (x_n - x_{r_{n,j}})^2,$$

and the Y-conditioned meant square distance:

$$R_n^{(k)}(X|Y) = \frac{1}{k} \sum_{j=1}^k (x_n - x_{s_{n,j}})^2.$$

The NIM $N(X|Y)$ is then computed as

$$N^{(k)}(X|Y) = \frac{1}{N} \sum_{n=1}^N \frac{R_n(X) - R_n^{(k)}(X|Y)}{R_n(X)}.$$

The asymmetry of NIM ($N(X|Y) \neq N(Y|X)$) is the main advantage of this nonlinear measures since it can deliver directional information about nodes in network. In the study done by Dimitriadis et al. [33], both SL and NIM were used to quantify the extent of association between nodes. Studying the sleeping EEG data from ten healthy subjects, they have found that SL and NIM are weakly correlated and thus should be considered to reveal complementary information about the brain functional connectivity.

Phase Lag Index

Phase lag index (PLAI) quantifies the asymmetry of the distribution of instantaneous phase differences between two time series [94]. Suppose one has calculated the relative phase time series, $\phi_1, 1(t)$, then the PLAI is defined as $|\langle \text{sign}[\delta\phi(t_k)] \rangle|$. PLAI values range from 0 to 1. Values greater than 0 suggest the existence of phase locking to some extent, and value equal 0 signifies no coupling between time series. One of the benefits of PLAI measure is that it rules out the synchronization in time series caused by instantaneous volume conduction or a common source propagating spurious synchronization.

The existence of small-world structure in the cortex of a human brain has been observed through a number of studies [12, 13, 36, 90]. An aging study [40] found that the clustering coefficient and the value of characteristic path length were both lower in the elderly compared to the young subject group. This implies that the

brains of the elderly subject group appear to be closer to random networks. This study confirmed analogous findings in fMRI data [2].

Group of studies analyzed changes in small-world brain architecture caused by neural disorders [93]. Ponten et al. [71] conducted a study on network analysis using intracerebral EEG recordings from patients having drug-resistant mesial temporal lobe epilepsy. They have found an increase of clustering coefficient in the lower frequency band (1–13 Hz) and an increase in the characteristic path length in alpha and theta bands during and after a seizure, comparing to interictal recordings [71]. This implies that the functional brain network changes from a more random organization to a small-world structure. In an Alzheimer's disease (AD) study conducted by de Hann et al. [31], EEG data from patients with AD were compared with those in control subjects. All AD patients showed small-world network traits in their functional networks in all frequency bands, but only in beta band these traits were statistically significant. Palva et al. [68] conducted a study on magnetoencephalogram (MEG) and EEG data recorded while subjects were performing visual working memory (VWM) tasks. The study recorded both MEG and EEG from 13 healthy subjects and applied PLV as the measure of association between time series. The results showed that small-world network structure appeared dynamically during the VWM task execution within alpha and beta frequency bands. Moreover, the small worldness was dependent on the VWM memory load. Van Dellen et al. [102] have analyzed interictal electrocorticography (ECoG) of 27 patients with pharmacoresistant temporal lobe epilepsy (TLE). The cluster coefficient and small-world index were both negatively correlated with TLE duration in the broad frequency band (0.5–48 Hz). This may result from the accumulative damage on the brain tissue due to intermittent excessive epileptic discharges for a long time. The optimal balanced small-world structure has been impaired to form a more randomized one as the TLE duration goes on. An interesting model work by Rothkegel and Lehnertz [76] revealed co-occurrence of local wave patterns and global collective firing in a two-dimensional small-world network. Boersma et al. [15] did a study on resting state EEG in the developing young brains. They performed resting state eyes-closed EEG recording (14 channels) from 227 children (age 5–7 years). They have found evidences that the clustering coefficient in functional network derived from alpha band was increasing with age. Also, characteristic path lengths were increasing with age in all frequency bands. This suggests that a brain shifts from a random toward more ordered small-world-like configurations during the maturation. Interestingly, girls showed higher mean clustering coefficients in alpha and beta bands compared with boys. In several studies the small-world network analysis was performed on data of patients with schizophrenia. Rubinov et al. [77] recorded resting state scalp EEG from 40 subjects with a recent first episode of schizophrenia and another 40 healthy matched controls. Nonlinear interdependences were identified from bipolar derivations of EEG data, and weighted connection networks were generated. Both groups possessed networks with a small-world topology, but networks in the schizophrenia group had lower clustering coefficient and shorter characteristic path lengths, indicating more random network structure. The randomization of brain functional network (loosing ordered small-world structure) may be the reason for

cognitive and behavioral disturbances in schizophrenia patients. Another similar study [67] focused on scalp EEG data from 20 schizophrenia patients and 20 healthy controls (age and sex matched) recorded while patients performing working memory tasks. The data were analyzed using conventional coherence. Afterward, the values of coherence were further thresholded, producing binary connectivity networks. The results confirmed that schizophrenia patients possess more random neuronal network organization, especially in the alpha frequency band.

3.2.2 Networks Derived from fMRI Data

Functional magnetic resonance imaging (fMRI) measures fluctuations in the blood oxygen level-dependent (BOLD) signal, which is related to local metabolism and neuronal activity [8, 74, 83]. The BOLD signal provides only indirect measure of neural activity, since coupling between blood oxygenation and neuronal activity has complex nature and may vary across the brain regions. fMRI technique provides spatial resolution at millimeter scale, but has low temporal resolution capabilities due to physical limitations of underlying processes [87].

Group of Cambridge scientists studied brain functional network with nodes defined according to the anatomical MNI brain template [101]. This template partitions brain into 90 regions of interest. Salvador et al. [78] analyzed fMRI data of 12 healthy patients in resting state. Interregional partial correlation of fMRI signals were then estimated, assuming that time series can be considered as jointly Gaussian stationary multivariate stochastic process. The partial correlation matrices from individual patients were then averaged in order to obtain healthy group mean functional connectivity matrix. Salvador et al. found that the most significant connections were intrahemispheric and often local, involving regions in the same lobe or closely adjacent.

The obtained functional network possessed small-world topology with clustering coefficient roughly twice larger than in random network with the same number of nodes and connections, and characteristic path length similar to that in random network.

Achard et al. [3] have studied neural networks in human brain in resting state at macroscopic level based on functional magnetic resonance imaging (fMRI) data. The network connections between brain regions were defined based on temporal correlations between fMRI time series in these regions. Regional mean time series was estimated by averaging times series over all voxels in each region. Pairwise correlations between mean time series were estimated, and the network was constructed with connections based on these correlations. High correlations were assumed to indicate strong connections, whereas low connections were considered a sign of weak connectivity. Achard et al. [3] used wavelet transform in order to decompose time series into six scales, corresponding to different frequency ranges. The reason for this was that initial signal apart from neural activity contained also nonneural sources of correlations, such as cardio- and respiratory rhythms, which are mainly presented at high frequency ranges, and therefore analysis at different scales can help to emphasize the neural contribution to the signal. The pairwise correlations between wavelet coefficients of mean time series were computed for

all six scales. The correlations then were thresholded for each scale, giving six binary connectivity matrices. These matrices were then considered as adjacency matrices for the binary networks, where nodes correspond to brain regions. Value of 1 of (i, j) th element of the matrix meant that there is a connection between nodes i and j .

In this work, in order to analyze small-world properties of neural network, Achard et al. [3] used technique proposed by Watts and Strogatz [104]. They have computed characteristic path length of whole brain network L , the clustering coefficient C , and compared them to those in random networks with identical size and mean nodes degree. They have found that the functional connectivity was the most salient in the frequency range of 0.03–0.06 Hz. The threshold for the correlation matrices was chosen in such a way that the resulting networks would be sparse, while still connected, like in Watts and Strogatz model. The criteria for the threshold was chosen such that resulting networks had $k \sim \log(n)$ edges, where n is the size of the network. The results suggested that the brain neural networks possess small-world properties at all six scales of wavelets. The characteristic path length in these brain networks was similar to that of random networks, while the clustering coefficient was about two times greater.

Achard et al. [3] have studied how small-world properties of neural networks depend on threshold value R for correlation matrices. They found that small worldness decreased monotonically with R , although the small-world properties, characterized by $L \sim L_{\text{random}}$, $C > C_{\text{random}}$, were present at all scales at a range of values of R .

The degree distribution of the network was not power law, and the networks themselves were not scale-free. The best-fitting distribution was exponentially truncated power law, which is

$$P(k) = k^{\alpha-1} e^{-k/k_c},$$

where estimated parameter α was 1.80 and cutoff parameter k_c was 5. In order to examine the resilience of brain functional network to random and targeted attacks, Achard et al. [3] conducted series of simulation experiments. They randomly removed nodes one by one from the network, including all the connections, adjacent to those nodes. After each removal the size of largest cluster in the network and the characteristic path length were recalculated. In this way random attacks (or errors) on the network were modeled. In the second set of experiments, the nodes with largest degree were being selectively removed, simulating the targeted attacks on the network. The results showed that the brain networks were approximately as resilient to random attacks, as random networks, but significantly more resilient to the targeted attacks. The most damaging attacks were generally on the regions from primary visual, somatosensory cortex, motor cortex, and thalamus.

In the consequent study Achard and Bullmore [2] described effect of drugs and aging on the dynamics of neural networks. The weighted networks were created with weights of connections equal to correlation between wavelet coefficients of averaged regional time series. Authors have focused on scale 3 wavelet coefficients,

corresponding to 0.06–0.12 Hz frequency range, since in this range the findings were most salient. The correlation matrices were thresholded in order to obtain adjacency matrices of simple binary networks. Authors have studied how economical properties of networks change over a range of threshold values. Clear that the value of threshold determines the cost of the networks, and increasing (decreasing) of threshold can be considered as moving from the network with higher cost to the one with lower cost (moving from lower cost to higher cost in case of decreasing of threshold value).

As it was reported in the previous study, authors found that all brain networks obtained by describing technique showed small-world properties [2]. In particular, networks with cost from 0.05 to 0.34 interval were apparent small worlds.

Older people had reduced global and local efficiency compared with younger people. The effect of age for given sample from the study on global efficiency was statistically significant ($p = 0.006$), as it was on local efficiency ($p = 0.05$). This reduction was present for whole range of thresholds corresponding to values of cost from 0.05 to 0.34 interval. The integrals of the global and local efficiency curves were calculated in order to compare older subjects to younger ones, and again the difference was statistically significant ($p = 0.008$ for global efficiency and $p = 0.02$ for local efficiency).

Also, the drug effect, compared with placebo, in particular dopamine blockade by a dose of sulpiride, reduced global and local efficiencies for low cost networks (Cost ~ 0.1) in both young and old subjects. The drug effects were more variable in the older age group. For both global and local efficiencies, the effect of the drugs was significant ($p = 0.005$ and $p = 0.0009$ correspondingly). Also, values of integrals of global and local efficiencies over the cost range 0.05–0.34 were reduced significantly ($p = 0.03$ for global efficiency and $p = 0.02$ for local efficiency) [2].

It is known that dopamine transmission is responsible in part for modulating the frequency, phase, and spatial coherence of signal oscillations in basal ganglia and cortex. The findings of this study suggest that it also may contribute to optimizing the performance of functional brain networks. The pharmacological change of this modulating input reduces network efficiency, which is an ability to efficiently transfer information [2].

Aging is also known to be associated with loss of dopamine cells, and it would be rather expected that effects of age on economical properties of functional brain networks are similar to those of dopamine blockade. However, the effects of age on economical properties of functional networks were more salient compared to drugs, which may imply that besides of reduced dopamine transmission in aged subjects, additional factors, caused by aging, might contribute to age-related changes in network properties [2].

4 Conclusion

Number of natural and human made networks exhibit small-world topology. These networks have well-defined local clustering structure with presence of certain number of long-range connections between distant nodes. Mathematically, these

characteristics can be expressed as high value of network clustering coefficient and low value of characteristic path length. Small-world networks possess important economical properties which distinguish them from vast pool of possible network configurations. It has been shown that small-world networks are efficient in parallel information transfer. At the same time, they are more resilient to random attacks (deleting nodes at random) than random networks and more resilient to targeted attacks (deleting nodes) than scale-free networks [3].

Multiple studies reported that neural systems of different animal species as well as those of human share certain common organizational principles. These networks were shown to be small worlds at different levels of spatial scale. A group of studies suggested that brain networks tend to optimize their small-world characteristics compared to other networks with the same number of nodes and edges but different topology. Arguably, brain might have developed during evolution process to maximize its efficiency of information processing and resilience to errors and damage while minimizing the total length of neural wiring. Small-world networks were shown to have all these attributes.

One of the implications of studying small-world characteristics of human brain lies in the analysis of neural disorders impact. Neural disorders affect brain function and consequently affect functional network configuration. Changes in network topology cause changes in network quantitative characteristics. Of course, different disorders may result in different network modifications, possibly variable across patients. However, under assumption that healthy brain networks tend to optimize its small-world characteristics, any change in network topology likely will result in degrading of these characteristics. Therefore, it is possible computationally to distinguish signs of disorder by comparing its small-world characteristics to those in healthy subjects. Several works have been done in this direction [31, 68, 71, 93], and results indicate that this is a promising area of research with broad range of diagnostic implications.

Abstract

This chapter mainly studies four problems proposed in social networks: they are link prediction problem, community detection problem, influence maximization problem, and routing problem for networks that satisfy power-law distribution property. As for these problems, corresponding efficient approximation algorithms with different aspects are introduced. Except numerical results of

experimental simulations of these algorithms, theoretical analysis for influence maximization problem and routing problem is provided.

1 Introduction

A social network is a kind of social structure that is made up of a finite set of individuals (called “nodes”) and relationships (friendship, kinship, common interest) defined on them. Social network existed before the emergence of internet. In a social network, a person can use existing contacts as potential social links to extend their relationships to more people. Recently, online social network, which appears after internet, becomes popular among the public. Most online social network such as MySpace, LinkedIn, and Facebook provide a convenient platform for people to communicate with each other, exchange their ideas or spread information, and so on. Therefore, based on the relationships established between people, communities are shown to be an important local structure, which can be used to efficiently predict new links or disseminate information to their members by already known information.

This chapter consists of four parts: social network structure, local structure, influence maximization problem, and routing scheme for power-law graphs in social networks. In Sect. 2, a link prediction problem, which is a basic computational problem underlying social network evolution, is introduced. Section 3 focuses on local structural properties of social networks, also known as community structure. Some community properties and several algorithms for community identification are introduced. Sections 4 and 5 present two hot research topics in social networks. Influence maximization problem is addressed when a new idea is supposed to have more people to believe it or a company would like to make more customers to purchase a new product with the “word-of-mouth” effect in a social network. How to choose the people and take advantage of the relationships between people to promote your idea or product is what the influence maximization problem concerns about. Routing problem mainly focuses on compact routing scheme by using the theory of unweighted random power-law graphs with fixed expected degree sequence. The method discussed has the first theoretical bound coupled to the parameter of the power-law graph model for a compact routing scheme.

2 Social Network Structure

In recent years, people have witnessed the rapid growth of interests in networks, which are pervasive in the real world. With extensive studies, many researchers point out that the real-world networks demonstrate certain surprising consistent structure properties across different fields. Particularly, studies on three major characteristics of the networks, which are small world, clustering, and scale-free, are of great popularity. And based on those structural properties, three basic topological measurements including average path length, clustering coefficient, and degree

distribution are proposed to study the network from the topological perspective. In general, the average path length is the average distance between any pair of nodes. The degree of a node is the number of edges connected to that node. Newman [51] defined the clustering coefficient measure as

$$C = \frac{3 \times \text{number of triangles in the graph}}{\text{number of connected triples}} \quad (1)$$

where a triangle is formed by a set of three vertices, among which each node is connected to both of the others. A connected triple is three vertices $u - v - w$, with both vertices u and w connected with v ($u - v - w$ and $w - v - u$ are considered as the same connected triple). According to topological features, networks fall into mainly four different classes, which are information network, social network, technological networks, and biological networks. In this section, we focus on social networks.

A social network is a set of people or groups of people with some pattern of contacts or interactions among them under certain situation. From a graph theory point of view, a social network structure is defined as this: among a set of nodes and edges, the nodes represent people or other entities embedded in an underlying social context, and the edges represent interaction, collaboration, or influence between two entities. For instance, in the academic domain, nodes represent scientists in a particular discipline, and an edge is generated between two individuals if they have coauthored papers.

On one hand, from a static perspective that all edges are considered simultaneous, a social network has many classical invariant structural properties, such as small world phenomenon, clustering, scare-free, and so on. All of these characteristics provide us important information for probing other features of networks. On the other hand, in reality, social networks are highly dynamic, that is, they grow and change over time by adding new edges between nodes, which means that new connections occur in underlying networks. In order to realistically model the real world networks, it is of great advantage to consider the structure of social networks from a dynamic perspective.

Nowadays, along with the development of online large networks and the availability of the dataset collected from social networks, people are able to use the existing information to understand social network evolution or the potential structure pattern already existing but unobserved in the whole network. In this section, we would like to introduce the link prediction problem, which is a basic computational problem concerned with social network evolution.

2.1 Link Prediction Problem on Social Network

As a subfield of social network analysis, unlike other problems such as influence maximization, community detection, and small network, link prediction problem is concerned with the problem of predicting the future existence of links among nodes in a social network.

The link prediction problem defined in [66] is as follows: Given a social network $G = (V, E)$, where V denotes the set of entities and E is the set of observed links among those groups, then the aim of the problem is to predict how likely an unobserved link $e_{ij} \notin E$ exists between an arbitrary pair of nodes (v_i, v_j) in the network. In general, the link prediction problem can be studied from three different perspectives: they are link existence prediction (Does a link exist between two nodes?), link classification (What type of the relationship between a pair of nodes?), and link regression (How does the user estimate the item?), separately.

Until recently, link prediction has obtained a wide variety of applications among areas including bibliographic domain, molecule biology, criminal investigations, recommendation systems, and so on.

The authors in [66] summarized that the techniques used in the link prediction problem for social network fall into three categories according to the types of models: node-wise similarity-based approaches, topological pattern-based approaches, and probabilistic model-based approaches. According to the resources used to predict links between nodes, methods are developed from two aspects: one is based on the attributes of nodes, and the other takes advantage of the structural properties of networks. Since it is hard to collect accurate individual attributes in real world, the structural properties make more contribution to the prediction problem.

In the following, we introduce approaches that use the topological features of social networks in link prediction problem.

2.2 Graph Proximity Approaches

The graph proximity measures for link prediction problem depend on structural features of the given network. The basic and intuitive method for predicting links is to rank all node pairs according to their graph topology measurements. That is, with regard to the input graph, a weight Score(x, y), which is a subtle predictor based on node neighborhood or path information, is assigned to a pair of nodes (x, y) ; after each pair of nodes get their own scores, these nodes are ranked in decreasing order according to the values of their associated scores, and the top-ranked pairs of nodes are predicted to have high probability to have links between them. In addition, the meanings of these scores vary according to certain contexts.

2.2.1 Original Graph Proximity Measures

In [39], Liben-Nowell et al. studied this problem through a number of proximity measures to predict the new collaborations in a coauthorship network. Given a network $G = (V, E)$, where V denotes the groups of authors, $e = (u, v) \in E$ represents the interactions(coauthorship) that take place at a particular time $t(e)$ between author u and author v .

In order to predict the interactions that will occur among those people, firstly, the authors in [39] chose four distinct time stamps $t_0 < t'_0 < t_1 < t'_1$. Assume $[t_0, t'_0]$ as

the training interval, in which the subgraph $G[t_0, t'_0]$ contains the edges that appear between the time period from t_0 to t'_0 . Meanwhile, regard $[t_1, t'_1]$ as the test interval, which is used to validate the prediction accuracy. Then, a variety of predictors modified from techniques adopted in graph theory and network analysis are applied to predict the similarity of pairs of nodes. These predictors are common neighbors, graph distance, Jaccard's coefficient, and so on, among which $\text{Score}(x, y)$ plays a vital role for predicting links that are likely to appear in the future. In this section, $\text{Score}(x, y)$ denotes the proximity or similarity between nodes x and y with respect to the network topology.

To estimate the validity of these predictors, the authors in [39] brought in two parameters, k_{training} and k_{test} , and focused on a set Core , which contains all nodes that are incident to at least k_{training} edges in $G[t_0, t'_0]$ and k_{test} edges in $G[t_1, t'_1]$. For each link predictor p , the ranked list L_p of pairs of nodes in $V \times V - E_{\text{old}}$ (the set of edges developed in training interval) is made up of predicted links, which are arranged in the order of decreasing probability to appear in the future. Denote $E_{\text{new}}^* := E_{\text{new}} \cap (\text{Core} \times \text{Core})$ and $n = |E_{\text{new}}^*|$, and take the initial n pairs of nodes in the set of $\text{Core} \times \text{Core}$; here, the size of the intersection component of these nodes with set E_{new}^* is used to measure the performance of predictor p . According to the experiment analysis of predictors on coauthorship networks from different conferences, it was suggested that the datasets applied to this kind of networks are less noisy compared to other online networks, that is, these coauthorship networks rely on their own topological features rather than other external factors. Moreover, the experiment results showed that the approaches based on the structural features outperform those ones obtained from random prediction. Meanwhile, the score proved to be better than others.

2.2.2 Weighted Graph Proximity Measures

Unlike previous methods based on structural features such as Newman's common neighbors [48], Adamic and Adar method [4], and preferential attachment [45, 46] took into account of the weight of a link, here, the weight can be viewed as the number of encounters of a user on QABB (question-answering bulletin boards) corresponding to the number of times they meet or communicate.

The authors in [46] defined new scores that combine both structure proximity and link weight as follows:

The score of weighted common neighbor:

$$\text{Score}(x, y) = \sum_{z \in N(x) \cap N(y)} \frac{w(x, z) + w(y, z)}{2}, \quad (2)$$

where $w(x, z)$ denotes the weight of the link between node x and node z .

The score of weighted Adamic and Adar method:

$$\text{Score}(x, y) = \sum_{x' \in N(x) \cap N(y)} \frac{w(x, z) + w(y, z)}{2} \times \frac{1}{\log(\sum_{z' \in N(z)} w(z', z))}. \quad (3)$$

The score of weighted preferential attachment:

$$\text{Score}(x, y) = \sum_{x' \in N(x)} w(x', x) \times \sum_{y' \in N(y)} w(y', y). \quad (4)$$

Murate and Moriyasu [46] collected the data information from the perspectives of encrypted user ID, categories, date, and time. The main idea is first, group QABB Data into two categories, that is, the early time data is used for training and the later one for testing, which aimed at making computation valid. Then, model a social network by adding links to all pairs of the answers in each question for each category. Finally, predict links that are possible to occur based on proximity measures. The validity of the predictors is measured by

$$\text{accuracy} = \frac{\text{number of correctly predicted links}}{\text{number of new links}}. \quad (5)$$

According to the experiment results in [46], it is shown that Adamic and Adar method performs better than the measure of common neighbors, and for networks whose degree distributions are almost uniform, preferential attachment performs bad. To be excited, the weighted Adamic and Adar method outperforms the original Adamic and Adar approach, weighted common neighbor measure also outperforms original common neighbors over almost all cases, and weighted preferential attachment works slightly better than original preferential attachment only when social networks are relatively dense. In general, when the weighted case is considered, the performances of link predictors are improved compared to previous pure proximity measures. The most important contribution of this measure is that it is fairly effective for open and dynamic online social networks, especially when the network is sufficiently dense.

2.2.3 Generalized Clustering Coefficient-Based Measures

The above two approaches solve the prediction problem under the condition that a network model has been given. However, when the model is not provided, how to build the model of a network? Moreover, it is shown that the methods for prediction problem have close relation with the topological structure of large-scale networks. Thus, it is plausible to generate parsimonious graph models, whose characteristics can be used to describe the significant mechanisms governing the structure of graphs.

Huang [33] showed that structural predictors summarize graph data categories with respect to graph generation model and explain link occurrences in an observed graph. Thus, those measures are of great value to predict the link appearance in the future. As for other predictors, more attention was paid on analyzing generalized

clustering coefficient, which is supposed to describe a cycle formation model. Based on the model, a new method for prediction problem was proposed.

Firstly, Huang [33] introduced relevant notations of a graph and defined the generalized clustering coefficient. Given $G = (V, E)$ a finite undirected graph with only simple edges, that is, there are no multiple edges or self-loops in the graph. $V = (1, 2, \dots, N)$ is the set of vertices of G , and $E = (e_1, e_2, \dots, e_M)$ is the set of edges of G , each e_s corresponds to a sequence of two vertices (i, j) , and the terms of link and edge can be viewed as the same one. A path of length k is denoted as $p = (v_0, v_1, \dots, v_k)$, where (v_i, v_{i+1}) is an edge of the graph for all $0 \leq i \leq k - 1$. Define a cycle of length k as a list of vertices $p = (v_0, v_1, \dots, v_k, v_0)$, where (v_i, v_{i+1}) is an edge of G for all $0 \leq i \leq k - 1$. P_{ijk} represents the set of paths of length k starting at i and ending at j , and $|P_{ijk}|$ is the number of such paths. A generalized clustering coefficient $C(k)$ of degree k was defined as

$$C(k) = \frac{\text{number of cycles of length } k \text{ in the graph}}{\text{number of paths of length } k}. \quad (6)$$

Then the algorithm applied to the cycle formation link probability model is introduced, in which the occurrence probability of a link is determined by the number of cycles (of different lengths) that will be formed by adding this link. The algorithm made the assumption that the clustering coefficient (of deferent degrees) is static.

The Algorithm [33]

In this algorithm, a cycle formation model of degree k ($k \geq 1$) is denoted as $CF(k)$, and a list of parameters c_1, \dots, c_k are adopted for corresponding link generation mechanisms $g(1), \dots, g(k)$, which are used to determine the probability that a link will appear. Here, $g(1)$ is a mechanism similar to a random link generation process. Other mechanisms $g(k)$'s ($k > 1$) are consistent with link probability governed by the paths of length k , where length one means one edge between two nodes. $c_k = \Pr((i, j) \in E | |P_{ijk}| = 1)$ is used to measure the probability that a length- k path will become a length- k cycle. Derive from an instance, an equation for c_k was generalized:

$$\Pr((i, j) \in E | |P_{ijk}| = m) = \frac{c_k^m}{(c_k^m + (1 - c_k)^m)}, \quad k > 1. \quad (7)$$

Considering the effects coming from multiple mechanisms, the above equation can be furthered as follows:

$$\begin{aligned} P_{m_2, \dots, m_k} &= \Pr((i, j) \in E | |P_{ij2} = m_2, \dots, |P_{ijk}| = m_k) \\ &= \frac{c_1 c_2^{m_2} \dots c_k^{m_k}}{c_1 c_2^{m_2} c_k^{m_k} + (1 - c_1)(1 - c_2)^{m_2}(1 - c_k)^{m_k}}, \end{aligned} \quad (8)$$

where P_{m_2, \dots, m_k} denotes the total link occurrence probability under the cycle formation model of degree k .

Then we introduce the approaches adopted to estimate the parameters of the cycle formation model based on the generalized clustering coefficients. Actually, when the parameters are figured out, to obtain the link probabilities, it only needs to apply the estimated parameters to Eq. (7). The operations used in this algorithm are iterative.

Firstly, according to the degree distribution, start the computation with a complete random model, then get the cycle formation probability c_1 . $C(k)$ is regarded as the generalized clustering coefficient and is calculated one by one. Secondly, compare $C(2)$ with c_1 , if $C(2)$ cannot be expressed by c_1 , then new formation mechanism for length-2 cycle will be generated. Then, continue to compare the observed $C(3)$ with the expected $C(3)$ under the length-2 cycle formation model, so the estimator c_3 can be derived. When it satisfies the degree of the model, the procedure terminates. The primary component of this method depends on the fact that $C(k)$ is a function of c_1 and has no relation with $c_{k'}$, here, $k' > k$. The method is formally described as follows:

1. Input information of $G = (V, E)$.
2. Compute the generalized clustering coefficients $C(2), \dots, C(k)$ through Eq. (6).
3. Compute the connecting probability under random graph with the degree distribution of G as c_1 , which is the cycle formation probability.
4. Denote c_2 as

$$c_2 = \frac{(1 - c_1)C(2)}{(c_1 - 2c_1C(2) + C(2))}.$$

5. Set $c_i = 0.5$, where $i = 3, \dots, k$.
6. For $i = 3, \dots, k$, iteratively apply the following equation:

$$c_i = \operatorname{argmin}_{c'_i} (|C(i) - f(c_1, \dots, c'_i, \dots, c_k)|).$$

7. Output the values of c_1, \dots, c_k that have been figured out.

The function which is denoted as

$$f(c_1, \dots, c'_i, \dots, c_k) = \sum_i \#(G_i) \Pr(G_i) \Pr((1, k+1) \in E | G_i) \quad (9)$$

is the total probability of link $(1, k+1)$'s occurrence conditional on a path $p = (1, 2, \dots, k+1)$. It is also the theoretical prediction of the expected clustering coefficient of degree k , denoted as $E[C(K)]$ based on the cycle formation model. For a given path of length k , G_i is supposed to be a possible graph pattern, $\#(G_i)$ denotes the number of subgraphs corresponding to this graph pattern, and $\Pr(G_i)$ is the probability for one of the subgraphs to occur, the probability for edge $(1, k+1)$ to occur under certain condition of G_i is denoted as $\Pr((1, k+1) \in E | G_i)$.

Experiment Evaluation ([33])

The experiments were carried out on Enron email dataset, which is a large email collection from a real organization over the course covering a 3.5 years period. In the experiment, the author mainly evaluated the performances of the cycle formation link probability model and the corresponding link prediction algorithm. The dataset analyzed contains 40,489 emails during May 11, 1999, to June 21, 2002. And this paper implements the link prediction analysis on the monthly email graph in 2001. The email graph is undirected and unweighted, and the edges connect senders and recipients of emails during the corresponding time periods. An edge (a, b) means that there is at least one email communication between a and b , that is, either a sends at least one email to recipients including b or b sends at least one email to recipients including a . And month t was set in 2001 to build the initial graph G_{tb} through the emails in the previous 3 months $(t - 3, t - 2, t - 1)$. This graph is regarded as the input for prediction of email links in G_t , thus, the primary goal is to predict the occurrence of links in G_t that do not exist in G_{tb} .

To evaluate the performance of link prediction, construct a receiver operating characteristics (ROC)-style curve with x-axis as the percent of total possible new links selected and y-axis as the percent of actual new links that are in the selected links, respectively. Then area under curve (AUC) measure is applied to estimate the link prediction performance. It is shown that the algorithm based on the cycle formation model performs better than others that already existed, and has great power to predict the probability of link occurrence.

2.3 Supervised Learning-Based Approaches

Facing the challenge of a wide application of the link prediction, it is necessary to construct both a powerful and universal framework. Although the work in [39] demonstrated improvement of measures for prediction problem over random predictors, they used the properties only based on network intrinsic topological structure, while there are other non-topological properties that proved to enhance the performance of methods for link prediction problem. In [32, 40, 43], the authors regarded the prediction problem as a classification modeling, in which they extracted the features both from topology and non-topology. Throughout their studies, supervised learning played a vital role, and [40] improved the predictive accuracy of supervised learning.

Firstly, we introduce the concept of supervised learning. Supervised learning is a task to infer a function from the supervised training data, which contains a big volume of samples, where each sample consists of an input object and a desired output value. Based on the data information, a supervised learning algorithm is used to analyze the training instances to produce the expected function, which will be applied to predict the output value of any input instances. In general, supervised learning contains the following steps:

1. Determine the types of training examples.
2. Collect a training set.
3. Determine the input feature representation for the learned function.
4. Determine the structure of the learned function and its corresponding learning algorithm.
5. Complete the design process.
6. Evaluate the performance accuracy of the learned function.

During supervised learning, four major issues should be considered. The first is the amount of training data available relative to the complexity of the “true” function (classifier or regression function), the second is the trade-off between bias and variance, the third is the dimensionality of the input space, and the fourth is the degree of noise in the desired output values (the supervisory targets).

2.3.1 Work of Madadhain et al. [43]

In this article, the authors studied an event-based network dataset, which consists of sets of events over time. They paid special attention to the temporal feature of the data, and two specific problems related to the event network data were extensively studied. Here, we only introduce one of them: predicting future event co-participation of entities, which aims to estimate to what extent that a given pair of individuals will co-participate in at least one event during some specific time period in the future.

To simplify the following analysis, we introduce the definition in [43], where $\mathcal{E} = \{e_1, \dots, e_m\}$ denotes a set of events and $\mathcal{V} = \{v_1, \dots, v_n\}$ represents the set of participating entities. The set of entities that participate in event e_i is named as P_i . Each event and each entity can have a set of attributes or covariates. And the covariates for e_i and v_j are denoted as y_i and x_j , respectively. The sets of all events and entity covariates are represented by \mathbf{Y} and \mathbf{X} , respectively. The time that an event e_i occurs is denoted as t_i , and i means that e_i is the i th occurred events. $v_j, v_k \in P_i$ means that v_j and v_k are co-participants in event e_i , and $v_j, v_k \in P_{t,t+\Delta t}$ means that v_j and v_k are co-participants in one or more events in the interval $[t, t + \Delta t]$. Meanwhile, name the subset of events taking place in the interval $\mathcal{E}_{t,t+\Delta t}$. Usually, a vertex corresponds to an entity in a network derived from such a dataset, and edges connect vertices that participate in the same events.

The prediction problem was considered as a data-driven classification problem, in which there are two classes consisting of co-participating and not co-participating. Firstly, probabilistic classifiers were used to offer a probability to each class according to the values of some specified features. The probability is defined as follows:

$$p(v_j, v_k \in P_{t,t+\Delta t} | f(\mathcal{E}_{1,t}, \mathcal{V}, \mathbf{X}, \mathbf{Y}) = \mathbf{w}), \quad (10)$$

where $v_j, v_k \in P_{t,t+\Delta t}$ is a binary suggestion determining whether entities v_j and v_k co-participate in any event in the time period $[t, t + \Delta t]$, f is a function used to produce a vector \mathbf{w} of feature values, $\mathcal{E}_{1,t}$ is the historical event data through to time t , and \mathbf{X}, \mathbf{Y} are the relevant entity and event covariate data, respectively. Then based on

the formulation, the problem can be regarded as learning the mapping from feature vectors to class probabilities, and it can be computed by standard “off-the-shelf” prediction algorithms.

To construct a classification model, the authors proposed foundational components for the operation of classification, which include feature selection, training sets and test sets, classification method, and evaluation metric. Then based on the model, experiments were implemented and indicated that relatively standard machine learning approaches could be used to draw predictive information from the event data, which could be regarded as a ranking machine to detect the individual pairs that have high probability to co-participate in future event.

2.3.2 Work of Lichtenwalter et al. [40]

As for previous supervised methods, the researchers were interested in a domain of the prediction problems with highly imbalanced class distributions [32], although the measures adopted work well, the results of the tests operated on the modified data cannot provide the precise information of the real world, and the performance measures in tests were not available to present the strength and weakness of the models. On the other hand, these models mainly use both the semantic and contextual information related almost exclusively with the bibliographic realm. In addition, the surprising influence of geodesic distance and the complexity of class imbalance specific to the task of link prediction were neglected in those works. Furthermore, many factors, which played significant role in influence and guide classification, had not been explored previously by supervised learning.

In [40], the authors first proposed a supervised framework, which considered the factors of the observational period in the network: generality of existing methods, variance reduction, topological causes, and degrees of imbalance. The attractive merit of the framework is its universality, which means that it can be used on any kind of networks, that is, whether a network is weighted, unweighted, directed, or undirected, the framework can be applied to it. Additionally, the framework has the capability of accepting vertex attributes even though it does not need them. Besides studies in supervised learning for prediction problems, an intuitive flow-based metric was applied to the unsupervised measures to obtain more predictive results.

Next, we would like to introduce the PropFlow method for unsupervised prediction, which was proved to be an efficient predictor. The procedure of the algorithm is given as follows.

The PropFlow method [40] corresponds to the possibility that a restricted random walker starts at v_i and terminates at v_j in k steps or fewer by using link weights as transition probabilities. The walker chooses links based on their weights, and the score in the method is applied to predict the occurrence of new links in the future. PropFlow is somewhat like rooted PageRank, but it is a more localized approach of diffusion and is insensitive to topological noise that is far from the source node. Furthermore, PropFlow simply employs a modified breadth-first search restricted to height k , by which it computes faster.

Algorithm 1 PropFlow predictor [40]

Input information of network $G = (V, E)$, node v_s and maximal length l

- 1: Add node v_s to a set denoted as *Found*
- 2: Put node v_s to another set called *NewSearch*
- 3: Add $(v_s, 1)$ into S
- 4: **For** CurrentDegree, which ranges from 0 to l, **do**
- 5: Assign the value of *NewSearch* to a set *OldSearch*
- 6: Make *NewSearch* as a empty set
- 7: **While** *OldSearch* is not empty, **do**
- 8: Bring out v_i from *OldSearch*
- 9: Find *NodeInput* through v_i in S
- 10: Assign *SumOutput* 0
- 11: **For** each v_j in v_i 's neighborhood **do**
- 12: Add weight of e_{ij} to *SumOutput*
- 13: **End for**
- 14: Set the value of *Flow* to be 0
- 15: **For** each v_j in v_i 's neighbors **do**
- 16: Assign the weight of e_{ij} to w_{ij}
- 17: Assign *Flow* the value of *NodeInput* $\times w_{ij}$ *SumOutput*
- 18: Sum $(v_j, Flow)$ and put it into S
- 19: **If** v_j is not in *Found* **then**
- 20: Add v_j into *Found*
- 21: Put v_j to *NewSearch*
- 22: **end if**
- 23: **end for**
- 24: **end while**
- 25: **end for**
- 26: **Output** score S_{sd} for all $n \leq 1$ -degree neighbors v_d of v_s

Supervised learning, which includes dataset collection, generalization, variance reduction, and sampling, was investigated. Based on the detailed study of those above operations, class imbalance is proposed. Combining the nature of the prediction problem and the benefit of supervised learning, the author implemented the supervised framework by classification including general feature extraction, ensemble of classifiers, and overcoming imbalance.

The experiments in [40] were carried out on two datasets: one is a stream of 712 million celluar from a major non-American cellular phone service provider, and the other is a stream of 19,464 multi-agent events representing condensed matter physics collaborations from 1995 to 2000. For the former dataset, a weighted, directed network (*phone*) was built, in which a node v_i represented a caller, and if v_i called v_j , a weighted and directed link e_{ij} would connect v_i with v_j , where weight was the number of calls on the link. For the latter dataset, a weighted, undirected network (*condmat*) from the collaborations was constructed, in which a node represented an author in the event, and a weighted, undirected link was used to denote the interactions between each pair of authors.

Based on those above experiments, it is shown that the general supervised framework outperformed other existing approaches, and the framework was demonstrated to be entirely general, that is, it is able to operate on any kinds of networks whether it

is weighted, unweighted, directed, or undirected. It has the capacity to accept vertex attributes though it does not need to consider them. Get more useful results reading [40].

3 Local Structure

One of the most significant characters of social networks is the local structure, also known as community structure. That is, a massive social network always contains many very dense subgraphs. Identifying these dense subgraphs or communities will help reveal the underlying network structure and analyze the common activities of individuals. In this section, we will introduce the community properties and review several algorithms for community identification.

3.1 Social Community

Several significant characters of social networks have drawn the attentions of many researchers, such as the small-world property, power-law degree distributions, and local structures, also known as communities. In this section, we will focus on this community property.

In a social network, individuals are shown as nodes, and interactions between the individuals are presented by edges, like relationships and influence. The individuals tend to form communities. A community is a group of nodes that are similar to each other and dissimilar from the rest nodes in the network. In a network, it is usually thought as a group where nodes are densely interconnected and sparsely connected to other parts of the network.

So far, several definitions for community structure have been derived. One of the most intuitive ways is to define community in terms of cliques. A clique in a graph is a subgraph in which any pair of nodes are linked. Based on this, the authors in [58] regard maximal cliques in a graph as communities. A maximal clique is a clique that is not contained by any larger clique. Abello et al. [1] generalized the definition of clique and proposed a structure named quasi-clique. A connected subgraph is considered to be a quasi-clique when it is dense enough. Filippo et al. [54] proposed two definitions for community structure. Consider a subgraph V of graph G . For any node $i \in V$, let K_i^{in} be the inside degree of node i , for example, the number of links toward nodes in V . And let K_i^{out} be the outside degree of node i . Then they defined that the subgraph V is a community in a strong sense if

$$K_i^{\text{in}} > K_i^{\text{out}}, \quad \forall i \in V. \quad (11)$$

In this strong community, each node has more connections within the community than with the rest of the graph. Also, they defined the community in a weak sense by

$$\sum_{i \in V} K_i^{\text{in}} > \sum_{i \in V} K_i^{\text{out}}. \quad (12)$$

In this weak community, the sum of all degrees within V is larger than the sum of all degrees toward the rest of the network.

Although none of the above definitions can be considered universal, they are all capable to capture the underlying properties of social networks.

3.2 Social Community Identification

Community identification is to find groups that either have an inherent or an externally specified notion of similarity among their nodes. As mentioned earlier, people in the same community are more similar than people from different communities. Which means that they might share more on information, interests, experiences, and other useful resources. So discovering the underlying community structures has direct impacts on optimizing and managing activities in a social network. Agarwal and Kempe [5] showed that identifying communities might help people study the whole massive network by communities. That is, after partitioning the graph into communities, one can start focusing on single community. Since nodes of the same community have considerable overlapping on their characters, the analysis inside one community would be more convenient and meaningful. They also claimed that by contracting each community into a node, one can simplify the original large-scale network considerably. This will help people get to know the network from a very high point of view.

Due to the above reasons, community identification has become a very important issue in the social network study. However, nowadays, social networks are usually huge massive networks consisting of millions of nodes, so in general, very little is known about the community structure of a graph; thus, one of the challenges in community identification is that the number of communities in a network and their sizes are not known beforehand. Furthermore, the communities need to be established by the community detection algorithm. Next, we will introduce algorithms within different categories and show how they deal with the challenge and generate communities effectively.

3.2.1 Hierarchical Clustering

Hierarchical clustering is the most widely used method among traditional community identification methods. The core of any hierarchical clustering method is the definition of a similarity measure between vertices. Once such a measure is set, one can compute and sort the similarity values for all pairs of nodes in the given network. Based on the direction of a community formulation procedure, the corresponding methods fall into the following two categories:

Agglomerative algorithms: start with a non-edge graph with only node set. Edges are iteratively added into this graph by decreasing order of similarity values until the original graph is formed.

Divisive algorithms: run in the opposite direction of agglomerative algorithms. They start with the original graph, and edges are deleted based on the increasing order of the similarity values.

The two categories of algorithms will finally generate a tree or dendrogram for the original graph. All the nodes of the given graph are presented by leaves. A non-leaf node on the tree denotes the community resulted from the merging of two smaller communities. The root would be the original graph.

The hierarchical clustering method does not provide any measure of when the clustering procedure should be terminated. So as for the size and number of communities, the terminating point should be manually decided according to the application scenario.

Several Similarity Measures

Structural equivalence is a property derived from sociological studies. Two nodes are of structural equivalence if they have the same set of neighbors. A measure called correlation coefficient was proposed in [63] based on structural equivalence. Suppose A_{ij} is the adjacent matrix for the given graph. Define means and variances of the columns as

$$\mu_i = \frac{1}{n} \sum_j A_{ij}, \quad \sigma_i^2 = \frac{1}{n} \sum_j (A_{ij} - \mu_i)^2; \quad (13)$$

the correlation coefficient is

$$x_{ij} = \frac{\frac{1}{n} \sum_k (A_{ik} - \mu_i) \sum_k (A_{jk} - \mu_j)}{\sigma_i \sigma_j}. \quad (14)$$

Vertices that have a high degree of structural equivalence will have high values of this similarity measure, and meanwhile, those that do not have a high degree of structural equivalence will have low values.

Another similarity measure is the number of edge (vertex)-independent paths between two nodes [64]. Intuitively, the more independent paths between two nodes, the more related they are. This measure is easy to calculate through augmenting path algorithm.

A measure called “edge betweenness” was proposed in [26]. Recall that in hierarchical clustering method, the algorithm iteratively finds the most “central” edges and adds them into communities. Different from those traditional similarity measures, “edge betweenness” describes how an edge is “between” communities and the algorithm will run in a divisive manner.

For edge e , the edge betweenness of e is defined to be the number of shortest paths between pairs of other vertices that run through e . The idea behind this definition is that if a network contains communities or groups that are only loosely connected by a few intergroup edges, then all shortest paths between different communities must go along one of these few edges. Thus, the edges connecting communities will have high edge betweenness.

Their algorithm is proposed as follows:

Algorithm 2 Algorithm based on edge betweenness [26]

- 1: For each edge in the graph, calculate its edge betweenness. Sort all the edges by decreasing order of the edge betweenness.
 - 2: Recalculate betweennesses for all edges (or for time efficiency, only those whose betweenness value are changed after the removal). Perform another sorting process.
 - 3: Repeat steps 2 and 3 until there is no edge left.
 - 4: Based on the removal, a hierarchical dendrogram can be generated. Then a community partition can be decided manually.
-

3.2.2 Modularity-Based Algorithm

As mentioned earlier, so far, there is no universal definition for communities. But a quantity known as modularity, derived by Newman and Girvan [50], can measure how good a community partition is.

For a given graph $G = (V, E)$, let A be its adjacent matrix; then

$$A_{vw} = \begin{cases} 1 & \text{when } (v, w) \in E, \\ 0 & \text{otherwise.} \end{cases} \quad (15)$$

Suppose all the vertices have been divided into communities. Let c_v denote the community node v belongs to. Define function δ to be

$$\delta(i, j) = \begin{cases} 1 & \text{if } i = j, \\ 0 & \text{otherwise.} \end{cases} \quad (16)$$

Then the fraction of edges that fall within communities, that is, edges that connect vertices that both lie in the same community, is

$$\frac{\sum_{vw} A_{vw} \delta(c_v, c_w)}{\sum_{vw} A_{vw}} = \frac{1}{2m} \sum_{vw} A_{vw} \delta(c_v, c_w), \quad (17)$$

where $m = \frac{1}{2} \sum_{vw} A_{vw}$ is the number of edges of graph G . This quantity is not suitable to measure the strength of community partitions for the case that all the nodes form the same community. Under this case, the quantity is maximized while there is no community structure information proposed at all. However, if the expected value of the same quantity is subtracted from it in the case that every edge is generated randomly, an effective measure can be obtained.

Set k_v to be the degree of node v :

$$k_v = \sum_w A_{vw}. \quad (18)$$

Then the probability that there is a random edge between node v and node w is

$$p_{vw} = \frac{k_v \cdot k_w}{2m}. \quad (19)$$

The modularity Q is defined to be

$$Q = \frac{1}{2m} \sum_{vw} \left[A_{vw} - \frac{k_v k_w}{2m} \right] \delta(c_v, c_w). \quad (20)$$

By defining modularity in this way, the case that the whole graph forms one community can be avoided since the corresponding quantity is 0. This modularity expression can be reformulated through the following two quantities:

$$e_{ij} = \frac{1}{2m} \sum_{vw} A_{vw} \delta(c_v, j) \delta(c_w, j), \quad (21)$$

which denotes the fraction of edges between community i and community j . Another quantity is

$$a_i = \frac{1}{2m} \sum_v k_v \delta(c_v, i), \quad (22)$$

which is the fraction of edges that have one endpoint falling in community i . Notice that

$$\delta(c_v, c_w) = \sum_i \delta(c_v, i) \delta(c_w, i), \quad (23)$$

then

$$\begin{aligned} Q &= \frac{1}{2m} \sum_{vw} \left[A_{vw} - \frac{k_v k_w}{2m} \right] \delta(c_v, c_w) \\ &= \frac{1}{2m} \sum_{vw} \left[A_{vw} - \frac{k_v k_w}{2m} \right] \sum_i \delta(c_v, i) \delta(c_w, i) \\ &= \sum_i \left[\frac{1}{2m} \sum_{vw} A_{vw} \delta(c_v, i) \delta(c_w, i) - \frac{1}{2m} \sum_v k_v \delta(c_v, i) \frac{1}{2m} \sum_w k_w \delta(c_w, i) \right] \\ &= \sum_i (e_{ii} - a_i^2). \end{aligned} \quad (24)$$

Newman and Girvan [50] showed that, in practice, values being greater than about 0.3 appear to indicate significant community structure. Based on modularity, many algorithms have been designed, which makes modularity currently the most widely used measurement for community identification. Next, we start introducing several of these algorithms.

Greedy Algorithms

One most intuitive algorithm is a greedy strategy derived by Newman [49]. At the beginning, each node forms a sole community. Then communities are integrated together in pairs repeatedly. Which pair to be combined is based on the increase

that they make on Q . The procedure continues until all the nodes are contained in one community. Clearly when the algorithm terminates, a dendrogram is generated, showing the order of these combinations. Then as introduced earlier, communities partition can be manually determined. Each step of the algorithm takes time $O(m + n)$ in worstcase. At most, $n - 1$ combination operations are needed to construct the complete dendrogram. So the algorithm runs in time $O((m + n)n)$. When it comes to sparse graph, it is $O(n^2)$.

Clauset et al. [16] improved the above algorithm and proposed another similar algorithm but has running time $O(md\log n)$, where d is the depth of the dendrogram describing the community structure. In their algorithm, instead of maintaining the adjacency matrix and calculating ΔQ_{ij} for each pair (i, j) , a matrix of value of ΔQ_{ij} was directly maintained and updated. Communities that have no edges between them will not make changes to the value of Q . Hence, the algorithm will only focus on communities that are linked by some edges. Additionally, another two data structures, which will further save both memory and time consumption of the algorithm, were maintained to track the largest Q_i . These two data structures are described as follows:

1. A vector array H recording the largest element of each row of matrix ΔQ_{ij} and the corresponding labels i, j
2. A vector array with elements a_i

The algorithm also starts with the state that each vertex forms a sole community. Initially

$$e_{ij} = \begin{cases} 1/2m & \text{if } (i, j) \in E, \\ 0 & \text{otherwise,} \end{cases} \quad (25)$$

and $a_i = k_i/2m$. So

$$\Delta Q_{ij} = \begin{cases} 1/2m - k_i k_j / (2m)^2 & (i, j) \in E, \\ 0 & \text{otherwise.} \end{cases} \quad (26)$$

The algorithm then proceeds as follows:

Algorithm 3 Greedy algorithm [16]

- 1: Calculate the values of ΔQ_{ij} and a_i , and construct vector array H .
 - 2: Choose the largest ΔQ_{ij} from H , merge the corresponding communities, and update the matrix ΔQ , vector array H , Q , and a_i .
 - 3: Repeat step 2 till there is only one community left.
-

Step 2 is supposed to be carried out faster according to the definition of H and a_i . If communities i and j are merged, then the i th row and column of ΔQ are removed and the j th row and column are updated. The update rules are as follows:

If community k is connected to both i and j , then

$$\Delta Q'_{jk} = \Delta Q_{ik} + \Delta Q_{jk}. \quad (27)$$

If k is only connected to i, then

$$\Delta Q'_{jk} = \Delta Q_{ik} - 2a_j a_k. \quad (28)$$

If k is only connected to j, then

$$\Delta Q'_{jk} = \Delta Q_{ik} - 2a_i a_k. \quad (29)$$

Searching Strategies

Simulated annealing [7] is an optimization technique that stochastically avoids local peaks by introducing a computational temperature T. When T is high, the searching direction is flexible. Which means that the algorithm is allowed to reach an area with an objective value worse than the current spot. When T decreases, such flexibility is weakened. And after T reaches 0, the algorithm will stop and output the current solution.

In [31], the authors applied the simulated annealing technique for modularity-based identification algorithm to maximize the modularity value. So here, the objective of the simulated annealing procedure is

$$C = -Q, \quad (30)$$

where Q is still the value of the modularity.

There are three operations during the annealing process:

1. Movements of nodes between communities
2. Merging two communities into a new community
3. Splitting one community into two new communities

These operations are performed with probability

$$p = \begin{cases} 1 & \text{if } C_f \leq C_i, \\ \exp\left(-\frac{C_f - C_i}{T}\right) & \text{if } C_f > C_i. \end{cases} \quad (31)$$

The algorithm starts with an initial value for T and runs iteratively. In each iteration, certain numbers of operation are performed based on the probability defined above. Then T is decreased for a fixed value and another iteration starts. Once T reaches 0, the algorithm will terminate and the final communities will be outputted.

3.2.3 Fast Algorithms

The real-world networks are usually huge in size and always have massive structure thus, time efficiency of the community detection algorithm is an important performance measure. The above several algorithms we introduced are usually very time-consuming while facing such complex networks. In this section, we will introduce several algorithms that have near linear running time.

In [65], the authors presented a method that allows for the discovery of communities within graphs of arbitrary size in times that scale linearly with their size. The basic idea behind the algorithm is as follows.

Firstly, partition the given graph $G = (V, E)$ into two communities. At the very beginning, two nodes A and B are selected and assumed to belong to two different communities (the selection policy will be introduced later). Suppose the two communities are presented by G_1 and G_2 . Then the whole graph is considered as an electric circuit. Edges of the graph are taken as resistors of the same resistance. A battery is placed with A and B as the poles, which will add constant voltages on them, suppose 1 on A and 0 on B. Then there will be flows flowing through all the edges. By solving Kirchhoff equations, the voltages V_i for each node i can be obtained, which lie between 0 and 1. Based on a threshold given beforehand, it will be easy to decide which community each node belongs to.

For a certain node C in the graph, suppose its neighbors are D_1, \dots, D_n . According to Kirchhoff equations, let I_i denote the current flowing from D_i to C, the following equation holds

$$\sum_{i=1}^n I_i = \sum_{i=1}^n \frac{V_{D_i} - V_C}{R} = 0, \quad (32)$$

which means that the total current flowing into C should sum up to zero. Hence the voltage of a node equals to the average of its neighbors, that is,

$$V_C = \frac{1}{n} \sum_{i=1}^n V_{D_i}. \quad (33)$$

According to the above equation, the Kirchhoff equations of G can be formulated as follows:

$$V_1 = 1, \quad (34)$$

$$V_2 = 0, \quad (35)$$

$$V_i = \frac{1}{k_i} \sum_{(i,j) \in E} V_j = \frac{1}{k_i} \sum_{j \in G} V_j a_{ij} \quad i = 3, 4, \dots, n, \quad (36)$$

where k_i is the degree of node i and a_{ij} is the element of the adjacency matrix of the graph. Equation (36) can be further written as

$$V_i = \frac{1}{k_i} \sum_{j=3}^n V_j a_{ij} + \frac{1}{k_i} a_{i1} \quad i = 3, 4, \dots, n. \quad (37)$$

By defining

$$V = (V_3, \dots, V_n)^T, \quad (38)$$

$$B = \begin{pmatrix} \frac{a_{33}}{k_3} & \dots & \frac{a_{3n}}{k_3} \\ \vdots & \ddots & \vdots \\ \frac{a_{n3}}{k_n} & \dots & \frac{a_{nn}}{k_n} \end{pmatrix}, \quad (39)$$

$$C = \left(\frac{a_{31}}{k_3}, \dots, \frac{a_{n1}}{k_n} \right)^T, \quad (40)$$

the Kirchhoff equations can be presented by a matrix form

$$V = BV + C. \quad (41)$$

The corresponding solution to the above equation is

$$V = (I - B)^{-1}C. \quad (42)$$

Furthermore, the equation can be simplified as

$$LV = D, \quad (43)$$

where

$$B = \begin{pmatrix} k_3 & -a_{34} & \dots & -a_{3n} \\ -a_{43} & k_4 & \dots & -a_{4n} \\ \dots & \dots & \dots & \dots \\ -a_{n3} & -a_{n4} & \dots & k_n \end{pmatrix}, \quad (44)$$

$$D = (a_{31}, \dots, a_{n1}). \quad (45)$$

To solve the equations, instead of applying the well-known spectral partitioning method, the authors derived a much faster technique that does not compute the eigenvectors of G . Their algorithm starts with a precomputing process which evaluates the initial values for each node. This process takes $O(V)$ time. Then iteratively, based on Eq. (33), the algorithm starts updating the voltage value of each node. The final precision is related to the number of such rounds. Therefore, the performance of the algorithm is proportional to the time it consumes, and this procedure costs $O(\sum_{i=3}^n k_i) = O(E)$ time.

After the above processes terminate, each node gets a voltage value. Then all nodes are sorted according to the voltage value. The authors applied a spectrum presentation, that is, each node is illustrated as a vertical line at the abscissa which is equal to the corresponding voltage value.

Then two challenges come up. One is that if the initial two poles are actually in the same community, obviously, the algorithm will fail. In [65], the authors gave a strategy based on the idea that two nodes that are far away from each other belong to different communities with high probability. So while determining the pole nodes, two nodes with as long distance between them as possible are considered firstly.

This is done by starting with an arbitrary node. Find a node farthest from it by breadth-first search, then find a node farthest from this second node. After certain steps, choose the farthest pair. The other challenge is how to identify the two communities based on the voltage spectrum. Their idea is to find the reasonable gap in the voltage spectrum as large as possible. Here, a reasonable gap is mentioned because the largest gap usually appears at the two endings of the voltage spectrum, which does not make clear sense.

Having shown the algorithm that partitions a network into two parts, it would be easy to discuss the condition that more than two communities are required. Wu and Huberman [65] explained this by an example of partitioning the US college football data into 13 conferences. Here totally 115 teams are involved. The algorithm runs in 13 iterations, in each of which, one community is found. At the beginning of the first iteration, two poles are selected. Then the algorithm for two community identifications is applied to generate the spectrum. Based on this spectrum, two communities are found from the two endings of the spectrum according to the preestimated community size. The process is repeated for 50 times to generate 100 such communities, which are called candidates. Then the rest task is to find 13 communities out of these 100 candidates. This is done by firstly specifying a node(team) that appear in the maximum number of candidate sets. Then select another several nodes based on the number of times they appear in the same candidate set with the specific node. Together, they form the first community. Then find the second specific node that appears in the maximum number of candidate sets, ignoring the nodes in the first community. After another 12 iterations, all the 115 teams will be partitioned into 13 conferences.

Recently, Raghavan et al. [55] proposed a localized community detection algorithm based on label propagation. In their algorithm, initially, each node is assigned a unique label. Then at every iteration of the algorithm, each node scans its neighbors, finds the label that most of them take, and adopts it. It is easy to regard the process as a label propagation through the network. Finally, nodes sharing the same label are considered to be of the same community. Clearly, this algorithm is distributed and takes almost linear time.

4 Influence Maximization Problem

A social network is like a huge container, in which thousands of individuals build up their relationships and interactions. Within a social network, ideas or information among its members spread like a cascade and the influence of the information has practical value. When it comes to marketing, for example, a salesman wants to promote the new products of his company, how should he make his marketing strategy such that the products are purchased by as many customers as possible? This kind of problem is called influence maximization problem in social networks. In order to estimate the influence between individuals and the probability of customers' acceptance, some promotion (discount) will be given to certain customers for free to maximize the sales of the products. Therefore, it can

be seen that the most important step is to select proper target customers, then the question is that by what standard a group of initial target customers will be chosen to get the best influence result. In other words, it is valuable to maximize “word-of-mouth” effect [8, 10, 27, 28, 44].

Due to the strong network effect, only taking into consideration the intrinsic value (the value that an individual purchases a product based on his own desire) is not enough. A more important values, say, network value should be taken into account. A network value is used to evaluate the positive influence of one customer on the others around him/her. The combination of the intrinsic value and network value comes up to be the standard that is used to target the initial customers.

In this section, we will introduce the influence maximization problem and its corresponding algorithms. Domingos and Richardson [20] firstly addressed this problem as a fundamental algorithmic problem. To solve this problem, we introduce two probabilistic models and two operational diffusion models in next section. Except the simplest linear function probabilistic model, the other three are all NP-hard problems. Greedy approximation algorithms with $(1 - 1/e)$ – approximation performance are given.

4.1 Two Probabilistic Models

4.1.1 A General Model

Suppose there are n potential customers in the system. Define them as X_i , which is a Boolean variable (Table 1). If customer i purchases the product, X_i is 1; otherwise, X_i is 0. X_i corresponds to the i th customer. N_i is the set of all neighbors of X_i , i.e., $N_i = \{X_{i,1}, \dots, X_{i,n_i}\} \subseteq X - X_i$, where $X = \{X_1, \dots, X_n\}$. Let $X^k(X^u)$ be the customers whose value is known(unknown), and let $N_i^k = N_i \cap X^k$ and $N_i^u = N_i \cap X^u$. Assume the product is described by a set of attributes $Y = \{Y_1, \dots, Y_m\}$. Define M_i as a variable showing the marketing action of customer i . For instance, M_i could be a Boolean variable, with $M_i = 1$ if the customer is offered a given discount, and $M_i = 0$ otherwise. Let $M = \{M_1, \dots, M_n\}$. Thus, for all $X_i \notin X^k$, there is

$$\begin{aligned}
 [20] P(X_i | X^k, Y, M) &= \sum_{C(N_i^u)} P(X_i, N_i^u | X^k, Y, M) \\
 &= \sum_{C(N_i^u)} P(X_i | N_i^u, X^k, Y, M) P(N_i^u | X^k, Y, M) \\
 &= \sum_{C(N_i^u)} P(X_i | N_i, Y, M) P(N_i^u | X^k, Y, M).
 \end{aligned} \tag{46}$$

Table 1 Symbols in the system model

Item	Description
\mathbf{X} :	$\{X_1, X_2, X_3, \dots, X_n\}$ denotes the set of customers or the purchase activity of customers
N_i :	$\{X_{i,1}, \dots, X_{i,n_i}\}$ denotes X_i 's neighbors
N_i^k :	Neighbors in N_i which are known of purchasing the product
N_i^u :	Neighbors in N_i which are unknown of purchasing the product
\mathbf{Y} :	$\{Y_1, \dots, Y_m\}$ denotes the set of product attributes
\mathbf{M} :	$\{M_1, \dots, M_n\}$ denotes the marketing plan
$C(N_i^u)$:	The set of all possible configurations of the unknown neighbors of X_i

According to [53], $P(N_i^u|X^k, Y, M)$ is approximated by its maximum entropy estimate if the marginal $P(X_j|X^k, Y, M)$ is given for $X_j \in N_i^u$. Then

$$[20] P(X_i|X^k, Y, M) = \sum_{C(N_i^u)} P(X_i|N_i, Y, M) \prod_{X_j \in N_i^u} P(X_j|X^k, Y, M). \quad (47)$$

Because in Eq. (47), $P(X_i|X^k, Y, M)$ is expressed as the function of themselves, it can be applied iteratively with an initial value. One of the initial value is $P(X_i|Y, M)$, which is the network-less probabilities. Note that the number of terms in Eq. (47) is exponential in the size of N_i^u . If this number of the unknown neighbors of X_i is small, this should not be a problem, otherwise, an approximate solution is necessary. Gibbs sampling [25] is one of the standard methods for this problem, and another one is based on an efficient k-shortest-path algorithm presented by Chakrabarti et al. [12].

If N_i and \mathbf{Y} are given, X_i should be independent of the marketing actions for other customers except its neighbors. Then a naive Bayesian model is used to present X_i as a function of N_i, Y_1, \dots, Y_m , and M_i :

$$\begin{aligned} [20] P(X_i|N_i, Y, M) &= P(X_i|N_i, Y, M_i) \\ &= \frac{P(X_i)P(N_i, Y, M_i|X_i)}{P(N_i, Y, M_i)} \\ &= \frac{P(X_i)P(N_i|X_i)P(M_i|X_i)}{P(N_i, Y, M)} \prod_{k=1}^m P(Y_k|X_i) \\ &= \frac{P(X_i|N_i)P(M_i|X_i)}{P(Y, M_i|N_i)} \prod_{k=1}^m P(Y_k|X_i). \end{aligned} \quad (48)$$

It is known that

$$P(Y, M_i|N_i) = P(Y, M_i|X_i = 1)P(X_i = 1|N_i) + P(Y, M_i|X_i = 0)P(X_i = 0|N_i).$$

The corresponding network-less probabilities are $P(X_i|Y, M) = P(X_i)P(M_i|X_i) \prod_{k=1}^m \frac{P(Y_k|X_i)}{P(Y, M_i)}$ [20].

To compute Eq. (47), it only needs to know the following probabilities if Eq. (48) is given. These probabilities are $P(X_i|N_i)$, $P(X_i)$, $P(M_i|X_i)$, and $P(Y_k|X_i)$ for all k . All of these are easily obtained except probability $P(X_i|N_i)$. The form of $P(X_i|N_i)$ depends on how the system is built. In other words, due to the mechanism by which customers are influenced by others, this probability will vary from application to application.

4.1.2 Approximate Algorithms Based on the Probability Model

For the sake of simplicity, it is assumed that \mathbf{M} is a Boolean vector. When marketing a product, suppose the cost is a constant. Use c to represent this number. Let r_0 and r_1 be the revenue from selling the product to the customer whether marketing action is performed. Let $f_i^1(\mathbf{M})$ show the result of setting M_i to 1 and leaving the rest of \mathbf{M} unchanged and $f_i^0(\mathbf{M})$, the result of setting M_i to 0 and remaining the rest of the part in \mathbf{M} the same as before. Thus, customer i 's expected lift in profit in isolation is

$$\begin{aligned} [20] \text{ELP}_i(X^k, Y, M) &= r_1 P(X_i = 1 | X^k, Y, f_i^1(\mathbf{M})) \\ &\quad - r_0 P(X_i = 1 | X^k, Y, f_i^0(\mathbf{M})) - c. \end{aligned} \quad (49)$$

Let M_0 be the null vector in which all the members are zero. The global lift in profit that after a particular choice \mathbf{M} of customers to market is as

$$\begin{aligned} [20] \text{ELP}(X^k, Y, M) &= \sum_{i=1}^n r_i P(X_i = 1 | X^k, Y, M) \\ &\quad - r_0 \sum_{i=1}^n P(X_i = 1 | X^k, Y, M) - |\mathbf{M}|c, \end{aligned} \quad (50)$$

where $r_i = r_1$ if $M_i = 1$, $r_i = r_0$ if $M_i = 0$, and the number of 1s in \mathbf{M} is $|\mathbf{M}|$. The goal is to find the assignment of values to \mathbf{M} that maximizes ELP. Trying to find the optimal \mathbf{M} is intractable. It needs to compute every possible combinations of the assignments to its members. There are three approximate methods that can finish this job. They are single-pass method, greedy search method, and hill-climbing method. Each method is much more expensive than the previous one but better solution. The algorithms are as follows:

Algorithm 4 Single pass [20]

```

1: For each i,
2:   if  $\text{ELP}(X^k, Y, f_i^1(M_0)) > 0$ 
3:      $M_i = 1;$ 
4:   else
5:      $M_i = 0;$ 
6:   end if
7: end for

```

Algorithm 5 Greedy search [20]

- 1: set $M = M_0$;
- 2: Loop through the M_i 's, until no change to M_i 's;
- 3: if $ELP(X^k, Y, f_i^l(M_0)) > ELP(X^k, Y, M)$ then
- 4: $M_i = 1$;
- 5: else
- 6: $M_i = 0$;
- 7: end if

Algorithm 6 Hill-climbing search [20]

- 1: Set $M = M_0$;
- 2: Set $M_{i_1} = 1$, where $i_1 = \operatorname{argmax}_i ELP(X^k, Y, f_i^l(M))$;
- 3: Set $M_{i_2} = 1$, where $i_2 = \operatorname{argmax}_i ELP(X^k, Y, f_i^l(f_{i_1}^l(M)))$;
- 4: Repeat until there is no i for which setting $M_i = 1$ increases ELP .

4.1.3 A Polynomial-Time Solvable Model

In last two subsections, we introduce a general probabilistic model for influence maximization problem, where the optimization problem cannot even be approximated to within a nontrivial factor. In this subsection, we introduce a similar but simpler model. Suppose the symbol is the same as listed in the last subsection, then, for all X_i , there is

$$\begin{aligned}[56] P(X_i | X - X_i, Y, M) &= P(X_i | N_i, Y, M) \\ &= \beta_i P_0(X_i | Y, M_i) + (1 - \beta_i) P_N(X_i | N_i, Y, M). \end{aligned} \quad (51)$$

$P_0(X_i | Y, M_i)$ is X_i 's internal probability of buying the new product. $P_N(X_i | N_i, Y, M)$ is the effect that X_i 's neighbors directly put on her. β_i is between 0 and 1 that measures how neighbor-reliant X_i is. In a general probabilistic model, these interactions between neighbors and X_i are modeled by a nonlinear function. In this model, a simpler linear model is used to approximate this effect instead, the probability is as follows:

$$[56] P_N(X_i = 1 | N_i, Y, M) = \sum_{X_j \in N_i} w_{ij} X_j. \quad (52)$$

w_{ij} represents the extent that customer i is affected by her/his neighbor j , with $w_{ij} \geq 0$ and $\sum_{X_j \in N_i} w_{ij} = 1$. Linear models often perform well, especially when data is sparse [19], and they provide significant advantage for computation. Thus, by combining the last two equations, there is

$$[56] P(X_i | N_i, Y, M) = \beta_i P_0(X_i | Y, M_i) + (1 - \beta_i) \sum_{X_j \in N_i} w_{ij} X_j. \quad (53)$$

Because the optimal marketing strategy for a product has not yet been introduced to the market, the state of the neighbors will not be known. Thus, a formula for computing $P(X_i = 1|Y, M)$ is listed as follows:

$$\begin{aligned}
 [56] P(X_i = 1|Y, M) &= \sum_{\tilde{N} \in C(N_i)} P(X_i = 1|\tilde{N}, Y, M)P(\tilde{N}|Y, M) \\
 &= \sum_{\tilde{N} \in C(N_i)} \beta_i P_0(X_i = 1|Y, M_i)P(\tilde{N}|Y, M) \\
 &\quad + \sum_{\tilde{N} \in C(N_i)} (1 - \beta_i) \sum_{X_j \in N_i} w_{ij}\tilde{N}_j P(\tilde{N}|Y, M) \\
 &= \beta_i P_0(X_i = 1|Y, M_i) \\
 &\quad + (1 - \beta_i) \sum_{X_j \in N_i} \sum_{(\tilde{N} \in C(N_i)) \text{ with } N_j=1} w_{ij}P(\tilde{N}|Y, M). \quad (54)
 \end{aligned}$$

Denote the set of all possible configurations of X_i 's neighbors as $C(N_i)$, and \tilde{N} is one of the state assignments. \tilde{N}_j is the value of X_j specified by \tilde{N} . Since the inner summation is over all possible values of \tilde{N} whenever $\tilde{N}_j = 1$, it is equivalent to $w_{ij}P(X_j = 1|Y, M)$, therefore,

$$\begin{aligned}
 [56] P(X_i = 1|Y, M) &= \beta_i P_0(X_i = 1|Y, M_i) \\
 &\quad + (1 - \beta_i) \sum_{X_j \in N_i} w_{ij}P(X_j = 1|Y, m). \quad (55)
 \end{aligned}$$

The equation above expresses the probabilities $P(X_i = 1|Y, M)$ as a function of themselves. It can be applied iteratively to find them, starting from a suitable initial assignment. A natural choice for initialization is to use the internal probabilities $P_0(X_i = 1|Y, M)$.

In this simple probabilistic model, both the propagation of influence and the effect of the initial targeting are linear. Thus, the influence can be maximized by solving a system of linear equations.

4.2 Two Operational Models

In the last section, we introduce two descriptive models which give a joint distribution over all vertex behaviors in a global view. In this section, operational models from mathematical sociology [29, 57] and interacting particle systems [21, 41], which show the dynamics of adoption step-by-step, are considered. Two basic diffusion models, linear threshold model and independent cascade model,

are presented. The influence maximization problem on these two models and their extension models are NP-complete, but can be approximated well. It is shown that the approximate algorithms for maximizing the spread of influence on these models can be developed in a general framework based on submodular functions. In the next subsections, the definition of submodular function and the description of these two models are given, and based on them, the influence function is shown to be submodular and the influence maximization problem is NP-hard on them.

4.2.1 Submodular Function

Consider a function $f(\cdot)$, which is submodular if it satisfies a natural “diminishing returns” property. This property states that the marginal gain from adding an element to a set A is at least as high as the marginal gain from adding the same element to a superset B . Formally, a submodular function satisfies

$$f(A \cup \{v\}) - f(A) \geq f(B \cup \{v\}) - f(B) \quad (56)$$

for all elements v and all pairs of sets $A \subseteq B$.

Suppose a function f has the following four attributes:

1. Submodular
2. Takes only non-negative values
3. Monotone
4. Not decreasing: $f(A \cup \{v\}) \geq f(A)$ for all elements v and sets A

The influence maximization problem is to find a k -element set A such that $f(A)$ is maximized. This problem is NP-hard, but Nemhauser, Wolsey, and Fisher [17, 47] showed that the greedy hill-climbing algorithm approximates the optimum to within a factor of $(1 - 1/e)$ (where e is the base of the natural logarithm): start with the empty set $A(0)$, and repeatedly add an element that gives the maximum marginal gain.

Theorem 1 ([17, 34, 47]) *For a nonnegative, monotone submodular function f , let S be a set of size k obtained by selecting elements one at a time, each time choosing an element that provides the largest marginal increase in the function value. Let S^* be a set that maximizes the value of f over all k -element sets. Then $f(S) \geq (1 - 1/e)f(S^*)$; in other words, S provides a $(1 - 1/e)$ -approximation.*

4.2.2 Independent Cascade Model

Regard A_0 as the initial node set, and the process proceeds in discrete steps according to the following randomized rule. When one node u wants to activate its neighbor v , the process can succeed only with a probability $p_{u,v}$. If u succeeds at step t , then v will become active in step $t + 1$, but whether or not u succeeds, it cannot make any further attempts to activate v in subsequent steps. When there are no more nodes that can be activated, the process terminates.

Theorem 2 ([34]) *For an arbitrary instance of the independent cascade model, the resulting influence function $\sigma(\cdot)$ is submodular.*

At first sight, it is hard to compute $\sigma(A \cup \{v\}) - \sigma(A)$ for arbitrary set A and node v . The increase of the diffusion effect is very difficult to analyze directly because of the hardness of computing the size of $\sigma(A)$. Fortunately, an equivalent view of the diffusion process can be formulated to an order-independent outcome. Since between each pair of nodes, for example, node v and node w , there is a probability $p_{v,w}$ between v and w , this can be regarded as a result of flipping a coin. From the aspect of process, no matter what is the sequence of the node being activated or whether the node is activated, the result is the same. Based on this fact, it can be assumed that for each pair of neighbors (v, w) , a coin of bias $p_{v,w}$ is flipped at the beginning of the influence diffusion. Store the result for the later check whether w is activated with v already active. If the activation is successful, the edge between the two nodes becomes live, otherwise, it is blocked. So, if the initial active set A and the outcome of the coin flips are fixed, the set of all the activated nodes will be determined.

Let X be one of the outcome and A the initial node set. Denote $\sigma_X(A)$ as the total number of nodes activated when the outcome is X and the initial target set is A . Let $R(u, X)$ be the number of nodes that can be reached on live-edge paths from u , so $\bigcup_{u \in A} R(u, X) = \sigma_X(A)$.

Let A and B be two sets of nodes and $A \subseteq B$. Consider the quantity $\sigma_X(A \cup \{u\}) - \sigma_X(A)$. This is the number of elements in $R(u, X)$ that are not already in the union $\bigcup_{u \in A} R(u, X)$, it is at least as large as the number of elements in $R(u, X)$ that are not in the (larger) union $\bigcup_{u \in B} R(u, X)$. It follows that $\sigma_X(A \cup \{u\}) - \sigma_X(A) \geq \sigma_X(B \cup \{u\}) - \sigma_X(B)$, which is the definition of submodularity. Finally, there is

$$[34]\sigma(A) = \sum_{\text{outcomes } X} \text{Prob}[X]\sigma_X(A). \quad (57)$$

since the expected number of nodes activated is just the weighted average over all outcomes. And a nonnegative linear combination of submodular functions is also submodular, hence $\sigma(\cdot)$ is submodular.

Theorem 3 ([34]) *The influence maximization problem is NP-hard for the independent cascade model.*

The influence maximization problem on independent cascade model can be reduced from set cover problem. Consider an instance of the NP-complete set cover problem, define a collection of subsets T_1, T_2, \dots, T_m and a ground set $Q = \{q_1, q_2, \dots, q_n\}$. The problem aims to find out whether there are k subsets whose union is equal to Q . It is assumed that $k < n < m$. This also can be viewed as a special case of the influence maximization problem.

Given an arbitrary instance of the set cover problem, define a corresponding directed bipartite graph with $n + m$ nodes: there is a node i corresponding to each set T_i , a node j corresponding to each element q_j , and a directed edge (i, j) with activation probability $p_{i,j} = 1$ whenever $q_j \in T_i$. The set cover problem is

equivalent to deciding whether there is a set A of k nodes in this graph with $\sigma(A) \geq n + k$. Note that for the instance we have defined, activation is a deterministic process, since all probabilities are 0 or 1. Initially activating the k nodes corresponding to sets in a set cover solution results in activating all n nodes corresponding to the ground set Q , and if any set Q of k nodes has $\sigma(Q) \geq n + k$, then the set cover problem must be solvable.

4.2.3 Linear Threshold Model

In the linear threshold model, a node v is influenced by each neighbor w according to a weight $b_{v,w}$ and $\sum_{w \text{ neighbor of } v} b_{v,w} \leq 1$. The dynamic process proceeds as follows: each node v chooses a threshold θ_v uniformly at random from the interval $[0,1]$, this shows that, in order to activate node v , all the weight between v and its active neighbors must be over the threshold. If there is an initial target set A_0 and a bunch of random thresholds between each pair of nodes, the diffusion process proceeds deterministically in discrete steps: at step t , all the active nodes are still active and inactive nodes whose neighbors' overall weight larger than their thresholds become active.

$$[34] \quad \sum_{w \text{ active neighbor of } v} b_{v,w} \geq \theta_v. \quad (58)$$

Theorem 4 ([34]) *For an arbitrary instance of the linear threshold model, the resulting influence function $\sigma(\cdot)$ is submodular.*

In the last subsection, the independent cascade model was transferred into the live-edge graph and the influence function on it proved to be submodular.

Similarly, in the linear threshold model, given a graph G , assume the active node set is A_t at step t , for $t = 0, 1, 2, \dots$, and A_0 is the initial set. If node v is inactive in step t , then the probability of v to be activated by its neighbors in step $t+1$ is $\frac{\sum_{u \in A_t \setminus A_{t-1}} b_{u,v}}{1 - \sum_{u \in A_{t-1}} b_{u,v}}$.

In the live-edge model, it also starts with an initial set A_0 . At step t , if node v 's edge is among the live-edge set, then v is known, otherwise, v is unknown. Then, at step $t+1$, the chance of v being known is equal to the chance that its live edge comes from $A_t \setminus A_{t-1}$, given that its live edge has not come from any of the earlier sets. The probability is $\frac{\sum_{u \in A_t \setminus A_{t-1}} b_{u,v}}{1 - \sum_{u \in A_{t-1}} b_{u,v}}$, same as above. Thus, the two distribution processes are the same.

Once the equivalence between live-edge model and linear threshold model is proved to be true, it can be used in the last subsection to show that the influence function in linear threshold model is also submodular.

Theorem 5 ([34]) *The influence maximization problem is NP-hard for the linear threshold model.*

Consider an instance of the NP-complete vertex cover problem: given an undirected n -node graph $G = (V, E)$ and an integer k , the problem is to find whether there is a set S with k nodes in G such that every edge has at least one endpoint in S .

It is shown that this is a special case of the influence maximization problem. Given an instance of the vertex cover problem involving a graph G , define a corresponding instance of the influence maximization problem by directing all edges of G in both directions. If there is a vertex cover S of size k in G , then one can deterministically make $\sigma(A) = n$ by targeting the nodes in the set $A = S$, conversely, this is the only way to get a set A with $\sigma(A) = n$.

4.2.4 Greedy Algorithms for Operational Models

In this section, two approximate algorithms are given for the operational model. One is the basic greedy heuristic algorithm [47]; the other is CELF (cost-effective lazy forward selection) algorithm [38].

Basic Greedy Heuristic Algorithm [47]

The natural way to find the solution of a submodular function model is to start with the empty set and add new element which has the largest influence increase. Repeat the same selection process until the stop condition is satisfied. For influence maximization problem, define $d_v(A) = f(A \cup \{v\}) - f(A)$. Concrete description of the algorithm is as follows:

Algorithm 7 Greedy heuristic for submodular function model [47]

- 1: $A_0 = \text{NULL}$
 - 2: $N_0 = N$ and $t = 1$.
 - 3: Iteration t
 - 4: Select $i(t) \in N_{t-1}$
 - 5: Loop $d_{i(t)}(A_{t-1}) = \max_{i \in N_{t-1}} d_i(A_{t-1})$
 - 6: with connection settled arbitrarily. Set $d_{t-1} = d_{i(t)}(A_{t-1})$
 - 7: $A_t = A_{t-1} \cup i(t)$ and $N_t = N_{t-1} - i(t)$.
 - 8: if $t < K$ then
 - 9: $t = t + 1$.
 - 10: end if
 - 11: repeat until $t = K$. Here K is the number of the total iteration.
-

Let f_g be the solution of the greedy heuristic. There is

$$[47] f_g = f_0 + f_1 + \dots + f_K \quad (59)$$

CELF Algorithm for Submodular Function Model [38]

The basic greedy heuristic algorithm has two drawbacks. One is time-consuming for the reason that at each iteration, it needs to reevaluate each node's marginal gain; the other is that greedy heuristic algorithm only applies to uni-cost problem (the cost of choosing each node is the same). In the case of different cost problem, this algorithm works badly. It will choose the node with highest marginal gain every time without considering the cost. For example, there are two nodes, say u and v . Choosing u will improve the influence at I and cost C , while selecting v will lead to influence increase at $I + \xi$ but cost $2 * C$. Here, I and C are two constant numbers. When $\xi \rightarrow 0$, one should definitely choose u rather than v with considering the cost.

A new greedy heuristic algorithm called benefit-cost algorithm was presented in [38]. Instead of only taking the benefit into account that $\text{argmax}_f(A_{k-1} \cup \{v\}) - f(A_{k-1})$, the new algorithm computes the ratio of benefit and cost, which is

$$\frac{\text{argmax}_f(A_{k-1} \cup \{v\}) - f(A_{k-1})}{c(s)}, \quad (60)$$

where $c(s)$ is the cost to choose node v .

But in fact, this new algorithm is much worse than the original one. For example, there are two nodes n_1 and n_2 with $c(n_1) = \xi$ and $c(n_2) = B$, the total budget is B . $R(n_1) = 2 * \xi$ and $R(n_2) = B$. $R(\{n_1\}) - R(\emptyset))/c(n_1) = 2$ and $R(\{n_2\}) - R(\emptyset))/c(n_2) = 1$. Here, $R(\cdot)$ is the benefit function, and $c(\cdot)$ is the cost function. The benefit-cost greedy algorithm would pick n_1 . After selecting n_1 , n_2 cannot be satisfied anymore, and the total reward would be ξ . However, the optimal solution would pick n_2 , achieving total penalty reduction of B . As ξ approaches 0, the performance of the benefit-cost greedy algorithm becomes arbitrarily bad.

When combining the two algorithms into one algorithm, here comes the CELF algorithm [38]. It has two steps:

- Set (solution) $R(A)$: use benefit-cost greedy algorithm
Set (solution) $R(B)$: use uni-cost greedy algorithm
- $\text{argmax}(R(A), R(B))$

It is shown that although both of the two solutions can be arbitrarily bad, there is at least one of them which is not too far away from optimum, and hence CELF provides a constant factor approximation.

Theorem 6 ([38]) *Let R be a nondecreasing submodular function with $R(\emptyset) = 0$. Then $\max\{R(A), R(B)\} \geq 1/2(1 - 1/e)\text{OPT}$, where OPT is the optimal value.*

In [35], a special case of the budgeted MAX-COVER problem is proved. For arbitrary nondecreasing submodular functions, the proof is shown in [30]. This theorem stated that the best solution of the basic greedy and benefit-cost greedy (which is returned by CELF) is at most a constant factor within $1/2(1 - 1/e)$ of the optimal solution. But CELF's running time is only $O(T|V|)$ compared to the basic greedy algorithm which is $(T|V|^4)$. Here, $|V|$ is the number of nodes and T is the budget. Sviridenko [60] showed that an approximation guarantee of $(1 - 1/e)$ can be achieved even in a nonconstant environment.

5 Compact Routing Scheme for Power-Law Graphs in Social Network

In the field of complex networks, a number of different characteristics [59] have been explored for social networks. These characteristics contain: (1) small-world property: although not all nodes are neighbors of one another, most nodes can be reached from each other through a small number of hops or steps; (2) heavy-tailed

degree distributions: degree distribution of this graph approximates a power-law distribution; (3) community structure: groups of nodes in a network are more densely connected internally in a community than with the rest in the network. Based on property (2), this section mainly focuses on compact routing scheme by using the theory of unweighted random power-law graphs with fixed expected degree sequence. The method here we introduce is the first theoretical bound coupled to the parameter of the power-law graph model for a compact routing scheme.

5.1 Compact Routing Scheme for Power-Law Graphs

For a network with n nodes, a routing scheme is only allowed to have routing tables with sizes sublinear in n and message header sizes polylogarithmic in n . In general, there are two classes of compact routing schemes: the first is the *labeled* scheme, which is allowed to add labels to node addresses to encode useful information for the sake of routing, where each label has length at most polylogarithmic in n . On the other hand, the second scheme, *name-independent* scheme, does not allow the renaming of node addresses, instead they must function with all possible addresses. Both of these two kinds of compact routing schemes have been studied widely recently. Therefore, this phenomenon demonstrates the relationship between compact routing scheme and power-law graphs, which will play an important role in social network routing problem.

Power-law graphs form an essential family of networks appearing in various real-world scenarios such as some collaboration networks and the famous World Wide Web, especially in social networks, which is a rapidly expanding network in social connectivity. In a power-law graph, for some constant τ , the number of nodes with degree x is proportional to $x^{-\tau}$. In general, the range of the power-law exponent τ for many real-world networks is between 2 and 3. However, power-law graphs do not seem to belong to any of the previous well-studied network families such as trees, planar graphs, or low doubling-dimension graphs, which means that the importance of the power-law graphs should be noticed, and this property is worth paying attention.

Recently, there are some other experimental studies which concentrate on compact routing in power-law graphs and Internet-like graphs. However, they all have some drawbacks. For example, although Krioukov et al. [37] evaluated the universal routing scheme of Thorup and Zwick (TZ) [61] on random power-law graphs and they also provided experimental evidence of much better performance than the theoretical worst-case bound, however, they did not provide a theoretical bound of the TZ scheme on power-law graphs such as stretch and table size. Some other papers such as Enahescu et al. [22] and Brady and Cowen [9], even though they contributed to compact routing schemes for power-law graphs, both of them did not provide rigorous analysis. Therefore, bridging the gap in the study of compact routing schemes for power-law graphs becomes a main optimization problem.

5.1.1 Related Work

Due to the comparison with Thorup and Zwick's routing schemes and other random power-law graph models, it is necessary to provide some related work. Thorup and Zwick [61] mainly contributed two different routing schemes. The first scheme is a stretch-3 scheme with an $O(n^{1/2} \log^{3/2} n)$ -bit routing table per node and $O(\log n)$ -bit labels and headers, which is based on Cowen's earlier scheme in [18]. They both used a small subset A of nodes, called *landmarks*, and they used the landmarks to route messages. In a graph $G = (V, E)$, for every node u , define its cluster $C(u) = \{v \in V : d(v, u) < d(v, A)\}$, where $d(v, u)$ and $d(v, A)$ denote the graph distance from v to u and A , respectively. Let $l(u)$ denote the landmark in A , which is the closest one to node u (ties are arbitrarily resolved). The routing table of node u stores the port identifiers to route messages to all nodes in A and $C(u)$. If a destination v is not in $A \cup C(u)$, u routes through $l(v)$, which guarantees a stretch bound of 3 because of the definition of the cluster $C(u)$. A resampling method was used by Thorup and Zwick to achieve $|A \cup C(u)| = O(n^{1/2} \log^{1/2} n)$ for every node u .

The second scheme of Thorup and Zwick [61] is on the basis of their approximate distance oracle in [62]. For any $k \geq 2$, they designed a compact routing scheme with the attributes of $\tilde{O}(n^{1/k})$ -bit tables, $O(k \log^2 n / \log \log n)$ -bit addresses, and $O(\log^2 n / \log \log n)$ -bit headers (both the bounds on addresses and headers are for fixed-port schemes). The stretch $2k - 1$ with a stretch $4k - 5$ handshake is achieved by this scheme. In order to reduce the stretch to 3, a *handshake* is needed. The scheme used and appeared in this article is similar to the second scheme. However, there are two main differences even both the two schemes use balls and landmarks to route messages. One difference is that high-degree nodes are chosen as landmarks instead of the randomly selected nodes. By using this strategy, $|A \cup B(u)| = O(n^\gamma)$ with $\gamma = \frac{\tau-2}{2\tau-3} + \epsilon$ and $\epsilon > 0$ is achieved. Another difference is that the improved scheme will directly encode the shortest path from $l(v)$ to v in v 's address. It is short within the probability of $1 - o(1)$ because of the distance properties in random power-law graphs. The result of the modified scheme shows smaller routing table size, and the address and header size of $O(\log n \log \log n)$ is better than the second scheme and near the result of the first scheme. However, the improvement of this scheme here is only tailored to unweighted power-law graphs.

5.1.2 Preliminaries

The method adopted in this section is the random graph model for fixed expected degree sequence as defined in [6, 14, 15, 42]. The expression fixed degree random graph (**FDRG**) is used to refer to the original random graph distribution. Consequently, from the previous related paper, a definition for the random power-law graph distribution **RPLG**(n, τ) is obtained.

Definition 1 ([13]) For a constant $\tau \in \{(2, 3)\}$, the random power-law graph distribution **RPLG**(n, τ) is defined as follows. First, we let the sequence of generating

parameters $\mathbf{w} = \{w_1, w_2, \dots, w_n\}$ obey a power law, which is $w_k = (\frac{n}{k})^{1/(\tau-1)}$ for $k \in \{1, 2, \dots, n\}$. Then we insert the edge between v_i and v_j into the random graph within the probability of $\min\{w_i w_j \alpha, 1\}$, where $\alpha = \frac{1}{\sum_k w_k}$.

In the **FDRG** model, the value w_i corresponds to the expected degree of vertex v_i , and \mathbf{w} is referred to as the *expected degree sequence*. The graph is sampled here because of the generating parameter values w_i . Let D_i be the random variable denoting the degree of node v_i . In this adapted model, it can be found that the expected degree $E[D_i]$ of node v_i is smaller than or equal to the generated parameter w_i .

It is required that $n = \|V(G)\|$ is sufficiently large, satisfying the following:

$$n^{\frac{\varepsilon(2\tau-3)}{(\tau-1)}} \geq \frac{2(\tau-1)}{\tau-2} \ln n. \quad (61)$$

The results do not have any other implicit dependencies on ε . Furthermore, the **core** of a graph consists of nodes having large degrees. Let $\gamma = \frac{\tau-2}{2\tau-3} + \varepsilon$ for some $\varepsilon > 0$ and $\gamma' = \frac{1-\gamma}{\tau-1}$.

Definition 2 ([13]) For a power-law graph which has the degree sequence \mathbf{w} and a graph G with n nodes, we can define the **core** with degree threshold $n^{\gamma'}$, $\gamma' \in (0, 1)$, this kind of equations form as follows:

$$\text{core}_{\gamma'}(\mathbf{w}) := \{v_i : w_i > n^{\gamma'}\}, \quad (62)$$

$$\text{core}_{\gamma'}(G) := \{v_i : \deg_G(v_i) > n^{\gamma'}/4\}, \quad (63)$$

where $\deg_G(v_i)$ is the degree of v_i in G (the subscript G is omitted when the graph is clear from the context).

The meaning of $n^{\gamma'}$ -Core is as what $\text{core}_{\gamma'}(\mathbf{w})$ means in [42].

For each vertex u of graph G , the ball relative to the core can be defined as

$$B_G(u) := \{v \in V(G) : d(u, v) < \min_{v' \in \text{core}_{\gamma'}(G)} d(u, v')\}. \quad (64)$$

5.2 The Adapted Compact Routing Scheme

The scheme adapted here is a fixed-port scheme, and it works with arbitrary permutations of port number assignments. Let the unweighted graph $G = (V, E)$ model the network. Each node v in the network has a unique $\lceil \log_2 n \rceil$ -bit static name. Whenever v is written in a routing table, a message header, or a node address, represents $\lceil \log_2 n \rceil$ -bit static name representation. Each node v has $\deg(v)$ ports connecting it with its neighbors. Number these ports by $0, 1, \dots, \deg(v) - 1$, and

thus each port number of v requires $\lceil \log_2 \deg(v) \rceil$ bits. For every packet, the routing scheme needs to determine clearly which port the packet is to be forwarded to.

5.2.1 Routing Scheme

The routing algorithm is based on [18, 61]. A set of landmarks $A \subseteq V$ is used, but it is different from [18, 61]. $\text{Core}_{\gamma'}(G)$ is used as landmarks instead of nodes sampled at random. For each node u in G , let $l(u)$ denote u 's closest landmark, which means $l(u) := \arg \min_{v \in \text{core}_{\gamma'}(G)} d(u, v)$. The local targets of node u are defined as the elements of its *ball* $B_G(u)$. Each node u stores the ports used to route messages along the shortest paths to all landmarks and its local targets. If the target v is neither a landmark nor a local target of u , the message is routed to v 's closest landmark $l(v)$ and from there to the target v .

The scheme used is a labeled scheme. For a node u knowing $l(v)$ of any target v , the address of node v contains an encoding of $l(v)$. Moreover, for a node w on the shortest path from $l(v)$ to v ($w \neq l(v)$ and $w \neq v$), v may not be in $B_G(w)$ and thus w may not know the port to route messages to v . To resolve this issue, it is necessary to extend the address of v by encoding the shortest path from the landmark $l(v)$ to v .

Let $s = u_0, u_1, \dots, u_m = t$ denote the sequence of nodes on a shortest path from s to t . Let $SP(s, t)$ be the encoding of this shortest path as an array with m entries, where $SP(s, t)$ can be encoded with $\sum_{i=0}^{m-1} \log_2 \lceil \deg(u_i) \rceil$ bits. The precise definitions of addresses, message headers, and local routing tables are provided as follows:

Definition 3 ([13]) The address of node $u \in V$ is $\text{addr}(u) := (u, l(u), SP(l(u), u))$.

The header of a message from node s to node t is in one of the following formats:

1. header = (route, s, t), where route = local,
2. header = (route, s, addr), where route = toLandmark and addr = $\text{addr}(t)$,
3. header = (route, s, t, pos, SP), where route \in fromLandmark, direct, pos is a nonnegative integer that may be modified along the route, and $SP = SP(s, t)$ if route = direct or $SP = SP(l(t), t)$ if route = fromLandmark,
4. header = (route, s, t, SP), where route = handshake and SP is a reversed shortest path from t to s to be encoded along the path from s to t .

The local routing table for each node u forms the information about routes to the core and the information about local routes:

$$\text{tbl}(u) := \{(v, \text{port}_u(v)) : v \in \text{core}_{\gamma'}(G)\} \cup \{(v, \text{port}_u(v)) : v \in B_G(u)\}, \quad (65)$$

where $\text{port}_u(v)$ is the local port of u to route messages toward node v along some shortest path from u to v .

5.2.2 Routing Algorithm

Algorithm 8 describes the routing procedure. It includes pseudocode for the source node s to determine the method of sending a message to target t which is based on whether t is local and whether a shortest path to t is known or not. It also describes

the details that an intermediate node u determines whether to forward the message using its local routing table, or forward the message using the shortest path encoded in the header, or to switch the routing direction from the landmark $l(t)$ to the target t . The correctness of the algorithm is based on the simple observation $t \in B_G(w) \cup \text{core}_{\gamma'}(G)$.

Moreover, an additional handshake protocol described here handles the special case when t does not belong to $B_G(s)$ but s belongs to $B_G(t)$. In this situation, the basic LANDMARKBALLROUTING scheme only achieves worst case stretch 5 not stretch 3. However, t knows the reverse path from t to s . Since the graph is undirected, t can send a special **handshake** message back to s , and each node along the path encodes the reverse port number such that, in the end, s knows the shortest path from s to t . For simplicity of expression, the reasonable assumption in [2] that node u knows port q on which the message is received is used. If this assumption does not hold, this handshake protocol can be adapted accordingly as follows. In the routing table of node u , for all $v \in B_G(u) \cup \text{core}_{\gamma'}(G)$, store a $\text{rev-port}_u(v) = \text{port}_w(u)$, where w is the first node on the path from u to v . Then, when forwarding the **handshake** message from t to s , every node u on the path (including t) pretends $\text{rev-port}_u(s)$ to the SP in the header. This adds the routing table size by at most $\lceil \log_2 n \rceil$ bits per entry. In the description of this algorithm, the case of $s \in \text{core}_{\gamma'}(G)$ is also included in the case that stretch can be improved from 3 to 1.

Both the performance of [Algorithm 1](#) and the statement described above are evaluated, we will induce the following theorem from the two previous algorithms in [13].

Theorem 7 ([13]) *LANDMARKBALLROUTING along with the handshake protocol is a routing scheme with the following properties: (1) the worst-case stretch is 5 and it is without handshaking, (2) the worst-case stretch is 3 after handshaking, and (3) every routing decision takes constant time. In addition, for random graphs sampled from $RPLG(n, \tau)$, the following properties hold: (4) the expected maximum table size is $O(n^\gamma \log n)$ bits; this bound also holds with probability at least $1 - 1/n$; (5) address length and message header size are $O(\log n \log \log n)$ bits with probability $1-o(1)$; and (6) addresses and routing tables can be generated efficiently in expected time $O(n^{1+\gamma} \log n)$, and this bound also holds with probability at least $1 - 1/n$.*

5.3 Analysis of Properties in Performance

This subsection analyzes the performance of LANDMARKBALLROUTING for random power-law graphs from different parts.

5.3.1 Analysis of Properties

In stretch part, LANDMARKBALLROUTING has worst-case stretch 5. After handshaking with stretch 5, LANDMARKBALLROUTING has worst-case stretch 3,

Algorithm 8 LANDMARKBALLROUTING on node u, with source s, target t ≠ s, and header [61]

```

1: First, if u = s then
2: if t ∈ BG(s) then
3: send packet with header = (local,s,t) using ports(t) stored in tbl(s)
4: else if u knows SP(s, t) then
5: send packet and the header = (direct,s,t,0,SP(s, t)) by using port SP(s, t)[0]
6: else
7: send packet and the header = (toLandmark,s,addr(t)) using ports(l(t)) stored in tbl(s)
8: end if
9: exit
10: end if
11: Under the condition u ≠ s, we decide if u = header.t then
12: exit as the packet arrived.
13: end if
14: if header.route = toLandmark then
15: if u = header.addr.l(t) then
16: header.route ← fromLandmark; header.pos ← 0; header.SP ← header.addr.SP(l(t), t);
17: forward packet with the new header using port header.SP[0]
18: else
19: forward the packet to portu(header.addr.l(t)) stored in tbl(u)
20: end if
21: else if header.route ∈ { fromLandmark,direct} then
22: We should do the header.pos + 1, then we assign it to header.pos
23: after doing the assignment, we forward the packet by using port header.SP[header.pos]
24: else if header.route = local then
25: forward the packet using portu(header.t) stored in tbl(u)
26: end if

```

which is proved by the triangle inequality as in [18, 61]. In random power-law graphs, some properties of the adapted random power-law graph model should be addressed. Let G be a random graph sampled from **RPLG**(n, τ), the *volume* $\text{Vol}(G)$ satisfies

$$n < \text{Vol}(G) \leq \frac{\tau - 1}{\tau - 2} n. \quad (66)$$

In random power-law graphs and their cores and ball parts, the concentration results for the actual degree of a vertex and for the volume of a set of vertices in the adapted **RPLG**(n, τ) model will be shown, and the corresponding results in the original **FDRG** model are also restated. For a random graph sampled from **FDRG**(w), the random variable D_i measuring the degree of vertex v_i is around its expectation w_i as follows:

$$\Pr[D_i > w_i - c\sqrt{w_i}] \geq 1 - e^{-c^2/2} \quad (67)$$

$$\Pr[D_i < w_i + c\sqrt{w_i}] \geq 1 - e^{-\frac{c^2}{2(1+c)(3\sqrt{w_i})}}. \quad (68)$$

For a random graph sampled from **FDRG**(w), a subset of vertices S and all $0 < c \leq \sqrt{\text{Vol}(S)}$, there is

$$\Pr[|\text{vol}(S) - \text{Vol}(S)| < c\sqrt{\text{Vol}(S)}] \geq 1 - 2e^{-c^2/6}. \quad (69)$$

Let $n \geq 4^{\frac{\tau-1}{(\tau-2)^2}}$. For a random graph sampled from **RPLG**(n, τ), if $w_i \geq 32 \ln n$, for vertex v_i , the degree D_i satisfies the following condition: $\Pr[w_i/4 \leq D_i \leq 3w_i] > 1 - 2/n^4$. Let G be a random graph sampled from **RPLG**(n, τ). For a subset of vertices S satisfying $\text{Vol}(S) \geq 192 \ln n$, it holds with probability at least $1 - 2/n^3$ that $\text{Vol}(S)/8 \leq \text{vol}(S) \leq 4\text{Vol}(S)$. From previous lemma, a corollary, in which the number of edges of a random graph sampled from **RPLG**(n, τ) is at most $\text{vol}(G)/2 \leq \frac{4(\tau-1)}{\tau-2}n$ with probability at least $1 - 1/n^2$, was obtained. For any two disjoint subsets S and T with $\text{Vol}(S).\text{Vol}(T) > c.\text{Vol}(G)$, there is

$$\Pr[d(S, T) > 1] = \prod_{v_i \in S, v_j \in T} \max\{0, (1 - w_i w_j / \text{Vol}(G))\} \leq e^{-c}. \quad (70)$$

Regarding to the issue of core size, let G be a random graph sampled from **RPLG**(n, τ). The probability of the core size is at least $1 - 1/n^2$, which holds that $\text{core}_{\gamma'}(w) = \{v_i : w_i > n^{\gamma'}\} \subseteq \{v_i : \deg(v_i) > n^{\gamma'}/4\} = \text{core}_{\gamma'}(G)$. Moreover, $|\text{core}_{\gamma'}(G)| = \Theta(n^{\gamma'})$.

Now we about the ball sizes. According to the original definition of a ball by Eq. (64), let $\beta = \gamma'(\tau - 2) + \frac{(2\tau-3)e}{\tau-1}$ be a constant. Assume Eq. (61) is satisfied. For a random graph G sampled from **RPLG**(n, τ), with probability at least $1 - 3/n^2$, it holds that for all $u \in V(G)$, there is

$$\begin{aligned} |B_G(u)| &= |\{u' \in V(G) : d(u, u') < d(u, \text{core}_{\gamma'}(w))\}| \\ &= O(n^\beta), |E(B_G(u))| = O(n^\beta \log n), \end{aligned} \quad (71)$$

where $E(B_G(u))$ is the set of internal edges among vertices in $B_G(u)$.

The *existence* of every edge in random graph G is determined only when it is needed. It is treated as a probability distribution before determining which is defined in the random graph model of this analysis. According to the probability distribution *revealing* the edge, it is easy to know when the existence of an edge is determined. Under the condition that given vertex $u \in V(G)$ and a sequence of balls $(B_0 = \{u\}, B_1, B_2, \dots)$, let $V' = V \setminus \text{core}_{\gamma'}(w)$ and $B_i = \{v : d_G(u, v) \leq i\}$. Circles $C_i = B_i \setminus B_{i-1}$ for $i \geq 0$ with $B_{-1} = \emptyset$. Then, focus on the result of E_i when the condition E_i , which is the number of edges between C_i and $C_i \cup C_{i+1}$, is given. For circle C_i , the following holds with probability at least $1 - 2/n^3$: (1) If $\text{Vol}(C_i) < 192 \ln n$, then $E_i \leq 4 \cdot 192 \ln n$ and (2) if $\text{Vol}(C_i) \geq 192 \ln n$, then $E_i \leq 4\text{Vol}(C_i)$.

For table sizes and their computation issue, it is known that $\text{core}_{\gamma'}(G)$ has size $\Theta(n^{\gamma'})$ with probability at least $1 - 1/n^2$ and all balls $B_G(u)$ have size $O(n^{\gamma'})$ with probability at least $1 - 3/n^2$. Therefore, for a random graph G sampled from **RPLG**(n, τ), for all $u \in V(G)$, the expected table size is at most

$|\text{tbl}(u)| = O(n^\gamma)$, and all tables can be generated in expected time at most $O(n^{1+\gamma} \log n)$. These bounds also hold with probability at least $1 - 1/n$.

Last but not least, the address lengths should be considered seriously. Bounding the number of bits for the address of each vertex is: for a node u ; its address contains the encoding of the shortest path $\text{SP}(u, l(u))$ from u to its landmark $l(u)$. Moreover, bounding the diameter of a random power-law graph and the diameter of its core is also needed. Therefore, for a random graph sampled from **RPLG**(n, τ), with probability at least $1 - o(1)$, the diameter of its largest connected component is $\Theta(\log n)$ [14]. If it holds for all $s, t \in V(G)$, $\text{SP}(s, t)$ can be encoded with $O(\log n \log \log n)$ bits. In order to extend the core, a definition is given as follows:

Definition 4 ([13]) The extended core of a random graph from **RPLG**(n, τ) contains all nodes v_i with w_i at least $n^{1/\log \log n}$, that is, $\text{core}^+(w) = \{v_i \in V : w_i \geq n^{1/\log \log n}\}$.

From the fact that the *extended core* “contains” a dense random graph [24], let G be a random graph sampled from **RPLG**(n, τ). The diameter of the subgraph induced by $\text{core}^+(w)$ in G is $O(\log \log n)$ with probability at least $1 - 1/n$ [14]. Moreover, from [14], it is known that there exists a constant C , such that each vertex v_i with $w_i \geq \log^C n$ is at distance $O(\log \log n)$ from the extended core, with probability at least $1 - 1/n^2$. However, from the previous statement, if the probability changed with at least $1 - 1/n$, the distance between any two vertices v_i and v_j with $w_i \geq \log^C n$ and $w_j \geq \log^C n$ is $O(\log \log n)$.

5.3.2 Analysis of Approximate Distance Oracle

For social networking sites, the graph of this kind of application is *preprocessed*, and a special data structure is used for efficient *queries*. Precomputing all shortest paths by using an all-pairs shortest path algorithm and reading a shortest path from a distance table is one way to prepare for queries. However, this approach is impractical due to the constraints of time and memory. If it is supposed to efficiently preprocess a graph to allow for fast distance queries, an approximation method is needed because of general and directed graphs with n vertices, which is necessary to return the shortest distance by using $\Omega(n^2)$ space. The trade-off between approximation ratio, space, preprocessing, and query time can be addressed by approximation distance oracle, and this kind of scenario can be interpreted as a generalization of the all-pairs (approximate) shortest path problem.

To solve this kind of distance oracle for power-law graphs problem, let $\gamma = \frac{\tau-2}{2\tau+3} + \epsilon$ be a constant and suppose Eq. (61) is satisfied. There exists a preprocessing algorithm for random power-law graphs from **RPLG**(n, τ), which creates a distance oracle of expected size $O(n^{1+\gamma})$ and runs in expected time $O(n^{1+\gamma} \log n)$. This method in this chapter is modified from Thorup and Zwick’s distance oracle, which guarantees stretch 3 when $k = 2$. Unlike Thorup and Zwick’s preprocessing method, each node $v \in V$ is chosen as a landmark independently at random with probability $n^{1/2}$ for general graphs, a better balance is possible by

using high-degree nodes as landmarks for power-law graphs. In this way, fewer landmarks will be chosen, and smaller-sized balls can be obtained than original method at the same time. In preprocessing period, the first step is to compute the core for any $v \in V$ and $\deg(v) > n^{\gamma'}/4$, then for each $v \in \text{core}$, run the breadth-first search from $v \in G$. Moreover, if for each node $u \neq v$, store $d(u, v)$ and set $\text{port}_u(v)$ to be the penultimate node on the shortest path. As for each $u \in V$, compute and store $B_G(u)$ and its distances. Finally, for each $v \in B_G(u)$, set $\text{port}_u(v)$ to be the first node on the shortest path to v .

As far as the exact distance(s, t) is concerned with, the distance query result $d(s, t)$ is exact if $s \in B(t)$ or $t \in B(s)$, which runs in time $O(1)$ and achieves stretch 3.

With the rapid development of society, people have more and more opportunities to communicate with each other. From the aspect of social networks, it is of great importance to find the shortest paths for pairs of nodes. In this section, we introduced some properties that theoretically justify the importance of high-degree nodes in power-law graphs. After analyzing the adapted compact routing scheme and its algorithm for random power-law graphs, it is shown that optimizing for power-law graphs may induce better algorithm performance for problems in social network. From both real-world graphs and random power-law graphs, the optimization algorithm shows the efficiency.

Apart from compacting routing scheme in power-law graphs, some techniques in universal graphs are proposed: in [3], the first optimal compact name-independent routing scheme for arbitrary undirected graphs is proposed, and in [52], tight upper and lower bounds for the efficiency of a routing scheme and its space requirement are presented; furthermore, the bounds are improved in [24]. In addition, new compacting schemes about special graphs appear for tree graphs [36], directed graphs [11], weighted graphs [61], and so on.

6 Conclusion

Social network has shown wide range applications in real world, therefore, it is practically necessary to probe into social network structure to find its special properties, based on which many optimization problems regarding social networks in real life can be solved efficiently. In this chapter, approximation algorithms for four problems including link prediction problem, community detection problem, influence maximization problem, and routing problem are investigated. It particular, it can be seen that almost all of these algorithms are designed by using the structure features of social networks. For example, the routing schemes in Sect. 5 take advantage of power-law link distribution property of certain social networks.

Abstract

Given a set of N cities, construct a connected network which has minimum length. The problem is simple enough, but the catch is that you are allowed to add junctions in your network. Therefore, the problem becomes how many extra junctions should be added and where should they be placed so as to minimize the overall network length. This intriguing optimization problem is known as the Steiner minimal tree (SMT) problem, where the junctions that are added to the network are called Steiner points.

This chapter presents a brief overview of the problem, presents an approximation algorithm which performs very well, then reviews the computational algorithms implemented for this problem. The foundation of this chapter is a parallel algorithm for the generation of what Paweł Winter termed T_list and its implementation. This generation of T_list is followed by the extraction of the proper answer. When Winter developed his algorithm, the time for extraction dominated the overall computation time. After Cockayne and Hewgill's work, the time to generate T_list dominated the overall computation time. The parallel algorithms presented here were implemented in a program called PARSTEINER94, and the results show that the time to generate T_list has now been cut by an order of magnitude. So now the extraction time once again dominates the overall computation time.

This chapter then concludes with the characterization of SMTs for certain size grids. Beginning with the known characterization of the SMT for a $2 \times m$ grid, a grammar with rewrite rules is presented for characterizations of SMTs for $3 \times m$, $4 \times m$, $5 \times m$, $6 \times m$, and $7 \times m$ grids.

1 Introduction

Minimizing a network's length is one of the oldest optimization problems in mathematics, and, consequently, it has been worked on by many of the leading mathematicians in history. In the mid-seventeenth century a simple problem was posed: Find the point P that minimizes the sum of the distances from P to each of three given points in the plane. Solutions to this problem were derived independently by Fermat, Torricelli, and Cavalieri. They all deduced that either P is inside the triangle formed by the given points and that the angles at P formed by the lines joining P to the three points are all 120° or P is one of the three vertices and the angle at P formed by the lines joining P to the other two points is greater than or equal to 120° .

In the nineteenth century a mathematician at the University of Berlin, named Jakob Steiner, studied this problem and generalized it to include an arbitrarily large set of points in the plane. This generalization created a star when P was connected to all the given points in the plane and is a geometric approach to the two-dimensional center of mass problem.

In 1934 Jarník and Kössler generalized the network minimization problem even further [41]: Given n points in the plane, find the shortest possible connected network containing these points. This generalized problem, however, did not become popular until the book, *What is Mathematics*, by Courant and Robbins [16], appeared in 1941. Courant and Robbins linked the name Steiner with this form of the problem proposed by Jarník and Kössler, and it became known as the Steiner minimal tree problem. The general solution to this problem allows multiple points to be added, each of which is called a Steiner point, creating a tree instead of a star.

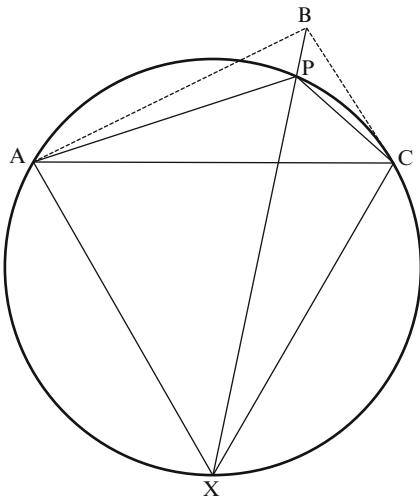

Much is known about the exact solution to the Steiner minimal tree problem. Those who wish to learn about some of the spin-off problems are invited to read the introductory article by Bern and Graham [5], the excellent survey paper on this problem by Hwang and Richards [37], or the volume in The Annals of Discrete Mathematics devoted completely to Steiner tree problems [38]. Some of the basic pieces of information about the Steiner minimal tree problem that can be gleaned from these articles are (a) the fact that all of the original n points will be of degree 1, 2, or 3, (b) the Steiner points are all of degree 3, (c) any two edges meet at an angle of at least 120° in the Steiner minimal tree, and (d) at most $n - 2$ Steiner points will be added to the network.

This chapter concentrates on the Steiner minimal tree problem, henceforth referred to as the SMT problem. Several algorithms for calculating Steiner minimal trees are presented, including the first parallel algorithm for doing so. Several implementation issues are discussed, some new results are presented, and several ideas for future work are proposed.

[Section 2](#) reviews the first fundamental algorithm for calculating SMTs. [Section 3](#) presents a proposed heuristic for SMTs. In [Section 4](#) problem decomposition for SMTs is outlined. [Section 5](#) presents Winter's sequential algorithm which has been the basis for most computerized calculation of SMTs to the present day. [Section 6](#) presents a parallel algorithm for SMTs. Extraction of the correct answer is discussed in [Section 7](#). Computational Results are presented in [Section 8](#) and Future Work and open problems are presented in [Section 9](#).

2 The First Solution

A typical problem-solving approach is to begin with the simple cases and expand to a general solution. As was seen in [Section 1](#), the trivial three point problem had already been solved in the 1600s, so all that remained was the work toward a general solution. As with many interesting problems, this is harder than it appears on the surface.

Fig. 1 $AP + CP = PX$ 

The method proposed by the mathematicians of the mid-seventeenth century for the three-point problem is illustrated in Fig. 1. This method stated that in order to calculate the Steiner point given points A , B , and C , you first construct an equilateral triangle (ACX) using the longest edge between two of the points (AC) such that the third (B) lies outside the triangle. A circle is circumscribed around the triangle, and a line is constructed from the third point (B) to the far vertex of the triangle (X). The location of the Steiner point (P) is the intersection of this line (BX) with the circle.

The next logical extension of the problem, going to four points, is attributed to Gauss. His son, who was a railroad engineer, was apparently designing the layout for tracks between four major cities in Germany and was trying to minimize the length of these tracks. It is interesting to note at this point that a general solution to the SMT problem has recently been uncovered in the archives of a school in Germany (Graham, Private Communication).

For the next 30 years after Kössler and Jarník presented the general form of the SMT problem, only heuristics were known to exist. The heuristics were typically based upon the minimum length spanning tree (MST), which is a tree that spans or connects all vertices whose sum of the edge lengths is as small as possible, and tried in various ways to join three vertices with a Steiner point. In 1968 Gilbert and Pollak [26] linked the length of the SMT to the length of an MST. It was already known that the length of an MST is an upper bound for the length of an SMT, but their conjecture stated that the length of an SMT would never be any shorter than $\frac{\sqrt{3}}{2}$ times the length of an MST. This conjecture was recently proved [17] and has led to the MST being the starting point for most of the heuristics that have been proposed in the last 20 years including a recent one that achieves some very good results [29].

In 1961 Melzak developed the first known algorithm for calculating an SMT [44]. Melzak's algorithm was geometric in nature and was based upon some simple extensions to Fig. 1. The insight that Melzak offered was the fact that you can reduce an n point problem to a set of $n - 1$ point problems. This reduction in size is accomplished by taking every pair of points, A and C in our example; calculating where the two possible points, X_1 and X_2 , would be that form an equilateral triangle with them; and creating two smaller problems, one where X_1 replaces A and C and the other where X_2 replaces A and C . Both Melzak and Cockayne pointed out however that some of these subproblems are invalid. Melzak's algorithm can then be run on the two smaller problems. This recursion, based upon replacing two points with one point, finally terminates when you reduce the problem from three to two vertices. At this termination the length of the tree will be the length of the line segment connecting the final two points. This is due to the fact that $BP + AP + CP = BP + PX$. This is straightforward to prove using the law of cosines, for when P is on the circle, $\angle APX = \angle CPX = 60^\circ$. This allows the calculation of the last Steiner point (P) and allows you to back up the recursive call stack to calculate where each Steiner point in that particular tree is located.

This reduction is important in the calculation of an SMT, but the algorithm still has exponential order, since it requires looking at every possible reduction of a pair of points to a single point. The recurrence relation for an n -point problem is stated quite simply in the following formula:

$$T(n) = 2 * \binom{n}{2} * T(n - 1).$$

This yields what is obviously a non-polynomial time algorithm. In fact Garey, Graham, and Johnson [18] have shown that the Steiner minimal tree problem is NP-Hard (NP-Complete if the distances are rounded up to discrete values).

In 1967, just a few years after Melzak's paper, Cockayne [11] clarified some of the details from Melzak's proof. This clarified algorithm proved to be the basis for the first computer program to calculate SMTs. The program was developed by Cockayne and Schiller [15] and could compute an SMT for any placement of up to seven vertices.

3 A Proposed Heuristic

3.1 Background and Motivation

By exploring a structural similarity between *stochastic Petri nets* (see [45, 49]) and *Hopfield neural nets* (see [27, 35]), Geist was able to propose and take part in the development of a new computational approach for attacking large, graph-based optimization problems. Successful applications of this mechanism include I/O subsystem performance enhancement through disk cylinder remapping [23, 24], file assignment in a distributed network to reduce disk access conflict [22], and new

computer graphics techniques for digital halftoning [21] and color quantization [20]. The mechanism is based on maximum-entropy Gibbs measures, which is described in Reynold’s dissertation [53], and provides a natural equivalence between Hopfield nets and the *simulated annealing* paradigm. This similarity allows you to select the method that best matches the problem at hand. For the SMT problem, the first author implemented the simulated annealing approach [29].

Simulated annealing [42] is a probabilistic algorithm that has been applied to many optimization problems in which the set of feasible solutions is so large that an exhaustive search for an optimum solution is out of the question. Although simulated annealing does not necessarily provide an optimum solution, it usually provides a good solution in a user-selected amount of time. Hwang and Richards [37] have shown that the optimal placement of s Steiner points to n original vertices yields a feasible solution space of the size

$$2^{-n} \binom{n}{s+2} \frac{(n-s-2)!}{s!}$$

provided that none of the original points have degree 3 in the SMT. If the degree restriction is removed, they showed that the number is even larger. The SMT problem is therefore a good candidate for this approach.

3.2 Adding One Junction

Georgakopoulos and Papadimitriou [25] have provided an $\mathcal{O}(n^2)$ solution to the *1-Steiner problem*, wherein exactly one Steiner point is added to the original set of points. Since at most $n - 2$ Steiner points are needed in an SMT solution, repeated application of the algorithm offers a “greedy” $\mathcal{O}(n^3)$ approach. Using their method, the first Steiner point is selected by partitioning the plane into oriented Dirichlet cells, which they describe in detail. Since these cells do not need to be discarded and recalculated for each addition, subsequent additions can be accomplished in linear time. Deletion of a candidate Steiner point requires regeneration of the MST, which Shamos showed can be accomplished in $\mathcal{O}(n \log n)$ time if the points are in the plane [50], followed by the cost for a first addition ($\mathcal{O}(n^2)$). This approach can be regarded as a natural starting point for simulated annealing by adding and deleting different Steiner points.

3.3 The Heuristic

The Georgakopoulos and Papadimitriou 1-Steiner algorithm and the Shamos MST algorithm are both difficult to implement. As a result, Harris chose to investigate the potential effectiveness of this annealing algorithm using a more direct, but slightly more expensive $\mathcal{O}(n^3)$ approach. As previously noted, all Steiner points have degree

```

#define EQUILIBRIUM ((accepts>=100 AND rejects>=200) OR
    (accepts+rejects > 500))
#define FROZEN ((temperature < 0.5) OR ((temperature < 1.0)
    AND (accepts==0)))

while(not(FROZEN)){
    accepts = rejects = 0;
    old_energy = energy();
    while(not(EQUILIBRIUM)){
        operation = add_or_delete();
        switch(operation){
            case ADD:
                ΔE = energy_change_from_adding_a_node();
                break;
            case DELETE:
                ΔE = energy_change_from_deleting_a_node();
                break;
        }
        if(rand(0,1) < emin{0.0,-ΔE/temperature}){
            accepts++;
            old_energy = new_energy;
        }else {
            /* put them back */
            undo_change(operation);
            rejects++;
        }
    }
    temperature = temperature*0.8;
}

```

Fig. 2 Simulated annealing algorithm

3 with edges meeting in angles of 120° . He considered all $\binom{n}{3}$ triples where the largest angle is less than 120° , computed the Steiner point for each (a simple geometric construction), selected that Steiner point giving greatest reduction, or least increase in the length of the modified tree (increases are allowed since the annealing algorithm may go uphill), and updated the MST accordingly. Again, only the first addition requires this (now $\mathcal{O}(n^3)$) step. He used the straightforward $\mathcal{O}(n^2)$ Prim's algorithm to generate the MST initially and after each deletion of a Steiner point.

The annealing algorithm can be described as a nondeterministic walk on a surface. The points on the surface correspond to the lengths of all feasible solutions, where two solutions are adjacent if they can be reached through the addition or deletion of one Steiner point. The probability of going uphill on this surface is higher when the temperature is higher but decreases as the temperature cools. The rate of this cooling typically will determine how good your solution will be. The major portion of this algorithm is presented in Fig. 2. This nondeterministic walk, starting with the MST, has led to some very exciting results.

3.4 Results

Before discussion of large problems, a simple introduction into the results from a simple six-point problem is in order. The annealing algorithm is given the coordinates for six points: (0,0), (0,1), (2,0), (2,1), (4,0), and (4,1). The first step is to calculate the MST, which has a length of 7, as shown in Fig. 3. The output of the annealing algorithm for this simple problem is shown in Fig. 4. In this case the annealing algorithm calculates the exact SMT solution which has a length of 6.616994.

Harris proposed as a measure of accuracy the percentage of the difference between the length of the MST and the exact SMT solution that the annealing algorithm achieves. This is a new measure which has not been discussed (or used) because exact solutions have not been calculated for anything but the most simple layouts of points. For the six-point problem discussed above, this percentage is 100.0 % (the exact solution is obtained).

After communicating with Cockayne, data sets were obtained for exact solutions to randomly generated 100-point problems that were developed for [14]. This allows us to use the measure of accuracy previously described. Results for some of these data sets provided by Cockayne are shown in Table 1.

An interesting aspect of the annealing algorithm that cannot be shown in the table is the comparison of execution times with Cockayne's program. Whereas Cockayne mentioned that his results had an execution cutoff of 12 h, these results were obtained in less than 1 h. The graphical output for the first line of the table,

which reaches over 96 % of the optimal value, appears as follows: The data points and the MST are shown in Fig. 5, the simulated annealing result is in Fig. 6, and the exact SMT solution is in Fig. 7. The solution presented here is obtained in less than $\frac{1}{10}$ of the time with less than 4 % of the possible range not covered. This indicates that one could hope to extend our annealing algorithm to much larger problems, perhaps as large as 1,000 points. If you were to extend this approach to larger problems, then you would definitely need to implement the Georgakopoulos–Papadimitriou 1-Steiner algorithm and the Shamos MST algorithm.

4 Problem Decomposition

After the early work by Melzak [44], many people began to work on the Steiner minimal tree problem. The first major effort was to find some kind of geometric bound for the problem. In 1968 Gilbert and Pollak [26] showed that the SMT for a set of points, S , must lie within the convex hull of S . This bound has since served as the starting point of every bounds enhancement for SMTs.

As a brief review, the convex hull is defined as follows: Given a set of points S in the plane, the convex hull is the convex polygon of the smallest area containing all the points of S . A polygon is defined to be convex if a line segment connecting any two points inside the polygon lies entirely within the polygon. An example of the convex hull for a set of 100 randomly generated points is shown in Fig. 8.

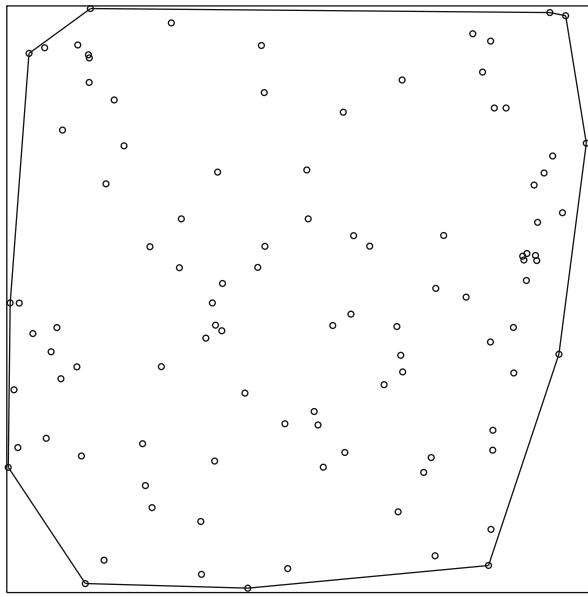

Fig. 8 The convex hull for a random set of points

Shamos in his PhD thesis [54] proposed a divide and conquer algorithm which has served as the basis for many parallel algorithms calculating the convex hull. One of the first such approaches appeared in the PhD thesis by Chow [8]. This approach was refined and made to run in optimal $\mathcal{O}(\log n)$ time by Aggarwal et al. [1], and Attalah and Goodrich [2].

The next major work on the SMT problem was in the area of problem decomposition. As with any non-polynomial algorithm, the most important theorems are those that say “If property \mathcal{P} exists, then the problem may be split into the following sub-problems.” For the Steiner minimal tree problem, property \mathcal{P} will probably be geometric in nature. Unfortunately, decomposition theorems have been few and far between for the SMT problem. In fact, at this writing there have been only three such theorems.

4.1 The Double Wedge Theorem

The first decomposition theorem, known as the Double Wedge Theorem, was proposed by Gilbert and Pollak [26]. This is illustrated in Fig. 9 and can be summarized quite simply as follows: If two lines intersect at point X and meet at 120° , they split the plane into two 120° wedges and two 60° wedges. If R_1 and R_2 denote the two 60° wedges and all the points of S are contained in $R_1 \cup R_2$, then the problem can be decomposed. There are two cases to be considered. In case 1 X

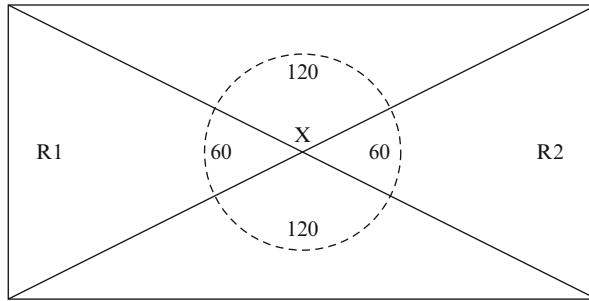

Fig. 9 An illustration of the Double Wedge

is not a point in \mathcal{S} ; therefore, the Steiner minimal tree for \mathcal{S} consists of the SMT for R_1 , the SMT for R_2 , and the shortest edge connecting the two trees. In case 2 \mathcal{X} is a point in \mathcal{S} ; therefore, the Steiner minimal tree for \mathcal{S} is the SMT for R_1 and the SMT for R_2 . Since \mathcal{X} is in both R_1 and R_2 , the two trees are connected.

4.2 The Steiner Hull

The next decomposition theorem is due to Cockayne [12] and is based upon what he termed the *Steiner hull*. The Steiner hull is defined as follows: Let P_1 be the convex hull. P_{i+1} is constructed from P_i by finding an edge (p, r) of P_i that has a vertex (q) near it such that $\angle pqr \geq 120^\circ$, and there is not a vertex inside the triangle pqr . The final polygon, P_i , that can be created in such a way is called the Steiner hull. The algorithm for this construction is shown in Fig. 10. The Steiner hull for the 100 points shown in Fig. 8 is given in Fig. 11.

After defining the Steiner hull, Cockayne showed that the SMT for \mathcal{S} must lie within the Steiner hull of \mathcal{S} . This presents us with the following decomposition: The Steiner hull can be thought of as an ordered sequence of points, $\{p_1, p_2, \dots, p_n\}$, where the hull is defined by the sequence of line segments, $\{p_1p_2, p_2p_3, \dots, p_np_1\}$. If there exists a point p_i that occurs twice in the Steiner hull, then the problem can be decomposed at point p_i . If a Steiner hull contains such a point, then the Steiner hull is referred to as *degenerate*. This decomposition is accomplished by showing that the Steiner hull splits \mathcal{S} into two contained subsets, R_1 and R_2 , where R_1 is the set of points contained in the Steiner hull from the first time p_i appears until the last time p_i appears, and R_2 is the set of points contained in the Steiner hull from the last time p_i appears until the first time p_i appears. With this decomposition it can be shown that $\mathcal{S} = R_1 \cup R_2$, and the SMT for \mathcal{S} is the union of the SMT for R_1 and the SMT for R_2 . This decomposition is illustrated in Fig. 12. Cockayne also proved that the Steiner hull decomposition includes every decomposition possible with the Double Wedge Theorem.

In their work on 100-point problems, Cockayne and Hewgill [14] mention that approximately 15 % of the randomly generated 100-point problems have degenerate

Fig. 10 The Steiner hull algorithm

```

The initial Steiner Polygon,  $P_1$ , is the Convex Hull.
Repeat
    Create Next Steiner Polygon  $P_{i+1}$  from  $P_i$  by
        1) find a set of points  $pqr \in S$  such that:
             $p$  and  $r$  are adjacent on  $P_i$ 
             $\angle pqr \geq 120^\circ$ 
             $\nexists$  a point from  $S$  in the triangle  $pqr$ 
        2) remove the edge  $pr$ .
        3) add edges  $pq$  and  $qr$ .
Until( $P_i == P_{i+1}$ )
Steiner Hull =  $P_i$ 
```

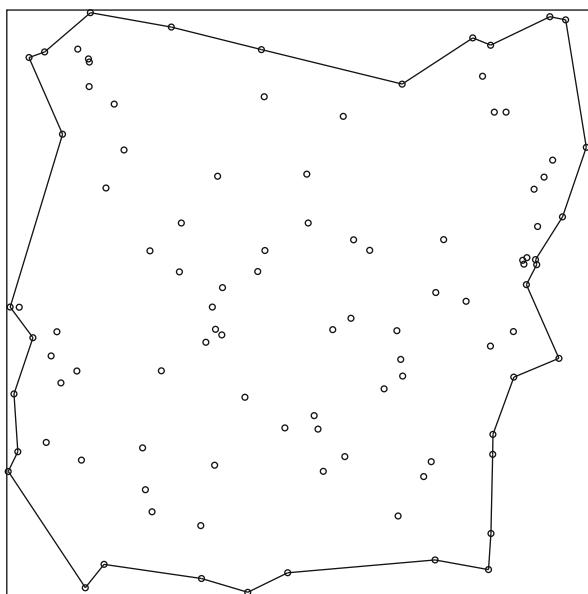

Fig. 11 The Steiner hull for a random set of 100 points

Steiner Hull's. The Steiner hull shown in Fig. 11 is not degenerate, while that in Fig. 12 is.

4.3 The Steiner Hull Extension

The final decomposition belongs to Hwang et al. [39]. They proposed an extension to the Steiner hull as defined by Cockayne. Their extension is as follows: If there exist four points a, b, c , and d on a Steiner hull such that:

Fig. 12 An illustration of the Steiner hull decomposition

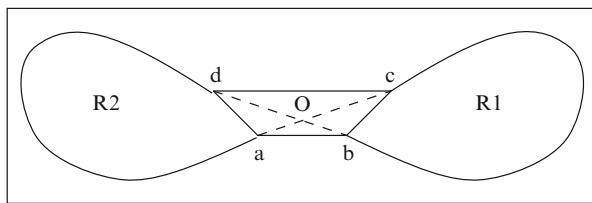

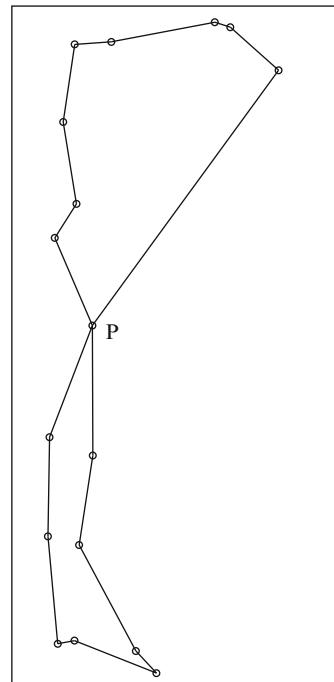

Fig. 13 An illustration of the Steiner hull extension

1. a, b, c , and d form a convex quadrilateral
2. There does not exist a point from \mathcal{S} in the quadrilateral (a, b, c, d)
3. $\angle a \geq 120^\circ$ and $\angle b \geq 120^\circ$
4. The two diagonals (ac) and (bd) meet at O , and $\angle bOa \geq \angle a + \angle b - 150^\circ$, then the SMT for \mathcal{S} is the union of the SMTs for R_1 and R_2 and the edge ab where R_1 is the set of points contained in the Steiner hull from c to b with the edge bc and R_2 is the set of points contained in the Steiner polygon from a to d with the edge ad . This decomposition is illustrated in Fig. 13.

These three decomposition theorems were combined into a parallel algorithm for decomposition presented in [28].

5 Winter's Sequential Algorithm

5.1 Overview and Significance

The development of the first working implementation of Melzak's algorithm sparked a move into the computerized arena for the calculation of SMTs. As we saw in [Section 2](#), Cockayne and Schiller [15] had implemented Melzak's algorithm and could calculate the SMT for all arrangements of 7 points. This was followed almost immediately by Boyce and Seery's program which they called STEINER72 [6]. Their work done at Bell Labs could calculate the SMT for all 10-point problems. They continued to work on the problem and in personal communication with Cockayne said they could solve 12-point problems with STEINER73. Yet even with quite a few people working on the problem, the number of points that any program could handle was still very small.

As mentioned toward the end of [Section 2](#), Melzak's algorithm yields invalid answers and invalid tree structures for quite a few combinations of points. It was not until 1981 that anyone was able to characterize a few of these invalid tree structures. These characterizations were accomplished by Paweł Winter and were based upon several geometric constructions which enable one to eliminate many of the possible combinations previously generated. He implemented these improvements in a program called GeoSteiner [60]. In his work he was able to calculate in under 30 s SMTs for problems having up to 15 vertices and stated that "with further improvements, it is reasonable to assert that point sets of up to 30 V-points could be solved in less than an hour [60]."

5.2 Winter's Algorithm

Winter's breakthrough was based upon two things: the use of extended binary trees and what he termed *pushing*. Winter proposed an extended binary tree as a means of constructing trees only once and easily identifying a full Steiner tree (FST: trees with n vertices and $n - 2$ Steiner points) on the same set of vertices readily.

Pushing came from the geometric nature of the problem and is illustrated in [Fig. 14](#). It was previously known that the Steiner point for a pair of points, a and b , would lie on the circle that circumscribed that pair and their equilateral third point. Winter set out to limit this region even further. This limitation was accomplished by placing a pair of points, a' and b' , on the circle at a and b , respectively, and attempting to push them closer and closer together. In his work Winter proposed and proved various geometric properties that would allow you to push a' toward b and b' toward a . If the two points ever crossed, then it was impossible for the current branch of the sample space tree to contain a valid answer.

Unfortunately, the description of Winter's algorithm is not as clear as one would hope, since the presence of `goto` statements rapidly makes his program difficult to understand and almost impossible to modify. Winter's goal is to build a list of

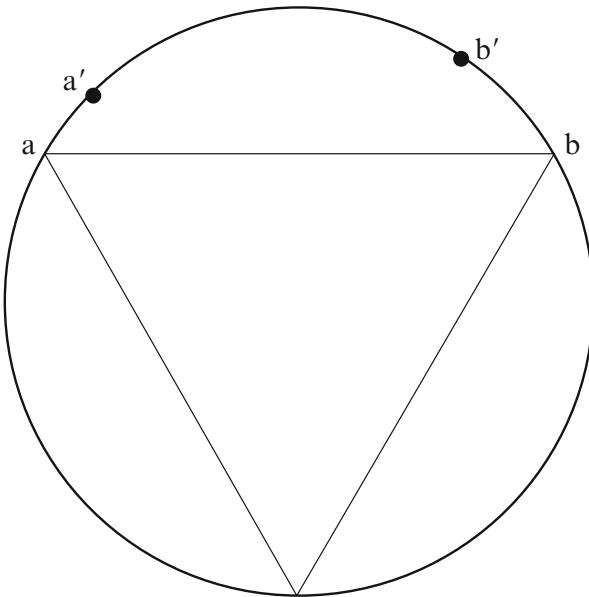

Fig. 14 An illustration of Winter’s pushing

FSTs which are candidates for inclusion in the final answer. This list, called T_list , is primed with the edges of the MST, thereby guaranteeing that the length of the SMT does not exceed the length of the MST.

The rest of the algorithm sets about to expand what Winter termed as Q_list , which is a list of partial trees that the algorithm attempts to combine until no combinations are possible. Q_list is primed with the original input points. The legality of a combination is determined in the *construct* procedure, which uses *pushing* to eliminate cases. While this combination proceeds, the algorithm also attempts to take newly created members of Q_list and create valid FSTs out of them. These FSTs are then placed onto T_list .

This algorithm was a turning point in the calculation of SMTs. It sparked renewed interest into the calculation of SMTs in general. This renewed interest has produced new algorithms such as the negative edge algorithm [57] and the luminary algorithm [36]. Winter’s algorithm has also served as the foundation for most computerized computation for calculating SMTs and is the foundation for the parallel algorithm we present in Section 6.

5.3 Algorithm Enhancements

In 1996, Winter and Zachariasen presented GEOSTEINER96 [61, 62] an enhancement to their exact algorithm that strongly improved the pruning and concatenation techniques of the GEOSTEINER algorithm just presented. This new algorithm modified the pruning tests to exploit the geometry of the problem (wedge property,

bottleneck Steiner distances) to yield effective and/or faster pruning of nonoptimal full Steiner trees (FSTs). Furthermore, efficient concatenation of FSTs was achieved by new and strong compatibility tests that utilize pairwise and subset compatibility along with very powerful preprocessing of surviving FSTs. GEOSTEINER96 has been implemented in C++ on an HP9000 workstation and solves randomly generated problem instances with 100 terminals in less than 8 min and up to 140 terminals within an hour. The hardest 100-terminal problem was solved in less than 29 min. Previously unsolved public library instances (OR-Library [3, 4]) have been solved by GEOSTEINER96 within 14 min. The authors point out that the concatenation of FSTs still remains the bottleneck of both GEOSTEINER96 and GEOSTEINER algorithms. However, the authors show that FSTs are generated 25 times faster by GEOSTEINER96 than by EDSTEINER89.

In their follow-up work [58], Winter and Zachariasen presented performance statistics for the exact SMT problem solved using the Euclidean FST generator from Winter and Zachariasen's algorithm [61, 62] and the FST concatenator of Warme's algorithm [59]. Optimal solutions have been obtained by this approach for problem instances of up to 2,000 terminals. Extensive computational experiences for randomly generated instances [100–500 terminals], public library instances (OR-Library [100–1,000 terminals] [3, 4], TSPLIB [198–7,397 terminals] [34]), and difficult instances with special structure have been shared in this work. The computational study has been conducted on an HP9000 workstation; the FST generator was implemented in C++ and the FST concatenator was implemented in C using CPLEX. Results indicate that (1) Warme's FST concatenation solved by branch-and-cut is orders of magnitude faster than backtrack search or dynamic programming based FST concatenation algorithms and (2) the Euclidean FST generator is more effective on uniformly randomly generated problem instances than for structured real-world instances.

6 A Parallel Algorithm

6.1 An Introduction to Parallelism

Parallel computation is allowing us to look at problems that have previously been impossible to calculate, as well as allowing us to calculate faster than ever before problems we have looked at for a long time. It is with this in mind that we begin to look at a parallel algorithm for the Steiner minimal tree problem.

There have been volumes written on parallel computation and parallel algorithms; therefore, we will not rehash the material that has already been so excellently covered by many others more knowledgeable on the topic, but will refer the interested readers to various books currently available. For a thorough description of parallel algorithms, and the PRAM model, the reader is referred to the book by Joseph JáJá [40], and for a more practical approach to implementation on a parallel machine, the reader is referred to the book by Vipin Kumar et al. [43], the book by Michael Quinn [51], or the book by Justin Smith [55].

6.2 Overview and Proper Structure

When attempting to construct a parallel algorithm for a problem, the sequential code for that problem is often the starting point. In examining sequential code, major levels of parallelism may become self-evident. Therefore, for this problem the first thing to do is to look at Winter's algorithm and convert it into structured code without `gos`. The initialization (step 1) does not change, and the translation of steps 2–7 appears in [Fig. 15](#).

Notice that the code in [Fig. 15](#) lies within a `for` loop. In a first attempt to parallelize anything, you typically look at loops that can be split across multiple processors. Unfortunately, upon further inspection, the loop continues while $p < q$ and, in the large if statement in the body of the loop, is the statement `q++` (line 30). This means that the number of iterations is data dependent and is not fixed at the outset. This loop cannot be easily parallelized.

Since the sequential version of the code does not lend itself to easy parallelization, the next thing to do is to back up and develop an understanding of how the algorithm works. The first thing that is obvious from the code is that you select a left subtree and then try to mate it with possible right subtrees. Upon further examination we come to the conclusion that a left tree will mate with all trees that are shorter than it and all trees of the same height that appear after it on `Q_list`, but it will never mate with any tree that is taller.

6.3 First Approach

The description of this parallel algorithm is in a master–slave perspective. This perspective was taken due to the structure of most parallel architectures at the time of its development, as well as the fact that all nodes on the `Q_list` need a sequencing number assigned to them. The master will therefore be responsible for numbering the nodes and maintaining the main `Q_list` and `T_list`.

The description from the slave's perspective is quite simple. A process is spawned off for each member of `Q_list` that is a proper left subtree (Winter's algorithm allows members of `Q_list` that are not proper left subtrees). Each new process is then given all the current nodes on `Q_list`. With this information the slave then can determine with which nodes its left subtree could mate. This mating creates new nodes that are sent back to the master, assigned a number, and added to the master's `Q_list`. The slave also attempts to create an FST out of the new `Q_list` member, and if it is successful, this FST is sent to the master to be added to the `T_list`. When a process runs out of `Q_list` nodes to check, it sends a request for more nodes to the master.

The master also has a simple job description. It has to start a process for each initial member of the `Q_list`, send them all the current members of the `Q_list`, and wait for their messages.

```

/* Step 2 */
1 for(p=0; p<q; p++){
2     AP = A(p);
3     /* Step 3 */
4     for(r=0; ((H(p) > H(r)) AND (r!=q)); r++) {
5         if((H(p) == H(r)) AND (r<p)) {
6             r = p;
7             if(Subset(V(r), AP)) {
8                 p_star = p;
9                 r_star = r;
10                for(Label = PLUS; Label <= MINUS; Label++) {
11                    /* Step 4 */
12                    AQ = A(q);
13                    if(Construct(p_star,r_star,&(E(q)))) {
14                        L(q) = p;
15                        R(q) = r;
16                        LBL(q) = Label;
17                        LF(q) = LF(p);
18                        H(q) = H(p) + 1;
19                        /* next line is different */
20                        Min(q) = max(Min(p)-1,H(r));
21                        if(Lsp(p) != 0)
22                            Lsp(q) = Lsp(p)
23                        else
24                            Lsp(q) = Lsp(r)
25                        if(Rsp(r) != 0)
26                            Rsp(q) = Rsp(r)
27                        else
28                            Rsp(q) = Rsp(p)
29                        q_star = q;
30                        q++;
31                        /* Step 5 */
32                        if(Proper_to_Add_Tree_to_Tlist(q_star)) {
33                            for_all(j in AP with Lf(R(q_star)) < j) {
34                                SRoot(t) = j;
35                                Root(t) = q_star;
36                                t++;
37                            }
38                        }
39                    }
40                    /* Step 6 */
41                    p_star = r;
42                    r_star = p;
43                }
44            }
45        }
46    }

```

Fig. 15 The main loop properly structured

This structure worked quite well for smaller problems (up to about 15 points), but for larger problems it reached a grinding halt quite rapidly. This was due to various reasons such as the fact that for each slave started the entire Q_list had to be sent. This excessive message passing quickly bogged down the network. Secondly, in their work on 100-point problems, Cockayne and Hewgill [14] made the comment that T_list has an average length of 220, but made no comment about the size of Q_list, which is the number of slaves that would be started. From our work on 100 point problems this number easily exceeds 1,000 which means that over 1,000 processes are starting, each being sent the current Q_list. From these few problems, it is quite easy to see that some major changes needed to be made in order to facilitate the calculation of SMTs for large problems.

6.4 Current Approach

The idea for a modification to this approach came from a paper by Quinn and Deo [52], on parallel algorithms for Branch-and-Bound problems. Their idea was to let the master have a list of work that needs to be done. Each slave is assigned to a processor. Each slave who requests work, is given some, and during its processing creates more work to be done. This new work is placed in the master's work list, which is sorted in some fashion. When a slave runs out of work to do, it requests more from the master. They noted that this leaves some processors idle at times (particularly when the problem was starting and stopping), but this approach provides the best utilization if all branches are independent.

This description almost perfectly matches the problem at hand. First, we will probably have a fixed number of processors which can be determined at runtime. Second, we have a list of work that needs to be done. The hard part is implementing a sorted work list in order to obtain a better utilization. This was implemented in what we term the Proc_list, which is a list of the processes that either are currently running or have not yet started. This list is primed with the information about the initial members of Q_list, and for every new node put on the Q_list, a node which contains information about the Q_list node is placed on the Proc_list in a sorted order.

The results for this approach are quite exciting, and the timings are discussed in [Section 8](#).

7 Extraction of the Correct Answer

7.1 Introduction and Overview

Once the T_list discussed in [Sect. 5](#) is formed, the next step is to extract the proper answer from it. Winter described this in step 7 of his algorithm. His description stated that unions of FSTs saved in T_list were to be formed subject to constraints described in his paper. The shortest union is the SMT for the original points.

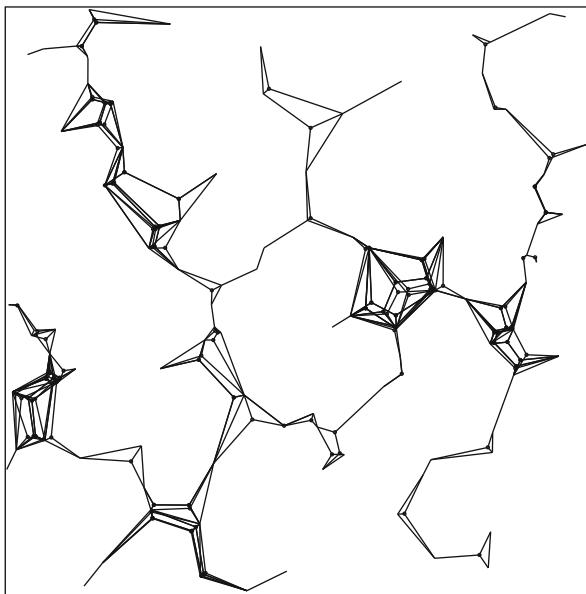

Fig. 16 T_list for a random set of points

The constraints he described were quite obvious considering the definition of an SMT. First, the answer had to cover all the original points. Second, the union of FSTs could not contain a cycle. Third, the answer is bounded in length by the length of the MST.

This led Winter to implement a simple exhaustive search algorithm over the FSTs in T_list. This approach yields a sample space of size $\mathcal{O}(2^m)$ (where m is the number of trees in T_list) that has to be searched. This exponentiality is born out in his work where he stated that for problems with more than 15 points “the computation time needed to form the union of FSTs dominates the computation time needed for the construction of the FSTs [60].” An example of the input the last step of Winter’s algorithm receives (T_list) is given in Fig. 16. The answer it extracts (the SMT) is shown in Fig. 17.

7.2 Incompatibility Matrix

Once Cockayne published the clarification of Melzak’s proof in 1967 [11] and Gilbert and Pollak published their paper giving an upper bound the SMT length in 1968 [26], many people were attracted to this problem. From this time until Winter’s work was published in 1985 [60], quite a few papers were published dealing with various aspects of the SMT problem, but the attempt to computerize the solution of the SMT problem bogged down around 12 vertices. It wasn’t until Winter’s

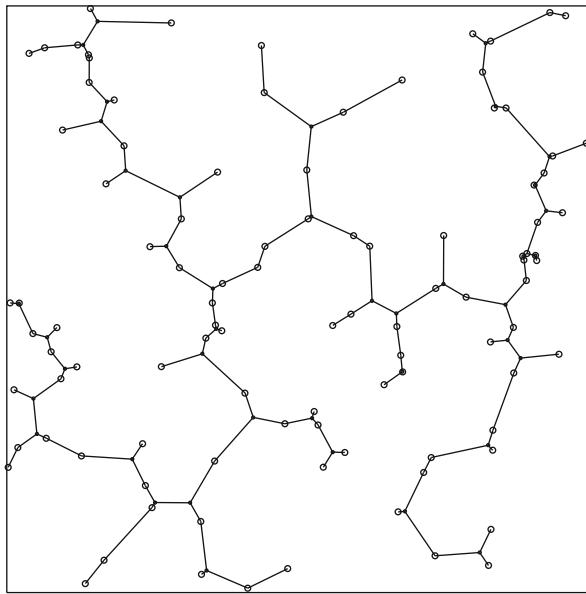

Fig. 17 SMT extracted from T_list for a random set of points

algorithm was published that the research community received the spark it needed to work on computerized computation of the SMT problem with renewed vigor. With the insight Winter provided into the problem, an attempt to computerize the solution of the SMT problem began anew.

Enhancement of this algorithm was first attempted by Cockayne and Hewgill at the University of Victoria. For this implementation Cockayne and Hewgill spent most of their work on the back end of the problem, or the extraction from T_list, and used Winter's algorithm to generate T_list. This work on the extraction focused on what they termed an *incompatibility matrix*. This matrix had one row and one column for each member of T_list. The entries in this matrix were flags corresponding to one of three possibilities: *compatible*, *incompatible*, or *don't know*. The rationale behind the construction of this matrix is the fact that it is faster to look up the value in a matrix than it is to check for the creation of cycles and improper angles during the union of FSTs.

The first value calculations for this matrix were straightforward. If two trees do not have any points in common, then we *don't know* if they are incompatible or not. If they have two or more points in common, then they form a cycle and are *incompatible*. If they have only one point in common and the angle at the intersection point is less than 120°, then they are also *incompatible*. In all other cases they are *compatible*.

This simple enhancement to the extraction process enabled Cockayne and Hewgill to solve all randomly generated problems of size up to 17 vertices in a little over 3 min [13].

7.3 Decomposition

The next focus of Cockayne and Hewgill's work was in the area of the decomposition of the problem. As was discussed earlier in Sect. 4, the best theorems for any problem, especially non-polynomial problems, are those of the form “If property \mathcal{P} exists then the problem can be decomposed.” Since the formation of unions of FSTs is exponential in nature, any theorem of this type is important.

Cockayne and Hewgill's theorem states: “Let A_1 and A_2 be subsets of A satisfying (a) $A_1 \cup A_2 = A$ (b) $|A_1 \cap A_2| = 1$ and (c) the leaf set of each FST in T_list is entirely contained in A_1 or A_2 . Then any SMT on A is the union of separate SMTs on A_1 and A_2 [13].” This means that if you break T_list into biconnected components, the SMT will be the union of the SMTs on those components.

Their next decomposition theorem allowed further improvements in the calculation of SMTs. This theorem stated that if you had a component of T_list left from the previous theorem and if the T_list members of that component form a cycle, then it might be possible to break that cycle and apply the previous algorithm again. The cycle could be broken if there existed a vertex v whose removal would change that component from one biconnected component to more than one.

With these two decomposition theorems, Cockayne and Hewgill were able to calculate the SMT for 79 of 100 randomly generated 30-point problems. The remaining 21 would not decompose into blocks of size 17 or smaller and thus would have taken too much computation time [13]. This calculation was implemented in the program they called EDSTEINER86.

7.4 Forest Management

Cockayne and Hewgill's next work focused on improvements to the *incompatibility matrix* previously described and was implemented in a program called EDSTEINER89. Their goal was to reduce the number of *don't know's* in the matrix and possibly remove some FSTs from T_list altogether.

They proposed two refinements for calculating the entry into the *incompatibility matrix* and one Tree Deletion Theorem. The Tree Deletion Theorem stated that if there exists an FST in T_list that is incompatible with all FSTs containing a certain point a , then the original FST can be deleted since at least one FST containing a will be in the SMT.

This simple change allowed Cockayne and Hewgill to calculate the SMT for 77 of 100 randomly generated 100-point problems [14]. The other 23 problems could not be calculated in less than 12 h and were therefore terminated. For those that did complete, the computation time to generate T_list had become the dominate factor in the overall computation time.

So the pendulum had swung back from the extraction of the correct answer from T_list to the generation of T_list dominating the computation time. In Sect. 8 we will look at the results of the parallel algorithm presented in Sect. 9 to see if the pendulum can be pushed back the other way one more time.

8 Computational Results

8.1 Previous Computation Times

Before presenting the results for the parallel algorithm presented in Sect. 6, it is worthwhile to review the computation times that have preceded this algorithm in the literature. The first algorithm for calculating FSTs was discussed in a paper by Cockayne [12] where he mentioned that preliminary results indicated his code could solve any problem up to 30 points that could be decomposed with the Steiner hull into regions of 6 points or less.

As we saw in Sect. 2, the next computational results were presented by Cockayne and Schiller [15]. Their program, called STEINER, was written in FORTRAN on an IBM 360/50 at the University of Victoria. STEINER could calculate the SMT for any 7-point problem in less than 5 min of CPU time. When the problem size was increased to 8, it could solve them if 7 of the vertices were on the Steiner hull. When this condition held it could calculate the SMT in under 10 min, but if this condition did not hold it would take an unreasonable amount of time.

Cockayne called STEINER a prototype for calculating SMTs and allowed Boyce and Serry of Bell Labs to obtain a copy of his code to improve the work. They improved the code, renamed it STEINER72, and were able to calculate the FST for all 9-point problems and most 10-point problems in a reasonable amount of time [6]. Boyce and Serry continued their work and developed another version of the code that they thought could solve problems of size up to 12 points, but no computation times were given.

The breakthrough we saw in Sect. 5 was by Pawel Winter. His program called GEOSTEINER [60] was written in SIMULA 67 on a UNIVAC-1100. GEOSTEINER could calculate SMTs for all randomly generated sets with 15 points in under 30 s. This improvement was put into focus when he mentioned that all previous implementations took more than an hour for nondegenerate problems of size 10 or more. In his work, Winter tried randomly generated 20-point problems but did not give results since some of them did not finish in his CPU time limit of 30 s. The only comment he made for problems bigger than size 15 was that the extraction discussed in Sect. 7 was dominating the overall computation time.

The next major program, EDSTEINER86, was developed in FORTRAN on an IBM 4381 by Cockayne and Hewgill [13]. This implementation was based upon Winter's results, but had enhancements in the extraction process. EDSTEINER86 was able to calculate the FST for 79 out of 100 randomly generated 32-point problems. For these problems the CPU time for T_list varied from 1 to 5 min, while for the 79 problems that finished the extraction time never exceeded 70 s.

Cockayne and Hewgill subsequently improved their SMT program and renamed it EDSTEINER89 [14]. This improvement was completely focused on the extraction process. EDSTEINER89 was still written in FORTRAN, but was run on a SUN 3/60 workstation. They randomly generated 200 32-point problems to solve and found that the generation of T_list dominated the computation time for problems of this size. The average time for T_list generation was 438 s, while the average time for

Table 2 SMT programs, authors, and results

Program	Author(s)	Points
STEINER	Cockayne & Schiller Univ of Victoria	7
STEINER72	Boyce & Serry ATT Bell Labs	10
STEINER73	Boyce & Serry ATT Bell Labs	12
GEOSTEINER	Winter Univ of Copenhagen	15
EDSTEINER86	Cockayne & Hewgill Univ of Victoria	30
EDSTEINER89	Cockayne & Hewgill Univ of Victoria	100
PARSTEINER94	Harris Univ of Nevada	100

forest management and extraction averaged only 43 s. They then focused on 100-point problems and set a CPU limit of 12 h. The average CPU time to generate T_list was 209 min for these problems, but only 77 finished the extraction in the CPU time limit. These programs and their results are summarized in [Table 2](#).

8.2 The Implementation

8.2.1 The Significance of the Implementation

The parallel algorithm we presented has been implemented in a program called PARSTEINER94 [28, 31]. This implementation is only the second SMT program since Winter’s GEOSTEINER in 1981 and is the first parallel code. The major reason that the number of SMT programs is so small is due to the fact that any implementation is necessarily complex.

PARSTEINER94 currently has over 13,000 lines of C code. While there is a bit of code dealing with the parallel implementation, certain sections of Winter’s algorithm have a great deal of code buried beneath the simplest statements. For example, line 13 of [Fig. 15](#) is the following:

```
if (Construct(p_star,r_star,&(E(q)))) { .
```

To implement the function `Construct()` over 4,000 lines of code were necessary, and this does not include the geometry library with functions such as `equilateral_third_point()`, `center_of_equilateral_triangle()`, `line_circle_intersect()`, and a host more.

Another important aspect of this implementation is the fact that there can now be comparisons made between the two current SMT programs. This would allow verification checks to be made between EDSTEINER89 and PARSTEINER94. This

verification is important since with any complex program it is quite probable that there are a few errors hiding in the code. This implementation would also allow other SMT problems, such as those we will discuss in [Sect. 9](#), to be explored independently, thereby broadening the knowledge base for SMTs even faster.

8.2.2 The Platform

In the design and implementation of parallel algorithms, you are faced with many decisions. One such decision is what will your target architecture be? There are times when this decision is quite easy due to the machines at hand or the size of the problem. In our case we decided not to target a specific machine, but an architectural platform called PVM [19].

PVM, which stands for Parallel Virtual Machine, is a software package available from Oak Ridge National Laboratory. This package allows a collection of parallel or serial machines to appear as a large distributed memory computational machine (MIMD model). This is implemented via two major pieces of software, a library of PVM interface routines, and a PVM demon that runs on every machine that you wish to use.

The library interface comes in two languages, C and ORTRAN. The functions in this library are the same no matter which architectural platform you are running on. This library has functions to spawn off (start) many copies of a particular program on the parallel machine, as well as functions to allow message passing to transfer data from one process to another. Application programs must be linked with this library to use PVM.

The demon process, called *pvmd* in the user's guide, can be considered the back end of PVM. As with any back end, such as the back end of a compiler, when it is ported to a new machine, the front end can interface to it without change. The back end of PVM has been ported to a variety of machines, such as a few versions of Crays, various Unix machines such as Sun workstations, HP machines, Data General workstations, and DEC Alpha machines. It has also been ported to a variety of true parallel machines such as the iPSC/2, iPSC/860, CM2, CM5, BBN Butterfly, and the Intel Paragon.

With this information it is easy to see why PVM was picked as the target platform. Once a piece of code is implemented under PVM, it can be recompiled on the goal machine, linked with the PVM interface library on that machine, and run without modification. In our case we designed PARSTEINER94 on a network of SUN workstations, but, as just discussed, moving to a large parallel machine should be trivial.

8.2.3 Errors Encountered

When attempting to implement any large program from another person's description, you often reach a point where you don't understand something. At first you always question yourself, but as you gain an understanding of the problem you learn that there are times when the description you were given is wrong. Such was the case with the SMT problem. Therefore, to help some of those that may come along and

attempt to implement this problem after us, we recommend that you look at the list of errors we found while implementing Winter’s algorithm [28].

8.3 Random Problems

8.3.1 Hundred-Point Random Problems

From the literature it is obvious that the current standard for calculating SMTs has been established by Cockayne and Hewgill. Their work on SMTs has pushed the boundary of computation out from the 15-point problems of Winter to being able to calculate SMTs for a large percentage of 100-point problems.

Cockayne and Hewgill, in their investigation of the effectiveness of EDSTEINER89, randomly generated 100 problems with 100 points inside the unit square. They set up a CPU limit of 12 h, and 77 of 100 problems finished within that limit. They described the average execution times as follows: T-list construction averaged 209 min, forest management averaged 27 min, and extraction averaged 10.8 min.

While preparing the code for this project, Cockayne and Hewgill were kind enough to supply us with 40 of the problems generated for [14] along with their execution times. These data sets were given as input to the parallel code PARSTEINER94, and the calculation was timed. The wall clock time necessary to generate T-list for the two programs appears in Table 3. For all 40 cases, the average time to generate T-list was less than 20 min. This is exciting because we have been able to generate T-list properly while cutting an order of magnitude off the time.

These results are quite promising for various reasons. First, the parallel implementation presented in this work is quite scalable and therefore could be run with many more processors, thereby enhancing the speedup provided. Second, with the PVM platform used, we can in the future port this work to a real parallel MIMD machine, which will have much less communication overhead, or to a shared memory machine, where the communication could all but be eliminated, and expect the speedup to improve much more.

It is also worth noting that proper implementation of the cycle breaking which Cockayne and Hewgill presented in [13] is important if extraction of the proper answer is to be accomplished. In their work, Cockayne and Hewgill mentioned that 58 % of the problems they generated were solvable without the cycle breaking being implemented, which is approximately what we have found with the data sets they provided. An example of such a T-list that would need cycles broken (possibly multiple times) is provided in Fig. 18.

8.3.2 Larger Random Problems

Once the 100-point problems supplied by Cockayne and Hewgill had been successfully completed, the next step was to try a few larger problems. This was done with the hope of gaining an insight into the changes that would be brought about from the addition of more data points.

Table 3 Comparison of T_list times

Test case	PARSTEINER94	EDSTEINER89
1	650	8,597
2	1,031	13,466
3	1,047	15,872
4	1,687	17,061

38	824	12,920
39	826	12,538
40	972	15,570
Avg.	939	13,748

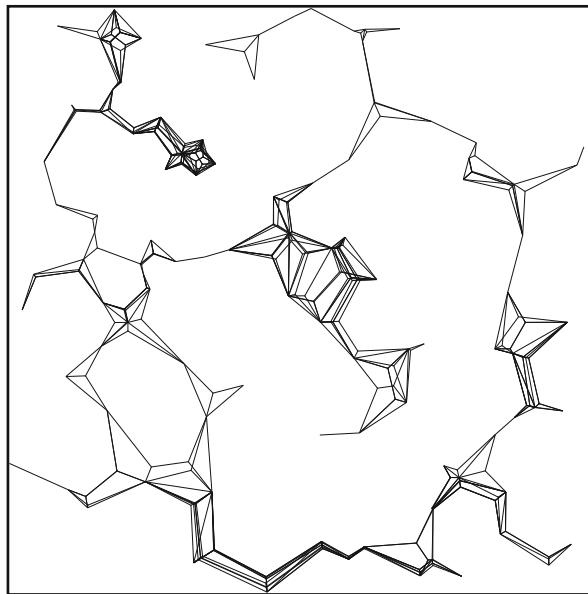

Fig. 18 T_list with more than 1 cycle

For this attempt we generated several random sets of 110 points each. The length of T_list increased by approximately 38 %, from an average of 210 trees to an average of 292 trees. The time to compute T_list also increased drastically, going from an average of 15 min to an average of more than 40 min.

The interesting thing that jumped out the most was the increase in the number of large biconnected components. Since the extraction process must do a complete search of all possibilities, the larger the component, the longer it will take. This is a classic example of an exponential problem, where when the problem size increases by 1, the time doubles. With this increased component size, none of the random problems generated finished inside a 12 h cut off time.

This rapid growth puts into perspective the importance of the work previously done by Cockayne and Hewgill. Continuation of their work with incompatibility matrices as well as decomposition of T_list components appears at this point to be very important for the future of SMT calculations.

8.4 Grids

The problem of determining SMTs for grids was mentioned to the author by Ron Graham. In this context we are thinking of a grid as a regular lattice of unit squares. The literature has little of information regarding SMTs on grids, and most of the information that is given is conjectured and not proven. In Sect. 8.4.1 we will

look at what is known about SMTs on grids. In the following subsections, we will introduce new results for grids up through $7 \times m$ in size. These results presented are computational results from PARSTEINER94 [28, 30, 31] which was discussed previously.

8.4.1 $2 \times m$ and Square Grids

The first proof for anything besides a 2×2 grid came in a paper by Chung and Graham [10] in which they proved the optimality of their characterization of SMTs for $2 \times m$ grids. The only other major work was presented in a paper by Chung, Gardner, and Graham [9]. They argued the optimality of the SMT on 2×2 , 3×3 , and 4×4 grids and gave conjectures and constructions for those conjectures for SMTs on all other square lattices.

In their work Chung, Gardner, and Graham specified three building blocks from which all SMTs on square $(n \times n)$ lattices were constructed. The first, labeled \mathcal{I} , is just a K_2 or a path on two vertices. This building block is given in Fig. 19a. The second, labeled \mathcal{Y} , is a full Steiner tree (FST) (n vertices and $n - 2$ Steiner points) on 3 vertices of the unit square. This building block is given in Fig. 19b. The third, labeled \mathcal{X} , is an FST on all 4 vertices of the unit square. This building block is given in Fig. 19c. For the generalizations we are going to make here, we need to introduce one more building block, which we will label \mathcal{S} . This building block is an FST on a 3×2 grid and appears in Fig. 19d.

SMTs for grids of size $2 \times m$ have two basic structures. The first is an FST on all the vertices in the $2 \times m$ grid. An example of this for a 2×3 grid is given in Fig. 19d. The other structure is constructed from the building blocks previously described. We hope that these building blocks, when put in conjunction with the generalizations for $3 \times m$, $4 \times m$, $5 \times m$, $6 \times m$, and $7 \times m$ will provide the foundation for a generalization of $m \times n$ grids in the future.

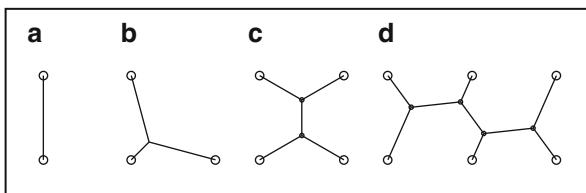

Fig. 19 Building blocks

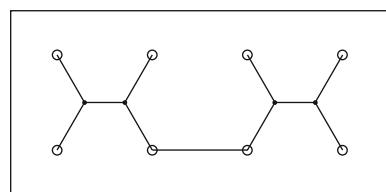

Fig. 20 SMT for a 2×4 grid

In their work on ladders ($2 \times m$ grids) Chung and Graham established and proved the optimality of their characterization for $2 \times m$ grids. Before giving their characterization, a brief review of the first few $2 \times m$ SMTs is in order. The SMT for a 2×2 grid is shown in Fig. 19c, the SMT for a 2×3 grid is shown in Fig. 19d, and the SMT for a 2×4 grid is given in Fig. 20.

Chung and Graham [10] proved that SMTs for ladders fell into one of two categories. If the length of the ladder was odd, then the SMT was the FST on the vertices of the ladder. The SMT for the 2×3 grid in Fig. 19d is an example of this. If the length of the ladder was even, the SMT was made up of a series of $(\frac{m}{2} - 1)$ $\mathcal{X}\mathcal{I}$ s followed by one last \mathcal{X} . The SMT for the 2×4 grid in Fig. 20 is an example of this.

8.4.2 $3 \times m$ Grids

The SMT for $3 \times m$ grids has a very easy characterization which can be seen once the initial cases have been presented. The SMT for the 3×2 grid is presented in Fig. 19d. The SMT for the 3×3 grid is presented in Fig. 21.

From here we can characterize all $3 \times m$ grids. Except for the 3×2 grid, which is an \mathcal{S} building block, there will be only two basic building blocks present, \mathcal{X} 's and \mathcal{I} 's. There will be exactly two \mathcal{I} 's and $(m - 1)\mathcal{X}$'s. The two \mathcal{I} 's will appear on each end of the grid. The \mathcal{X} 's will appear in a staggered checkerboard pattern, one on each column of the grid the same way that the two \mathcal{X} 's are staggered in the 3×3 grid. The 3×5 grid is a good example of this and is shown in Fig. 22.

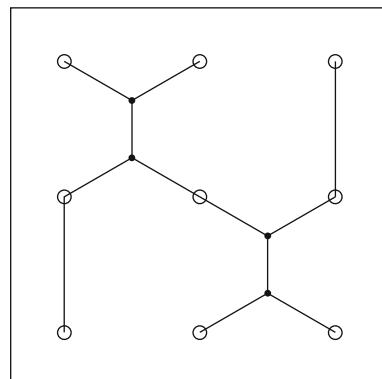

Fig. 21 SMT for a 3×3 grid

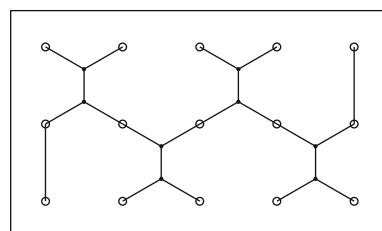

Fig. 22 SMT for a 3×5 grid

8.4.3 $4 \times m$ Grids

The foundation for the $4 \times m$ grids has already been laid. In their most recent work, Cockayne and Hewgill presented some results on square lattice problems [14]. They looked at $4 \times m$ grids for $m = 2$ to $m = 6$. They also looked at the SMTs for these problems when various lattice points in that grid were missing. What they did not do, however, was characterize the structure of the SMTs for all $4 \times m$ grids.

The 4×2 grid is given in Fig. 20. From the work of Chung et al. [9], we know that the SMT for a 4×4 grid is a checkerboard pattern of 5 \mathcal{X} 's. This layout gives us the first two patterns we will need to describe the $4 \times m$ generalization. The first pattern, which we will call pattern \mathcal{A} , is the same as the 3×4 grid without the two \mathcal{I} 's on the ends. This pattern is given in Fig. 23. The second pattern, denoted as pattern \mathcal{B} , is the 2×4 grid in Fig. 20 without the connecting \mathcal{I} . This is shown in Fig. 24.

Before the final characterization can be made, two more patterns are needed. The first one, called pattern \mathcal{C} , is a 4×3 grid where the pattern is made up of two non-connected 2×3 SMTs, shown in Fig. 25. The next pattern, denoted by pattern \mathcal{D} ,

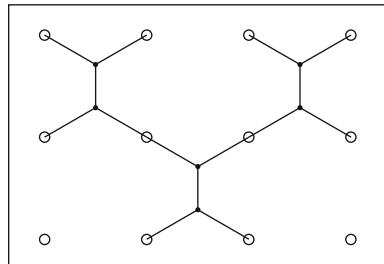

Fig. 23 $4 \times m$ pattern \mathcal{A}

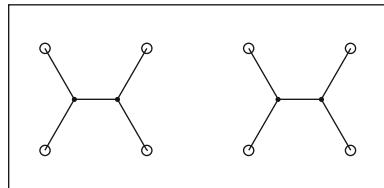

Fig. 24 $4 \times m$ pattern \mathcal{B}

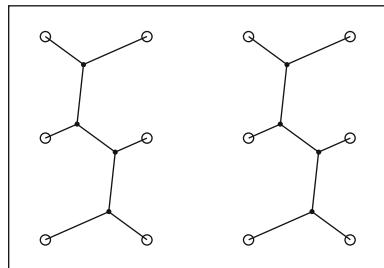

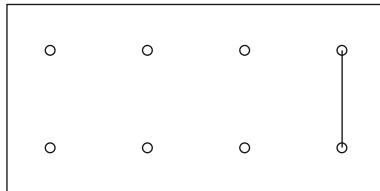

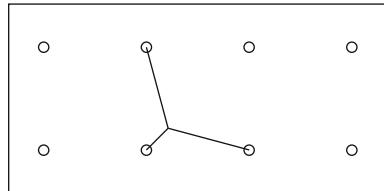

Fig. 25 $4 \times m$ pattern \mathcal{C}

Fig. 26 $4 \times m$ pattern \mathcal{D} **Fig. 27** $4 \times m$ pattern \mathcal{E} **Table 4** Rewrite rules for $4 \times m$ grids

1	$B \rightarrow C$
2	$C \rightarrow BD\mathcal{B}$
3	$DC \rightarrow EAB$

Table 5 String representations for $4 \times m$ grids

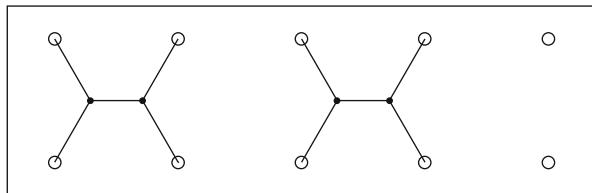

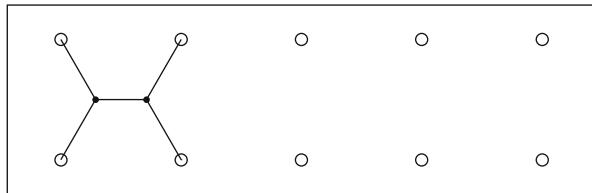

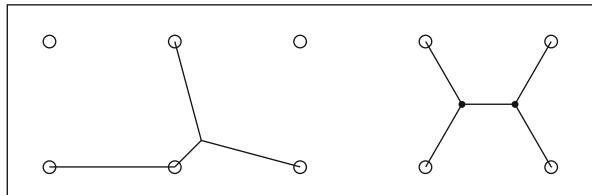

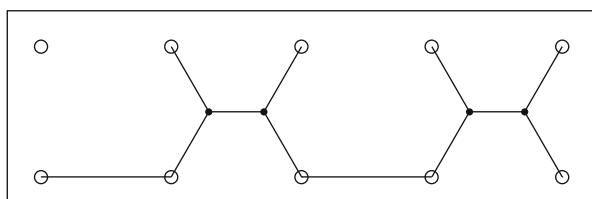

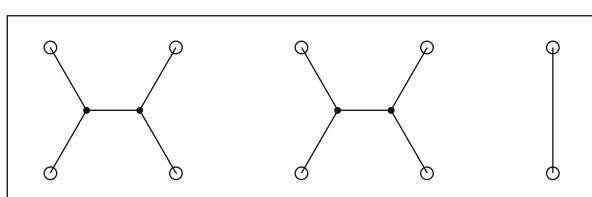

m	5	6	7	8
String	AC	$ABDB$	$ABDC$	$ABEA$
m	9	10	11	
String	$ABEAC$	$ABEABDB$	$ABEABDC$	

is quite simply a \mathcal{Y} centered in a 2×4 grid. This is shown in Fig. 26. The final pattern, denoted by \mathcal{E} , is just an \mathcal{I} on the right side of a 2×4 grid. This is shown in Fig. 27.

Now we can begin the characterization. The easiest way to present the characterization is with some simple string rewriting rules. Since the 4×2 , 4×3 , and 4×4 patterns have already been given, the rules will begin with a 4×5 grid. This grid has the string AC . The first rule is that whenever there is a C on the right end of your string, replace it with $BD\mathcal{B}$. Therefore, a 4×6 grid is $ABDB$. The next rule is that whenever there is a B on the right end of your string, replace it with a C . The final rule is whenever there is a DC on the right end of your string, replace it with an EAB . These rules are summarized in Table 4. A listing of the strings for m from 5 to 11 is given in Table 5.

8.4.4 $5 \times m$ Grids

For the $5 \times m$ grids, there are 5 building blocks (and their mirror images which are denoted with an ') that are used to generate any $5 \times m$ grid. These building blocks appear in Figs. 28–32.

**Fig. 28** $5 \times m$ pattern \mathcal{A} **Fig. 29** $5 \times m$ pattern \mathcal{B} **Fig. 30** $5 \times m$ pattern \mathcal{C} **Fig. 31** $5 \times m$ pattern \mathcal{D} **Fig. 32** $5 \times m$ pattern \mathcal{E}

With the building blocks in place, the characterization of $5 \times m$ grids is quite easy using grammar rewrite rules. The rules used for rewriting strings representing a $5 \times m$ grid are given in [Table 6](#). The SMTs for 5×2 , 5×3 , and 5×4 have already been given. For a 5×5 grid the SMT is made up of the following string: $\mathcal{E}\mathcal{A}'\mathcal{B}\mathcal{D}$. As a reminder, the \mathcal{A}' signifies the mirror of building block \mathcal{A} . A listing of the strings for m from 5 to 11 is given in [Table 7](#).

8.4.5 $6 \times m$ Grids

For the $6 \times m$ grids, there are five building blocks that are used to generate any $6 \times m$ grid. These building blocks appear in [Figs. 33–37](#).

The solution for $6 \times m$ grids can now be characterized by using grammar rewrite rules. The rules used for rewriting strings representing a $6 \times m$ grid are given in [Table 8](#). The basis for this rewrite system is the SMT for the 6×3 grid which is \mathcal{AC} .

Table 6 Rewrite rules for $5 \times m$ grids

1	$\mathcal{C} \rightarrow \mathcal{B}'\mathcal{D}'$
2	$\mathcal{D} \rightarrow \mathcal{A}'\mathcal{E}$
3	$\mathcal{E} \rightarrow \mathcal{AC}$
4	$\mathcal{C}' \rightarrow \mathcal{BD}$
5	$\mathcal{D}' \rightarrow \mathcal{AE}'$
6	$\mathcal{E}' \rightarrow \mathcal{AC}'$

Table 7 String representations for $5 \times m$ grids

m	5	6	7	8
String	$\mathcal{E}\mathcal{A}'\mathcal{B}\mathcal{D}$	$\mathcal{E}\mathcal{A}'\mathcal{B}\mathcal{A}'\mathcal{E}$	$\mathcal{E}\mathcal{A}'\mathcal{B}\mathcal{A}'\mathcal{A}\mathcal{C}$	$\mathcal{E}\mathcal{A}'\mathcal{B}\mathcal{A}'\mathcal{A}\mathcal{B}'\mathcal{D}'$
m	9	10	11	
String	$\mathcal{E}\mathcal{A}'\mathcal{B}\mathcal{A}'\mathcal{A}\mathcal{B}'\mathcal{A}\mathcal{E}'$	$\mathcal{E}\mathcal{A}'\mathcal{B}\mathcal{A}'\mathcal{A}\mathcal{B}'\mathcal{A}\mathcal{A}'\mathcal{C}'$	$\mathcal{E}\mathcal{A}'\mathcal{B}\mathcal{A}'\mathcal{A}\mathcal{B}'\mathcal{A}\mathcal{A}'\mathcal{B}\mathcal{D}$	

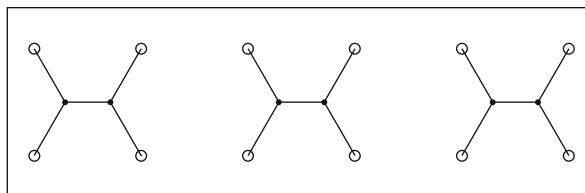

Fig. 33 $6 \times m$ pattern \mathcal{A}

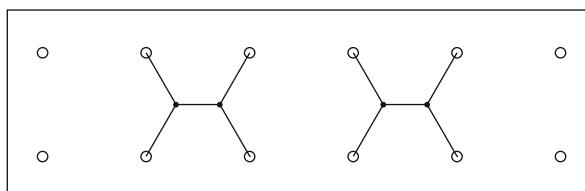

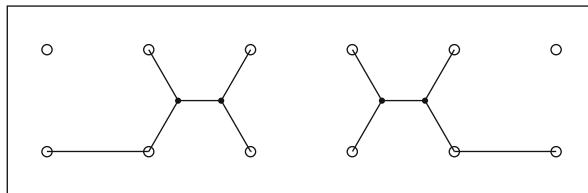

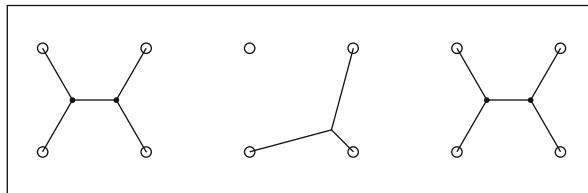

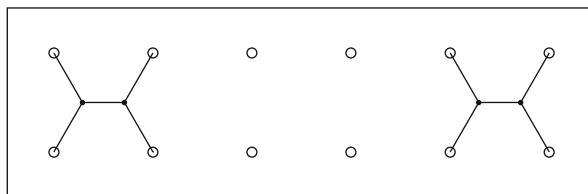

Fig. 34 $6 \times m$ pattern \mathcal{B}

**Fig. 35** $6 \times m$ pattern \mathcal{C} **Fig. 36** $6 \times m$ pattern \mathcal{D} **Fig. 37** $6 \times m$ pattern \mathcal{E} **Table 8** Rewrite rules for $6 \times m$ grids

1	$\mathcal{C} \rightarrow \mathcal{BD}$
2	$\mathcal{D} \rightarrow \mathcal{EC}$

Table 9 String representations for $6 \times m$ grids

$m =$	6	7	8
String	$\mathcal{ABE}\mathcal{BD}$	$\mathcal{ABE}\mathcal{BEC}$	$\mathcal{ABE}\mathcal{BEBD}$
$m =$	9	10	11
String	$\mathcal{ABE}\mathcal{BEBEC}$	$\mathcal{ABE}\mathcal{BEBEBD}$	$\mathcal{ABE}\mathcal{BEBEBEC}$

It is also nice to see that for the $6 \times m$ grids, there is a simple regular expression which can characterize what the string will be. That regular expression has the form $\mathcal{A}(\mathcal{BE})^*(\mathcal{C}|\mathcal{BD})$, which means that the \mathcal{BE} part can be repeated 0 or more times and the end can be either \mathcal{C} or \mathcal{BD} . A listing of the strings for m from 6 to 11 is given in Table 9.

8.4.6 $7 \times m$ Grids

For the $7 \times m$ grids, there are six building blocks that are used to generate any $7 \times m$ grid. These building blocks appear in Figs. 38–43.

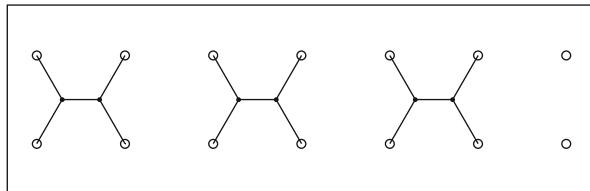

Fig. 38 $7 \times m$ pattern \mathcal{A}

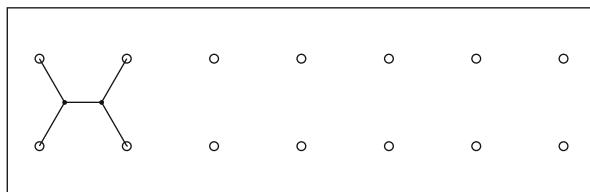

Fig. 39 $7 \times m$ pattern \mathcal{B}

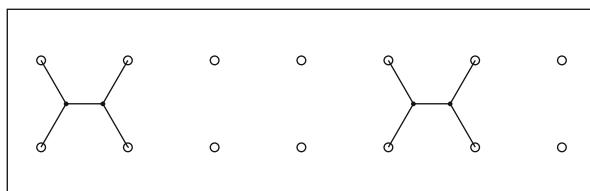

Fig. 40 $7 \times m$ pattern \mathcal{C}

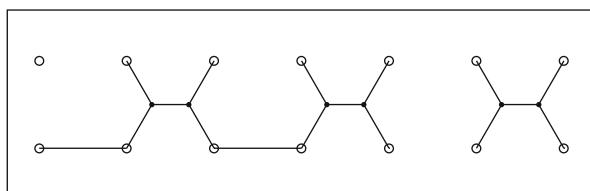

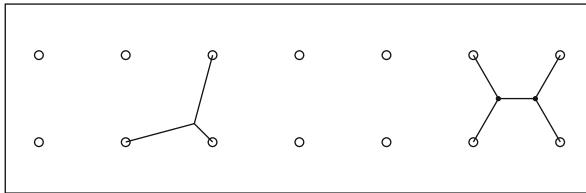

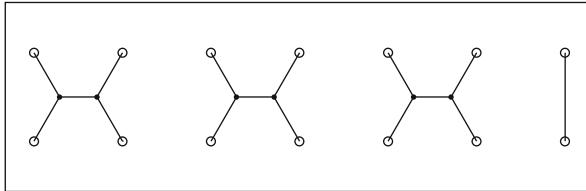

Fig. 41 $7 \times m$ pattern \mathcal{D}

**Fig. 42** $7 \times m$ pattern \mathcal{E} **Fig. 43** $7 \times m$ pattern \mathcal{F} **Table 10** Rewrite rules for $7 \times m$ grids

1	$\mathcal{E}'\mathcal{F}' \rightarrow \mathcal{B}\mathcal{A}'\mathcal{F}$
2	$\mathcal{F} \rightarrow \mathcal{C}\mathcal{D}$
3	$\mathcal{C}\mathcal{D} \rightarrow \mathcal{A}\mathcal{E}\mathcal{F}$
4	$\mathcal{E}\mathcal{F} \rightarrow \mathcal{B}'\mathcal{A}\mathcal{F}'$
5	$\mathcal{F}' \rightarrow \mathcal{C}'\mathcal{D}'$
6	$\mathcal{C}'\mathcal{D}' \rightarrow \mathcal{A}'\mathcal{E}'\mathcal{F}'$

Table 11 String representations for $7 \times m$ grids

m	6	7	8	9
String	$\mathcal{F}\mathcal{A}'\mathcal{B}\mathcal{A}'\mathcal{F}$	$\mathcal{F}\mathcal{A}'\mathcal{B}\mathcal{A}'\mathcal{C}\mathcal{D}$	$\mathcal{F}\mathcal{A}'\mathcal{B}\mathcal{A}'\mathcal{A}\mathcal{E}\mathcal{F}$	$\mathcal{F}\mathcal{A}'\mathcal{B}\mathcal{A}'\mathcal{A}\mathcal{B}'\mathcal{A}\mathcal{F}'$
m	10	11	12	
String	$\mathcal{F}\mathcal{A}'\mathcal{B}\mathcal{A}'\mathcal{A}\mathcal{B}'\mathcal{A}\mathcal{C}'\mathcal{D}'$	$\mathcal{F}\mathcal{A}'\mathcal{B}\mathcal{A}'\mathcal{A}\mathcal{B}'\mathcal{A}\mathcal{A}'\mathcal{E}'\mathcal{F}'$	$\mathcal{F}\mathcal{A}'\mathcal{B}\mathcal{A}'\mathcal{A}\mathcal{B}'\mathcal{A}\mathcal{A}'\mathcal{B}\mathcal{A}'\mathcal{F}$	

The grammar rewrite rules for strings representing a $7 \times m$ grid are given in [Table 10](#). The basis for this rewrite system is the SMT for the 7×5 grid which is $\mathcal{F}\mathcal{A}'\mathcal{E}'\mathcal{F}'$. A listing of the strings for m from 6 to 11 is given in [Table 11](#).

9 Future Work

9.1 Grids

In this work we reviewed what is known about SMTs on grids and then presented results from PARSTEINER94 [28, 31] which characterize SMTs for $3 \times m$ to $7 \times m$ grids. The next obvious question is the following: What is the characterization for an $8 \times m$ grid or an $n \times m$ grid? Well, this is where things start getting nasty. Even though PARSTEINER94 cuts the computation time of the previous best program

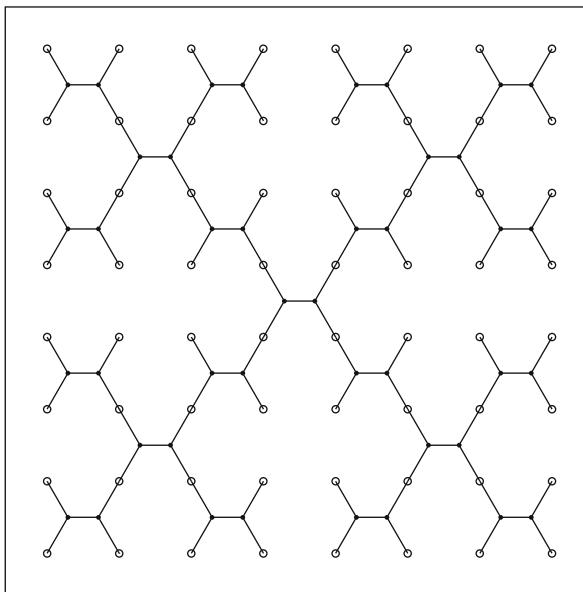

Fig. 44 8×8

for SMTs by an order of magnitude, the computation time for an NP-Hard problem blows up sooner or later, and $8 \times m$ is where we run into the computation wall.

We have been able to make small chips into this wall though and have some results for $8 \times m$ grids. The pattern for this seems to be based upon repeated use of the 8×8 grid which is shown in Fig. 44. This grid solution seems to be combined with smaller $8 \times$ solutions in order to build larger solutions. However, until better computational approaches are developed, further characterizations of SMTs on grids will be very hard and tedious.

9.2 Further Parallelization

9.2.1 Algorithm Enhancements

There remains a great deal of work that can be done on the Steiner minimal tree problem in the parallel arena. The first thing to consider is whether there are other ways to approach the parallel generation of T_list that would be more efficient. Improvement in this area would push the computation pendulum even further away from T_list generation and toward SMT extraction.

The next thing to consider is the entire extraction process. The initial generation of the *incompatibility matrix* has the appearance of easy parallelization. The forest management technique introduced by Cockayne and Hewgill could also be put into a parallel framework, thereby speeding up the preparation for extraction quite a bit.

With this initialization out of the way, decomposition could then be considered. The best possible enhancement here might be the addition of thresholds. As with most parallel algorithms, for any problem smaller than a particular size, it is usually faster to solve it sequentially. These thresholds could come into play in determining whether to call a further decomposition, such as the cycle decomposition introduced by Cockayne and Hewgill that was discussed in Sect. 7.

The final option for parallelization is one that may yield the best results and that is in the extraction itself. Extraction is basically a branch-and-bound process, using the *incompatibility matrix*. This branch and bound is primed with the length of the MST as the initial bound and continues until all possible combinations have been considered. The easiest implementation here would probably be the idea presented in the paper by Quinn and Deo [52] that served as the basis for the parallel algorithm in Sect. 6.

9.2.2 GPU Implementation

With games and visualization driving the evolution of graphics processors, the fixed functionality of the rendering pipeline once offered has been steadily replaced by the introduction of programmable pipeline components called shaders. These shaders not only allow the GPU to be used for more elaborate graphical effects but also allow it to be used for more general purpose computations. By storing general data as texture data, user-programmed vertex and fragment shaders can transform the GPU into a highly data parallel multiprocessor [48].

In 2007, Nvidia released CUDA [46], a programming language which allows for direct GPGPU programming in a C-like environment. Modern GPUs offer 512 processing cores [47], which is far more than any CPU currently provides. Many researchers have taken advantage of the environment provided by CUDA to easily map their parallel algorithms to the GPU.

Of note is the work being done by Joshua Hegie [33]. In his thesis, Hegie has mapped out an implementation of Winter's work onto the GPU. Preliminary results are very promising, and in the future work, he maps out a methodology for the use of multiple GPUs which will open the door for much larger problems at a reasonable computation time.

9.3 Additional Problems

9.3.1 1-Reliable Steiner Tree Problem

If we would like to be able to sustain a single failure of any vertex, without interrupting communication among remaining vertices, the minimum length network problem takes on a decidedly different structure. For example, in any FST all of the original vertices are of degree 1, and hence, any one can be disconnected from the network by a single failure of the adjacent Steiner point.

We would clearly like a minimum length 2-connected network. The answer can be the minimum length Hamiltonian cycle (consider the vertices of the unit square), but it does not need to be, as shown in the Θ graph given in Fig. 45.

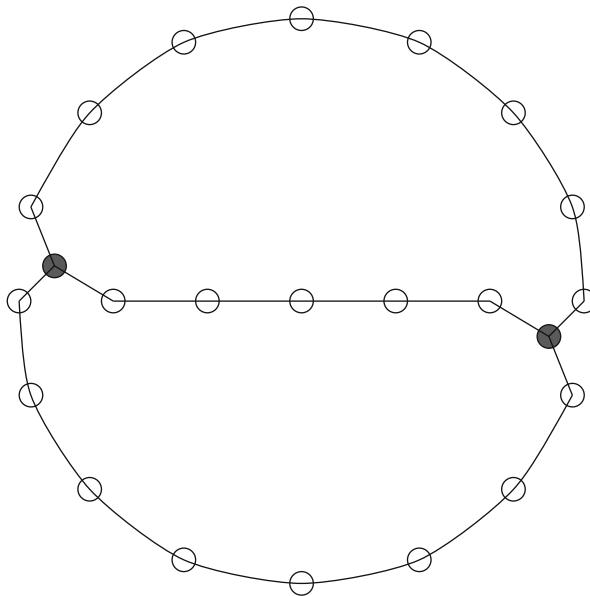

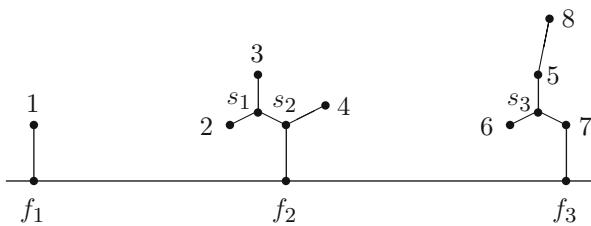

Fig. 45 Theta graph

Here we can add Steiner points near the vertices of degree 3 and reduce the network length without sacrificing 2-connectivity. This is not just a single graph, but is a member of a family of graphs that look like ladders, where the Θ graph has only one internal rung. We hope to extend earlier work providing constructions on 2-connected graphs [32] to allow effective application of an annealing algorithm that could walk through graphs within the 2-connected class.

9.3.2 Augmenting Existing Plane Networks

In practical applications, it frequently happens that new points must be joined to an existing Steiner minimal tree. Although a new and larger SMT can, in principle, be constructed which connects both the new and the existing points, this is typically impractical, e.g., in cases where a fiber optic network has already been constructed. Thus, the only acceptable approach is to add the new points to the network as cheaply as possible. Cockayne has presented this problem which we can state as follows:

Augmented Steiner Network: Given a connected plane graph $G = (V, E)$ (i.e., an embedding of a connected planar graph in E^2) and a set V' of points in the plane which are not on edges of G , construct a connected plane supergraph $G'' = (V'', E'')$, such that V'' contains $V \cup V'$, E'' contains E , and the sum of the Euclidean lengths of the set of edges in $E'' - E$ is a minimum. In constructing the plane graph G'' , it is permitted to add an edge connecting a point in V' to an

Fig. 46 An optimal forest

interior point of an edge in G . It is also permitted to add Steiner points. Thus, strictly speaking, G'' does not need to be a supergraph of G .

The Augmented Steiner Network Problem clearly has applications in such diverse areas as canal systems, rail systems, housing subdivisions, irrigation networks, and computer networks. For example, given a (plane) fiber optic computer network $G = (V, E)$ and a new set V' of nodes to be added to the network, the problem is to construct a set F' of fiber optic links with minimum total length that connects V' to G . The set F' of new links is easily seen to form a forest in the plane, because the minimum total length requirement ensures that there cannot be cycles in F' .

As an example, consider the situation in Fig. 46 where G consists of a single, long edge and $V' = v_1, \dots, v_8$. The optimal forest F' consists of three trees joining G at f_1, f_2 , and f_3 . It is necessary that extra Steiner points s_1, s_2 , and s_3 be added so that F has minimum length.

While we are aware of several algorithms for solving special cases of the Augmented Existing Plane Network Problem, such as those by Chen [7] and Trietsch [56] or the special case where the graph G consists of a single vertex, in which case the problem is equivalent to the classical Steiner minimal tree problem, we are not aware of any algorithms or computer programs available for exact solutions to the general form of this problem. Here, “exact” means provably optimal except for roundoff error and machine representation of real numbers. Non-exact (i.e., heuristic) solutions are suboptimal although they may often be found considerably faster.

Abstract

This chapter summarizes some of the most important properties, algorithms, and heuristic properties for the solution of Euclidean Steiner minimal trees (ESMTs) in E^3 . Starting from the problem in E^2 , the basic primal and dual approaches to the problem in E^3 are presented. Given the \mathcal{NP} -hardness of the problem, the challenge of solving this combinatorial optimization problem is discussed not only with the solution of small order point sets but point sets with special structure. Heuristic solutions are examined, and the complexity of computing these solutions is discussed. Also of some interest are the applications of ESMTs to computational biology through the secondary structure of the protein-folding problem. Detailed studies of the application of ESMTs to the secondary structure of the protein-folding problem are described. Finally, the application of this fascinating problem to other areas of science and engineering is described.

1 Introduction

If someone is going to design a new electronic circuit at the molecular/atomic level where it was known beforehand the basic number of atomic elements of the circuit and they wished to arrange them so that they achieved an optimal configuration that is both compact, stable, and integrated electrically, *how should they configure the atoms?* If one assumes that the total cost of putting together the molecular structure is proportional to distance, i.e., the potential energy in the system, then one would want to minimize the overall interconnecting distance between the atoms. This is fundamentally the Steiner problem in E^3 . **Figure 1** demonstrates a geometric construction for the Steiner minimal tree of $N = 6$ vertices in E^3 .

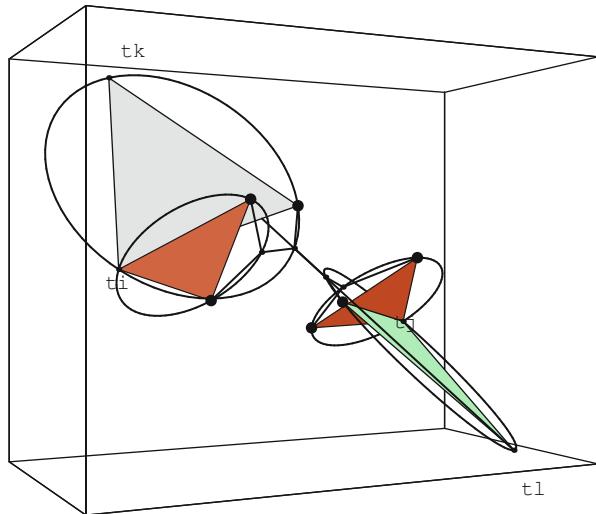

Fig. 1 $N = 6$ 3-sausage dual construction

The Steiner problem seeks to minimize the total length of a network, given a fixed set of vertices V that must be in the network and another set S from which vertices may be added [9, 13, 20, 21, 23, 42, 47, 62, 86]. The cardinality of S is not known beforehand which makes the problem very difficult, and the focus of this chapter is on a better understanding of the theory, algorithms, and potential applications of Steiner trees in E^3 . The Euclidean minimal spanning tree (EMST) is the optimal solution to the problem for which no vertices may be added from the set S [16, 81]. The Steiner ratio is the ratio of the length of the Steiner tree (or a heuristic approximation) to that of the EMST of the given set. The smaller this ratio is, the more advantage there is in finding the Steiner tree, since it indicates the configuration of vertices which achieves the minimum possible value. Thus, studying the problem of finding sets of vertices for which this ratio is a minimum is of central interest. The algorithmic process is designed to examine configurations which have a Steiner ratio close to the minimum. Configurations which have a ratio equal to the conjectured minimum for the same number of vertices are called *optimal configurations*.

Research results developed in 1992 [70] revealed some surprising insights into the properties of Steiner trees and their influence on the design of algorithms for computing them, and all of these will be explored in this chapter. The decomposition and recomposition processes underlying the algorithmic approach also have some impact on the potential applications of these results, and these will be briefly discussed.

Lastly, the problem of computing Steiner minimal trees is viewed from two fundamental questions or issues:

Issue I: *Given a set of vertices V in E^3 , how should they be decomposed into subsets so that optimal and suboptimal solutions for each subset may be combined to yield an effective solution to the Steiner minimal tree for the whole set?*

Issue II: *On the other hand, how should a set of vertices V in E^3 be arranged or comprised to yield the best configuration possible?*

The first issue arises where the vertex sets either have some fixed special structure or are generated randomly from some probability distribution. The second issue arises from the need to determine how the optimal configurations may be identified and combined to yield the best possible configurations for large vertex sets. This is important for potential applications as will be shown. Both issues overlap, and their interplay integrates much of what follows.

One of the truly fascinating features of Steiner trees in E^3 is how all the algebraic, geometric, and optimization issues are intertwined. Because of the complexity of these networks, algebraic, computational geometry, and numerical optimization concepts and tools are often necessary for understanding, constructing, and analyzing these networks. It is hoped that this chapter, in some small way, may illuminate the understanding of how the methodological issues underlying Steiner trees are woven together.

Chapter Outline

In Sect. 2, a detailed background is provided of known results in E^2 as well as for the unit sphere. In Sect. 3, the optimization and geometric constructions possible for $N = 3, 4, 5$, and 6 vertices are examined in detail, since a geometric understanding of the problem for small vertex sets gives one a good intuitive grasp of not only the complexity of computing Steiner trees in E^3 but also some insights as to ways of computing them. Section 4 describes one heuristic for computing Steiner trees in E^3 along with computational results. In Sects. 5–8, potential applications of Steiner trees for minimizing energy configurations are provided, e.g., protein modeling and computational biology issues, along with a small sample of experimental results and open research questions, and, finally, a brief summary and conclusions is provided in Sect. 9.

2 Background

It is well known that the complexity of computing Steiner minimal trees in the plane is \mathcal{NP} -hard [39, 40]. Also, because the Euclidean version is not known to be in \mathcal{NP} , then the complexity of computing optimal Steiner minimal trees in d-space $d \geq 3$ is demonstrably more difficult since there is no inherent combinatorial structure present in the problem [68].

2.1 Assumptions

- A set of finite vertices (possibly infinite) $V = \{v_1, v_2, \dots, v_\infty\}$ is given or randomly generated within a bounded region of the Euclidean plane or space E^2, E^3 with Cartesian coordinates (x_i, y_i, z_i) for $i = 1, 2, \dots, \infty$. The bounded region is often necessary for the probabilistic analysis of the algorithms. In the Steiner network problems described later in Sect. 5, the set V will be augmented with points from the set S so that the entire vertex set for the network design problem may contain $Z = V \cup S$ vertices. For the sake of clarity, “points” will refer to the additional vertices from the Steiner set S , while “vertices” will refer to those from the given set V .
- When necessary, it is assumed that total cost of the network is a linear function of the flows in the network unless specified otherwise. In many problems to be described, one assumes that the cost of an edge is proportional to its length. In Sect. 5 on applications, the relationship of distance to potential energy minimization is shown.
- For the purposes of this chapter, no obstacles impede or restrict the location of nodes and arcs in the network, although for many practical applications, such restrictions are very important.

2.2 Notation

The following are additional useful notation:

$ESMT(V)$:= Euclidean Steiner minimal tree of a given vertex set V

$EMST(V)$:= Euclidean minimum spanning tree of a given vertex set V

ρ_d := The minimal Steiner ratio of all vertex sets V in dimension d , i.e.,

$\rho = \inf_{V \in E^d} \rho(V)$ where $\rho(V) = \frac{ESMT(V)}{EMST(V)}$

$|S|$:= Cardinality of the number of vertices in the Steiner tree

M := Number of Steiner points from set S

N := Number of given vertices from set V

FST := Full Steiner tree with $|S| = n - 2$

As demonstrated, FSTs are more prevalent in E^3 than they are in E^2 . In E^2 , there are more degenerate situations, even where optimal solutions to vertex sets may occur (see Fig. 2). In Fig. 2, for the lattice structure in E^2 , an FST would have $S = 9$ vertices, whereas the optimal solution here has only $S = 5$.

2.3 Steiner Properties in E^2

There are certain elemental facts in the planar Steiner-tree problem which are applicable. They are:

- $|S| \leq N - 2$ [41]. This is an important upper bound on the cardinality of Steiner points, although the minimum number of Steiner points for a given vertex set is unknown.

- In the plane, the ESMT is a union of disjoint FSTs. Even for lattice configurations with special structure, computation of the optimal configurations is non-trivial for large n . For the best algorithm for computing Steiner trees in E^2 the reader is referred to Warne, Winter and Zachariasen's work [84].

- There are many interesting special structures besides the equilateral decomposition such as checkerboards and ladders, see [12, 17, 18, 35] for additional details and examples.

- On the right, we have the E^3 solution for the unit cube. There are a total of eight given vertices and six Steiner points found for this optimal solution. Notice that all of the Steiner points lie in a plane in space. This actually turns out to be an important property of Steiner trees in modeling proteins as described in §6 of this Chapter.

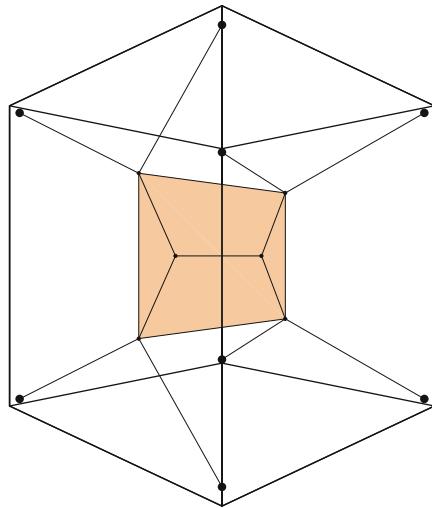

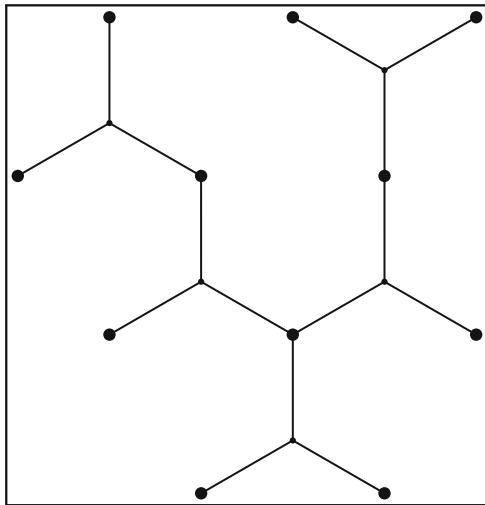

Fig. 2 E^2 lattice, $N = 11$; E^3 unit cube, $N = 8$

- $\rho_2 = \sqrt{3}/2 \forall V$ [33, 41]. This optimal ratio exists for a single equilateral triangle and certain collections of equilateral triangles and lattices. Recently, Ivanov and Tuzhilin have shown that the Gilbert-Pollak conjecture is still open [48].

For two dimensions and three given vertices, the mathematical programming problem in E^2 is a classical nonlinear programming problem to find the coordinates of a single Steiner point S with coordinates (x, y) such that

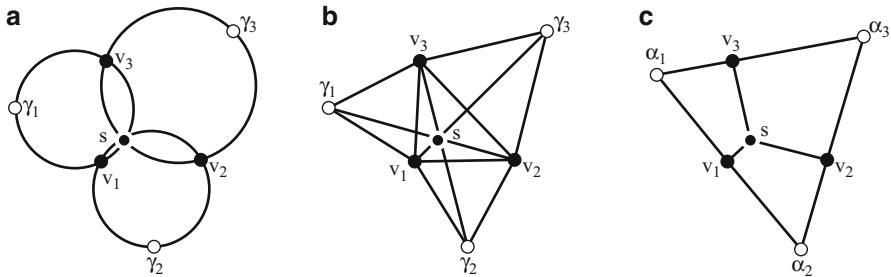

Fig. 3 Alternative E^2 constructions of a Steiner point in a triangle (v_1, v_2, v_3)

$$\text{Min } Z = \sum_{i=1}^3 [(x - x_i)^2 + (y - y_i)^2]^{\frac{1}{2}}$$

In E^2 , (see Fig. 3) geometric constructions are possible for constructing optimal Steiner trees for small vertex sets.

Figure 3 indicates three alternative methods in the plane for constructing the Steiner point in a triangle. Methods (a) and (b) are similar since by reflection of equilateral triangles on the sides of the original triangle, one creates three new vertices $\gamma_i, i = 1, 2, 3$ [24]. In method (a), one passes a circle through the reflected vertex γ_i and the base of the edge which generated it, while in method (b), one joins the reflected vertex γ_i with the vertex of the given triangle opposite it. Method (c) is carried out by solving a geometric dual problem which entails constructing the circumscribing triangle of the given triangle with maximum altitude [50, 53].

Some of these planar algorithmic and geometric concepts carry over to E^3 , although the construction problems become measurably more difficult since an optimization step becomes necessary. Heuristic approaches in E^2 also are extendable to E^3 , and one heuristic approach which will be briefly described in this chapter is directly applicable in E^3 with a slight twist.

2.4 E^2 Heuristic

One heuristic for E^2 is based on computational geometry \mathcal{CG} data structures of the Voronoi diagram $VOR(V)$ and the Delaunay triangulation $DT(V)$ [5, 73]. There are also other related data structures such as Gabriel graphs and relative neighborhood graphs that could be utilized in the design of a heuristic, and these are discussed in [72]. The $DT(V)$ provides a combinatorial framework for the construction of the ESMT solution, while the $VOR(V)$ provides locus information for concatenating local optimal solutions for small vertex set clusters. The data structures of the $VOR(V)$ and $DT(V)$ are now defined, as they will become important in higher dimensions.

- The polygon $VOR(v_i)$ is convex and its interior is the locus of vertices closer to v_i than to any other V -vertex (Figure 4).
- The union of these polygonal boundaries forms the *Voronoi diagram* for V (Figure 4), denoted by $VOR(V)$.

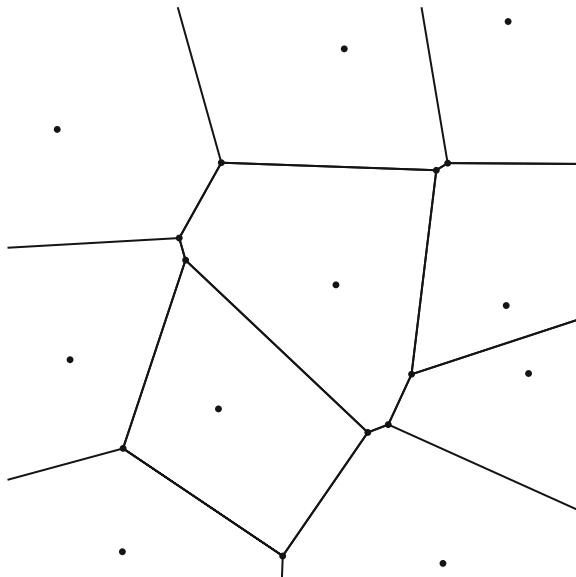

Fig. 4 Voronoi diagram for $N = 10$

Let v_i and v_j denote two distinct vertices. Furthermore, let $H_2(v_i, v_j)$ denote the set of vertices not farther from v_i than from v_j . $H_2(v_i, v_j)$ is a half plane. Let a Voronoi polygon around a given vertex v_i be defined as

$$VOR(v_i) = \bigcap_{v_j \in V \setminus \{v_i\}} H_2(v_i, v_j)$$

Further, let $P(v_i)$ denote the boundary of $VOR(v_i)$. The boundary edges are called *Voronoi edges*. Vertices where Voronoi edges meet are called *Voronoi points*. Voronoi points are similar to Steiner points in that they are extra vertices with degree 3, but their similarity to Steiner points ends there, at least for the Euclidean case. Voronoi diagrams form the foundation of many CG algorithms in geometric TND. For a detailed survey on Voronoi diagrams, the reader is referred to Boots [10] and Aurenhammer [4] and also [36, 58].

One of the most important properties of the $DT(V)$ is that the EMST is a subgraph of the $DT(V)$. Thus, once the $DT(V)$ is constructed, one has an $O(N)$ algorithm for constructing the EMST. Since the EMST provides an upper bound on the ESMT, then using the $DT(V)$ and $VOR(V)$ results in a performance-guaranteed heuristic. In fact, the algorithm provides a $2/\sqrt{3} \approx 1.1547$ performance ratio guarantee.

An $O(N \log N)$ geometric heuristic based on the concatenation of appropriately chosen ESMTs for clusters of 2, 3, and 4 V -vertices was given by Smith et al. [73].

- The straight-line dual of $VOR(V)$ obtained by connecting a pair v_i and v_j of vertices if and only if $P(v_i)$ and $P(v_j)$ share a common side yields in fact the $DT(V)$.
- Hence, the $DT(V)$ can be determined in $\Theta(N \log N)$ time. The optimality of this algorithm follows from the fact that sorting of n numbers is linear-time transformable to the problem of finding a triangulation of V -vertices (Figure 5).

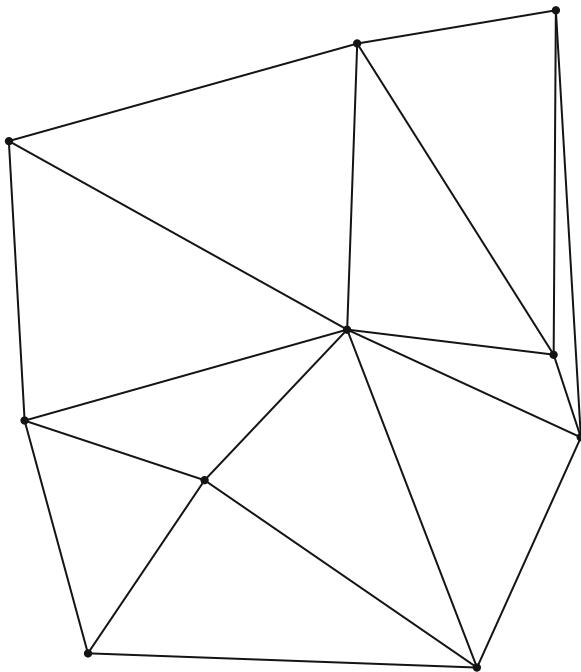

Fig. 5 Delaunay triangulation for $N = 10$

The identification of 2, 3, and 4 V -vertex sets is based on the information available from the Delaunay triangulation $DT(V)$ and the Voronoi diagram $VOR(V)$ along with the EMST for V . The Delaunay and Voronoi diagrams act as data structures for the Steiner constructions. More specifically, only the following cluster subsets of size $k = 2, 3, 4$ are considered during the concatenation phase:

- $k = 2$: pairs of vertices connected by an edge of the EMST
- $k = 3$: triples of vertices on a common triangle of $DT(V)$ and with two of its edges in the EMST
- $k = 4$: quadruples of vertices based on minimizing the Voronoi edge distance of two adjacent edge-sharing triangles of the $DT(V)$ which are also connected by EMST edges

The heuristic, in fact, first attempts to construct the $k = 4$ clusters based on the Voronoi information, then the $k = 3$, and finally the $k = 2$ edges.

The efficacy of the heuristic is based upon the data structure provided by the $DT(V)$ and $VOR(V)$, since the Delaunay tends to create “equilateral” triangles in its decomposition, which closely approximate the “best” solution in E^2 , i.e., $\rho_2 = \sqrt{3}/2$. This essential idea of decomposing the vertex set around the “best” configuration possible is important in higher dimensions and especially in E^3 as will be demonstrated.

2.5 Results from the Unit Sphere

The *unit sphere* Φ [29] provides a logical transition between E^2 and E^3 . Computing Steiner trees even for triangles on the sphere becomes more difficult because the distance metric is more complex and the Steiner vertices are affected by the curvature and wraparound effects of the spherical surface.

The geodesic minimum spanning tree (GMST) problem and the geodesic Steiner minimal tree (GSMT) problem on Φ will both be examined. The problems are computationally complex, and the focus of concern will be the development of algorithms and heuristics for these problems from a \mathcal{CG} vertex of view [61]. For the problem on the sphere, locations of the given vertices are defined by their latitude and longitude, namely, (ϕ_i, θ_i) for $i = 1, 2, \dots, n$. In order to discuss the minimal networks on the sphere, one needs a metric for length. The standard metric, which corresponds to the L_2 metric in Euclidean space, is the great circle distance. A *great circle* is any circle having a radius equal to that of the sphere. The distance between a pair of vertices on the sphere is the length (in the L_2 sense) of the lesser arc of a great circle between the vertices.

[Figure 6](#) nicely illustrates the minimization problem and some of the natural difficulties of finding vertices inside spherical triangles. The problem is to identify the additional vertex $s_i(\phi_i, \theta_i)$, if it exists, where the sum of the geodesic distances is minimized [2, 31, 52, 53, 84].

The following unconstrained optimization problem is presented for three given vertices Φ :

$$\text{Minimize } Z(X) = \sum_{j=1}^3 D(X, v_j) \quad (1)$$

where $X = (x_1, x_2)$ are the latitude and longitude coordinates of the Steiner point and $D(X, v_j)$ is the shortest geodesic or great circle distance on the surface of the sphere between the Steiner point X and an existing vertex j located at $v_j = (\phi_j, \theta_j)$. In fact, the geodesic distance is given by Donnay [30]:

$$D(X, v_j) = \cos^{-1} [\cos x_1 \cos \phi_j \cos(x_2 - \theta_j) + \sin x_1 \phi_j] \quad (2)$$

There are a number of issues related to the geometry of the sphere that complicate attempts to directly compute *GMST* and *GSMT* solutions on Φ .

- *First and most obviously, the sphere embodies degeneracies usually associated with antipodes – e.g., the multiplicity of geodesics between antipodal vertices. Such events require special tests and conventions to handle.*
- *Second, the sphere is bounded – i.e., the wraparound that exists complicates the neighbor relation. For example, a triangle of vertices on the sphere defines two spherical triangles, usually a major and a minor one. Without information about the rest of the spanning network, it is unclear in which of these to search for a Steiner point. The Delaunay triangulation and Voronoi diagrams, however, provide this oriented proximity information, since by first computing these data*

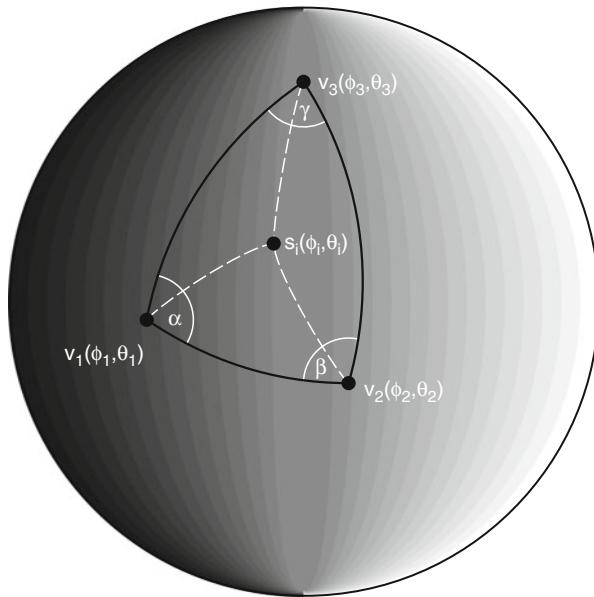

Fig. 6 Steiner minimal tree on Φ

structures, the task of constructing spanning trees is simplified, and ultimately the basis for the GSMT is formed.

- Third, the sphere lacks a natural ordering by means of which positional relations such as left-of and right-of are defined. The use of stereographic projection imparts such an ordering during the Delaunay construction process.

2.6 Steiner Points in a Spherical Δ

Some of the known properties of Steiner points in spherical triangles that have already been developed and form the foundation for the heuristic search for Steiner trees on Φ are now presented.

Theorem 1 ([19, 43]) *Let v_1, v_2, v_3 be three distinct vertices on the surface of a sphere, not all of which are on the same great circle, then any vertex X which minimizes the sum of the minor great circle arcs as in (1):*

$$\sum_{j=1}^3 D(X, v_j) \in \Delta v_1 v_2 v_3$$

is a Steiner point.

Theorem 2 ([19]) Either there is a unique point X which minimizes

$$\sum_{j=1}^3 D(X, v_j)$$

or X coincides with one of the given vertices v_1, v_2, v_3 or if

$$\angle v_1 v_2 v_3 \text{ or } \triangle v_1 v_2 v_3 < 2\pi/3$$

then the minimum vertex of $v_1 v_2 v_3 \neq v_2$.

Theorems 1 and 2 provide the analogues for locating Steiner points on Φ as they occur in E^2 . Also, under an azimuthal equidistant projection, with a Steiner vertex as a pole, an optimum Steiner point for three given vertices on Φ is the optimum for the corresponding problem in the plane E^2 [52]. In fact, it is this local projection property for three and four vertices on Φ that will be explored in the development of a heuristic for the general Steiner problem on Φ .

Finally, there are numerical difficulties with directly solving for the Steiner points on Φ as a continuous nonlinear optimization problem as can be surmised from the trigonometric relations of the distance function [53]. In fact, in problems where the given fixed vertices cannot be covered by a disc of radius $\frac{\pi}{4}$, local minima, maxima, and flat vertices must be dealt with [31]. As an alternative to solving for the GSMT as a continuous nonlinear optimization problem, the heuristic based on a computational geometry approach is briefly summarized.

2.7 Heuristic on Φ

As in E^2 , the approach utilizes the $DT(V)$ and $VOR(V)$ as data structures. Stereographic projection is utilized to project V onto the plane where the $DT(V)$ and $VOR(V)$ are constructed and then are mapped back to the unit sphere. See [29] for more details. The heuristic for the GSMT works by utilizing the simplicial decomposition of the $DT(V)$ and the GMST to decompose the vertex set into local optimal solutions of the GSMT then concatenates these local optimal solution into a suboptimal solution for \mathcal{V} .

The concatenation part of the heuristic is largely based on the ideas for solving the ESMT in E^2 [73], although there are some unique problems associated with solving for the local three and four vertex cases on Φ . As in the planar solution, only 2, 3, and 4-vertex cluster components are identified, since experimentally, they have the most significant reduction in GSMT solutions.

Thus, to briefly summarize the algorithmic approach, the Delaunay triangulation is utilized to partition the vertex set and help avoid degeneracies, the Voronoi diagram is then employed to provide locus information, and finally, stereographic

projection is employed to provide a natural ordering of the vertices for solutions to the *GMST* and *GSMT* problems.

All in all, the overall worst case running time of the algorithm is bounded by the time complexity of constructing the Delaunay triangulation which is $O(N \log N)$. All the remaining major steps and sub-steps of the algorithm for the *GMST* and the suboptimal solution for the *GSMT* are either $O(1)$ or in the worst case $O(N)$. Storage is also $O(N)$.

3 E^3 Problem

Now as one transitions to E^3 , most properties and features of Steiner trees in the plane will carry over, some will be different, and some new properties will emerge. In particular, the maximum number of Steiner points in E^3 is also $N - 2$. For a collection of other properties, see [68]. Not all optimal configurations require FSTs as will be demonstrated, since some of the given vertices can act as degenerate Steiner points. Things that one should be especially prepared for are the dynamic nature of ρ_3 , the recurring sets of planar Steiner solutions found in E^3 , and the elongated optimal nature of some of the Steiner point sets. These features will occur over and over again not only in this section but in [Sects. 4](#) and [5](#).

To start, the three vertex cases in E^3 are presented.

3.1 $N = 3$ Case

Take, for example, the following three regular vertices:

$$v_i : 1. \ 1. \ 1.; \ v_j : 1. \ -1. \ -1.; \ v_k : -1. \ 1. \ -1.$$

An assumption about these vertices is that the largest interior angle is less than $\frac{2\pi}{3}$ otherwise the Steiner point would be degenerate with one of the three given vertices. For three vertices in E^3 , they define a plane which thus reduces the three vertex problems to the planar version of the Steiner minimal tree problem. By the fundamental properties of constructing a Steiner vertex in the plane, (see [Fig. 3](#)) any reflected equilateral vertex and corresponding Melzak circle define the length of the SMT and the location of the Steiner point [41, 55].

Given that the three vertices lie in a plane, the arbitrary oriented plane is found in E^3 , and then one utilizes one of the previous methods in E^2 to construct an ESMT solution. The optimal length of this solution is defined as *SMT**. As a consequence of the Melzak circle construction in the arbitrary oriented plane, the equilateral vertex will be located farthest from the third given vertex v_k .

To understand why this occurs, as the Melzak circle is extended from say vertices v_i and v_j , the equilateral vertex on the circle will trace a sphere in space (see [Fig. 7](#)). The distance from the equilateral vertex on the Melzak circle to the opposite vertex v_k represents the length of the Steiner tree and is sometimes known as the Simpson line. As the Melzak circle rotates in space, the Simpson line and the length of the

- That it is the furthest vertex is an important property in looking at the $N \geq 4$ cases which will now be examined.

- The construction example for the 3 given vertices is nicely illustrated in Figure 7 showing the equilateral vertex, Melzak circle, and SMT length connecting t_{ij} and v_k .

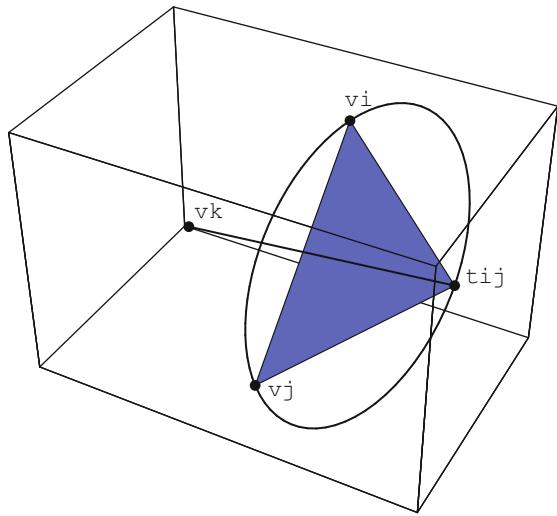

Fig. 7 Triangle in E^3

Steiner tree will vary in length. Further, as a consequence of this rotation process, the length of the Steiner tree will be longest when the circle lies in the arbitrary oriented plane, because if it did not lie in this space plane, then the planar construction would yield a Steiner point without the 120° angle property, a contradiction to the optimal solution.

Thus, one alternative to solve the problem is to find the orientation of the equilateral vertex and Melzak circle, by establishing the following quadratic optimization problem, where the location of t_{ij} with coordinates x_{ij} , y_{ij} , and z_{ij} is sought:

$$\text{Maximize } \Phi = \|t_{ij} - v_k\| \quad (3)$$

s.t.

$$\left[(x_{ij} - x_i)^2 + (y_{ij} - y_i)^2 + (z_{ij} - z_i)^2 \right]^{\frac{1}{2}} = e_{ij} \quad (4)$$

$$\left[(x_{ij} - x_j)^2 + (y_{ij} - y_j)^2 + (z_{ij} - z_j)^2 \right]^{\frac{1}{2}} = e_{ij} \quad (5)$$

The solution to this optimization problem will yield a chord length Φ^* , with t_{ij} and the Melzak circle lying in the same plane, otherwise $\Phi^* < SMT^*$, a contradiction to the optimality of SMT^* , thus $\Phi^* = SMT^*$, and t_{ij} is the furthest from v_k .

In the example construction, the length of the Simpson line is $2\sqrt{6}$, and since the length of each edge of the equilateral triangle is $\sqrt{8}$, the optimal Steiner solution of $\rho_3(V) = \sqrt{3}/2$ results.

3.2 $N = 4$ Case

Starting with an equilateral tetrahedron with the following four vertices, a description of the primal approach to constructing a solution for the $N = 4$ case will be presented followed by a dual formulation which is based on some of the distance optimization ideas found for the $N = 3$ case.

$$\begin{aligned} v_i : & \quad 1. \quad 1. \quad 1.; & v_j : & \quad 1. \quad -1. \quad -1. \\ v_k : & -1. \quad 1. \quad -1.; & v_\ell : & -1. \quad -1. \quad 1. \end{aligned}$$

There are three alternative topologies for a SMT in a tetrahedron. It will be useful to consider the three topologies in relation to the edge-pair orientations of the tetrahedron.

The three alternative topologies for the edge pairs are given in relation to the direction in which the (s_i, s_j) edge length exists:

$$(v_i, v_j) \cap (v_k, v_l); \quad (v_i, v_k) \cap (v_j, v_l); \quad (v_i, v_l) \cap (v_j, v_k)$$

3.3 Primal Problem

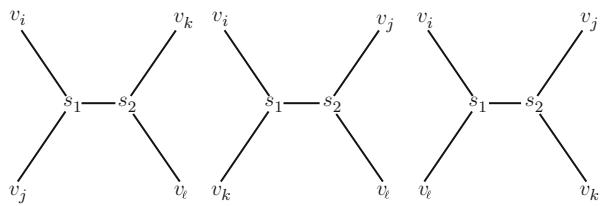

Because an equilateral tetrahedron is being examined, the first topology on the left of Fig. 8 with vertices as given will be conveniently assumed. Since the Steiner link geometry depends upon the topology of how the given vertices and Steiner points interact, establishing the topology is essential in formulating the optimization problem for constructing the Steiner tree (Fig. 9).

If one wishes to find the SMT geometry directly along with the coordinates of the Steiner points, one can minimize the following unconstrained nonlinear programming problem:

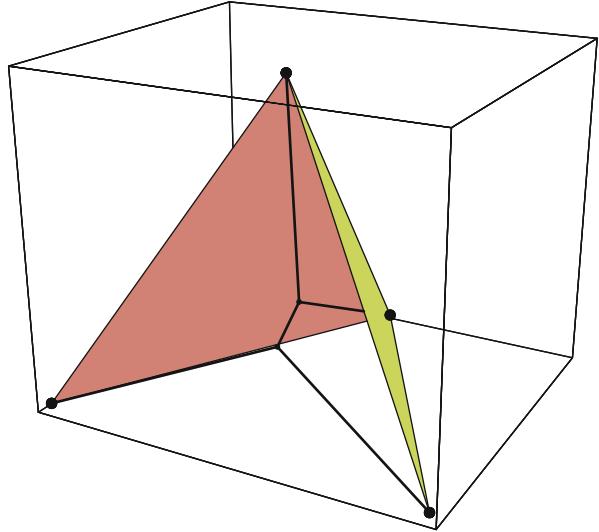

$$\text{Min } Z = \sum_{i \in V \cup S} \sum_{j \in S} [(x_i - s_{jx})^2 + (y_i - s_{jy})^2 + (z_i - s_{jz})^2]^{\frac{1}{2}} \quad (6)$$

where the indices in the summation are dependent on the three alternative topologies possible for the Steiner tree. In particular, writing out the primal problem, the following formulation is obtained (see Fig. 10 for how the topology and the constraint equations are interrelated):

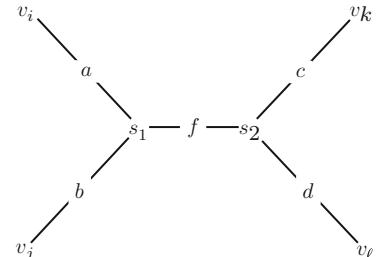

Directly solving the primal problem is carried out through such an algorithm as Warren Smith's [68] where a branch-and-bound code plays off iteratively searching the alternative FST topologies and numerical estimates of the Steiner points within the FSTs. Interestingly enough, Warren Smith's algorithm does not use a lower bounding schema which impedes its efficiency in pruning the enumeration tree. An alternative to the primal algorithmic approach is through the following dual quadratic programming formulation which must be generated for each topology as in the primal.

Fig. 8 Vertex set

- It was postulated by Gilbert and Pollack in 1968, [41] that the simplex in d -dimensional space would yield the optimal Steiner tree ratio.
- In 1996, the Gilbert-Pollack conjecture was shown to be false [34, 35].

**Fig. 9** Tetrahedron $\rho_3(V) = 0.81305$

$$\begin{aligned}
 a &= [(x_i - s_{ix})^2 + (y_i - s_{iy})^2 + (z_i - s_{iz})^2]^{\frac{1}{2}} \\
 b &= [(x_j - s_{ix})^2 + (y_j - s_{iy})^2 + (z_j - s_{iz})^2]^{\frac{1}{2}} \\
 c &= [(x_k - s_{ix})^2 + (y_k - s_{iy})^2 + (z_k - s_{iz})^2]^{\frac{1}{2}} \\
 d &= [(x_\ell - s_{jx})^2 + (y_\ell - s_{jy})^2 + (z_\ell - s_{jz})^2]^{\frac{1}{2}} \\
 f &= [(s_{ix} - s_{jx})^2 + (s_{iy} - s_{jy})^2 + (s_{iz} - s_{jz})^2]^{\frac{1}{2}}
 \end{aligned}$$

**Fig. 10** Primal tetrahedron topology

3.4 Complexity of the Primal Problem

There is a property which states that given four regular sites in 3-space such that their SMT is a full topology with $N - 2$ Steiner vertices that no *ruler and compass* geometric solution is possible [68]:

Theorem 3 *The coordinates of the two Steiner points may be expressed as the root of an essentially general (e.g., generally irreducible) eighth-degree polynomial. Therefore, the points are not obtainable by any straightedge and compass construction nor by solving any sequence of equations of degree ≤ 7 .*

While there may be no *exact* solution, the theorem does not say anything about the development of geometric constructions based on numerical methods or approximations to the optimal solution which is the focus of this chapter. It is felt that unless one views the construction of Steiner trees from this geometric construction process, one does not have a true understanding of both the complexity and the beauty of these Steiner constructions in E^3 .

3.5 Dual Problem

In this dual formulation related to the geometric construction in Fig. 7, the location of Melzak circle vertices t_{ij} and $t_{k\ell}$ that are furthest apart from each other is sought [68]. The argument for using this optimization formulation to find the furthest Melzak circle vertices follows a similar one as in the $N = 3$ case [68]. Finding these Melzak circle vertices and the resulting line segment between them as depicted in Fig. 11 yields a lower bound on the length of the Steiner problem for the particular topology.

The dual formulation is edge-based, and the Steiner points are found after the optimization of the edges, while the Primal is vertex-based, and one directly seeks the location of the Steiner vertices. The following optimization problem with the constraints ensuring the equilateral edges are satisfied is presented:

$$\text{Maximize } \Phi = \|t_{ij} - t_{k\ell}\| \quad (7)$$

subject to:

$$[(x_{ij} - x_i)^2 + (y_{ij} - y_i)^2 + (z_{ij} - z_i)^2]^{\frac{1}{2}} = e_{ij} \quad (8)$$

$$[(x_{ij} - x_j)^2 + (y_{ij} - y_j)^2 + (z_{ij} - z_j)^2]^{\frac{1}{2}} = e_{ij} \quad (9)$$

$$[(x_{k\ell} - x_k)^2 + (y_{k\ell} - y_k)^2 + (z_{k\ell} - z_k)^2]^{\frac{1}{2}} = e_{k\ell} \quad (10)$$

$$[(x_{k\ell} - x_\ell)^2 + (y_{k\ell} - y_\ell)^2 + (z_{k\ell} - z_\ell)^2]^{\frac{1}{2}} = e_{k\ell} \quad (11)$$

The SMT is equal to the distance between t_{ij} and $t_{k\ell}$ and, in fact, $SMT = 2\sqrt{6} + 2$ and the Steiner ratio $\rho_3(n) = \frac{2\sqrt{6}+2}{3\sqrt{8}} \approx 0.81305$ which is the optimal Steiner ratio of a regular tetrahedron [70]. In the construction Fig. 12, the twist angle between the two Melzak circles is 90° which is due to the mutual orthogonality of the edge pairs (v_i, v_j) and (v_k, v_ℓ) .

This quadratic optimization formulation does not admit to a polynomial time algorithm for its solution and, thus, remains a very difficult optimization problem

Fig. 11 Dual Simpson line construction

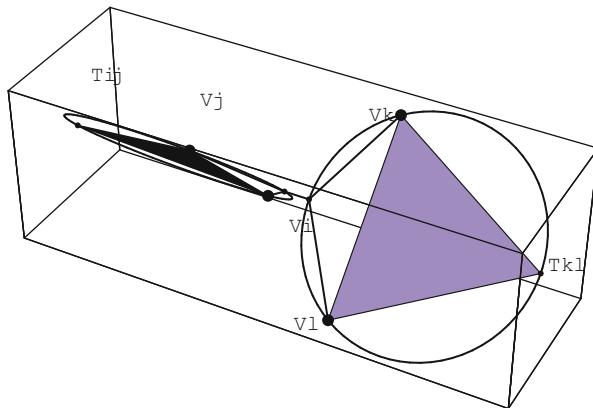

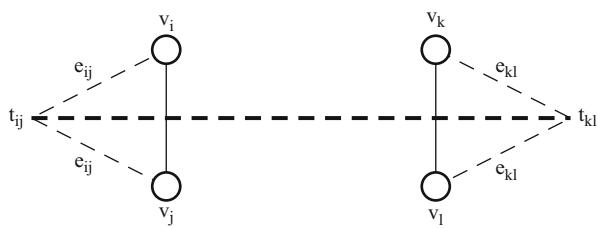

Fig. 12 $N = 4$ equilateral triangles and Melzak circles

even for four vertices. Even though the problem is convex, the objective function is a maximization one, so there may not be a unique optimum.

The beauty of solving this dual optimization problem is that one clearly sees the underlying geometry for constructing the Steiner tree in E^3 . Solving the quadratic optimization problem will work for any irregular tetrahedra, not just equilateral ones. In the dual problem, one can establish a relaxed version of the general problem if one uses a distance-squared formulation. The Lagrangian of the distance-squared formulation of the dual is

$$L(\bar{x}, \bar{\lambda}) = f(\bar{x}) + \bar{\lambda} h(\bar{x})$$

If the above is then differentiated, $\partial f / \partial x_{ij}, \partial f / \partial \lambda_i$ generating 10 nonlinear equations in the 10 independent variables and setting them equal to 0:

$$\frac{\partial f}{\partial x_{ij}} : 2(x_{ij} - x_{k\ell}) + 2\lambda_1(x_{ij} - x_i) + 2\lambda_2(x_{ij} - x_j) = 0$$

$$\frac{\partial f}{\partial x_{k\ell}} : -2(x_{ij} - x_{k\ell}) + 2\lambda_3(x_{k\ell} - x_k) + 2\lambda_4(x_{k\ell} - x_l) = 0$$

$$\begin{aligned}
\frac{\partial f}{\partial y_{ij}} : & 2(y_{ij} - y_{k\ell}) + 2\lambda_1(y_{ij} - y_i) + 2\lambda_2(y_{ij} - y_j) = 0 \\
\frac{\partial f}{\partial y_{k\ell}} : & -2(y_{ij} - y_{k\ell}) + 2\lambda_3(y_{k\ell} - y_k) + 2\lambda_4(y_{k\ell} - y_l) = 0 \\
\frac{\partial f}{\partial z_{ij}} : & 2(z_{ij} - z_{k\ell}) + 2\lambda_1(z_{ij} - z_i) + 2\lambda_2(z_{ij} - z_j) = 0 \\
\frac{\partial f}{\partial z_{k\ell}} : & -2(z_{ij} - z_{k\ell}) + 2\lambda_3(z_{k\ell} - z_k) + 2\lambda_4(z_{k\ell} - z_l) = 0 \\
\frac{\partial f}{\partial \lambda_1} : & -e_{ij}^2 + (x_{ij} - x_i)^2 + (y_{ij} - y_i)^2 + (z_{ij} - z_i)^2 = 0 \\
\frac{\partial f}{\partial \lambda_2} : & -e_{ij}^2 + (x_{ij} - x_j)^2 + (y_{ij} - y_j)^2 + (z_{ij} - z_j)^2 = 0 \\
\frac{\partial f}{\partial \lambda_3} : & -e_{k\ell}^2 + (x_{k\ell} - x_k)^2 + (y_{k\ell} - y_k)^2 + (z_{k\ell} - z_k)^2 = 0 \\
\frac{\partial f}{\partial \lambda_4} : & -e_{k\ell}^2 + (x_{k\ell} - x_l)^2 + (y_{k\ell} - y_l)^2 + (z_{k\ell} - z_l)^2 = 0
\end{aligned}$$

In the above, the first six equations represent the dual feasibility conditions, while the latter four represent the primal feasibility conditions. Including the complementary slackness conditions together in the Lagrangian objective function $\bar{h}(x) = 0$, one sees that indeed the dual does solve the primal since maximizing the distance between two extreme vertices is equivalent to the primal objective function.

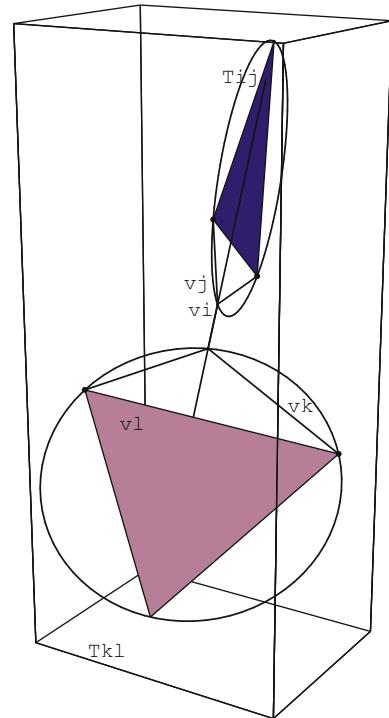

As an example of the irregular four-vertex case, the optimal length of a general tetrahedron is given as follows (this is a slight perturbation of the equilateral tetrahedra):

$$\begin{aligned}
v_i : & 1.25 \ 1. \ 1. \ v_j : 1. \ -1.75 \ -1. \ v_k : -1. \ 1. \ -2. \\
& v_\ell : -1. \ -1. \ 1.
\end{aligned}$$

Carrying out the modified algorithm with the nonlinear programming approach embedded in *Mathematica*, which is based on a Newton-type procedure for solving a set of nonlinear equations, the coordinates were found to be

$$\begin{aligned}
t_{ij} &= (-0.200706, 0.366419, 3.56057); \\
t_{k\ell} &= (0.374448, -1.17195, -4.44045)
\end{aligned}$$

The Lagrange multipliers for this irregular configuration are $\lambda_1 = -1.36566$, $\lambda_2 = -1.75906$, $\lambda_3 = -1.53361$, and $\lambda_4 = -1.11645$. The chordal distance between the extreme vertices was found to yield an $SMT = 8.16789$ with a Steiner ratio $\rho_3(V) = 0.861507$ (Fig. 13).

Fig. 13 Dual construction $N = 4$ 

3.6 $N = 5$ Case

As the next logical vertex set, the case for $N = 5$ vertices is considered. Two adjacent equilateral tetrahedra form the foundation of this vertex set. In general, for the $N = 5$ vertex case, there are a total of 15 possible FST topologies, so that the solution procedure becomes slightly more complex with the additional vertex. Let us consider the following regular vertex set:

$$\begin{aligned} v_i : & \quad 1. \quad 1. \quad 1.; \quad v_j : \quad 1. \quad -1. \quad -1.; \quad v_c : \quad -1. \quad 1. \quad -1. \\ v_k : & \quad -1. \quad -1. \quad 1.; \quad v_\ell : \quad -5/3, \quad -5/3, \quad -5/3 \end{aligned}$$

One of the topologies appears in Fig. 14, and this is the one used in the example discussion.

For the above topology, the Melzak circles are constructed iteratively, pairing up edges (v_i, v_j) and finding t_{ij} , pairing up edges (v_k, v_ℓ) and finding $t_{k,\ell}$, then taking t_{ij} and $t_{k,\ell}$ to find the vertex t_{ijkl} and the resulting maximum distance between t_{ijkl} and v_c the central vertex.

The dual formulation is again dependent upon specifying the topology of the vertices in the network. The dual formulation for $N = 5$ requires the solution of the following quadratic optimization problem (*n.b.* the squared distance function is used to simplify somewhat the optimization problem):

- Figure 14 illustrates the mapping between the example configuration and the optimization problem.
- The difficulty of this optimization problem stems from the need to simultaneously locate t_{ijkl}, t_{ij}, t_{kl} .

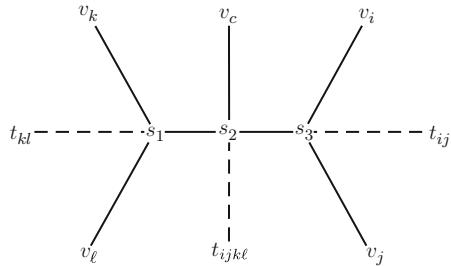

Fig. 14 Dual construction for vertex set $N = 5$

$$\text{Maximize } \Phi = \|t_{ijkl} - v_c\| \quad (12)$$

subject to:

$$(x_{ij} - x_i)^2 + (y_{ij} - y_i)^2 + (z_{ij} - z_i)^2 = e_{ij}^2 \quad (13)$$

$$(x_{ij} - x_j)^2 + (y_{ij} - y_j)^2 + (z_{ij} - z_j)^2 = e_{ij}^2 \quad (14)$$

$$(x_{kl} - x_k)^2 + (y_{kl} - y_k)^2 + (z_{kl} - z_k)^2 = e_{kl}^2 \quad (15)$$

$$(x_{kl} - x_\ell)^2 + (y_{kl} - y_\ell)^2 + (z_{kl} - z_\ell)^2 = e_{kl}^2 \quad (16)$$

$$(x_{ijkl} - x_{ij})^2 + (y_{ijkl} - y_{ij})^2 + (z_{ijkl} - z_{ij})^2 - \\ (x_{k\ell} - x_{ijk\ell})^2 + (y_{k\ell} - y_{ijk\ell})^2 + (z_{k\ell} - z_{ijk\ell})^2 = 0 \quad (17)$$

$$(x_{ijkl} - x_{ij})^2 + (y_{ijkl} - y_{ij})^2 + (z_{ijkl} - z_{ij})^2 - \\ (x_{k\ell} - x_{ij})^2 + (y_{k\ell} - y_{ij})^2 + (z_{k\ell} - z_{ij})^2 = 0 \quad (18)$$

Figure 15 illustrates the resulting optimal solution for the $N = 5$ vertex case. In order to solve this difficult nonlinear programming problem, a sequential quadratic programming (SQP) algorithm available in the IMSL Library was utilized. For the $N = 5$ equilateral configuration, the $\rho_3(V) = 0.815469$ which is larger than the $N = 4$ case. In what follows, it will be shown that for a certain configuration of $N = 6$ equilateral vertices, one can reduce this $\rho_3(V)$ value below the $N = 5$ vertex case.

3.7 $N = 6$ Case

Now consider three equilateral tetrahedra with the following vertex set coordinates and corresponding topology:

Figure 16 represents one of the 120 possible topologies interconnecting the set of six given vertices and the Steiner points. This particular topological arrangement,

- It is clear from Figure 15 that the edge segment between $tijkl$ and v_c is the lower bound length that is sought.

- What is the difficulty here is in the simultaneous location of the vertices tij , tkl , $tijk\ell$.

- An important feature of the dual construction is the resulting conjunction of the planes of Melzak Circles and the intersecting Simpson lines in E^3 .

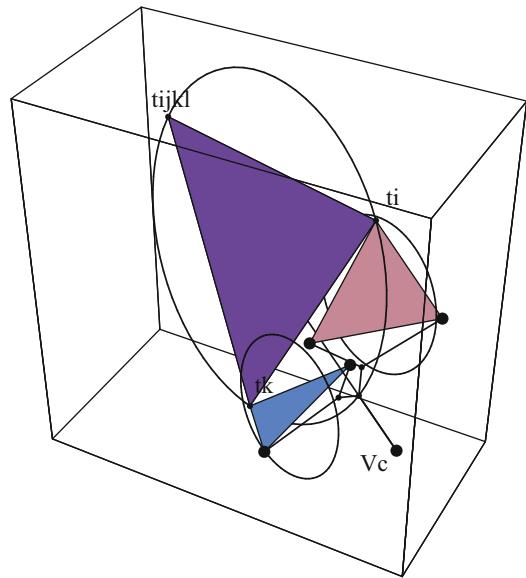

Fig. 15 $N = 5$ dual construction

$$v_i; 1, 1, 1.; \quad v_j; 1, -1, -1.; \quad v_c; -1, 1, -1.$$

$$v_d; -1, -1, 1.; \quad v_k; -5/3, -5/3, -5/3; \quad v_\ell; -3.444, -1/9, -1/9$$

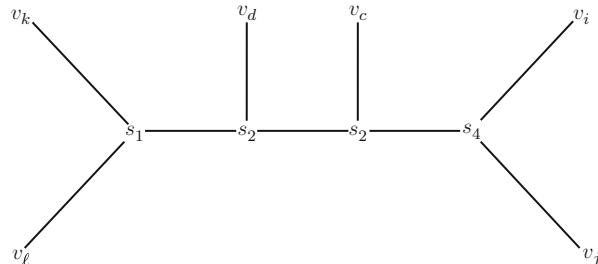

Fig. 16 Vertex set $N = 6$

however, represents a special property of the vertex set, referred to as a “path topology” which will be defined formally later. This “path topology” is very important for vertex sets $N \geq 6$ as will be demonstrated.

3.7.1 $N = 6$ Dual Construction

The detailed dual optimization formulation for $N = 6$ is similar to the $N = 5$ case and will not be repeated here for the sake of brevity. It again requires the construction of Melzak circles for adjacent pairs of vertices and further Melzak circles built upon these pairs. The quadratic optimization formulation was also solved with the SQP algorithm described earlier for the $N = 5$ case.

- Figure 1 (previously shown at the beginning of the Chapter) and Figure 17 reveal the rather interesting solutions for the $N = 6$ case.

- Again, the planes of Melzak Circles and intersecting Simpson lines are a unique trademark of what happens in the ESMT solutions in E^3 ,

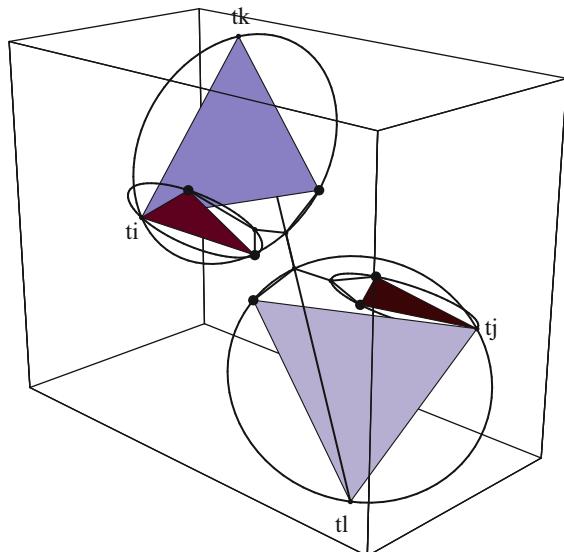

Fig. 17 $N = 6$ optimal dual construction $\rho_3(V) = 0.80865$

For this special configuration of three tetrahedra, it is curious why it should decrease the Steiner ratio after two tetrahedra raised it above the simplex, but, in one sense, this is related to the planar case, since the $N = 5$ optimal configuration in E^2 is the degenerate $N = 4$ tetrahedron with the fifth vertex and ϵ -distance removed from one of the four given vertices.

3.7.2 Conjectured Optimal Construction in E^3

While for $N = 6$ vertices one can construct an optimal solution using the past dual formulations, there are other properties of this vertex set which have even further significance for Steiner trees in E^3 .

In order to add additional vertices to the $N = 6$ base construction, the following construction technique referred to as the “buckyball” rule is presented [70]:

Rule: Successively add vertices so that the N th vertex added is always equidistant to the min ($3, N - 1$) most recently added vertices.

This rule affords a way and a corresponding data structure to configure chains of tetrahedra built upon the $N = 6$ basic equilateral structure. In fact, as vertices are added to this basic structure, one creates a ribbon sausage of vertices which dramatically decreases the ρ_3 value. The names of the tetrahedra structures generated are based on the fact that a single carbon atom forms a tetrahedron and more complex carbon molecules are simply built upon this single carbon atom base via the buckyball rule.

This monotonically decreasing property of these structures is truly remarkable. One possible explanation of why six vertices are needed is that the convex hull of the

three tetrahedra becomes the foundation of the triple helix geometry which forms the basis of the conjectured optimal configuration.

3.8 \mathcal{R} -Sausages

The search for the conjectured optimal configuration for minimizing ρ_3 in E^3 , Issue #2 raised at the beginning of the chapter, began by looking at two and three tetrahedra as well as gluing various types and combinations of Platonic solids (cubes, octahedron, etc.) together [70].

As an aside, Fejes Tóth conjectured in 1975 [80, 85] that the optimal configuration of spheres in $d \geq 3$ for the penny-packing problem was a set of unit balls on a line. This is the famous “sausage” conjecture. The conjectured configuration for the Steiner problem in E^3 is slightly different, since the unit balls with each tetrahedron are slightly offset from one another and not *in a line*. To distinguish the problem and conjecture from that of the sausage conjecture, since it is really different, the conjectured optimal configuration will be called a “ribbon/sausage” or \mathcal{R} -sausage for short.

The most interesting property of this \mathcal{R} -sausage is that it appears to be the optimal configuration of vertices in E^3 , it is thus equivalent to the best configuration, the equilateral triangle in E^2 which as was shown earlier is critical in any heuristic algorithm for vertex set decomposition.

Conjecture The \mathcal{R} -sausage achieves ρ_3 , and

$$\rho_3 = \sqrt{\frac{283}{700} - \frac{3\sqrt{21}}{700} + \frac{9\sqrt{11-\sqrt{21}}\sqrt{2}}{140}} \approx 0.784190373377122247108395477.$$

Of some note, Diaconis and Graham recently offered a prize of \$1000 to anyone who can prove or disprove this conjecture [25].

3.9 \mathcal{R} -Sausage Properties

For a known ribbon topology, the following properties within the \mathcal{R} -sausage exist, namely,

Path Topology As can be seen in Fig. 18, the \mathcal{R} -sausage has a unique path topology which relates the given vertex set V with the Steiner points in S . For the \mathcal{R} -sausage, there are $(N - 2)$ Steiner points, Steiner point i being connected to Steiner point $i + 1$ for $i = 1 \dots N - 3$. Also sausage vertex i is attached to Steiner point $i - 1$ for $i = 2 \dots N - 1$, and also sausage vertex 1 is attached to Steiner point 1, and sausage vertex n is attached to Steiner point $N - 2$. This path topology is an important indicator of the fundamental structure of a particular set of vertices.

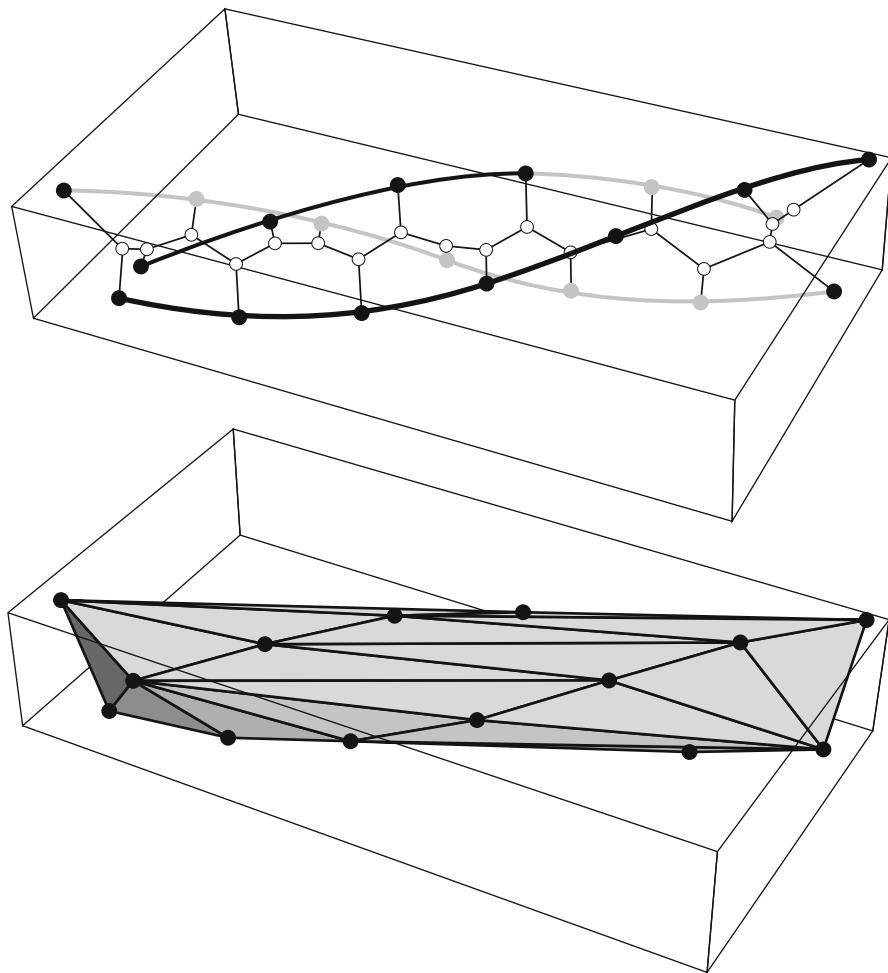

Fig. 18 $N=20$ helix geometry and path topology

Monotonically Decreasing [70] The Steiner ratio is monotonically decreasing, as the number of vertices in V increases in the \mathcal{R} -sausage. This is exemplified in [Table 1](#).

This dynamic nature of the Steiner ratio implies that the longer the \mathcal{R} -sausage the better. This would seem to imply some importance to the computational biological applications examined in [Sect. 6](#).

FSTs In particular, the maximum number of Steiner points in E^3 is also $N-2$. For a collection of other properties, see [68]. Not all optimal configurations require FSTs as will be shown in [Sects. 4](#) and [5](#), since some of the given vertices act as degenerate Steiner points.

Angles All the angles at the Steiner junctions are 120° . This is the same property as in the plane. When the applications to biochemical proteins are discussed, this

Table 1 Steiner ratios for N-vertex \mathcal{R} -sausages

n	rho	name
4	0.813052529585	(regular tetrahedron)
5	0.815469669674	(triangular bipyramid)
6	0.808064936179	("propane")
7	0.802859896946	(1 of 2 "chain butanes")
8	0.800899342742	pentane
9	0.798704227344	hexane
10	0.797013231353	heptane
11	0.795785747249	octane
12	0.794720989050	nonane
13	0.793838038891	decane
14	<= 0.7934	
15	<= 0.7926	
infinity	<= 0.784190373377122	R-sausage

angular requirement will not hold in all cases since the mass of the atoms and the electrodynamic forces interrelating them are not uniformly equivalent.

Steiner point Degree All the Steiner points have three arcs incident to each vertex or $\delta(s_j) = 3, \forall j$. All given vertices have $\delta(v_i) = 1, \forall i$. Figure 18 illustrates the convex hull and Steiner tree for $n = 20$ vertices. The diagram clearly indicates the triple helix construction. Notice that all vertices from V lie on the convex hull of the \mathcal{R} -sausage, while all the Steiner points lie in the interior.

Helical Axis There is a well-defined axis of rotation about which both the V and S vertices rotate.

Figures 19 and 20 illustrate two end views of the vertex set for $n = 75$, the former very close to the start of the \mathcal{R} -sausage while the latter from a distance. The chords across this end view in Fig. 20 represent the Steiner points and line segments at both ends of this finite \mathcal{R} -sausage, yet for an infinite \mathcal{R} -sausage, these would not exist, one would have two concentric convex hulls or 3d onions as they are called in Computational Geometry.

Periodicity Curiously enough, it has been shown that the \mathcal{R} -sausage is not periodic. If one selects a single vertex as a starting vertex for the \mathcal{R} -sausage, then after 28 tetrahedra or 11 chords along the helix, because of the screw symmetry of the \mathcal{R} -sausage, it should reappear after a 360° revolution, but it reappears slightly off at $354^\circ 20'$. This was demonstrated by Coxeter (p. 412) [24].

3.10 Sausage Experiments

Many hundreds of thousands of computational experiments were tried to see if there was a better optimal configuration of vertices which has the smallest ρ_3 , and the remarkable result so far is that nothing surpasses the \mathcal{R} -sausage for minimizing ρ_3 [70]. While one cannot conclusively prove it is the optimal configuration at this vertex in time, at least it yields a very strong upper bound on the Steiner ratio. This

- Figure 19 illustrates that for vertices propagating out along the R-Sausage, they appear in clusters of essentially 7 vertices.
- Since there are a total of $n = 75$ vertices, two clusters have 6 vertices, while there are nine clusters of 7 vertices.

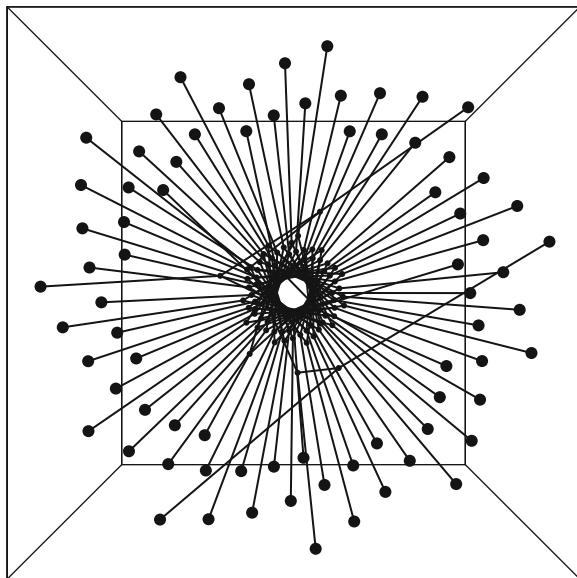

Fig. 19 \mathcal{R} -sausage screw symmetry

- Figure 20 is another view of the same R-Sausage from a further distance where it is clear that all the given vertices V lie on the convex hull of V and all the Steiner points S lie in an interior convex hull.
- This view also reconfirms the distance symmetries which are present in the R-Sausage along with the existence of a cylindrical Steiner convex hull inside the given vertex set V .

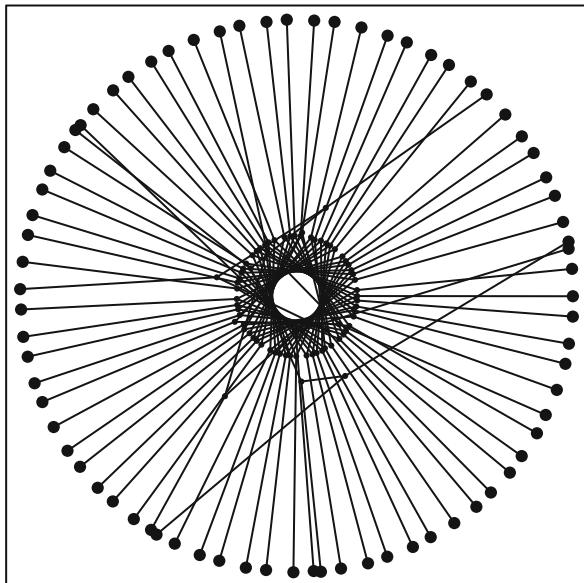

Fig. 20 End view of \mathcal{R} -sausage

- Figure 21 illustrates a Steiner tree construction where there are subsets of small vertex clusters $N = 2, 3, 4, 5, 6$ which comprise the Steiner tree solution.
- Thus, the discussion of the properties of Steiner trees in §3 carry over to the discussion of an effective heuristic algorithm.

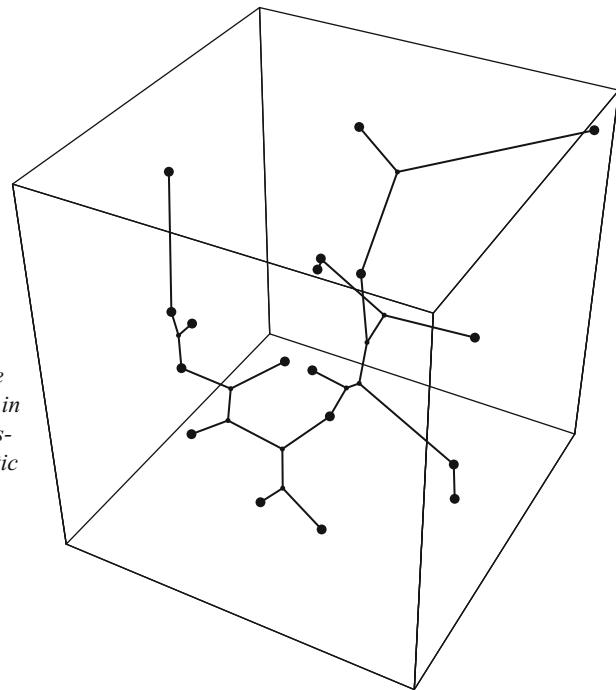

Fig. 21 Steiner construction $N = 18$

is important in the next section of this chapter for the development of a methodology to decompose an arbitrary vertex set and eventually develop a heuristic algorithm. As was the case in E^2 and on the unit sphere, decomposing according to the optimal vertex set configuration should yield an effective heuristic.

4 Heuristics

In general, when faced with computing a Steiner tree for a large randomly generated vertex set in E^3 with no special structure, optimal solutions will probably not be possible. Thus, some type of decomposition procedure is necessary to make solutions tractable. Of course the most natural decomposition tool is the \mathcal{R} -sausage itself, since as was the case in E^2 and the unit sphere, the equivalent optimal configuration vertex set should be a good decomposition strategy. Once the subsets of vertices are carved out of the larger set, then fast computation of these small subsets is important to the overall Steiner construction for the entire vertex set. If this construction can be done in better time than with an exponential worst-case time algorithm, then the overall running time and performance of a heuristic will be greatly enhanced.

4.1 CG Approach

The general strategy followed here in constructing E^3 Steiner trees is a locus-based strategy and is founded on past approaches for E^2 [73] and on the unit sphere [29]. These past approaches rely on computational geometry \mathcal{CG} data structures from which the local optimal solutions are formed. The crucial concepts needed in E^3 are the following [36]:

Voronoi Polyhedra: Given a set of vertices V in E^3 , the *Voronoi cell* of a vertex v_i is the set of vertices in E^3 closer to v_i than to any other given vertex v_j , $j \in V$. This set can also be described as an intersection of half-spaces.

$$VOR(v_i) = \cap_{i \neq j}^N H_3(v_i, v_j)$$

Voronoi diagram: Is the collection of all nonempty Voronoi cells. The intersection of two adjacent Voronoi polyhedra is a *Voronoi plane*, and the Voronoi planes intersect in Voronoi edges and eventually Voronoi vertices.

Delaunay tetrahedralization: Is also a cluster of simplicial polyhedra in E^3 and is the mathematical dual of the Voronoi diagram. In addition, the facets of the Delaunay tetrahedralization can be characterized by the property: *For T a proper triangulation, let $\text{maxrad}(\Phi)$ be the maximum radius of any minimum containment sphere of any simplex in T , then overall proper triangulations T in E^3 , the Delaunay triangulation minimizes $\text{maxrad}(\Phi)$* [36].

The Delaunay tetrahedralization is utilized as the basis for the algorithms since the equilateral tetrahedra are crucial for the optimal Steiner point set configurations as discussed in Sect. 3. Beasley and Goffinet's use of the Delaunay triangulation in their heuristic for the SMT problem in the E^2 yields the best results so far for the plane [6] and reinforces the approach for E^3 . There are other methods of tetrahedralization possible, yet for the purposes of computing Steiner trees, the more equilateral the tetrahedralization, the better in light of the \mathcal{R} -sausage properties.

4.2 Ribbon Decomposition Problem

Given the fact that the infinite ribbon or triple helix is conjectured to be the optimal configuration, one needs to utilize these ribbons to effectively decompose a vertex set so that an overall solution to the problem can be achieved. Even if it turns out that the infinite ribbon is not optimal, it still provides a valid decomposition strategy for a heuristic to the problem. In this section, vertex sets which are comprised of ribbons of regular tetrahedra joined together are examined. Although this is still not the most general case, one needs to illustrate how the tetrahedra join together, and it is clearer to illustrate the algorithmic concepts with equilateral tetrahedra.

Keeping in mind how the buckyball rule generates ribbons, it is instructive to consider junctions of these ribbons when this rule is not followed. If the next vertex in generating a ribbon is chosen to be equidistant from three vertices that are not the

ones most recently added, then one achieves a *two-way* junction. For example, if the ribbon has 10 vertices, then choosing a vertex equidistant from 7, 9, and 10 would break the \mathcal{R} -sausage structure. If in addition the 12th vertex were chosen to be equidistant from 7, 8, and 10, one would get a *three-way* junction.¹ This construction can be generalized to non-equilateral tetrahedra as well.

Some additional notation and definitions are useful at his vertex:

Centroid Spanning Tree (CST): Given the Delaunay triangulation, the MST of edges which is a subgraph of the Delaunay has for each tetrahedron a centroid. For the equilateral tetrahedra, it is also a Voronoi vertex. The collection of tetrahedra with these centroids is referred to as a centroid spanning tree (CST). With irregular tetrahedra, the Voronoi vertex which is the center of a sphere through the tetrahedral vertices may lie outside the tetrahedral convex hull, yet with a regular tetrahedra, this problem will not be encountered.

Ribbon (\mathcal{R}): Within the CST, there are chains (links) of tetrahedra which for the sake of the argument will be called ribbons \mathcal{R} . They are ribbons of varying length ℓ_i and corresponding ρ^i which for the regular tetrahedra can be estimated without actually calculating the Steiner-tree solution since the ρ_3 is a decreasing function as was shown earlier.

Ribbon Junctions: Within the CST, the ribbons intersect at junctions $\delta_0, \delta_2, \delta_3$, and δ_4 of degree 0, 2, 3, and 4 of tetrahedra, respectively.

δ_0 -Junction: An “empty” junction of two ribbons with no common tetrahedron between them. However, the two ribbons share a common degenerate Steiner point.

δ_2 -Junction: A junction of 2 Delaunay tetrahedra with $\rho^{2j} = 0.8155$

δ_3 -Junction: A junction of 3 Delaunay tetrahedra with $\rho^{3j} = 0.8288$

δ_4 -Junction: A junction of 4 Delaunay tetrahedra with $\rho^{4j} = 0.9005$

The example illustrates an optimal SMT configuration where two of the given vertices act as degenerate Steiner points. While $N = 16$, there are only $M = 12$ Steiner points. Empty junctions are interesting because they allow the \mathcal{R} -sausage topologies to be independent, i.e., there is no loss in the Steiner ratio across the ribbons. These empty junctions deserve a study in their own right, since they may exist in natural phenomenon and may also be the foundation for certain organic and inorganic applications, e.g., single- and double-chain silicate compounds and other ceramic structures [54].

The other δ_i junctions are problematic since the sausage topologies get corrupted and the ρ_3 becomes less than the expected optimal value. Actually, however, for the heuristic algorithm, it is exactly how the junctions are dealt with that is the key problem in the ribbon decomposition process.

¹Following the buckyball rule, a *one-way* junction is simply the \mathcal{R} -sausage.

- Figure 22 represents a junction of 3 Delaunay tetrahedra with $\rho_{3j} = 0.8288$.

- The solid circles are vertices from the original set. Empty circles are additional Steiner points.

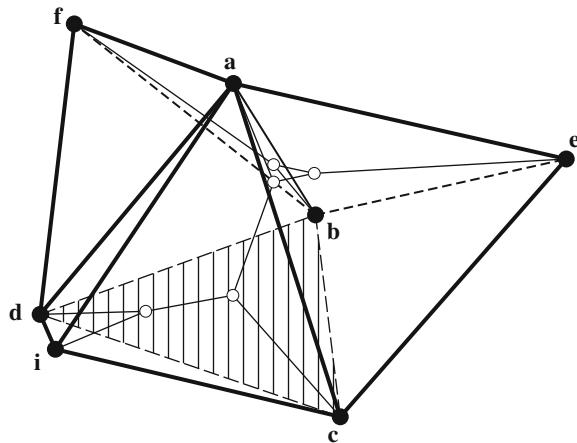

Fig. 22 3-way junction $\rho_3(V) = 0.8288$

4.3 Heuristic Algorithm

The algorithm is essentially a greedy one based on using the MST as a decomposition guide and the Delaunay triangulation to construct the ribbons of tetrahedra. It seeks to decompose the ribbon data structures in such a way as to minimize the Steiner ratio for each piece. The Steiner ratio depends on two factors: *the length of each ribbon and the degree of each junction*. Therefore, the algorithm tries to *maximize the minimum length ribbon*, but at the same time it seeks to reduce the degree of each junction in the ribbon data structure. Figure 24 illustrates diagrammatically how the heuristic works. The sawtooth line of Fig. 24 represents the MST and the tetrahedral ribbon data structure defined by the MST. The entire ribbon structure is to be decomposed while seeking to maximize the minimum length of ribbon, unioning the largest junctions of ribbons wherever possible and concatenating the local optimal solutions within the decomposition process.

In the following section, a formal description of the algorithm is presented. Data structures used in the algorithm are described in [74].

4.4 General Algorithm Description

The algorithm carefully examines the junctions of the ribbons and attempts to unite the local optimal solutions as efficiently as possible.

Step 1.0 Establish the CG Data Structure: Construct the convex hull and Delaunay triangulation data structure in E^3 , $DT(V)$.

Step 2.0 Establish an Upper Bound on the SMT: Solve the MST with the $DT(V)$ edge set.

- Figure 23 illustrates one cluster of three separate chains where each chain has three tetrahedra formed via the Bucky-ball rule and there is no degradation in ρ_3 for the entire vertex set i.e. the ρ_3 for each separate, ribbon is the optimal ρ_3 expected for 3 tetrahedra.

- The shaded triangles in the upper 3-d figure are the large ones in the lower figure, which is the 2-d representation of the same vertex set.

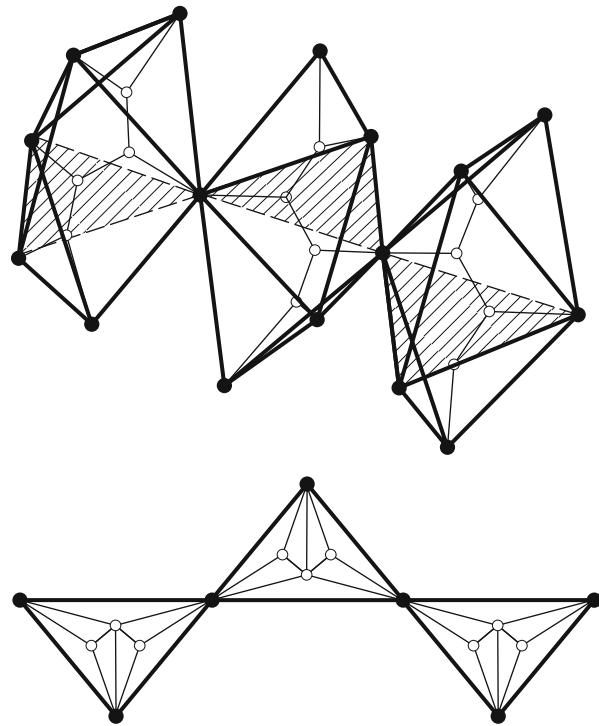

Fig. 23 3-disjoint ribbons with empty junctions $\rho_3(V) = 0.808065$

Step 3.0 *Construct the \mathcal{R} Data Structure:* Identify the tetrahedra t_i, t_j, \dots, t_q sharing edges in the MST.

Step 3.1: Utilize the Voronoi locus information to determine adjacent tetrahedra in the MST.

Step 3.2: Utilize the CST to construct the longest chains \mathcal{R}_i of tetrahedra in the MST.

Step 3.3: Identify ρ^i within each \mathcal{R}_i .

Step 3.4: Identify the junctions of the \mathcal{R}_i .

Step 4.0 *Local Optimal Solutions:* Create a priority queue \mathcal{Q} of \mathcal{R}_i sorted on their Steiner ratio.

Step 4.1: Select an \mathcal{R}_i and determine adjacent \mathcal{R}_j incident to \mathcal{R}_i at both ends if possible of \mathcal{R}_i

Step 4.2: Choose the largest junction and determine the adjacent \mathcal{R}_j which maximize the minimum length \mathcal{R}_j . If the sets of ribbons can be unioned together, go to Step 4.3, otherwise:

4.2.1: Using the longest \mathcal{R}_i at the junction, determine the face \mathcal{F}_i of the tetrahedron which ribbon \mathcal{R}_i is adjacent.

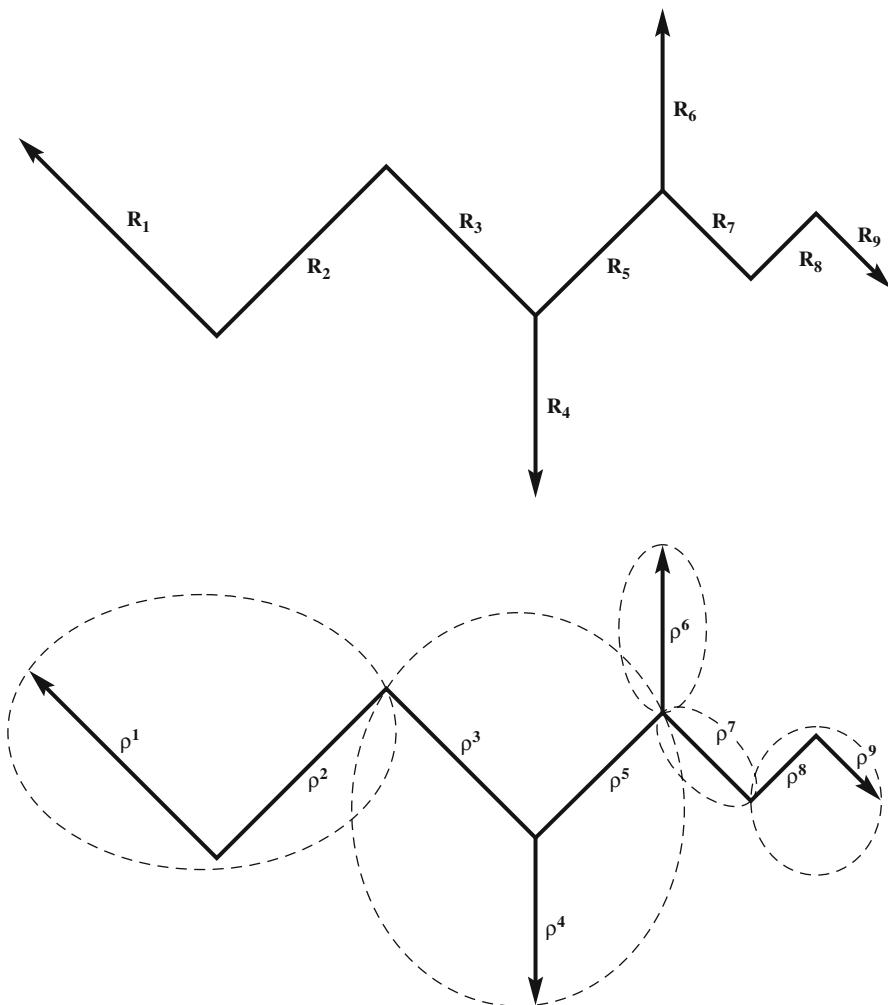

Fig. 24 \mathcal{R} -sausage decomposition process

4.2.2: Using this face, \mathcal{F}_i , determine the vertex of the tetrahedral junction nearest to the first three vertices of \mathcal{R}_i . Call this vertex v_k as the critical root vertex of the \mathcal{R}_i .

4.2.3: Using v_k to find a local optimal solution for the \mathcal{R}_i .

4.2.4: Find the local optimal solutions for the remaining \mathcal{R}_j , $j = 2, 3, 4$ using the appropriate root vertex of the junction tetrahedra.

Step 4.3: Unite the \mathcal{R}_i and \mathcal{R}_j , $j = 2, 3, 4$ and find the SMT of the union.

Step 4.4: Store the SMT solution and $k \leftarrow k + 1$ and return to 4.1.

Step 4.5: The process is complete once the priority queue \mathcal{Q} is exhausted.

4.5 Heuristic Example

The working of the heuristic is best described by way of an example. Consider the case of three ribbons connected by two 2-way junctions, as shown in Fig. 25. Figure 25 is a two-dimensional projection representation of the MST passing through the Delaunay data structure. The length of each ribbon is 3 tetrahedra, and they are numbered 0, 1, and 2.

1. *Locate the longest ribbon.* The program searches the list of ribbons, looking for the longest one. Since in this instance all ribbons are of identical length, the “chosen one” is \mathcal{R}_0 , the first one in the list of ribbons.
2. *Identify the ends of the chosen ribbon.* Check whether:
 - The chosen ribbon has junctions at both ends. If so, choose the junction with the larger number of ribbons and call it the “join.”
 - If all the ribbons at the join tetrahedron are as yet untagged, by which is meant that they have not yet been included in any collection of data vertices, then concatenate all the ribbons at this join, as well as the join itself into one data file. Mark all the concatenated ribbons as tagged.
 - If any of the ribbons that start/end at join are tagged, go to the other junction of the chosen ribbon, and repeat the above process. If this junction too has at least one previously tagged ribbon, return to the junction originally selected. In such cases, the vertices of the chosen ribbon will be the only vertices in the data set (Fig. 26).

In the example, the chosen ribbon, \mathcal{R}_0 , has junctions at both ends, both of which are two-way junctions. Neither of the other two ribbons has as yet been tagged, and so \mathcal{R}_0 are chosen and \mathcal{R}_1 as the ribbons to concatenate into a single data set, along with the junction tetrahedron, i.e., tetrahedron number 0.

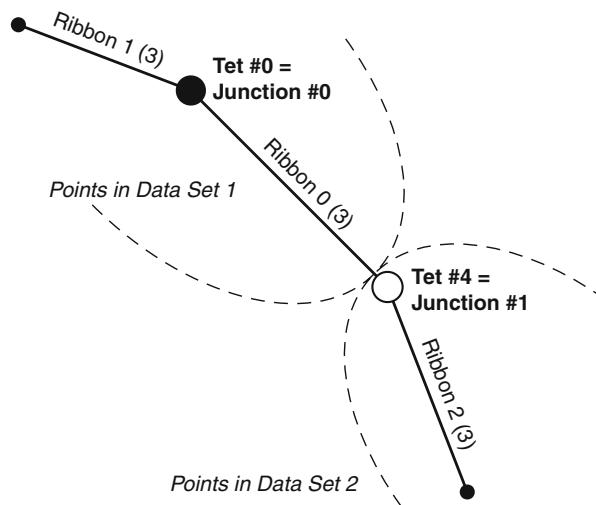

Fig. 25 Example two-way junctions

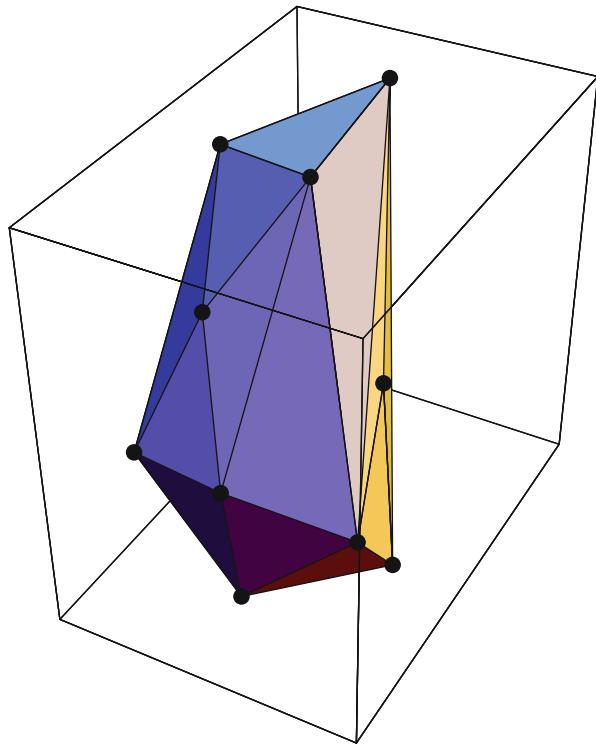

Fig. 26 Convex hull of example vertex set $N = 14$

3. *For each of the ribbons* that are to be concatenated together, one must check whether it has a junction at the other end. If so, one will need to “split out” that junction.
4. *Print out* the relevant vertices from each of the concatenated ribbons. These vertices are run through the SMT program, and the resultant tree is shown in Fig. 27 (left). The lighter lines represent the edges of the entire set of tetrahedra.
5. *The remaining vertices.* The algorithm is now run again on the remaining vertices in the data set, i.e., it searches from among the untagged ribbons the longest one and examines its junctions. In the example, the only remaining ribbon is \mathcal{R}_2 . Therefore, the second file of data vertices will consist of the vertices from \mathcal{R}_2 , along with the vertices of Junction 1, which is the connector to the data vertices in the first file. These vertices are now passed to the SMT program, and the resultant tree is in Fig. 27 (right).
6. *Calculating the ρ_3 ratio.* For each of the segregated data sets that the heuristic creates, a ρ_3 value is calculated. The SMT/MST ratio for the entire data set is then taken as the average of the individual ρ_3 ’s.
7. *Splitting out a junction.* This is a critical part of the heuristic. When a junction such as Junction 1 in the example above is to be split out, it is important to do it

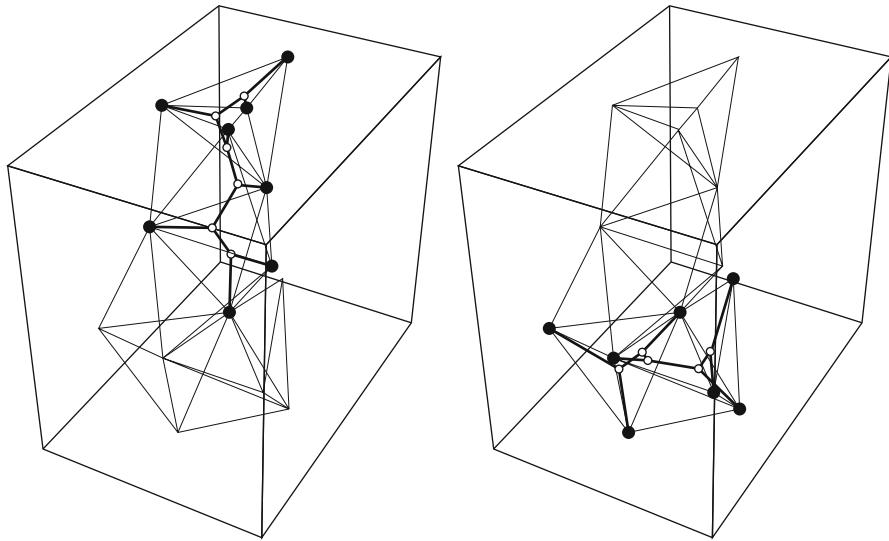

Fig. 27 SMT top part (*left*) and bottom part (*right*) of the data set

in a manner that allows one to maintain continuity between the different vertex sets, and also not introduce any additional distance into the overall tree. In the heuristic, this is achieved by examining the junction tetrahedron to be split out and identifying the vertex that is closest to the ribbon from which it is being separated. This vertex is then concatenated with the separated ribbon, so that a good connection vertex is available to link the Steiner minimal trees obtained from the different data sets.

The overall SMT is obtained by the superposition of the individual trees, and Fig. 28 on the left shows the overall SMT for the sample data set. The average ρ_3 value for the entire data set is 0.804496 and was obtained in 31 s.

By contrast, the tree that would have been obtained had the entire data set been passed directly to the SMT program is shown on the right in Fig. 28. The ρ_3 value thus obtained is 0.809361 and was obtained in 10 min (600 s) of computing time. This solution is obviously not guaranteed to be optimal.

4.6 Complexity Analysis

The worst case time bound for the three-dimensional $DT(V)$ must be $\Omega(n^2)$ [8]. An implementation of the Delaunay triangulation based on the work of Beichel and Sullivan [7] was employed. Steps 2.0 requires $O(N^2)$ time in the worst case, although some implementations of MST in E^3 will run faster. Step 3.0 is also $O(N^2)$ because there could be $O(N^2)$ tetrahedra. Step 4.0 and its substeps can be carried out in constant time if the search process is bounded above by a fixed

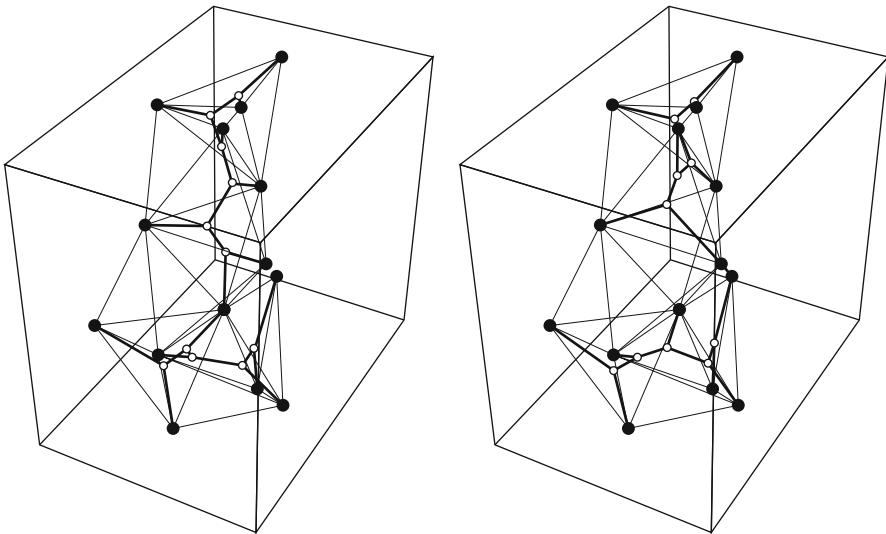

Fig. 28 Heuristic and optimal algorithm solutions

constant amount of time. Otherwise, it will be exponential; in fact, it will require $O(2^N N!)$ time since the numerical solution procedure is a branch-and-bound algorithm [68].

For the most general case where V are uniformly distributed within the unit cube and where the local optimal solution procedure is bounded by a constant search time C_R , then one can show:

Lemma 1 *The greedy heuristic will require $O(C_1 N^2)$ time.*

The result follows from the previous complexity analysis. The data structure is the key to the underlying complexity of the algorithm.

Since optimality is not being sought, and one knows the approximate length of the CST chains, then the local optimal search can be controlled, and one can achieve reasonably good solutions in polynomial time. The key factor here will be the expected ribbon length.

For the special case where equilateral tetrahedra are studied, one knows the ρ_3 function as a function of the length of R_i , then one can also achieve:

Lemma 2 *For the equilateral tetrahedra case, the greedy heuristic will require $O(C_2 N^2)$ time.*

It is this latter case that is tested in this heuristic procedure for this chapter, where the V have special structure. While one could be criticized for testing the heuristic

on this special equilateral case, this is a case where many degeneracies occur, so it is actually quite general.

Unfortunately, one cannot provide a performance guarantee like that provided in the E^2 because of the lack of knowing the optimal ρ_3 in E^3 .

4.7 Experiments

As one measure of the worst case running time performance of the heuristic process, the capability of the optimal seeking subroutine algorithm to solve long chains of tetrahedra needs to be assessed. To estimate the feasibility of this, the following experiments were performed on \mathcal{R} -sausage chains of lengths $N = 25, 50, 100$. Those values which are blank in [Table 2](#) represent the fact that the algorithm stopped without any solution obtained. Thus, as one sees, relatively short chains will be examined in order to keep the computing times reasonable, and this underscores the need for the heuristic. Also one sees that for $N = 100$, one is coming quite close to the conjectured optimal $\rho_3(V)$ for E^3 , although the above results are not guaranteed to be optimal. In order to test the heuristic, the following experimental design was established (see [Fig. 29](#)):

- Two-way \mathcal{R} – sausage networks • Three-way \mathcal{R} – sausage networks
- Four-way \mathcal{R} – sausage networks • Many-way \mathcal{R} – sausage networks

[Figure 29](#) represents $2-d$ projections of the MST and tetrahedral ribbons through which it passes. No δ_0 ribbon junction examples were included, since that would bring one into the domain of examining how the optimal sausage/ribbon topology should be combined to yield the best possible vertex sets *a la* Issue #2. This will be examined in a future monograph.

Also, the length of the \mathcal{R} -sausage chains was kept relatively small so that the local optimal search procedure is reasonably bounded in running time. Larger vertex sets are feasible with a consequent increase in running time although very reasonable. [Figure 30](#) on the left illustrates the performance of the heuristic in relation to the optimal seeking algorithm for short symmetric vertex sets of two-way, three-way, four-way, and multi-way junctions. [Figure 30](#) also illustrates on the right a series of experiments for short asymmetric vertex sets. [Figure 31](#) illustrates the

Table 2 Optimal seeking experiments

Time (min)	$N = 25$	$N = 50$	$N = 100$
1	0.793215	-?-	-?-
2	0.793215	-?-	-?-
3	0.793215	0.787845	-?-
10	0.793215	0.787845	-?-
15	0.793215	0.787845	0.786049
20	0.793215	0.787845	0.786049

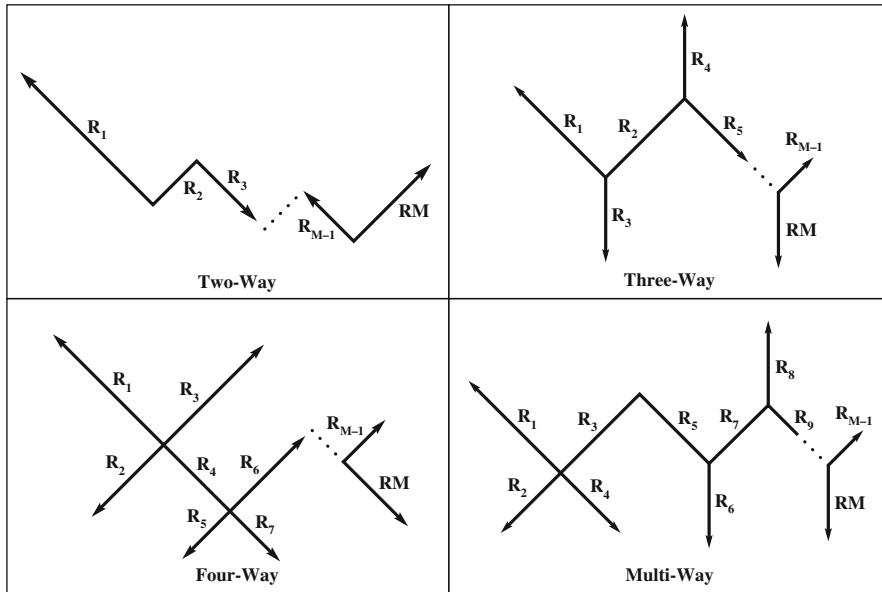

Fig. 29 Experimental design

longer experiments for symmetric and asymmetric vertex sets. Running times for the heuristic on all these vertex sets are arrayed in Table 3. Certainly for some of the smaller vertex sets, the optimal seeking program can do better, yet the percentage improvement over the heuristic is not significantly different. Also, for some of the longer more complex configurations, the run times and the ρ_3 values for the optimal seeking algorithm are much worse.

As for a more general heuristic for arbitrary point configurations of much larger cardinality, the reader is referred to the paper by Toppur and Smith [79] where they develop an $O(N^2)$ heuristic for points generally distributed in space. They utilize the \mathcal{R} -sausage to decompose the point set. The percentage reduction in the Steiner ratio is not as significant as that which occurs in the previously described heuristic, but this is understandable in light of the special structure nature of the previous heuristic.

5 Applications

Given what has been shown so far about Steiner trees in E^3 , it is quite natural to wonder whether the long extended structure of the conjectured optimal configuration might imply or have relevance to certain physical, biochemical, or engineering applications. The most obvious application that occurred was that the Steiner problem in E^3 might help explain the reason for the long molecular chains of atoms in proteins and DNA and other molecular structures found in

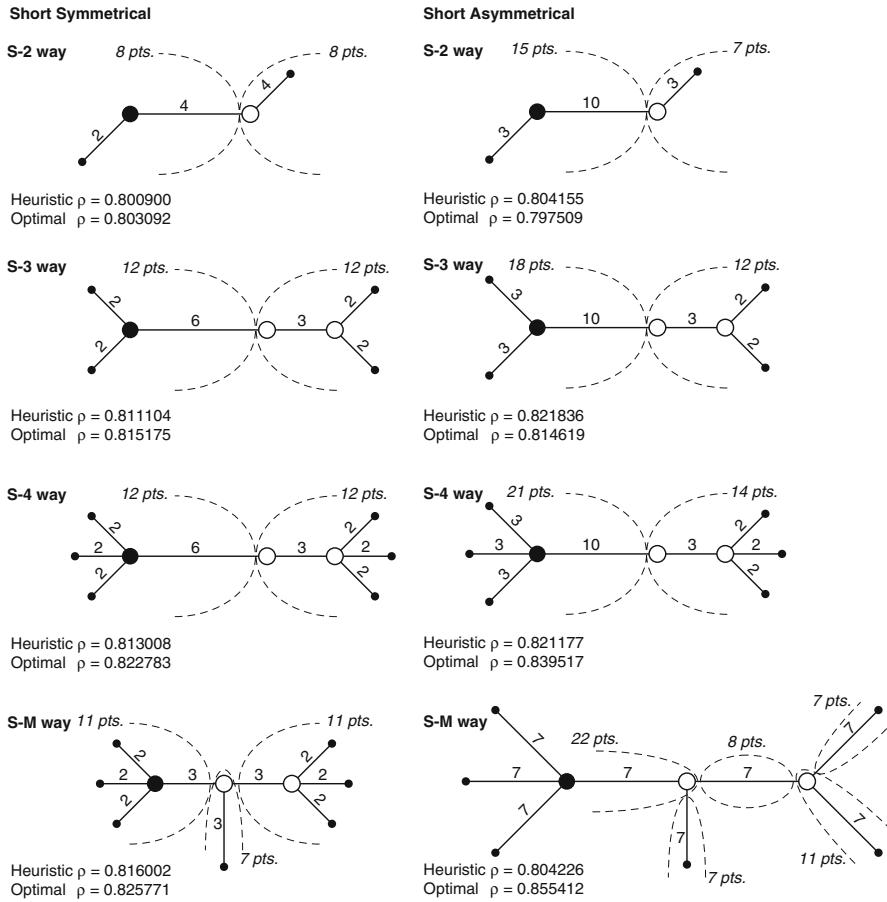

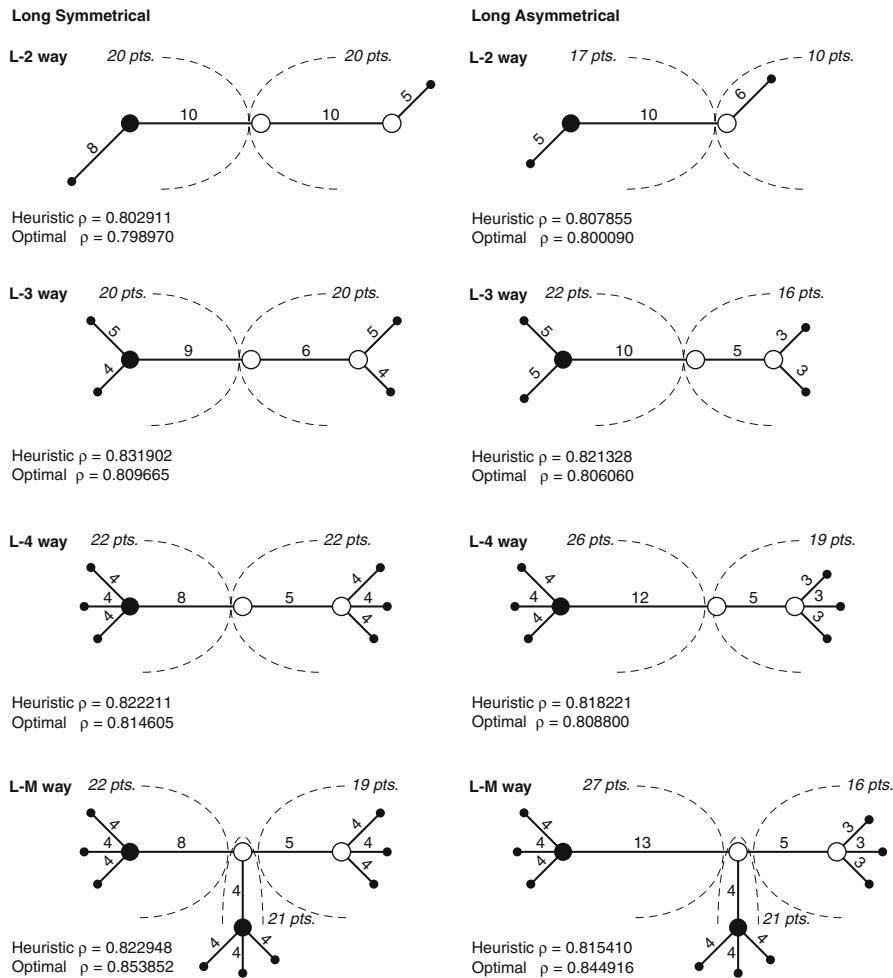

Fig. 30 Short-chain experiments

biochemistry [11, 45, 59, 71]. In order to examine this potential application area and others related to it, possible linkages between the objective function of the Steiner problem and objective functions of these applications in the physical, biochemical, or engineering sciences need to be examined.

5.1 Minimum Energy Configurations (MECs)

To clarify and delineate the connection between the scientific and engineering applications and the Steiner problem, one needs another property of the Steiner problem which was first shown in the classic paper on Steiner trees by Gilbert and Pollak [41]. It is recounted as Maxwell's theorem after the famous physicist.

**Fig. 31** Long chain experiments**Table 3** Computation times (secs.) heuristic vs. optimal algorithm

Topology	Short symmetric	Short asymmetric	Long symmetric	Long asymmetric
Two-way	65/120	57/120	120/240	129/240
Three-way	120/240	129/240	120/240	165/360
Four-way	120/240	131/240	121/240	273/360
Multi-way	128/600	174/600	300/600	678/720

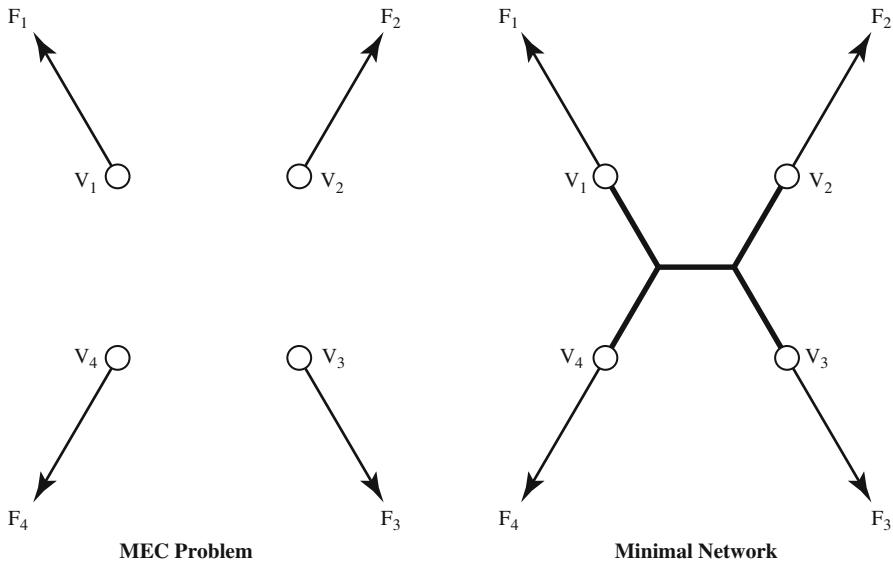

Fig. 32 Maxwell's theorem illustration

Let F_1, F_2, F_3 , and F_4 be unit forces acting at fixed vertices v_1, v_2, v_3 , and v_4 , respectively. Also, if one tried to design a network with moveable Steiner vertices to link up the fixed ends with elastic bands where each band will have a tensile force, then one seeks to find the network where these tensile forces will be in equilibrium. Figure 32 nicely illustrates the MEC.

Theorem 4 *If one draws unit vectors from a Steiner tree in the direction of each of the lines incident to v_1, v_2, \dots, v_n and lets F_i denote the sum of the unit vectors at v_i , then in mechanical terms, F_i is the external force needed at v_i to hold the tree in equilibrium. The length of the tree T has the simple formula*

$$T = \sum_{i=1}^n v_i \cdot F_i$$

The proof is in their paper [41].

What Maxwell's theorem implies is that the minimal-length Steiner tree is equivalent to the equilibrium configuration of vertices which minimizes the potential energy between them. Maxwell's application was to determine the minimum weight truss made from pin-jointed rigid rods and holding a given set of forces $\{F_1, \dots, F_n\}$. Maxwell's theorem is more general in that it applies to circuits as well as trees, and the forces need not be all uniform, although for the Steiner problem, the uniform forces are required [63].

5.2 Lower Bounds

The importance of the Steiner tree for MECs is that if there are unit forces acting at the nodes, then the Steiner tree which is the minimal-length network yields the optimal MEC. On the other hand, if the forces are not all uniform, e.g., some forces are in compression as well as tension or vary in order of magnitude, then the Steiner minimal tree yields only a lower bound. What will be shown in the experiments on proteins which follow is that this lower bound provided by the SMTs is surprisingly *tight*.

6 Fundamentals of Protein Structures

There are four major types of macromolecules of interest in the biological sciences: carbohydrates, nucleic acids, proteins, and lipids. Protein structures will be the focus because the structural geometry of proteins relates most closely to what has been found with the ideal Steiner R —sausage geometry, but as will be argued, a similar type of structural analysis could be mounted for the other types of macromolecules, especially DNA and RNA.

A key issue in biochemistry today, as pointed out in the introduction, is to predict the 3-D structure of proteins from the primary sequence of amino acids [11, 45]. Basically, two approaches to this problem have been developed over the years; see [22]: (i) threading or homological methods and (ii) hierarchical condensation methods. Threading methods rely on the comparison of unknown protein structures with known protein structures. Basically, researchers decompose a protein into its constituent parts, analyze the parts independently, then match the proteins to those in the known database; see [27, 66].

The other approach to protein prediction is to rely on the fundamental building blocks of protein structure, i.e., the amino acids and how they are assembled together in E^3 according to a set of rules. This approach to protein modeling harbors the most power and flexibility in dealing with unknown protein structures. For the hierarchical condensation methods, researchers view the problem with identifying and predicting protein structures in the following manner: First they define the fundamental building blocks of the amino acid sequence as the *primary* level. With the known amino acid sequence, the types of geometric structures these linked sequences can develop are viewed as the *secondary* level. Most typically, the geometry of the secondary structures can be either an alpha-helix, beta sheet, or combinations of these structures. The way the geometric structures pack or “fold up” in space is called the *tertiary* level, and finally, the *quaternary* level represents the final composite structure of all the secondary and tertiary structures within the protein. This hierarchical approach is the one considered here.

6.1 Steiner-Algorithm Approach

A computer algorithm similar to that used in [70] to evaluate the proteins will be utilized. It is a branch-and-bound optimization algorithm as in [68] for solving Steiner trees in E^d , and the version used to solve the problem in E^3 seeks an optimal solution. Since it seeks to find an optimal solution by adding a maximum of $N - 2$ Steiner points so that the structure is an FST, its running time is exponential. Performance for running time will be traded off since to know the optimal configuration of the amino acids and proteins, if possible, is most desirable. However, unless the terminal vertex sets are $N \leq 13$ or have special topological structure, optimality cannot be achieved within a reasonable amount of computing time. Running times for the amino acids and the proteins included in this chapter were on the order of 0–600 min of computing time.

In the experimental part of this chapter, the fundamental geometry of the individual amino acids will be examined for their Steiner properties, then proceeding to modeling protein secondary structures and perturbations for their structure. When HIV-1 protease is modeled, the tertiary structure will also be examined. Ultimately, how the Steiner properties transcend all the structural levels will be the goal, but in this chapter, the primary and secondary levels will be the main focus [77].

6.2 Primary Structure of Amino Acids

The individual amino acids will be first examined to see what Steiner properties result. After this, the robustness of different proteins with respect to how the Steiner ratio can be used to model the proteins will be evaluated.

The primary structure of a protein is made up of different amino acids coupled head to tail like beads on a string. Each amino acid has a carbon atom with an R group bonded to it, an amino group on the left, and a carboxyl group to its right. Each amino acid differs in its side chain, i.e., its R group. The carbon atom connecting the side chain is called the α carbon, and subsequent carbon atoms in the side chain are alphabetically ordered $\beta, \gamma, \delta, \dots$. A typical schematic diagram of an amino acid occurs in Fig. 33 on the left.

There are 20 amino acids that naturally occur in proteins, and these 20 are combined in a variety of ways to yield the various proteins and protein structures. For those not familiar with amino acids, a functional classification of the 20 amino acids appears in Fig. 33 from [22] on the right.

What has been done in the experimental part of this section is simply to take each amino acid and calculate its Steiner tree. Remember, in solving for the Steiner points, the algorithm does not know a priori where the Steiner points should be located. The algorithm systematically adds $N - 2$ Steiner points to the given terminal vertex set V in order to reduce the overall length of the spanning tree connecting V . It seeds the points through the midpoints of the edges of the set V , then tries to relocate them according to topology and derivative information from the objective

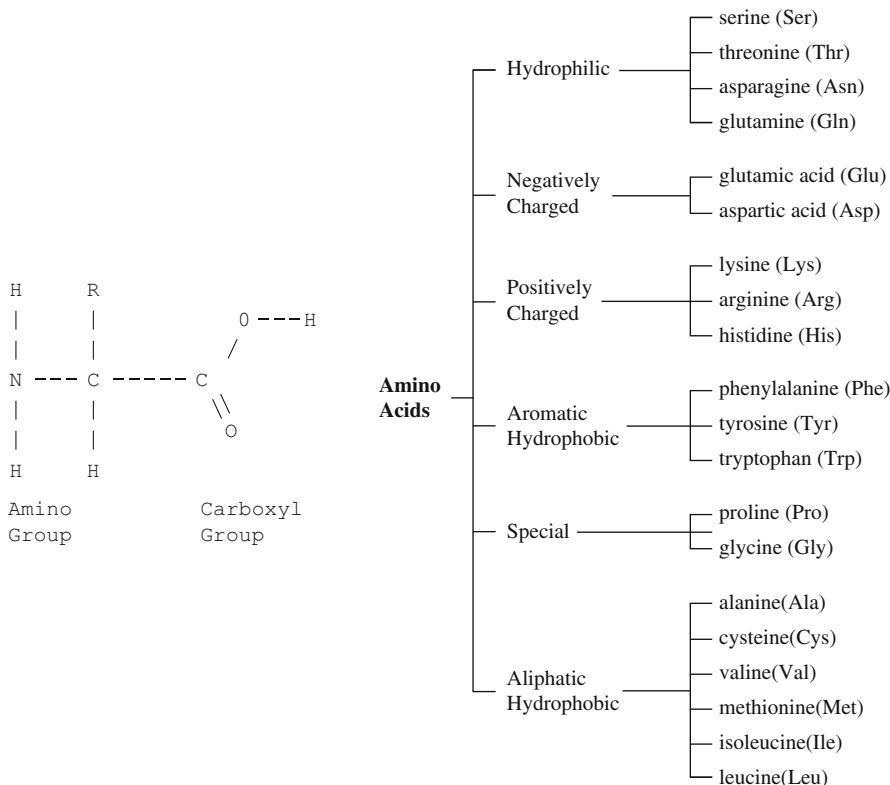

Fig. 33 Amino acid structure and classification

function of the Steiner-tree problem so as to satisfy the 120-degree-angle property of the edges incident to the Steiner points. The algorithm does not start off with any prior information on where the Steiner points should be located. It terminates after it examines all possible topologies and cannot reduce the SMT length further. As will be shown, the carbon and nitrogen atoms function as Steiner points in the amino acid structures. Table 4 illustrates the results found. All 20 different amino acids available from the education site of the [64] will be examined. It needs to be shown what information can be derived from computing the Steiner tree for each amino acid. Different data set realizations of the amino acids would reveal different SMT and MST solutions, yet similar topological results should occur as in Table 4. The detailed Steiner-tree outputs for each acid are available from the author.

In reading the rightmost two columns of Table 4, the $S' \subseteq S$ column represents the subset of Steiner points that correspond to the given carbon and nitrogen atoms in the amino acid, and the last column represents the combined number of carbon and nitrogen atoms within each acid. That the Steiner program basically identifies all the carbon and nitrogen atoms as Steiner points from first principles is quite

Table 4 Amino acid results

Name	SMT	MST	ρ	V	$S' \subseteq S$	$C + N$

Valine (Val)	21.752	21.885	0.9939	19	6	6

remarkable. It is remarkable that one can predict the placement of certain atoms within a molecule without using quantum mechanics.

In [Table 4](#), the alanine and glycine amino acid SMTs are optimal solutions. It took 440 min of computing time to find optimality for the ($N = 13$) alanine while only 8 min for the glycine ($N = 10$). In the other amino acids, the results are upper bounds, since the algorithm did not converge within a reasonable amount of running time (≤ 600) min. For instance, since cysteine has $N = 14$ atoms, as a test, the program was run for 1,000 min of computing time, but it did not converge to optimality. The design of more efficient algorithms for SMTs ($N > 13$) is crucial to future progress in this area.

Alternatively, as was developed in [\[75\]](#), a heuristic with polynomial running time of $O(N^2)$ could be used, but it is the optimal structure for the proteins sought, and that is why the branch-and-bound algorithm was chosen. There are some theoretical heuristics by Arora [\[3\]](#) that are supposedly better than the $O(N^2)$ one, yet they are not practical, and no implementation is known that is either available or better than the algorithms used in this and previous papers. Also, the fact that optimal solutions are sought, especially for the small-cardinality points sets of the amino acids, implies that the branch-and-bound algorithm is the one desired. The program comes with an output file generation so that the Steiner-tree output of the solution can be viewed in *Mathematica*; see [\[87\]](#). The algorithm is available from the author upon written request.

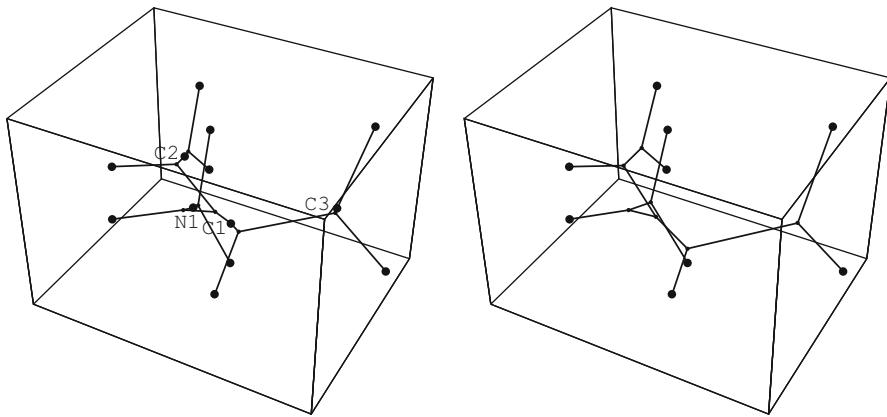

Fig. 34 Alanine native (*left*) and perturbed structure (*right*)

With the exception of histidine, phenylalanine, and tryptophan, the algorithm identified all the carbon and nitrogen atoms as Steiner points. Only for the histidine it did not locate the single nitrogen atom, and in the phenylalanine and tryptophan it did fail to identify one of the carbon atoms. The reasons for this are probably due to the inability of the computer program for the Steiner trees to check exhaustively all the full Steiner topologies and optimally locate all the correct Steiner points within a reasonable amount of computing time, since the number of atoms (terminals) in the histidine, phenylalanine, and tryptophan acids are relatively large. The number of possible full topologies for a given terminal vertex set is exponential in N ; see [41]. Remember, optimal results are sought here. In all other cases, it exactly identified the carbon and nitrogen atoms acting as Steiner points.

While some of the carbon and nitrogen atoms are Steiner points of degree 3, many of them are degenerate since their degree is 2 and their angles do not equal $2\pi/3$. Figures 34 on the left and 35 on the left illustrate this situation where some of the carbon and nitrogen atoms are degenerate Steiner points. All in all, it appears that the resulting Steiner network acts as a rigid structural framework for the amino acid, much in the spirit of Maxwell's theorem. The importance of this framework in the next section will be illustrated when the structure is perturbed.

None of the oxygen or sulfur atoms are ever identified as Steiner points. The hydrogens are terminal vertices of degree 1, so they cannot be Steiner points. An open research question here is the following: *Is there any significance to the Steiner points that do not correspond to the given atoms in V ?*

Also, of some note is the surprisingly high $\rho \approx 1.0$ value in the amino acids, which corresponds to some previous experimental results. When one considers the possible ρ associated with the R -sausage, one might think that the ρ of the amino acids should be closer to 0.7841903733 rather than 1. Why is there such a difference in the ρ values of the amino acids and the R -sausage? That the ρ value is also remarkably consistent in value across all the amino acids is indicative of

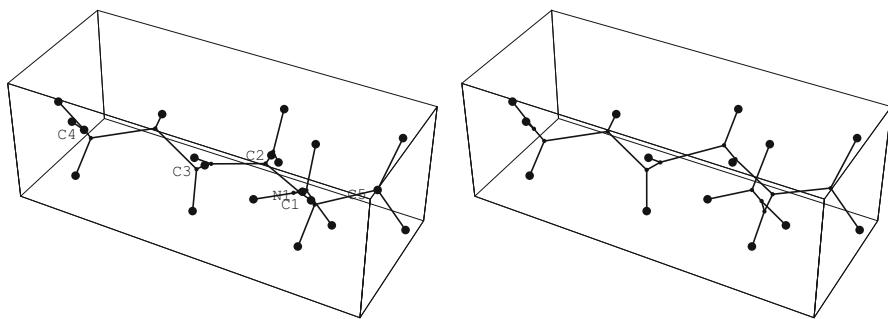

Fig. 35 Methionine amino acid native (*left*) and perturbed Steiner structure (*right*)

its importance in conformation of a protein, as will be argued in the next set of experiments.

Table 5 illustrates one detailed output from the Steiner program for the isoleucine acid describing the relationship between the carbon and nitrogen atoms and the Steiner points. When viewing the outputs of the amino acids, two columns were created, and those atoms identified as Steiner points (→) were aligned with those of

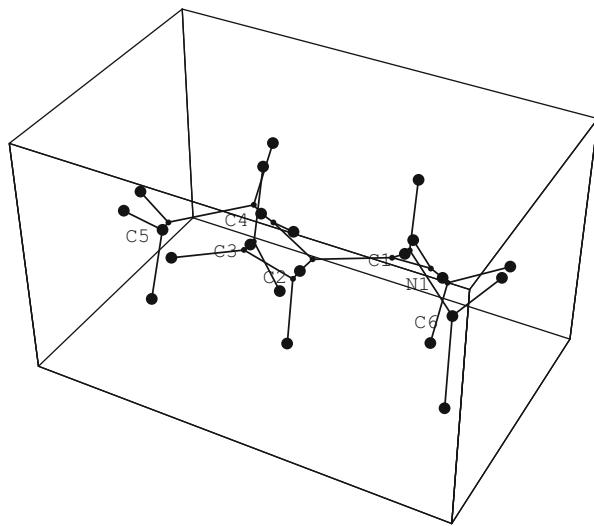

Fig. 36 Isoleucine acid Steiner tree

the input data set V , so the correspondence is clear. The indexing of the atoms in Fig. 36 corresponds to the order of the atoms given in the PDB file [65]. Since isoleucine has $N = 22$ atoms, the computer program added $M = 20$ Steiner vertices to create an FST, so that there should be a total of 42 vertices in all. Actually, the program found duplicates of Steiner point s_{38} so only 21 unique Steiner points are shown in Table 2. In fact, 7 of the 20 additional Steiner vertices that the program added happen to coincide exactly with the carbon and nitrogen atoms. Remember, when the program tries to find the additional vertices, it does not know beforehand the location of the Steiner points. Notice in Fig. 36 that atoms C_5 and C_6 are degree-3 Steiner points while the others are degenerate ones. Thus, the presence of the carbon and nitrogen atoms within the amino acids acting as Steiner points serves to move $\rho \rightarrow 1$, while in the R -sausage the Steiner points in the interior of the sausage are necessary, so $\rho \rightarrow 0.7841903733$.

6.3 Perturbed Amino Acids

If one generates an optimal SMT with a given terminal set V and Steiner points S , then one can create a new terminal vertex set $V' = V \cup S$ and resolve the SMT, and then $\rho = 1$, since there is no better way to improve the SMT.

In order to test the significance of the carbon and nitrogen atoms acting as Steiner points for the amino acids, they will be removed from the amino acids and examined to see what occurs experimentally as they are resolved with the Steiner program. Will the program replace the carbon and nitrogen atoms with Steiner points in the exact same locations?

Table 6 Perturbed amino acid results

Name	SMT	MST	ρ	SMT'	MST'	ρ'
Alanine (Ala)	14.394	14.478	0.9942	14.355	16.459	0.8721
Arginine (Arg)	31.162	31.357	0.9938	29.468	32.132	0.9171
Asparagine (Asn)	19.382	19.481	0.9949	19.180	20.857	0.9196
Aspartic acid (Asp)	17.292	17.391	0.9943	17.144	18.800	0.9119
Cysteine (Cys)	16.395	16.541	0.9915	16.347	18.425	0.8872

Isoleucine (Ile)	25.417	25.586	0.9934	25.135	28.009	0.8974
Leucine (Leu)	25.447	25.588	0.9945	25.276	27.812	0.9088
Lysine (Lys)	28.912	29.102	0.9935	28.674	32.636	0.8786
Methionine (Met)	23.801	23.990	0.9918	23.767	26.714	0.8897
Phenylalanine (Phe)	27.222	27.300	0.9972	26.132	26.969	0.9690
Proline (Pro)	19.491	19.756	0.9866	19.062	20.793	0.9168
Serine (Ser)	15.696	15.792	0.9940	15.660	17.719	0.8838
Threonine (Thr)	19.359	19.494	0.9931	19.255	21.330	0.9027
Tryptophan (Trp)	32.253	32.478	0.9931	29.774	29.976	0.9993
Tyrosine (Tyr)	28.473	28.562	0.9969	26.112	27.698	0.9427
Valine (Val)	21.752	21.885	0.9939	21.687	24.365	0.8901

As can be seen in [Table 6](#), removing the carbon and nitrogen atoms has a significant impact on the Steiner ratio. In most cases, the ρ for each acid dramatically drops to around $0.90 \pm 2\%$. This underscores the significant Steiner role of the carbon and nitrogen atoms.

In [Figures 34 and 35](#) on the right, the perturbed SMT solutions are comparable to the Steiner tree topology of the alanine and methionine native structures on the left in these respective figures. The algorithm roughly located new Steiner points in the locations abandoned by the carbon and nitrogen atoms. This further emphasizes the role of the Steiner tree and the Steiner ratio as a lower bound on the overall MEC topology since in all cases, when the amino acids were re-optimized, a better lower bound on the Steiner tree was realized.

Another interesting thing is that the actual length of the Steiner-tree in the perturbed structures SMT' is very close to the Steiner-tree length when the carbon and nitrogen atoms are included in the acid. In fact, in all cases, the $SMT' \leq SMT$ of the unperturbed structures in [Table 3](#). This lower bound is due to Maxwell's theorem.

This presence of the \mathcal{C} and \mathcal{N} atoms will increase the overall Steiner network length since the forces in the amino acids are not all uniform. Only for the arginine acid was the lower bound not very tight, i.e., the perturbed Steiner-tree length is much lower than the unperturbed structure. In [Fig. 37](#), it is seen that there is

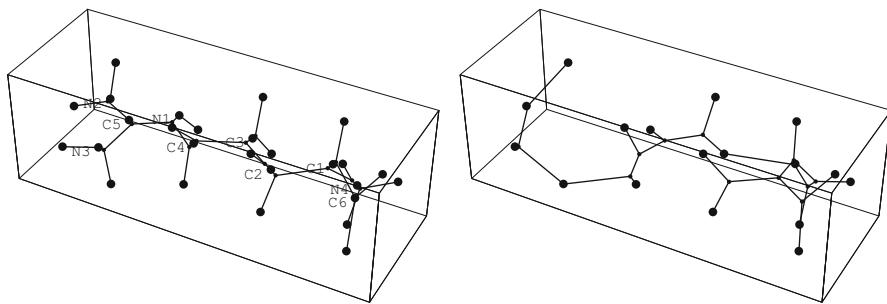

Fig. 37 Native arginine SMT (*left*) and perturbed SMT (*right*)

a dramatic change in the topology of the SMT from the native to the perturbed structure.

The Steiner points as generated in the acids without the carbon and nitrogen atoms are not “exactly” colocated with the coordinates of the displaced carbon and nitrogen atoms. There appear to be three reasons for this occurrence:

1. When the carbon and nitrogen atoms are removed from the amino acid, this reduces the cardinality of the amino acid N , and when the Steiner-tree program adds $N - 2$ Steiner points to make it a FST, the $N - 2$ Steiner points are not necessarily going to equal the number of carbon and nitrogen atoms that were removed. For instance, for alanine, $N = 13$ with four carbon and nitrogen atoms. If one removes the carbon and nitrogen atoms, $N = 9$ and so the Steiner program will try to add seven Steiner vertices rather than the 11 when alanine was unperturbed. Thus, the total number of Steiner atoms will not match the number of carbon and nitrogen atoms, so the Steiner points that are added will not likely coincide, and this might change the network structure dramatically, as it did in some cases.
2. The carbon and nitrogen atoms are functionally very important to each amino acid; they are really part and parcel of the terminal set V (witness the arginine acid in Fig. 37), and their coordinate presence is important to the entire acid structure and function. In Table 6, for the aromatic acids histidine, phenylalanine, tryptophan, and tyrosine, the MST' of the perturbed acid structure is below the SMT value of the unperturbed, which makes no sense, so removing the carbon and nitrogen atoms fundamentally changes the minimal-length network structure. This can probably best be seen in Fig. 38, with the amino acid tryptophan. The presence of the indole ring structure greatly affects the Steiner tree, because the carbon atoms are in the center part of the ring, and without them, the Steiner tree gravitates to the hydrogen atoms.
3. The forces in the amino acids are not all uniform, and this feature will cause variations in Maxwell’s theorem, so that the Steiner coordinates will likely be slightly different. The actual closeness of the Steiner lengths before and after the removal of the carbon and nitrogen atoms attests to these differences in Table 6.

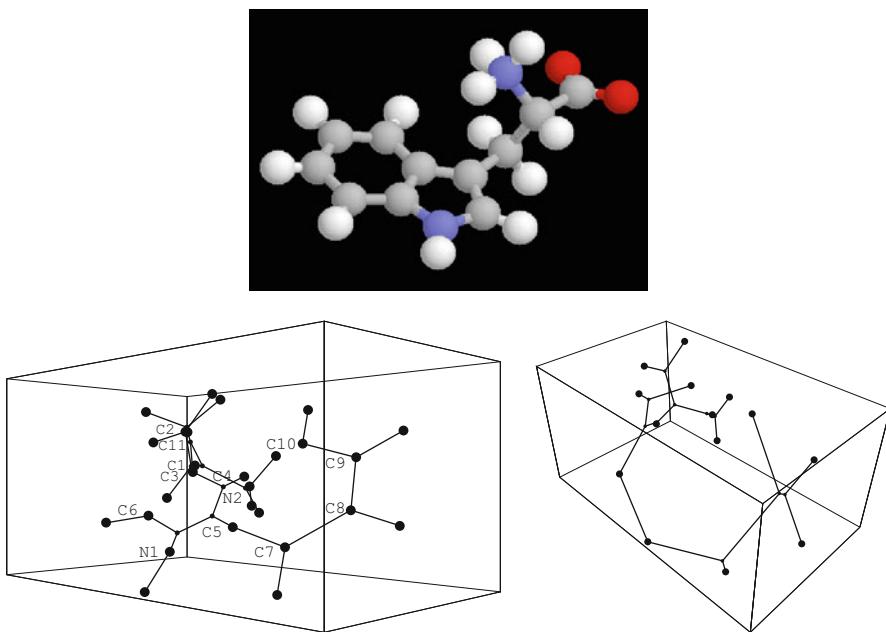

Fig. 38 Native tryptophan (*top*), Steiner (*left*), and perturbed structure (*right*)

Thus, as shown, the carbon and nitrogen atoms within the amino acids act as Steiner points in the chemical structure. What is needed here is to examine the Steiner role of the carbon and nitrogen atoms in the secondary structure of the proteins. In the experiments that follow, the perturbation experiments will be measured by programs that calculate the energies in the proteins. Thus, the importance of ρ and the energies in the proteins that give rise to the structures in 3-D are being conjoined.

7 Secondary Structure

The secondary structure of a protein is a linked sequence of rigid peptide groups; see Fig. 39 as described in [82]. Thus, as the amino acids are linked together across the peptide bond, and a water molecule is eliminated. As the amino acids are strung together, they are connected together by the peptide bond planes, which in effect are planar Steiner trees themselves. The geometry of the peptide bond planes is very important from the perspective of Steiner-tree modeling of the proteins. A chemical schematic diagram appears in Fig. 40. Figure 41 illustrates the three-dimensional orientations possible with two rigid amide planes and the two degrees of freedom based on the torsion angles Φ and Ψ they maintain, while Fig. 39 illustrates the typical conjoining of the amino acids in a protein with the amide planes and side

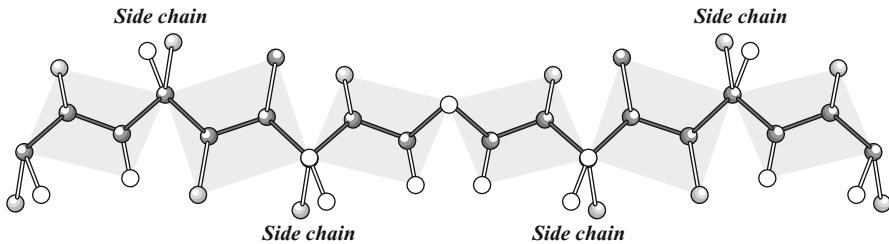

Fig. 39 Network of amide planes in a protein

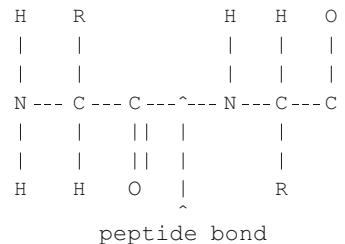

Fig. 40 Chemical diagram of amide planes in a protein

chains. That the rigid planes are strikingly similar to the SMT solution for $N = 4$ in E^2 is quite remarkable. For an instance of $N = 4$, see the right-hand illustration in Fig. 32.

To explore this further, what types of forces are at work in these proteins needs to be demonstrated. In protein modeling, the potential energy objective function often used to measure the MEC is the following, where K_{b_i} , K_{θ_i} , A_{ij} , B_{ij} , and ϵ are adjustable weights; see [22]. This potential energy objective function is based on the theoretical molecular mechanical force field model used to model most molecular structures; see [51]. It is interesting to see that the objective function is a sum of nonlinear terms with little interaction between the terms. The fact that the function is separable is of some debate, as discussed in [28]:

$$\begin{aligned}
E_{tot} = & \sum_i K_{b_i} (b_i - b_0)^2 && \text{bond lengths } [E_{bs}] \\
& + \sum_i K_{\theta_i} (\theta_i - \theta_0)^2 && \text{bond angles } [E_{ab}] \\
& + \sum_i K_{\tau_i} (\cos(3\tau_i - \gamma_0)) && \text{torsion angles } [E_{tor}] \\
& + \sum_i \sum_j A_{ij} d_{ij}^{-6} + B_{ij} d_{ij}^{-12} && \text{van der Waals } [E_{14vdW}] \\
& + \sum_i \sum_j V_i V_j / \epsilon d_{ij} && \text{electrostatic interactions } [E_{14e}]
\end{aligned}$$

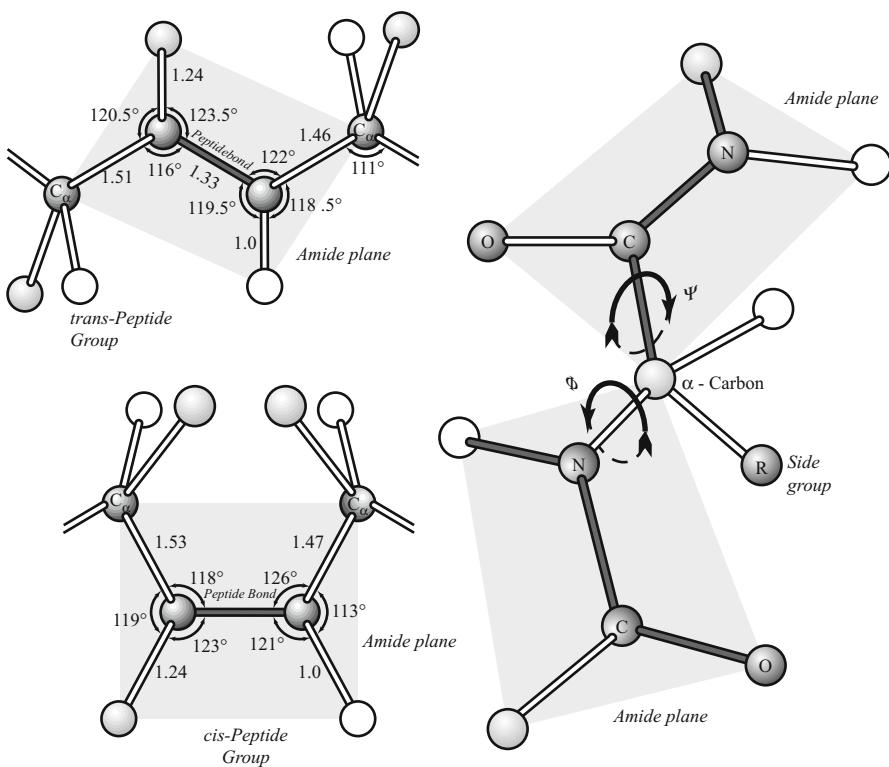

Fig. 41 Peptide or amide plane

where:

E_{bs} : The first term is the sum of energies arising from bond stretching or compression beyond the optimum bond length, and b_i and b_0 are the actual equilibrium bond lengths.

E_{ab} : The second term is the sum of energies for angles that are distorted from their optimum values, and θ_i and θ_0 are the equilibrium bond angles.

E_{tor} : The third term is the sum of the torsional energies that arise from rotations about each respective dihedral angle, and τ_i and γ_0 are the torsion angles.

E_{14vdW} : The sum of energies due to van der Waals interactions.

E_{14e} : The final term is for the electrostatic interactions.

The resulting geometry of the secondary structures can either be an alpha-helix, a beta sheet, random coils, or combinations of these structures. In this next part of the chapter, the results for modeling of collagen, silk, and myosin data sets will be reexamined to see how robust they were to changes in the given atom configurations, much as was done for the individual amino acids. If one changes the atomic structure from the PDB and perturbs the bond lengths, bond angles, and torsion angles, what

effects will occur on the Steiner ratio and on the individual terms in the potential energy equation, i.e., stretching energy, bending, torsion, vdw, and electrostatic?

The protocol for the secondary structure analysis was as follows: All the PDB files were downloaded from the Internet; the file names reflect their PDB code. To isolate one or more specific amino acids, such as Asp25 used in the HIV-1 protease experiments, the PDB file was read into Microsoft Word, and the text was edited. The PDB file could then be imported into [14] or read directly by Sculpt, which were the two programs used to evaluate the individual energies in the proteins. The atomic coordinates of the atoms were systematically perturbed within the proteins by separately changing (a) bond length, (b) bond angles, and (c) dihedral angles. Sculpt was used only to identify the amino acids in the active site fragment that was of interest in using the “tug” function, which allows one to change the location of single atoms; see [78]. Chembuilder calculated the energy values without the hydrogens. Steiner files were created by reading the PDB files into Word and creating a new document with the desired coordinates.

7.1 Collagen

Collagen consists of three polypeptide chains woven together in a triple helix structure, much like the *R*–sausage; see Fig. 42 [57]. Collagen contains 33 % Gly, 33 % proline and hydroxyproline, and 33 % Lys. The repeating unit is $(Gly - X - Y)_n$, where Y is Pro or HyPro. Lys is in position X . Glycine must be every third residue; see [26]. Each polypeptide chain in the collagen structure contains around

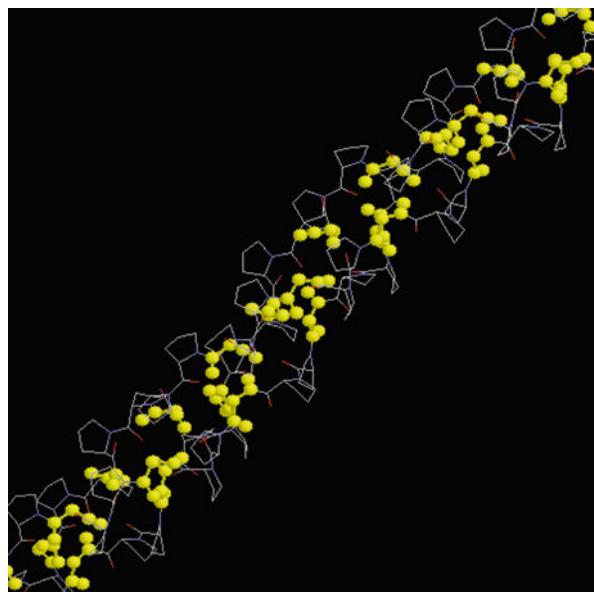

Fig. 42 Collagen structure

1,000 amino acids. The collagen helix is fully extended, unlike the alpha-helix, so it is much more rigid and is not as flexible as the alpha-helix; see [82].

Collagen is the most abundant protein in vertebrates, and it also occurs in invertebrate species in bone, skin, tendon, cornea, and basement membrane and is a rigid, strong *connective* ligament for transmitting the structural forces in these tissues; see [56] and [26]. That collagen is the *connective* network for transmitting structural forces in human and animal tissues is remarkable when you compare this with the mathematical properties and objective of the geometric Steiner problem and the recent discussion of Maxwell's theorem. Collagen is a natural implementation of the Steiner network problem.

Many, many perturbation experiments were carried out. A sample of the experiments appears in Table 7. In these experiments, since $N \leq 13$, the algorithm was able to converge to the optimal solution in a reasonable amount of running time. What can be seen in the comparison of results in Table 7 for the data set from [15] is that the Steiner ρ for the perturbed collagen structure decreased in value and the energy of the perturbed structure increased in value: from a $\rho = 0.996725$

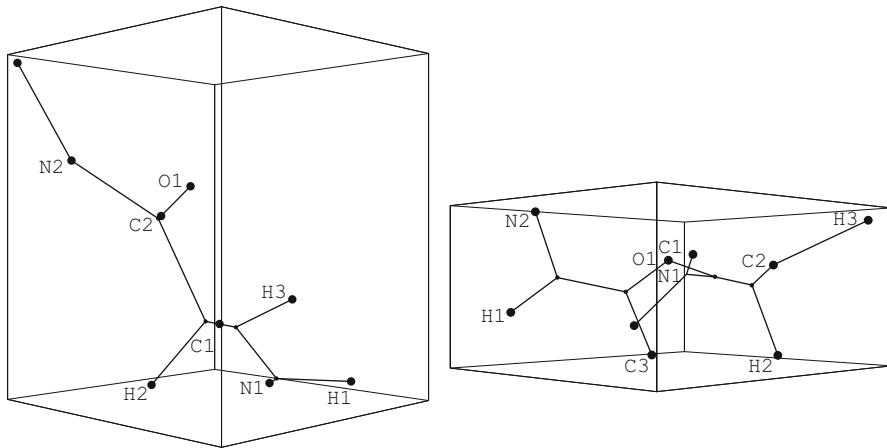

Fig. 43 Native collagen (*left*) perturbation (*right*) SMT

with a total MEC energy = 741.7761 kcal to a $\rho = 0.937688$ and a total MEC energy = 1,004.6121 kcal. Stretching, bending, and van der Waals energy levels increased in the perturbed residue. The experiment is based on systematically perturbing the atomic coordinates of the fragments in 3-D, as described in the protocol above. Since the terminal vertex set is small, the results are optimal from the Steiner algorithm. Figure 43 and Table 7 illustrate the before and after of the perturbation of the collagen fragment. Figure 43 illustrates the two data sets of Table 7. One can see that in the perturbed structure, different Steiner points are necessary, and the geometry of the Steiner tree is vastly different than the native structure.

This is what should be expected, i.e., that the minimum energy levels increase in the perturbed structure under stretching and rotation transformations. In Table 7, the Steiner points corresponding to the terminal vertices are marked with boldface coordinates. One may wonder why more Steiner points did not show up as nitrogen and carbon atoms, but this is probably due to the fact that the atoms were randomly selected within the collagen polypeptide chain, and the carbon and nitrogen atoms sometimes are acting as leaf vertices V in the chain rather than acting as true Steiner points.

7.2 Silk

This second structural protein is one of the most thoroughly studied proteins, called Fibroin, and is the material of silk; see [26] and [82]. The silk protein is a structural protein used by insects and spiders to create cocoons, webs, nests, etc. The peptide chains are arranged in antiparallel β -pleated structures in which the chains extend parallel to the fiber axis; see [82].

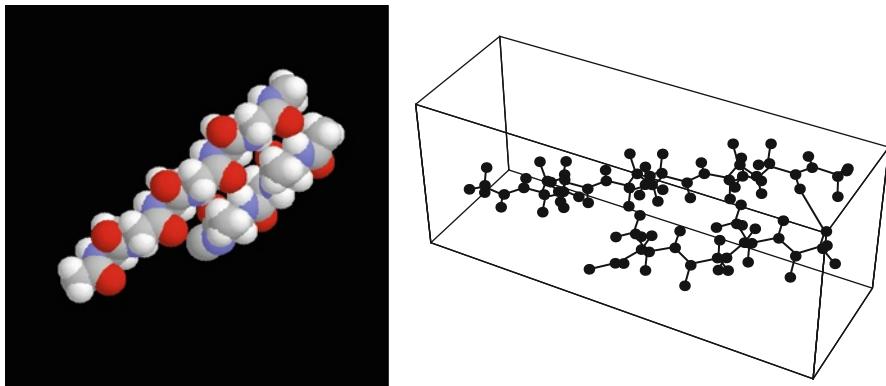

Fig. 44 Silk protein space-fill (*left*) and Steiner tree $n = 99$ (*right*)

Fibroin contains large amounts of glycine, alanine, tyrosine, and serine, as well as small amounts of other amino acids. The repeating elements of fibroin are $(Gly - Ser - Gly - Ala)_n$. Gly extends on one side of the sheet, Ala and Ser on the other, much as depicted in Fig. 44.

Again, as in the collagen results based on the data from [37], the perturbation of the bond lengths, bond angles, and torsion angles of the silk atoms lowers the ρ so improvements in the length of the Steiner tree can be made, yet these improvements in length cause an increase in the potential energy equation. The results contained in Table 8 are optimal.

Thus, once again, if a protein in the PDB is a MEC, the Steiner ratio should be close to ≈ 1.00 , and the carbon and nitrogen atoms should all be acting as Steiner-points. In this sense, Steiner-tree properties act as a very good evaluation tool for protein conformation.

To be more specific:

- ρ appears to vary inversely with bending energy (bond angles).
- ρ appears to be independent or insignificantly affected by stretching energy (bond length).

7.3 Myosin

Myosin occurs in muscle and, together with the protein actin, provides the catalytic and structural properties and mechanism to accommodate and transfer the structural forces within muscle; see Fig. 45. To produce force, cross-bridges from the myosin filaments associate with the actin [49] filament then rotate slightly to pull the filaments across each other (much like the oars of a rowboat pull across the water); see [1]. During the myosin–actin interaction, the overall effect is the contraction of the muscle.

Since myosin is basically a catalytic protein with a globular and alpha-helix structure, it is an interesting protein to examine from a Steiner-tree point of view. The two previous proteins, collagen and silk, are considered structural proteins, whereas because myosin is catalytic, one would not necessarily think that the Steiner-tree properties found earlier with the structural proteins in collagen and silk would carry over, but they do.

As one can see again from the experimental results in Table 9, perturbations in the myosin atoms decrease the Steiner ρ value and increase the potential energy, except when the stretching is significant, as is the case here. Notice that the stretching increased the energy significantly and also the ρ value. In the limit, if all the myosin atoms were in a straight-line, then $\rho \rightarrow 1$. Also notice that the overall length increased for the SMT beyond the SMT of the native structure when the bonds were stretched. It appears that changing the bond stretching, bond angles, and torsion angles all individually and simultaneously affect the Steiner ratio and the potential energy equation.

So at this point in our journey, the following issues become important where the quantitative relationship between the Steiner ratio and the various energies of the amino acids in more detail. To be more specific:

- ρ appears to vary inversely with bending energy (bond angles).
- ρ appears to be independent or insignificantly affected by stretching energy (bond length).
- ρ appears to vary inversely with van der Waals energy.
- ρ may vary inversely with torsional energy.

7.4 HIV-1 Protease

Finally, the last secondary structure experimental evaluation involving HIV-1 protease is presented. HIV-1 protease is a catalytic protein (enzyme) that functions to cleave other proteins that are necessary to the life cycle of the HIV-1 virus. This cleavage serves to render these proteins functional. Therefore, HIV protease is absolutely essential to the survival and proliferation of the virus. For this reason, HIV protease has recently come under close scrutiny. In fact, one of the most popular drug therapies in the United States is a combination of protease inhibitors and another important enzyme, reverse transcriptase, inhibitors. Inhibitors are simply any chemical species or molecule that binds to the protein, either directly in the catalytic site or another site, and disrupts the proper function of the protein. Upon binding of any inhibitor (or the molecules that are involved in the reaction catalyzed by the enzyme), the conformation of the enzyme changes due to the forces involved in binding. A major obstacle to inhibitor therapy is mutation. Once an individual had been treated with a protease inhibitor, the viruses that have “normal” (wild-type) proteases are killed since the protease is no longer able to cleave the other essential viral proteins. However, there exists in the virus population mutants that have proteases that deviate by one to several amino acids. Despite the difference, the mutant enzyme may still be functional. In this case, the individual treated with inhibitors may be killing off viruses with the wild-type enzyme, but not viruses with functional mutant enzymes. Therefore, the virus is able to proliferate and continue causing disease. This phenomenon has led to increased attempts to understand and model the different enzyme/inhibitor complexes.

The HIV-1 protease enzyme is a dimeric protein – made up of two identical polypeptide chains referred to as subunits. Each subunit is 99 amino acid residues long. The active site, or the residues that are involved in protein cleavage, is found at the center of protein, symmetric between the two chains. At the bottom of the active site cleft lies two catalytically active Asp residues, Asp25 and Asp125. In these studies, how the binding of different inhibitors affects the conformation of Asp25 and 125 was to be examined, as well as a larger segment of the active site. It was expected that the conformational change induced upon binding of the inhibitors would cause a difference in the ρ values ([Table 10](#)).

Thus, as can be seen in the tables of results:

- *For the Asp25, when bound to different inhibitors, ρ did not significantly vary, $\approx 0.3\%$.*
- *For the active site fragments, again as in the Asp25 experiments, ρ did not significantly vary $\approx 0.3\%$.*

Also the chain binding symmetry is examined. Recall that the active site is symmetric between the two subunits. However, the inhibitors looked at are asymmetric and therefore bind to the two subunits in an asymmetric fashion. It was expected that the asymmetrical binding would cause a difference in ρ between the two subunits. What was found was:

- *For the chain and binding symmetry, ρ varied only between $\approx 0.001\%$ and $\approx 0.2\%$*

*** The Steiner points correspond to an existing atom in the protein structure

The final analysis was a look at mutant enzymes. A mutant enzyme implies that the amino acid sequence of the protein has changed in some way – therefore changing the conformation somewhat. The aim of all of these studies was to determine whether or not these changes in conformation would bring about a change in the value of ρ . It would be of interest to determine the binding energies of the various inhibitors and see if there is a relationship with the ρ value:

- *For the mutants, ρ varied between $\approx 0.01\%$ and $\approx 0.1\%$ of the wild type.*

This would indicate a very slight difference between the conformational changes in binding of the various inhibitors. Thus, in all the HIV protease studies, the Steiner ratio varied little if not at all. This seems to indicate that all the HIV protease/inhibitor complexes were very stable MEC structures.

In the next section, the relationship between the Steiner ratio and the torsion energy in proteins is examined in some detail.

7.5 Steiner Ratio Versus Torsion Energy

What needs to be done in this section is to take a subset of the amino acids and perturb the atomic coordinates and examine how the energy in the acid changes with variations in the torsion angles of the acids. At the same time, the Steiner ratio will be evaluated for the changing torsion angle conformations. If it is true that variations in the torsion angle of the amino acids correlate with an increase/decrease in the Steiner ratio, then the properties of Steiner trees should be a useful approximation to the potential energy function.

In order for this to occur, one can argue that the native state of an amino acid correlates strongly with the minimum energy conformation of the acid. Changes in the torsion energy can then be also measured by the Steiner ratio.

7.5.1 Alanine Torsion Angle Variation

[Figure 46](#) illustrates the variation in torsion energy of alanine with respect to its side-chain torsion angle χ_1 . The energy measures are captured by the software program Chembuilder [14]. Variations in the potential energy curve are plotted with variations in the torsion angle χ_1 . [Figure 46](#) also illustrates the corresponding changes in the Steiner ratio as a function of variations in the torsion angle. From these two plots, it is observed that the Steiner ratio is inversely proportional to the torsion angle.

Why should this be the case? As in Maxwell's theorem, if a structure is a MEC, then perturbations in the Steiner structure will increase the Steiner ratio away from the MEC. The native alanine structure with a staggered conformation (set $\chi_1 = 0^\circ$) achieves the lowest energy value or consequently the highest Steiner ratio, whereas the highest energy value occurs when the conformation is not staggered ($\chi_1 = 60^\circ$). [Figure 47](#) shows the optimal Steiner tree results from the native alanine structure and the highest energy conformation, respectively. As before in the previous section, the planes of the atoms in the twist angles of alanine were utilized.

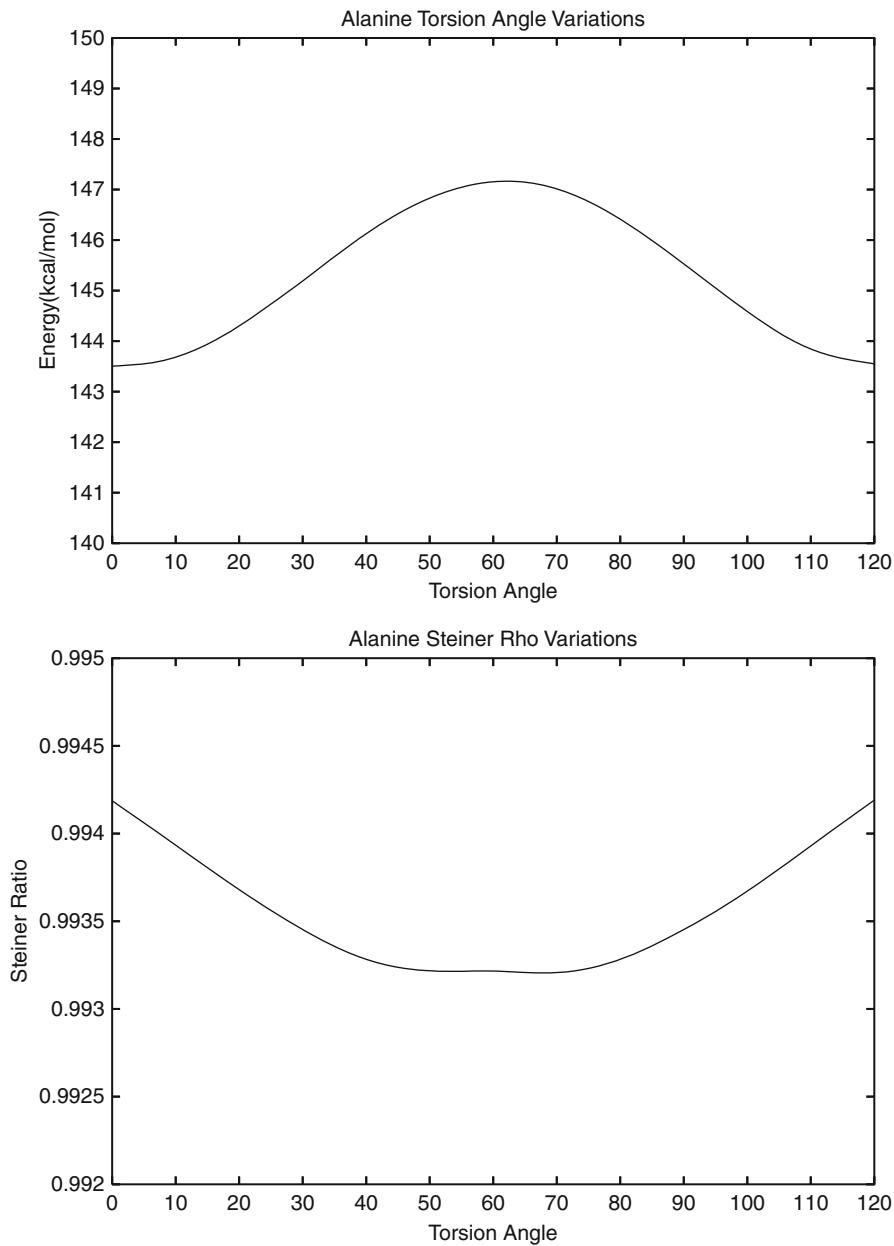

Fig. 46 Alanine torsion energy and Steiner ρ variations

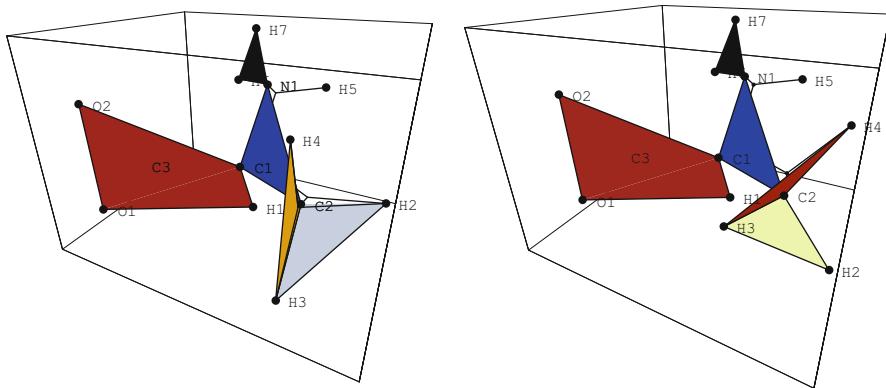

Fig. 47 Ala native conformation ($\chi_1 = 0^\circ$) (left) and MEC (right)

The most obvious difference of the non-perturbed conformation is the twisting of the planes involving the ${}_1H_\beta$, ${}_2H_\beta$, and ${}_3H_\beta$ atoms which results in actually a shorter Steiner tree ($SMT^{0^\circ} = 14.3942$ vs. $SMT^{60^\circ} = 14.3803$) and smaller Steiner ratio ($\rho^{0^\circ} = 0.9942$ vs. $\rho^{60^\circ} = 0.9932$). [Equation 19](#) displays the twist angle matrix for the perturbed Ala when $\chi_1 = 60^\circ$:

$$\begin{aligned}\mathcal{P}_1 &:= \{C_\alpha, N_1, C_2\} & \mathcal{P}_2 &:= \{C_\alpha, H_1, O_2\} \\ \mathcal{P}_3 &:= \{C_2, H_3, H_4\} & \mathcal{P}_4 &:= \{N_1, H_6, H_7\} \\ \mathcal{P}_5 &:= \{C_2, H_2, H_3\}\end{aligned}$$

$$\begin{array}{c|ccccc} \mathcal{P} & 1 & 2 & 3 & 4 & 5 \\ \hline 1 & 0.0 & 90.0 & 60.0 & 60.0 & 60.0 \\ 2 & & 0.0 & \mathbf{33.6} & 60.0 & \mathbf{33.6} \\ 3 & & & 0.0 & 90.0 & \mathbf{2.4} \\ 4 & & & & 0.0 & 90.0 \\ 5 & & & & & 0.0 \end{array} \quad (19)$$

One can see that there are some new plane twist angles of about 33.6° . They were 60° before in the native alanine structure. The value of 2.4° computed by the software program in the right-hand matrix is expected to be approximately zero.

7.5.2 Cysteine Torsion Angle Variation

As with the alanine variations, variations are performed of the torsion angle with cysteine. [Figure 48](#) illustrates the energy variations with respect to χ_1 , while the Steiner ratio still varies inversely proportional to the torsion energy. The plane twist angles for the minimum and maximum energy conformations are also examined in [Eq. 20](#), respectively. The irregular twist angles of $\{36.7^\circ, 54.8^\circ\}$ appear in the maximum energy or minimum Steiner ratio conformation. The tetrahedra and planes defined for Cys after solving for the Steiner minimal tree are as follows:

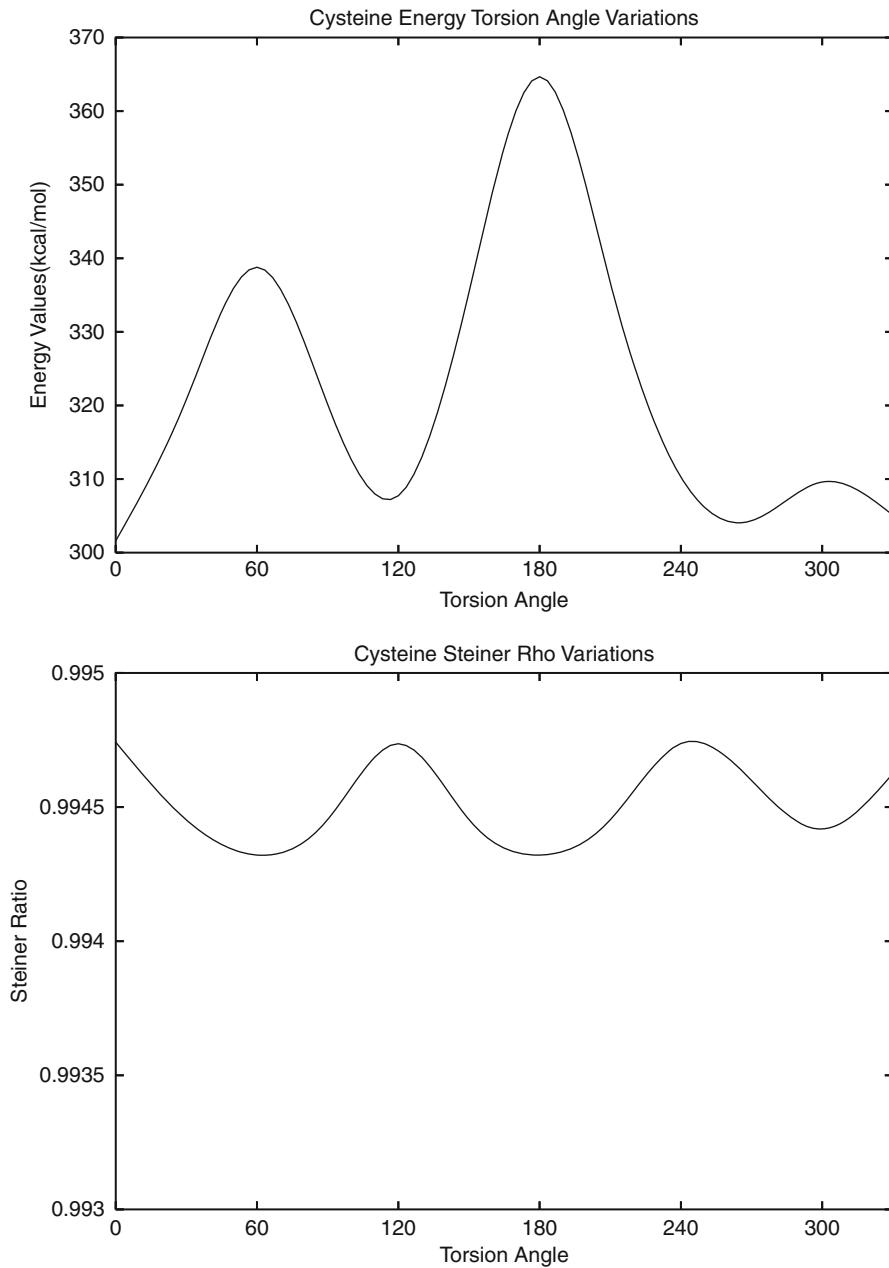

Fig. 48 Cysteine torsion energy and Steiner ρ variation

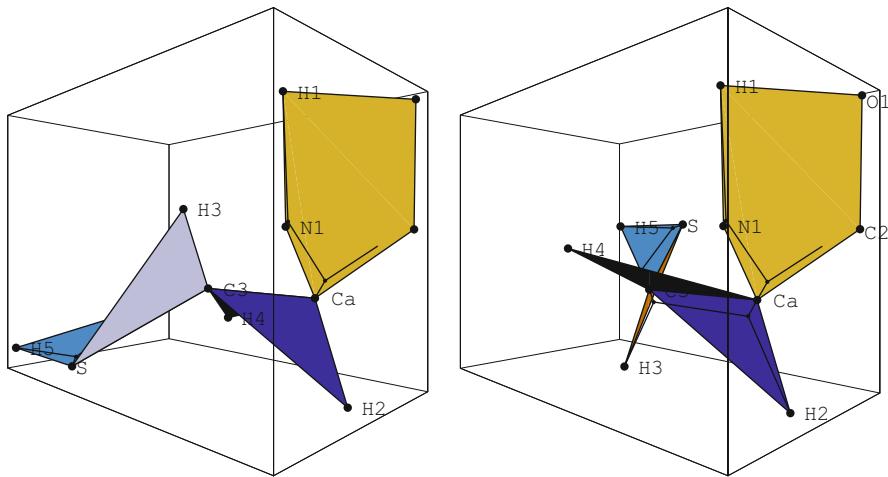

Fig. 49 Cysteine MEC *left* ($\chi_1 = 0^\circ$) and *right* ($\chi_1 = 180^\circ$)

$$\mathcal{T}_1 := \{O_1, O_2, C_\alpha, H_\alpha\}; \mathcal{P}_1 := \{H_\alpha, O_2, C_\alpha\};$$

$$\mathcal{P}_2 := \{C_\alpha, C_\beta, N\}; \mathcal{P}_3 := \{S_\gamma, C_{\beta,1}, H_\beta\};$$

$$\mathcal{P}_4 := \{N, H_1, H_2\}; \mathcal{P}_5 := \{N, H_2, H_3\};$$

\mathcal{P}	1	2	3	4	5	\mathcal{P}	1	2	3	4	5
1	0.0	90.0	60.0	60.0	60.0	1	0.0	90.0	36.7	60.0	60.0
2		0.0	60.0	60.0	60.0	2		0.0	54.8	60.0	60.0
3			0.0	60.0	90.0	3			0.0	54.8	90.0
4				0.0	60.0	4				0.0	60.0
5					0.0	5					0.0

(20)

From the experimental comparison of the two selected amino acids, it is postulated that the torsion energy varies inversely with the Steiner ratio. It is expected that if all the 20 amino acids were examined, a similar result would follow. Thus, if a native amino acid achieves a minimum energy conformation, variations in the torsion angle should be captured by the Steiner ratio denoted through its ρ value (Fig. 49).

7.6 Theoretical Versus Empirical ρ Values

Table 11 shows the ideal ρ_t values for all the 20 amino acids. This represents the best ρ values found so far with the computing capability presently available. While

^aThose acids marked with *a* are optimal structures^bThose acids where some of the C, N atoms are leaf vertices^cEmpirical ρ_e value is computed optimal for all acids except Trp^dEstimated standard deviation

not all the ρ_t values are optimal, they represent a best upper bound on the Steiner ratio, so they should still be useful benchmarks.

Table 11 also includes the empirical ρ_e values statistically obtained from thousands of randomly selected amino acids from the PDB. The standard deviation σ of the empirical data sets is also included in the table, and one recognizes that it is indeed very small. The mean and standard deviation will be useful in comparing whether the Steiner ρ_e value for certain PDB files is unusual or not. All 20 amino acids have been analyzed, and a sample result with basic statistics and a histogram of the sample acid is presented in [Fig. 50](#). These sample results for all the amino acids are also available from the authors.

In reading the last two columns of **Table 11**, the $S' \subseteq S$ column represents the subset of Steiner points that correspond to the given carbon and nitrogen atoms in the amino acid, and the last column represents the combined number of carbon and nitrogen atoms within the amino acid.

With certain exceptions, the empirical ρ_e values are larger than the theoretical values since the theoretical ρ_t values include the hydrogen atoms. The exceptions are interesting because they largely have some of the carbon and nitrogen atoms as

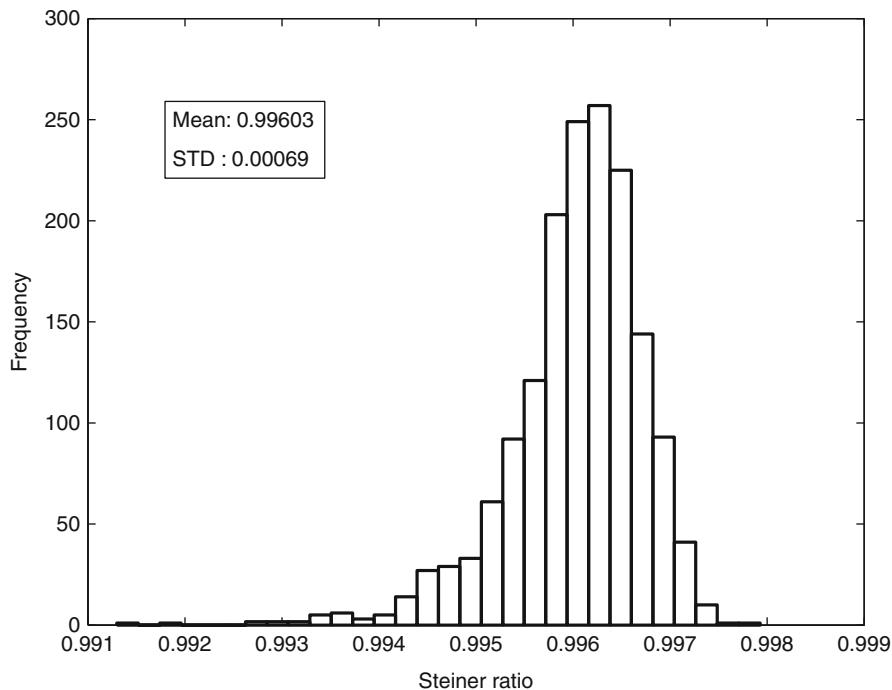

Fig. 50 Histogram of Ile empirical ρ values. Coordinates of 1,628 Ile residues are randomly sampled from the PDB, and those Steiner rho values are calculated individually. The average and standard deviation of Ile empirical rho values are also provided in the *inset box*

leaf vertices in the Steiner tree. The hydrogen atoms add more structure and can greatly affect the Steiner ratio. The empirical ρ_e value along with the theoretical measure ρ_t will be used as scoring markers in the next section to compare native and decoy protein structures.

7.7 Protein Fold Recognition Using Steiner Ratio

In order to test the Steiner ratio as a surrogate for the potential energy function, folded and misfolded protein data sets were examined. They were obtained from the Web site <http://dd.stanford.edu>. There are a total of 26 different data sets with folded and misfolded conformations. The given native folded structures were radically misfolded via a computer program where the main chains were swapped between folds and the side chains were annealed using a Monte Carlo process [46].

7.7.1 Native Versus Decoy Experiments

What is important here is to realize that in the misfolded proteins, all the detailed energy values in the potential energy equation such as the bond lengths, bond angles,

and torsion angles are being perturbed so that the Steiner ratio varies with all these quantities. While only a systematic analysis of the inverse relationship of the Steiner ratio with the side-chain torsion angle was carried out, it appears that, in general, the Steiner ratio varies inversely with the potential energy of the entire system.

Can the Steiner ratio ρ be used as a predictive measure? As a first detailed step, let us select three of the decoy data sets and compare the first three residues of the native with the decoy data sets. As one can see in [Table 12](#), when the residues 1–3 are examined for these three native proteins and their misfolded decoys, the ρ values for the decoys are mainly much higher than they should be for the native proteins. The energy computations are carried out for each structure using Swiss-Pdb Viewer, in which computations have been done in vacuo with the GROMOS96 43B1 parameter set without reaction field [44]. In all cases, each misfolded protein segment (dipeptide or tripeptide in this context) has a higher Steiner ratio but lower energy value than the corresponding folded one. This inverse relationship is as expected with the Steiner ratio and the energy within the protein as was demonstrated earlier in this chapter. A detailed printout of the experimental results for the first comparison of “1bp2” and “1bp2on2paz” is provided in [Table 12](#).

The energy comparison in [Table 12](#) probably misleads one to consider the misfolded decoy as the best candidate for the native one in the protein-folding prediction based on the energy minimization. This is counterintuitive to the belief that the native-folded protein abides by the minimum energy conformation, implying that the potential energy functions, most of which have been defined in empirical manner, are not perfect enough to be used as a predictive tool for the

protein-folding problem. Alternatively, the Steiner ratio in this experiment shows the consistent result such that the ρ value for a native protein segment is much closer to the ideal value than that of the corresponding misfolded one. Here the ideal Steiner ratio is computed by averaging the ρ values of amino acids involved.

What is important here is to realize that the misfolded proteins vary the bond lengths, bond angles, torsion angles, van der Waals energies, and all the factors in the potential energy equation, so that the Steiner ratio varies with all these quantities. While only a systematic analysis of the inverse relationship of the Steiner ratio with the torsion angles has been done, it appears that, in general, the Steiner ratio varies inversely with the potential energy of the entire system. A detailed printout of the experimental results for the first comparison of *Ibp2* and *Ibp2on2paz* is provided in [Table 13](#).

At this point, all the amino acids of all the 26 decoy data sets and their native counterparts are compared. The Steiner ratios of each residue in both native and decoy structures are calculated. These observed rho values are compared with empirical and theoretical ρ values, respectively. [Table 14](#) presents the resulting root-mean-square-difference (RMSD) values of all 26 data sets. Decoy structures have significantly lower RMSD values with respect to empirical ρ values, while the RMSD values of native structures are slightly lower than those of decoy structures with respect to theoretical ρ values. This indicates that the native Steiner ratio is much closer to the theoretical (ideal) value than the decoy Steiner ratio is. [Figure 51](#) illustrates one sample experiment, namely, “1bp2” and its decoy structure “1bp2on2paz” isolated from the entire set of the native and decoy Steiner values for all 123 residues of this sample data set.

Table 14 RMSD of decoy sets with respect to empirical and theoretical Steiner ratios

^a 26 decoy sets are renamed in alphabetic order for convenience only

One may think of Fig. 51 as a statistical signature of the empirical and theoretical ρ values one should expect. The empirical ρ value acts as an upper bound of the Steiner ratio value of the native protein. Notice that the native Steiner ratio underestimates the decoy Steiner ratio and the decoy structure indicates a lower energy value (higher ρ) than that of the native structure. The experiment underscores the inverse relationship between the Steiner ratio and the energy level. Thus, the Steiner ratio for each individual acid in the PDB structure is a useful indicator of the energy levels of the entire protein.

An additional hypothesis is that it appears that the native structure more closely matches the theoretical ρ_t value, since actually the native structure has the hydrogens even though they are not recorded in the PDB structure. Therefore, while not a perfect measure, the theoretical Steiner ρ value by itself becomes a useful benchmark to distinguish correctly folded structures.

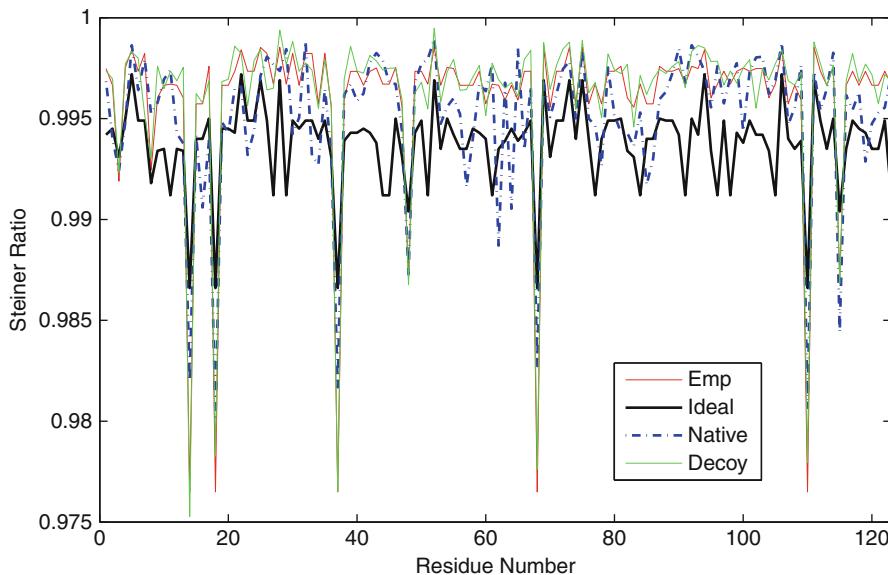

Fig. 51 Graphs of native and decoy Steiner ratios of data set A (1bp2 and 1bp2on2paz). The empirical ρ value acts as an *upper bound*, while the theoretical (ideal) ρ value is a *lower bound* of the Steiner ratio of the native protein. Decoy Steiner values are much closer to the empirical plot. Native Steiner values largely follow the theoretical plot with some marginal error

7.7.2 Experimental Error Detection

Besides the comparison of the native and decoy data structures, it appears that computing and graphing the Steiner ratio of all the amino acids in a native protein deposited on the PDB could indicate whether the PDB structure is a true accurate indicator of the native structure. The graphs of data sets C ("1fdx" and its decoy "1fdxon5rxn") and U ("2paz" and its decoy "2pazon1bp2"), although the latter are not shown, are examined in the comparison of the native and decoy data sets (see Fig. 52). Both proteins are interesting because they have statistical outliers that indicate the Steiner ratio for the amino acids in the PDB data are probabilistically unrealistic.

Using a standard normality test, Table 15 compares the ρ values of the observed amino acids which are outliers and computes the probability that the observed amino acid ρ values would occur. In all instances, the probabilities are essentially zero. Even if one assumed that the theoretical values were distributed in a similar manner as the empirical ρ values, the probabilities of the observed conformation would still be essentially zero.

Thus, the computed ρ values should be a very useful measure to indicate suspected conformational outliers or abnormalities in a protein structure obtained experimentally.

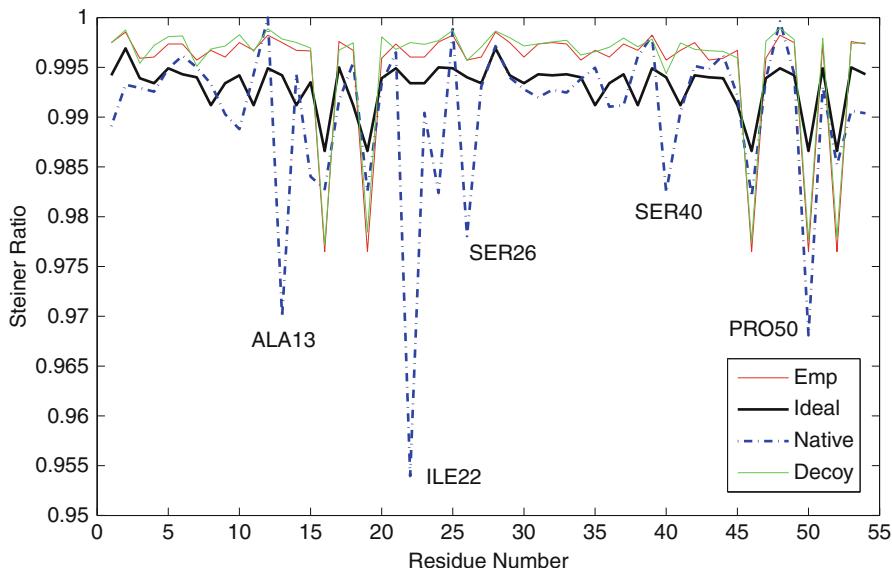

Fig. 52 Graphs of native and decoy Steiner ratios of data set C (1fdx and 1fdxon5rxn). Residue type and number of the five largest outliers are indicated. By comparison of the Steiner ratio, one can detect abnormalities of the native structure corrupted by experimental noise

Table 15 Statistical comparison of outliers in proteins

Protein C	Observed $\rho_{e'}$	ρ_t	ρ_e	σ	Z-score ^a
ALA13	0.969951	0.9942	0.99748	0.00099	-27.807
ILE22	0.953953	0.9934	0.99603	0.00069	-60.981
SER26	0.978052	0.9940	0.99573	0.00100	-17.678
SER40	0.982450	0.9940	0.99573	0.00100	-13.280
PRO50	0.968086	0.9866	0.97649	0.00209	-4.021
Protein U	$\rho_{e'}$	ρ_t	ρ_e	σ	Z-score
MET84	0.982605	0.9918	0.99245	0.00144	-6.837
SER104	0.974016	0.9940	0.99573	0.00100	-21.714

^aFrom the standardized normal distribution approximation of the probability distribution of the various acids, one can compute the Z-score $Z = \frac{x-\mu}{\sigma}$ which represents the probability of the particular acid having a ρ value below the empirical ρ_e value and in particular $P(X \leq a) = \Phi(\frac{a-\mu}{\sigma})$ of the standardized normal distribution. By convention, a Z-value of $Z \leq -3.4$ or less corresponds to essentially a zero probability value

8 Overall Protein Results

In order to summarize the results for protein modeling, let us posit the following:

Conjecture For an arbitrary sequence of n -amino acid residues denoted by $\{\rho_1, \rho_2, \dots, \rho_n\}$ within a protein chain, the smallest Steiner ratio is bounded below by the smallest Steiner ratio of the amino acid residues in the chain, i.e., $\rho_{Protein} \geq \min\{\rho_1, \rho_2, \dots, \rho_n\}$.

Obviously, if there are impurities and other unknowns acting within the protein, then perhaps this conjecture may not hold. Ideally, the property should hold because of the nature of assembling together the amino acids in the rigid peptide bond planes and the bottleneck property of most serial systems. The reasons why the conjecture should hold are:

- The Steiner-tree properties, i.e., ρ , give a dimensionless quantitative measure of the individual amino acids as well as the secondary structure of proteins. This is an important signature for each amino acid as well as for each protein.
- Steiner trees seek to find the shortest network possible. In Maxwell's theorem, this shortest network is equivalent to the minimum energy configuration that minimizes the potential energy in a system with uniform forces at each terminal vertex. Unfortunately, the forces are not all uniform in a protein, so the SMT can yield only a lower bound on the MEC topology. Especially in the amino acid experiments, however, it has been shown that this lower bound length for each amino acid is very tight.
- From the amino acid experiments of this chapter, the carbon and nitrogen atoms all act as Steiner points. This occurred in the unperturbed as well as in the perturbed acid structures. As displayed in Fig. 39 along with the previous experimental studies of secondary structure in [76], the rigid peptide bond planes are interconnected Steiner trees, and they maintain a constant Steiner ratio, so the only difference in ρ for a protein is due to the side chains.

This is felt to be significant, since in the secondary, tertiary, and quaternary evaluation of proteins, the carbon and nitrogen atoms should all be acting as Steiner points. It would also seem to indicate that, in an arbitrary sequence of amino acids, the Steiner ratio of the entire protein cannot be smaller than the Steiner ratio of the amino acid residues in the chain.

Future research will focus on studying larger systems of atoms that actually incorporate a good amount of secondary structure instead of just focusing on single amino acids. Still, however, improvements in the Steiner-tree algorithm need to be made to allow it to find the optimal solutions for larger N . One facet that may be valuable here for proteins is the regularity of the backbone topology and the knowledge of the topologies of the Steiner structure within each amino acid.

Also, more sophisticated tools and software techniques should be used in order to carry out the perturbations of the locations of the atoms and the measurement of the resultant energies. Finally, exploration of how SMTs can be used more directly to predict and evaluate low-energy conformation structures of proteins in the protein-folding problem should be conducted.

8.1 Other Applications

While the application of E^3 ESMT trees to other fields of science and engineering are speculative at this juncture, some mention of what is already known is worth exploring.

The structure of glass silicates exhibits a similar geometry to the triple helix pattern found with the conjectured optimal configuration for the Steiner problem [54].

As might be expected from what is known of collagen's structural properties, this may be applied to the design of columnar structures and space frame trusses. Buckminster Fuller [38, 60] laid down groundwork in this area, although his viewpoint was not from a Steiner perspective, but simply from the geometry of putting together tetrahedra. Fuller did not know the relationship of the triple helix to the Steiner problem and was simply fascinated by the helical shape when putting the tetrahedra together. He felt that such a regular repeating structure might have some stability characteristics other skeletal structures might not have, but he was not able to realize it in any manner. It would appear from the previous discussion on MECs and Maxwell's theorem that the Steiner coordinates and its network topology are crucial to the stability of the \mathcal{R} -sausage in any structural engineering application.

Of related interest to the above structural system properties includes the design of building systems, i.e., the heating, ventilating, air-conditioning, plumbing, and electrical systems that provide the utilities in normal building construction. Since minimizing overall length [69] tends to be the predominant objective of these building systems, the understanding of the optimal topology of ESMTs should be of major import for this application.

Other areas of science and engineering such as the design of polymers, antenna design (often helical antennas are employed), VLSI, and massively parallel computer network design would seem to be ideal candidates for examining how the ESMT and MEC problems relate, yet no more speculation at this point will be attempted.

9 Conclusion

Many of the properties, algorithmic methodologies, and applications of Steiner trees in E^3 have been collected together in this chapter. While the results so far are very new and just developing, they should give the reader an idea of the potential for Steiner trees for future theoretical and algorithmic research as well as the potential for their applications in science and engineering.

That all theory, methodological approaches (algebraic, geometric, and optimization), and application areas related to MECs and Steiner trees are closely intertwined is both fascinating and compelling. The tools of minimal-length network algorithms should help in the future verification and illumination of computational biological structures and perhaps other problems and applications in science and engineering.

Abstract

Tabu search, also called adaptive memory programming, is a method for solving challenging problems in the field of optimization. The goal is to identify the best decisions or actions in order to maximize some measure of merit (such as maximizing profit, effectiveness, quality, and social or scientific benefit) or to minimize some measure of demerit (cost, inefficiency, waste, and social or scientific loss).

Practical applications in optimization addressed by tabu search are exceedingly challenging and pervade the fields of business, engineering, economics, and science. Everyday examples include problems in resource management, financial and investment planning, healthcare systems, energy and environmental policy, pattern classification, biotechnology, and a host of other areas. The complexity and importance of such problems has motivated a wealth of academic and practical research throughout the past several decades, in an effort to discover methods that are able to find solutions of higher quality than many found in the past and capable of producing such solutions within feasible time limits or at reduced computational cost.

Tabu search has emerged as one of the leading technologies for handling optimization problems that have proved difficult or impossible to solve with classical procedures that dominated the attention of textbooks and were considered the mainstays of available alternatives until recent times. A key feature of tabu search, underscored by its *adaptive memory programming* alias, is the use of special strategies designed to exploit adaptive memory. The idea is that an effective search for optimal solutions should involve a process of flexibly responding to the solution landscape in a manner that permits it to learn

appropriate directions to take along with appropriate departures to explore new terrain. The adaptive memory feature of tabu search allows the implementation of procedures that are capable of searching this terrain economically and effectively.

1 Introduction

Faced with the challenge of solving hard optimization problems that abound in the real world, classical methods often encounter great difficulty. Vitally important applications in business, engineering, economics, and science cannot be tackled with any reasonable hope of success, within practical time horizons, by solution methods that have been the predominant focus of academic research throughout the past three decades (and which are still the focus of many textbooks).

The meta-heuristic approach called tabu search (TS) is dramatically changing our ability to solve problems of practical significance. Current applications of TS span the realms of resource planning, telecommunications, VLSI design, financial analysis, scheduling, space planning, energy distribution, molecular engineering, logistics, pattern classification, flexible manufacturing, waste management, mineral exploration, biomedical analysis, environmental conservation, and scores of others. In recent years, journals in a wide variety of fields have published tutorial articles and computational studies documenting successes by tabu search in extending the frontier of problems that can be handled effectively – yielding solutions whose quality often significantly surpasses that obtained by methods previously applied. **Table 1** gives a partial catalog of example applications. A more comprehensive list, including summary descriptions of gains achieved from practical implementations, can be found in Glover and Laguna [31]. Recent TS developments and applications can also be found in the Tabu Search Vignettes section of the web page <http://spot.colorado.edu/~glover>.

2 Tabu Search Features and Relevance

A distinguishing feature of tabu search is embodied in its exploitation of adaptive forms of memory, which equips it to penetrate complexities that often confound alternative approaches. Yet we are only beginning to tap the rich potential of adaptive memory strategies, and the discoveries that lie ahead promise to be as important and exciting as those made to date. The knowledge and principles that have emerged from the TS framework give a foundation to create practical systems whose capabilities markedly exceed those available earlier. At the same time, there are many untried variations that may lead to further advances. A conspicuous feature of tabu search is that it is dynamically growing and evolving, drawing on important contributions by many researchers.

Table 1 Illustrative tabu search applications

<i>Scheduling</i>	<i>Telecommunications</i>
Flow-time cell manufacturing	Call routing
Heterogeneous processor scheduling	Bandwidth packing
Workforce planning	Hub facility location
Classroom scheduling	Path assignment
Machine scheduling	Network design for services
Flow shop scheduling	Customer discount planning
Job shop scheduling	Failure immune architecture
Sequencing and batching	Synchronous optical networks
<i>Design</i>	<i>Production, inventory and investment</i>

Coordination of energy resources	All-or-none networks
Space station construction	Bilevel programming
DNA sequencing	Multi-objective discrete optimization
Circuit cell placement	Hyperplane splitting
Computer aided molecular design	General mixed integer optimization

2.1 General Tenets

The word *tabu* (or *taboo*) comes from Tongan, a language of Polynesia, where it was used by the aborigines of Tonga island to indicate things that cannot be touched because they are sacred. According to Webster's Dictionary, the word now also means "a prohibition imposed by social custom as a protective measure" or of something "banned as constituting a risk." These current more pragmatic senses of the word accord well with the theme of tabu search. The risk to be avoided in this case is that of following a counterproductive course, including one which may lead to entrapment without hope of escape. On the other hand, as in the broader social context where "protective prohibitions" are capable of being superseded when the occasion demands, the "tabus" of tabu search are to be overruled when evidence of a preferred alternative becomes compelling.

The most important association with traditional usage, however, stems from the fact that tabus as normally conceived are transmitted by means of a social memory which is subject to modification over time. This creates the fundamental link to the meaning of "tabu" in tabu search. The forbidden elements of tabu search receive their status by reliance on an evolving memory, which allows this status to shift according to time and circumstance.

More particularly, tabu search is based on the premise that problem solving, in order to qualify as intelligent, must incorporate *adaptive memory* and *responsive exploration*. The adaptive memory feature of TS allows the implementation of procedures that are capable of searching the solution space economically and effectively. Since local choices are guided by information collected during the search, TS contrasts with memoryless designs that heavily rely on semirandom processes that implement a form of sampling. Examples of memoryless methods include semi-greedy heuristics and the prominent "genetic" and "annealing" approaches inspired by metaphors of physics and biology. Adaptive memory also contrasts with rigid memory designs typical of branch and bound strategies (It can be argued that some types of evolutionary procedures that operate by combining solutions, such as genetic algorithms, embody a form of implicit memory. Special links with evolutionary methods, and implications for establishing more effective variants of them, are discussed in [Sect. 6](#)).

The emphasis on responsive exploration in tabu search, whether in a deterministic or probabilistic implementation, derives from the supposition that a bad strategic choice can yield more information than a good random choice. In a system that uses memory, a bad choice based on strategy can provide useful clues about how the strategy may profitably be changed (Even in a space with significant randomness, a purposeful design can be more adept at uncovering the imprint of structure).

Responsive exploration integrates the basic principles of intelligent search, that is, exploiting good solution features while exploring new promising regions. Tabu search is concerned with finding new and more effective ways of taking advantage of

the mechanisms associated with both adaptive memory and responsive exploration. The development of new designs and strategic mixes makes TS a fertile area for research and empirical study.

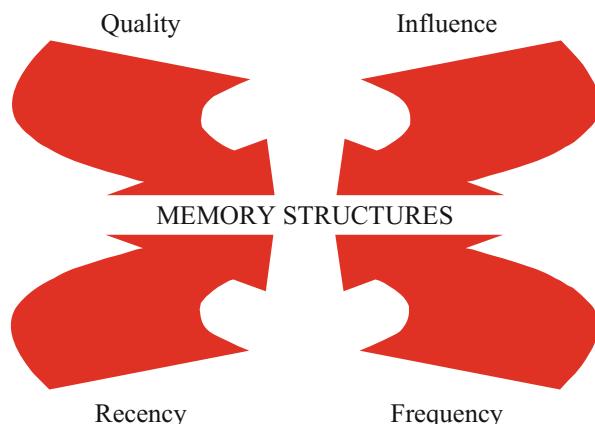

2.2 Use of Memory

The memory structures in tabu search operate by reference to four principal dimensions, consisting of recency, frequency, quality, and influence (Fig. 1). *Recency-based* and *frequency-based* memory complement each other and have important characteristics we amplify in later sections. The *quality* dimension refers to the ability to differentiate the merit of solutions visited during the search. In this context, memory can be used to identify elements that are common to good solutions or to paths that lead to such solutions. Operationally, quality becomes a foundation for incentive-based learning, where inducements are provided to reinforce actions that lead to good solutions and penalties are provided to discourage actions that lead to poor solutions. The flexibility of these memory structures allows the search to be guided in a multi-objective environment, where the goodness of a particular search direction may be determined by more than one function. The tabu search concept of quality is broader than the one implicitly used by standard optimization methods.

The fourth dimension, *influence*, considers the impact of the choices made during the search, not only on quality but also on structure (In a sense, quality may be regarded as a special form of influence). Recording information about the influence of choices on particular solution elements incorporates an additional level of learning. By contrast, in branch and bound, for example, the separation rules are prespecified and the branching directions remain fixed, once selected, at a given node of a decision tree. It is clear however that certain decisions have more influence than others as a function of the neighborhood of moves employed and the way that this neighborhood is negotiated (e.g., choices near the root of a branch and bound tree are quite influential when using a depth-first strategy). The assessment and exploitation of influence by a memory more flexible than embodied in such tree searches is an important feature of the TS framework.

The memory used in tabu search is both *explicit* and *attributive*. Explicit memory records complete solutions, typically consisting of elite solutions visited during the search. An extension of this memory records highly attractive but unexplored neighbors of elite solutions. The memorized elite solutions (or their attractive neighbors) are used to expand the local search, as indicated in Sect. 4. In some cases, explicit memory has been used to guide the search and avoid visiting solutions more than once. This application is limited, because clever data structures must be designed to avoid excessive memory requirements.

Alternatively, TS uses attributive memory for guiding purposes. This type of memory records information about solution attributes that change in moving from one solution to another. For example, in a graph or network setting, attributes can consist of nodes or arcs that are added, dropped, or repositioned by the moving mechanism. In production scheduling, the index of jobs may be used as attributes to inhibit or encourage the method to follow certain search directions.

Fig. 1 Four TS dimensions

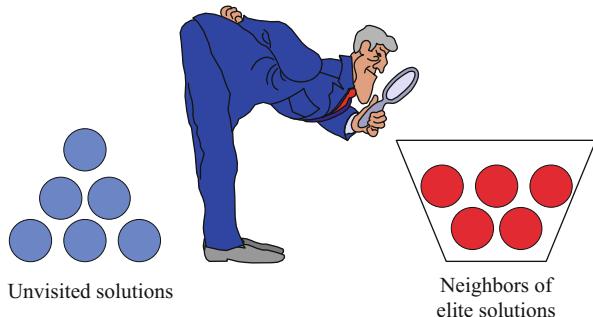

2.3 Intensification and Diversification

Two highly important components of tabu search are intensification and diversification strategies. Intensification strategies are based on modifying choice rules to encourage move combinations and solution features historically found good. They may also initiate a return to attractive regions to search them more thoroughly. Since elite solutions must be recorded in order to examine their immediate neighborhoods, explicit memory is closely related to the implementation of intensification strategies. As Fig. 2 illustrates, the main difference between intensification and diversification is that during an intensification stage, the search focuses on examining neighbors of elite solutions.

Here the term “neighbors” has a broader meaning than in the usual context of “neighborhood search.” That is, in addition to considering solutions that are adjacent or close to elite solutions by means of standard move mechanisms, intensification strategies generate “neighbors” by either grafting together components of good solution or by using modified evaluation strategies that favor the introduction of such components into a current (evolving) solution. The diversification stage on the other hand encourages the search process to examine unvisited regions and to generate solutions that differ in various significant ways from those seen before. Again, such an approach can be based on generating subassemblies of solution components that are then “fleshed out” to produce full solutions or can rely on modified evaluations as embodied, for example, in the use of penalty/incentive functions.

Intensification strategies require a means for identifying a set of elite solutions as basis for incorporating good attributes into newly created solutions. Membership in the elite set is often determined by setting a threshold which is connected to the objective function value of the best solution found during the search. However, considerations of clustering and “anti-clustering” are also relevant for generating such a set and more particularly for generating subsets of solutions that may be used for specific phases of intensification and diversification. In the following sections, we show how the treatment of such concerns can be enhanced by making use of

Fig. 2 Intensification and diversification

special memory structures. The TS notions of intensification and diversification are beginning to find their way into other meta-heuristics, and it is important to keep in mind (as we subsequently demonstrate) that these ideas are somewhat different than the old control theory concepts of “exploitation” and “exploration,” especially in their implications for developing effective problem-solving strategies.

3 Tabu Search Foundations and Short-Term Memory

Tabu search can be applied directly to verbal or symbolic statements of many kinds of decision problems, without the need to transform them into mathematical formulations. Nevertheless, it is useful to introduce mathematical notation to express a broad class of these problems, as a basis for describing certain features of tabu search. We characterize this class of problems as that of optimizing (minimizing or maximizing) a function $f(x)$ subject to $x \in X$, where $f(x)$ may be linear or nonlinear, and the set X summarizes constraints on the vector of decision variables x . The constraints may include linear or nonlinear inequalities and may compel all or some components of x to receive discrete values. While this representation is useful for discussing a number of problem-solving considerations, we emphasize again that in many applications of combinatorial optimization, the problem of interest may not be easily formulated as an objective function subject to a set of constraints. The requirement $x \in X$, for example, may specify logical conditions or interconnections that would be cumbersome to formulate mathematically but may be better left as verbal stipulations that can be then coded as rules.

Tabu search begins in the same way as ordinary local or neighborhood search, proceeding iteratively from one point (solution) to another until a chosen termination criterion is satisfied. Each $x \in X$ has an associated neighborhood $N(x) \subset X$, and each solution $x' \in N(x)$ is reached from x by an operation called a *move*.

As an initial point of departure, we may contrast TS with a simple descent method where the goal is to minimize $f(x)$ (or a corresponding ascent method where the goal is to maximize $f(x)$). Such a method only permits moves to neighbor solutions that improve the current objective function value and ends when no improving solutions can be found. A pseudo-code of a generic descent method is presented in Fig. 3. The final x obtained by a descent method is called a local optimum, since

Fig. 3 Descent method

- 1) Choose $x \in \mathbf{X}$ to start the process.
- 2) Find $x' \in N(x)$ such that $f(x') < f(x)$.
- 3) If no such x' can be found, x is the local optimum and the method stops.
- 4) Otherwise, designate x' to be the new x and go to 2).

it is at least as good or better than all solutions in its neighborhood. The evident shortcoming of a descent method is that such a local optimum in most cases will not be a global optimum, that is, it usually will not minimize $f(x)$ over all $x \in X$.

The version of a descent method called *steepest descent* scans the entire neighborhood of x in search of a neighbor solution x' that gives a smallest $f(x')$ value over $x' \in N(x)$. Steepest descent implementations of some types of solution approaches (such as certain path augmentation algorithms in networks and matroids) are guaranteed to yield globally optimal solutions for the problems they are designed to handle, while other forms of descent may terminate with local optima that are not global optima. In spite of this attractive feature, in certain settings, steepest descent is sometimes impractical because it is computationally too expensive, as where $N(x)$ contains many elements or each element is costly to retrieve or evaluate. Still, it is often valuable to choose an x' at each iteration that yields a “good” if not smallest $f(x')$ value.

The relevance of choosing good solutions from current neighborhoods is magnified when the guidance mechanisms of tabu search are introduced to go beyond the locally optimal termination point of a descent method. Thus, an important first-level consideration for tabu search is to determine an appropriate *candidate list strategy* for narrowing the examination of elements of $N(x)$, in order to achieve an effective trade-off between the quality of x' and the effort expended to find it. Here quality may involve considerations beyond those narrowly reflected by the value of $f(x')$. If a neighborhood space is totally random, then of course nothing will work better than a totally random choice (In such a case, there is no merit in trying to devise an effective solution procedure). Assuming that neighborhoods can be identified that are reasonably meaningful for a given class of problems, the challenge is to define solution quality appropriately so that evaluations likewise will have meaning. By the TS orientation, the ability to use history in creating such evaluations then becomes important for devising effective methods

To give a foundation for understanding the basic issues involved, we turn our attention to the following illustrative example, which will also be used as a basis for illustrating various aspects of tabu search in later sections.

3.1 Memory and Tabu Classifications

An important distinction in TS arises by differentiating between short-term memory and longer-term memory. Each type of memory is accompanied by its own special

strategies. However, the effect of both types of memory may be viewed as modifying the neighborhood $\mathbf{N}(x)$ of the current solution x . The modified neighborhood, which we denote by $\mathbf{N}^*(x)$, is the result of maintaining a selective history of the states encountered during the search.

In the TS strategies based on short-term considerations, $\mathbf{N}^*(x)$ characteristically is a subset of $\mathbf{N}(x)$, and the tabu classification serves to identify elements of $\mathbf{N}(x)$ excluded from $\mathbf{N}^*(x)$. In TS strategies that include longer-term considerations, $\mathbf{N}^*(x)$ may also be expanded to include solutions not ordinarily found in $\mathbf{N}(x)$. Characterized in this way, TS may be viewed as a dynamic neighborhood method. This means that the neighborhood of x is not a static set, but rather a set that can change according to the history of the search. This feature of a dynamically changing neighborhood also applies to the consideration of selecting different component neighborhoods from a *compound* neighborhood that encompasses multiple types or levels of moves and provides an important basis for parallel processing. Characteristically, a TS process based strictly on short-term strategies may allow a solution x to be visited more than once, but it is likely that the corresponding reduced neighborhood $\mathbf{N}^*(x)$ will be different each time. With the inclusion of longer-term considerations, the likelihood of duplicating a previous neighborhood upon revisiting a solution, and more generally of making choices that repeatedly visit only a limited subset of \mathbf{X} , is all but nonexistent. From a practical standpoint, the method will characteristically identify an optimal or near-optimal solution long before a substantial portion of \mathbf{X} is examined.

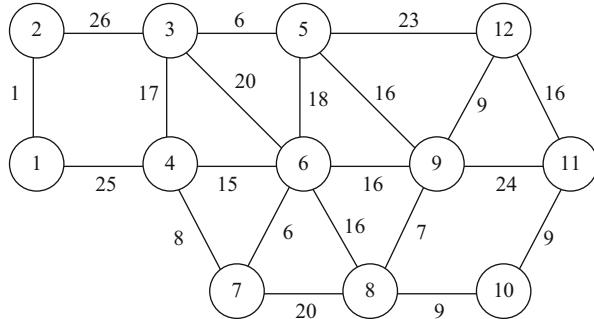

A crucial aspect of TS involves the choice of an appropriate definition of $\mathbf{N}^*(x)$. Due to the exploitation of memory, $\mathbf{N}^*(x)$ depends upon the trajectory followed in moving from one solution to the next (or upon a collection of such trajectories in a parallel processing environment).

The approach of storing complete solutions (*explicit* memory) generally consumes an enormous amount of space and time when applied to each solution generated. A scheme that emulates this approach with limited memory requirements is given by the use of hash functions (Also, as will be seen, explicit memory has a valuable role when selectively applied in strategies that record and analyze certain “special” solutions). Regardless of the implementation details, short-term memory functions provide one of the important cornerstones of the TS methodology. These functions give the search the opportunity to continue beyond local optima, by allowing the execution of nonimproving moves coupled with the modification of the neighborhood structure of subsequent solutions. However, instead of recording full solutions, these memory structures are generally based on recording attributes (*attributive* memory). In addition, short-term memory is often based on the most recent history of the search trajectory.

3.2 Recency-Based Memory

The most commonly used short-term memory keeps track of solutions attributes that have changed during the recent past and is called *recency-based* memory. This

Fig. 4 Weighted undirected graph

is the kind of memory that is included in most short descriptions of tabu search in the literature (although a number of its aspects are often left out by popular summaries).

To exploit this memory, selected attributes that occur in solutions recently visited are labeled *tabu-active*, and solutions that contain tabu-active elements, or particular combinations of these attributes, are those that become tabu. This prevents certain solutions from the recent past from belonging to $\mathbf{N}^*(x)$ and hence from being revisited. Other solutions that share such tabu-active attributes are also similarly prevented from being visited. Note that while the tabu classification strictly refers to solutions that are forbidden to be visited, by virtue of containing tabu-active attributes (or more generally by violating certain restriction based on these attributes), we also often refer to moves that lead to such solutions as being tabu. We illustrate these points with the following example.

Minimum k -Tree Problem Example

The *Minimum k -Tree* problem seeks a tree consisting of k edges in a graph so that the sum of the weights of these edges is minimum [49]. An instance of this problem is given in Fig. 4, where nodes are shown as numbered circles and edges are shown as lines that join pairs of nodes (the two “endpoint” nodes that determine the edge). Edge weights are shown as the numbers attached to these lines. A tree is a set of edges that contains no cycles, that is, that contains no paths that start and end at the same node (without retracing any edges).

Assume that the move mechanism is defined by edge swapping, as subsequently described, and that a greedy procedure is used to find an initial solution. The greedy construction starts by choosing the edge (i, j) with the smallest weight in the graph, where i and j are the indexes of the nodes that are the endpoints of the edge. The remaining $k-1$ edges are chosen successively to minimize the increase in total weight at each step, where the edges considered meet exactly one node from those that are endpoints of edges previously chosen. For $k = 4$, the greedy construction performs the steps in Table 2.

The construction starts by choosing edge $(1, 2)$ with a weight of 1 (the smallest weight of any edge in the graph). After this selection, the candidate edges are those that connect the nodes in the current partial tree with those nodes not in the tree (i.e., edges $(1, 4)$ and $(2, 3)$). Since edge $(1, 4)$ minimizes the weight increase, it is

Table 2 Greedy construction.

Step	Candidates	Selection	Total weight
1	(1,2)	(1,2)	1
2	(1,4), (2,3)	(1,4)	26
3	(2,3), (3,4), (4,6), (4,7)	(4,7)	34
4	(2,3), (3,4), (4,6), (6,7), (7,8)	(6,7)	40

chosen to be part of the partial solution. The rest of the selections follow the same logic, and the construction ends when the tree consists of 4 edges (i.e., the value of k). The initial solution in this particular case has a total weight of 40.

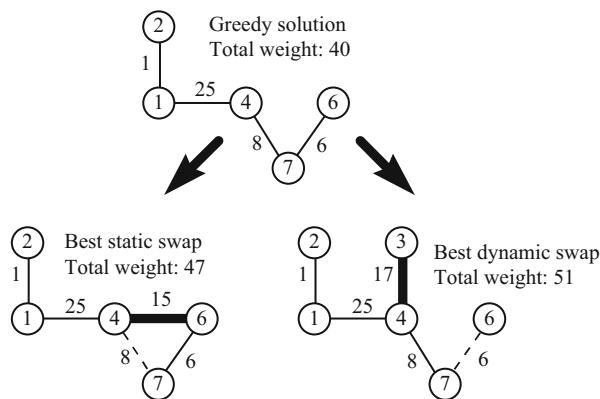

The swap move mechanism, which is used from this point onward, replaces a selected edge in the tree by another selected edge outside the tree, subject to requiring that the resulting subgraph is also a tree. There are actually two types of such edge swaps, one that maintains the current nodes of the tree unchanged (static) and one that results in replacing a node of the tree by a new node (dynamic). [Figure 5](#) illustrates the best swap of each type that can be made starting from the greedy solution. The added edge in each case is shown by a heavy line, and the dropped edge is shown by a dotted line.

The best move of both types is the static swap of [Fig. 5](#), where for our present illustration, we are defining *best* solely in terms of the change on the objective function value. Since this best move results in an increase of the total weight of the current solution, the execution of such move abandons the rules of a descent approach and sets the stage for a tabu search process. (The feasibility restriction that requires a tree to be produced at each step is particular to this illustration, since in general the TS methodology may include search trajectories that violate various types of feasibility conditions.)

Given a move mechanism, such as the swap mechanism we have selected for our example, the next step is to choose the key attributes that will be used for the tabu classification. Tabu search is very flexible at this stage of the design. Problem-specific knowledge can be used as guidance to settle on a particular design. In problems where the moves are defined by adding and deleting elements, the labels of these elements can be used as the attributes for enforcing tabu status. Here, in the present example, we can simply refer to the edges as attributes of the move, since the condition of being *in* or *out of the tree* (which is a distinguishing property of the current solution) may be assumed to always be automatically known by a reasonable solution representation.

Choosing Tabu Classifications

Tabu classifications do not have to be symmetric, that is, the tabu structure can be designed to treat added and dropped elements differently. Suppose, for example, that after choosing the static swap of [Fig. 5](#), which adds edge (4,6) and drops edge (4,7), a tabu status is assigned to both of these edges. Then one possibility is to classify both of these edges tabu-active for the same number of iterations. The tabu-active status has different meanings depending on whether the edge is added or dropped. For an added edge, tabu-active means that this edge is not allowed to be dropped

Fig. 5 Swap move types

from the current tree for the number of iterations that defines its tabu tenure. For a dropped edge, on the other hand, tabu-active means the edge is not allowed to be included in the current solution during its tabu tenure. Since there are many more edges outside the tree than in the tree, it seems reasonable to implement a tabu structure that keeps a recently dropped edge tabu-active for a longer period of time than a recently added edge. Notice also that for this problem, the tabu-active period for added edges is bounded by k , since if no added edge is allowed to be dropped for k iterations, then within k steps, all available moves will be classified tabu.

The concept of creating asymmetric tabu classifications can be readily applied to settings where add/drop moves are not used.

Illustrative Tabu Classifications for the Min k-Tree Problem

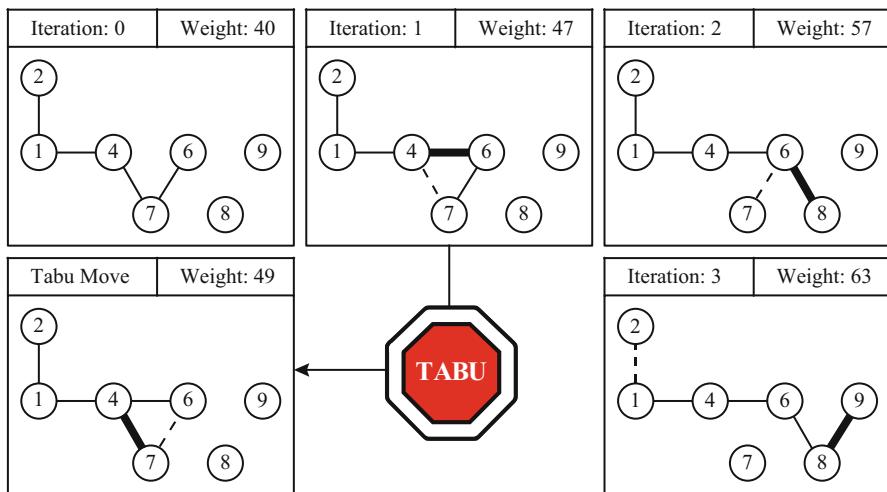

As previously remarked, the tabu-active classification may in fact prevent the search from visiting solutions that have not been examined yet. We illustrate this phenomenon as follows. Suppose that in the Min k -Tree problem instance of Fig. 4, dropped edges are kept tabu-active for two iterations, while added edges are kept tabu-active for only one iteration (The number of iterations an edge is kept tabu-active is called the *tabu tenure* of the edge). Also assume that we define a swap move to be tabu if either its added or dropped edge is tabu-active. If we examine the full neighborhood of available edge swaps at each iteration, and always choose the best that is not tabu, then the first three moves are as shown in Table 3 below (starting from the initial solution found by the greedy construction heuristic). The move of iteration 1 is the static swap move previously identified in Fig. 5. Diagrams showing the successive trees generated by these moves, starting with the initial greedy solution, are given in Fig. 6.

The net tenure values of 1 and 2 in Table 3 for the currently tabu-active edges indicate the number of iterations that these edges will remain tabu-active (including the current iteration).

At iteration 2, the reversal of the move of iteration 1 (i.e., the move that now adds (4,7) and drops (4,6)) is clearly tabu, since both of its edges are tabu-active at iteration 2. In addition, the move that adds (4,7) and drops (6,7) is also classified tabu, because it contains the tabu-active edge (4,7) (with a net tenure of 2).

Table 3 TS iterations

Iteration	Tabu-active net tenure		Add	Drop	Weight
	1	2			
1			(4,6)	(4,7)	47
2	(4,6)	(4,7)	(6,8)	(6,7)	57
3	(6,8), (4,7)	(6,7)	(8,9)	(1,2)	63

**Fig. 6** Effects of attributive short-term memory

This move leads to a solution with a total weight of 49, a solution that clearly has not been visited before (see Fig. 6). The tabu-active classification of (4,7) has modified the original neighborhood of the solution at iteration 2 and has forced the search to choose a move with an inferior objective function value (i.e., the one with a total weight of 57). In this case, excluding the solution with a total weight of 49 has little effect on the quality of the best solution found (since we have already obtained one with a weight of 40).

In other situations, however, additional precautions must be taken to avoid missing good solutions. These strategies are known as aspiration criteria and are the subject of Sect. 3.6. For the moment, we observe simply that if the tabu solution encountered at the current step instead had a weight of 39, which is better than the best weight of 40 so far seen, then we would allow the tabu classification of this solution to be overridden and consider the solution admissible to be visited. The aspiration criterion that applies in this case is called the *improved-best* aspiration criterion (It is important to keep in mind that aspiration criteria do not compel particular moves to be selected, but simply make them available, or alternately rescind evaluation penalties attached to certain tabu classifications).

One other comment about tabu classification deserves to be made at this point. In our preceding discussion of the Min k -Tree problem, we consider a swap move

tabu if either its added edge or its dropped edge is tabu-active. However, we could instead stipulate that a swap move is tabu only if both its added and dropped edges are tabu-active. In general, the tabu status of a move is a function of the tabu-active attributes of the move (i.e., of the new solution produced by the move).

3.3 A First-Level Tabu Search Approach

We now have on hand enough ingredients for a first-level tabu search procedure. Such a procedure is sometimes implemented in an initial phase of a TS development to obtain a preliminary idea of performance and calibration features or simply to provide a convenient staged approach for the purpose of debugging solution software. While this naive form of a TS method omits a number of important short-term memory considerations and does not yet incorporate longer-term concerns, it nevertheless gives a useful starting point for demonstrating several basic aspects of tabu search.

We start from the solution with a weight of 63 as shown previously in Fig. 6 which was obtained at iteration 3. At each step, we select the least-weight non-tabu move from those available and use the improved-best aspiration criterion to allow a move to be considered admissible in spite of leading to a tabu solution. The reader may verify that the outcome leads to the series of solutions shown in Table 4, which continues from iteration 3, just executed. For simplicity, we select an arbitrary stopping rule that ends the search at iteration 10.

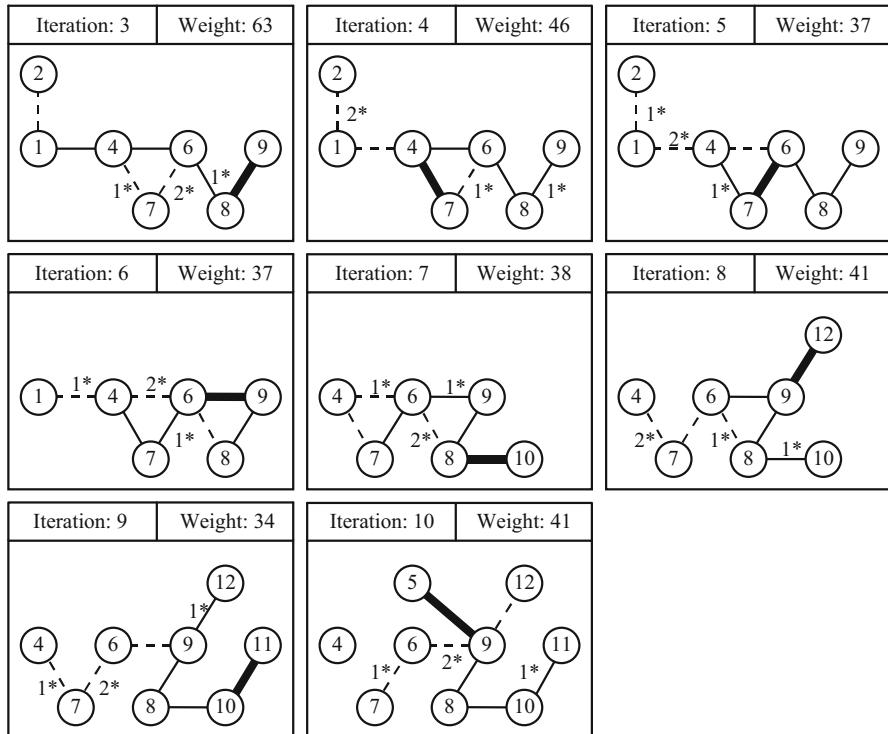

The successive solutions identified in Table 4 are shown graphically in Fig. 7 below. In addition to identifying the dropped edge at each step as a dotted line, we also identify the dropped edge from the immediately preceding step as a dotted line which is labeled 2^* to indicate its current net tabu tenure of 2. Similarly, we identify the dropped edge from one further step back by a dotted line which is labeled 1^* to indicate its current net tabu tenure of 1. Finally, the edge that was added on the immediately preceding step is also labeled 1^* to indicate that it likewise has a current net tabu tenure of 1. Thus, the edges that are labeled with tabu tenures are those which are currently tabu-active and which are excluded from being chosen by a move of the current iteration (unless permitted to be chosen by the aspiration criterion).

As illustrated in Table 4 and Fig. 7, the method continues to generate different solutions, and over time, the best-known solution (denoted by an asterisk) progressively improves. In fact, it can be verified for this simple example that the solution obtained at iteration 9 is optimal (In general, of course, there is no known way to verify optimality in polynomial time for difficult discrete optimization problems, i.e., those that fall in the class called NP-hard. The Min k -Tree problem is one of these).

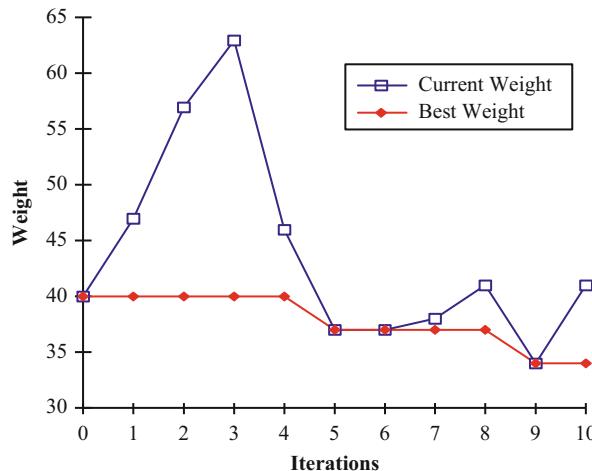

It may be noted that at iteration 6, the method selected a move with a move value of zero. Nevertheless, the configuration of the current solution changes after the execution of this move, as illustrated in Fig. 7.

Table 4 Iterations of a first-level TS procedure

Iteration	Tabu-active net tenure		Add	Drop	Move value	Weight
	1	2				
3	(6,8), (4,7)	(6,7)	(8,9)	(1,2)	6	63
4	(6,7), (8,9)	(1,2)	(4,7)	(1,4)	-17	46
5	(1,2), (4,7)	(1,4)	(6,7)	(4,6)	-9	37*
6	(1,4), (6,7)	(4,6)	(6,9)	(6,8)	0	37
7	(4,6), (6,9)	(6,8)	(8,10)	(4,7)	1	38
8	(6,8), (8,10)	(4,7)	(9,12)	(6,7)	3	41
9	(4,7), (9,12)	(6,7)	(10,11)	(6,9)	-7	34*
10	(6,7), (10,11)	(6,9)	(5,9)	(9,12)	7	41

**Fig. 7** Graphical representation of TS iterations

The selection of moves with certain move values, such as zero move values, may be strategically controlled to limit their selection as added insurance against cycling in special settings. We will soon see how considerations beyond this first-level implementation can lead to an improved search trajectory, but the non-monotonic,

Fig. 8 TS search trajectory

gradually improving, behavior is characteristic of TS in general. [Figure 8](#) provides a graphic illustration of this behavior for the current example.

We have purposely chosen the stopping iteration to be small to illustrate an additional relevant feature and to give a foundation for considering certain types of longer-term considerations. One natural way to apply TS is to periodically discontinue its progress, particularly if its rate of finding new best solutions falls below a preferred level, and to restart the method by a process designated to generate a new sequence of solutions.

Classical restarting procedures based on randomization evidently can be used for this purpose, but TS often derives an advantage by employing more strategic forms of restarting. We illustrate a simple instance of such a restarting procedure, which also serves to introduce a useful memory concept.

3.3.1 Critical Event Memory

Critical event memory in tabu search, as its name implies, monitors the occurrence of certain *critical events* during the search and establishes a memory that constitutes an aggregate summary of these events. For our current example, where we seek to generate a new starting solution, a critical event that is clearly relevant is the generation of the previous starting solution. Correspondingly, if we apply a restarting procedure multiple times, the steps of generating all preceding starting solutions naturally qualify as critical events. That is, we would prefer to depart from these solutions in some significant manner as we generate other starting solutions.

Different degrees of departure, representing different levels of *diversification*, can be achieved by defining solutions that correspond to critical events in different ways (and by activating critical event memory by different rules). In the present setting, we consider it important that new starting solutions not only differ from preceding starting solutions but that they also differ from other solutions generated during previous passes. One possibility is to use a blanket approach that considers each

complete solution previously generated to represent a critical event. The aggregation of such events by means of critical event memory makes this entirely practicable, but often, it is quite sufficient (and, sometimes preferable) to isolate a smaller set of solutions.

For the current example, therefore, we will specify that the critical events of interest consist of generating not only the starting solution of the previous pass(es) but also each subsequent solution that represents a “local TS optimum,” that is whose objective function value is better (or no worse) than that of the solution immediately before and after it. Using this simple definition, we see that four solutions qualify as critical (i.e., are generated by the indicated critical events) in the first solution pass of our example: the initial solution and the solutions found at iterations 5, 6, and 9 (with weights of 40, 37, 37, and 34, respectively).

Since the solution at iteration 9 happens to be optimal, we are interested in the effect of restarting before this solution is found. Assume we had chosen to restart after iteration 7, without yet reaching an optimal solution. Then the solutions that correspond to critical events are the initial solution and the solutions of iterations 5 and 6. We treat these three solutions in aggregate by combining their edges to create a subgraph that consists of the edges (1,2), (1,4), (4,7), (6,7), (6,8), (8,9), and (6,9) (Frequency-based memory, as discussed in Sect. 5, refines this representation by accounting for the number of times each edge appears in the critical solutions and allows the inclusion of additional weighting factors).

To execute a restarting procedure, we penalize the inclusion of the edges of this subgraph at various steps of constructing the new solution. It is usually preferable to apply this penalty process at early steps, implicitly allowing the penalty function to decay rapidly as the number of steps increases. It is also sometimes useful to allow one or more intervening steps after applying such penalties before applying them again.

For our illustration, we will use the memory embodied in the subgraph of penalized edges by introducing a large penalty that effectively excludes all these edges from consideration on the first two steps of constructing the new solution. Then, because the construction involves four steps in total, we will not activate the critical event memory on subsequent construction steps but will allow the method to proceed in its initial form.

Applying this approach, we restart the method by first choosing edge (3,5), which is the minimum weight edge not in the penalized subgraph. This choice and the remaining choices that generate the new starting solution are shown in Table 5.

Beginning from the solution constructed in Table 5, and applying the first-level TS procedure exactly as it was applied on the first pass, generates the sequence of solutions shown in Table 6 and depicted in Fig. 10 (Again, we have arbitrarily limited the total number of iterations, in this case to 5).

It is interesting to note that the restarting procedure generates a better solution (with a total weight of 38) than the initial solution generated during the first construction (with a total weight of 40). Also, the restarting solution contains 2 “optimal edges” (i.e., edges that appear in the optimal tree). This starting solution allows the search trajectory to find the optimal solution in only two iterations,

Table 5 Restarting procedure

Step	Candidates	Selection	Total weight
1	(3,5)	(3, 5)	6
2	(2,3), (3,4), (3,6), (5,6), (5,9), (5,12)	(5, 9)	22
3	(2,3), (3,4), (3,6), (5,6), (5,12), (6,9), (8,9), (9,12)	(8, 9)	29
4	(2,3), (3,4), (3,6), (5,6), (5,12), (6,8), (6,9), (7,8), (8,10), (9,12)	(8, 10)	38

Table 6 TS iterations following restarting

Iteration	Tabu-active net tenure		Add	Drop	Move value	Weight
	1	2				
1			(9,12)	(3,5)	3	41
2	(9,12)	(3,5)	(10,11)	(5,9)	-7	34*
3	(3,5), (10,11)	(5,9)	(6,8)	(9,12)	7	41
4	(5,9), (6,8)	(9,12)	(6,7)	(10,11)	-3	38
5	(9,12), (6,7)	(10,11)	(4,7)	(8,10)	-1	37

illustrating the benefits of applying a critical event memory within a restarting strategy. As will be seen in Sect. 5, related memory structures can also be valuable for strategies that drive the search into new regions by “partial restarting” or by directly continuing a current trajectory (with modified decision rules).

Now we return from our example to examine elements of TS that take us beyond these first-level concerns and open up possibilities for creating more powerful solution approaches. We continue to focus primarily on short-term aspects and begin by discussing how to generalize the use of recency-based memory when neighborhood exploration is based on add/drop moves. From these foundations, we then discuss issues of logical restructuring, tabu-activation rules, and ways of determining tabu tenure. We then examine the important area of aspiration criteria, together with the role of influence.

3.4 Recency-Based Memory for Add/Drop Moves

To understand procedurally how various forms of recency-based memory work, and to see their interconnections, it is useful to examine a convenient design for implementing the ideas illustrated so far. Such a design for the Min k -Tree problem creates a natural basis for handling a variety of other problems for which add/drop moves are relevant. In addition, the ideas can be adapted to settings that are quite different from those where add/drop moves are used.

As a step toward fuller generality, we will refer to items added and dropped as *elements*, though we will continue to make explicit reference to edges (as particular types of elements) within the context of the Min k -Tree problem example (Elements

are related to, but not quite the same as, solution attributes. The difference will be made apparent shortly). There are many settings where operations of adding and dropping paired elements are the cornerstone of useful neighborhood definitions. For example, many types of exchange or swap moves can be characterized by such operations. Add/drop moves also apply to the omnipresent class of *multiple choice* problems, which require that exactly one element must be chosen from each member set from a specified disjoint collection. Add/drop moves are quite natural in this setting, since whenever a new element is chosen from a given set (and hence is “added” to the current solution), the element previously chosen from that set must be replaced (and hence “dropped”). Such problems are represented by discrete *generalized upper bound* (GUB) formulations in mathematical optimization, where various disjoint sets of 0-1 variables must sum to 1 (hence exactly one variable from each set must equal 1, and the others must equal 0). An add/drop move in this formulation consists of choosing a new variable to equal 1 (the “add move”) and setting the associated (previously selected) variable equal to 0 (the “drop move”).

Add/drop moves further apply to many types of problems that are not strictly discrete, that is, which contain variables whose values can vary continuously across specified ranges. Such applications arise by taking advantage of *basis exchange* (pivoting) procedures, such as the simplex method of linear programming. In this case, an add/drop move consists of selecting a new variable to enter (add to) the basis and identifying an associated variable to leave (drop from) the basis. A variety of procedures for nonlinear and mixed-integer optimization rely on such moves and have provided a useful foundation for a number of tabu search applications. Additional related examples will be encountered throughout the course of this book.

3.4.1 Some Useful Notation

The approach used in the Min k -Tree problem can be conveniently described by means of the following notation. For a pair of elements that is selected to perform an add/drop move, let *Added* denote the element that is added and *Dropped* the element that is dropped. Also denote the current iteration at which this pair is selected by *Iter*. We maintain a record of *Iter* to identify when *Added* and *Dropped* start to be tabu-active. Specifically, at this step we set

$$\text{TabuDropStart}(\text{Added}) = \text{Iter}$$

$$\text{TabuAddStart}(\text{Dropped}) = \text{Iter}.$$

Thus, *TabuDropStart* records the iteration where *Added* becomes tabu-active (to prevent this element from later being dropped), and *TabuAddStart* records the iteration where *Dropped* becomes tabu-active (to prevent this element from later being added).

For example, in the Min k -Tree problem illustration of [Table 4](#), where the edge (4,6) was added and the edge (4,7) was dropped on the first iteration, we would establish the record (for $\text{Iter} = 1$)

$$\text{TabuDropStart}(4, 6) = 1$$

$$\text{TabuAddStart}(4, 7) = 1.$$

To identify whether or not an element is currently tabu-active, let *TabuDropTenure* denote the tabu tenure (number of iterations) to forbid an element to be dropped (once added), and let *TabuAddTenure* denote the tabu tenure to forbid an element from being added (once dropped) (In our Min k -Tree problem example of Sect. 3.2, we selected *TabuAddTenure*=2 and *TabuDropTenure*=1).

As a point of clarification, when we speak of an element as being tabu-active, our terminology implicitly treats elements and attributes as if they are the same. However, to be precise, each element is associated with two different attributes, one where the element belongs to the current solution and one where the element does not. Elements may be viewed as corresponding to variables and attributes as corresponding to specific value assignments for such variables. There is no danger of confusion in the add/drop setting, because we always know when an element belongs or does not belong to the current solution, and hence, we know which of the two associated attributes is currently being considered.

We can now identify precisely the set of iterations during which an element (i.e., its associated attribute) will be tabu-active. Let *TestAdd* and *TestDrop* denote a candidate pair of elements, whose members are respectively under consideration to be added and dropped from the current solution. If *TestAdd* previously corresponded to an element *Dropped* that was dropped from the solution and *TestDrop* previously corresponded to an element *Added* that was added to the solution (not necessarily on the same step), then it is possible that one or both may be tabu-active and we can check their status as follows. By means of the records established on earlier iterations, where *TestAdd* began to be tabu-active at iteration *TabuAddStart* (*TestAdd*) and *TestDrop* began to be tabu-active at iteration *TabuDropStart* (*TestDrop*), we conclude that as *Iter* grows, the status of these elements will be given by

TestAdd is tabu-active when:

$$\text{Iter} \leq \text{TabuAddStart}(\text{TestAdd}) + \text{TabuAddTenure}$$

TestDrop is tabu-active when:

$$\text{Iter} \leq \text{TabuDropStart}(\text{TestDrop}) + \text{TabuDropTenure}.$$

Consider again the Min k -Tree problem illustration of Table 4. As previously noted, the move of Iteration 1 that added edge (4,6) and dropped edge (4,7) was accompanied by setting the *TabuDropStart*(4,6)=1 and *TabuAddStart*(4,7)=1 to record the iteration where these two edges start to be tabu-active (to prevent (4,6) from being dropped and (4,7) from being added). The edge (4,6) will then remain tabu-active on subsequent iterations, in the role of *TestDrop* (as a candidate to be dropped), as long as

$$\text{Iter} \leq \text{TabuDropStart} (4, 6) + \text{TabuDropTenure}.$$

Hence, since we selected $\text{TabuDropTenure} = 1$ (to prevent an added edge from being dropped for 1 iteration), it follows that (4,6) remains tabu-active as long as

$$\text{Iter} \leq 2.$$

Similarly, having selected $\text{TabuAddTenure} = 2$, we see that the edge (4,7) remains tabu-active, to forbid it from being added back, as long as

$$\text{Iter} \leq 3.$$

An initialization step is needed to be sure that elements that have never been previously added or dropped from the solutions successively generated will not be considered tabu-active. This can be done by initially setting TabuAddStart and TabuDropStart equal to a large negative number for all elements. Then, as Iter begins at 1 and successively increases, the inequalities that determine the tabu-active status will not be satisfied, and hence will correctly disclose that an element is not tabu-active, until it becomes one of the elements *Added* or *Dropped* (Alternately, TabuAddStart and TabuDropStart can be initialized at 0, and the test of whether an element is tabu-active can be skipped when it has a 0 value in the associated array).

3.4.2 Streamlining

The preceding ideas can be streamlined to allow a more convenient implementation. First, we observe that the two arrays, TabuAddStart and TabuDropStart , which we have maintained separately from each other to emphasize their different functions, can be combined into a single array TabuStart . The reason is simply that we can interpret $\text{TabuStart}(E)$ to be the same as $\text{TabuDropStart}(E)$ when the element E is in the current solution and to be the same as $\text{TabuAddStart}(E)$ when E is not in the current solution (There is no possible overlap between these two states of E and hence no danger of using the TabuStart array incorrectly). Consequently, from now on, we will let the single array TabuStart take the role of both TabuAddStart and TabuDropStart . For example, when the move is executed that (respectively) adds and drops the elements *Added* and *Dropped*, the appropriate record consists of setting

$$\text{TabuStart}(\text{Added}) = \text{Iter}$$

$$\text{TabuStart}(\text{Dropped}) = \text{Iter}.$$

The TabuStart array has an additional function beyond that of monitoring the status of tabu-active elements (As shown in Sect. 5, this array is also useful for determining a type of frequency measure called a *residence frequency*). However, sometimes it is convenient to use a different array, TabuEnd , to keep track of tabu-active status for recency-based memory, as we are treating here. Instead of recording

when the tabu-active status starts, *TabuEnd* records when it ends. Thus, in place of the two assignments to *TabuStart* shown above, the record would consist of setting

$$\text{TabuEnd}(\text{Added}) = \text{Iter} + \text{TabuDropTenure}$$

$$\text{TabuEnd}(\text{Dropped}) = \text{Iter} + \text{TabuAddTenure}.$$

(The element *Added* is now available to be dropped, and the element *Dropped* is now available to be added). In conjunction with this, the step that checks for whether a candidate pair of elements *TestAdd* and *TestDrop* are currently tabu-active becomes:

TestAdd is tabu-active when

$$\text{Iter} \leq \text{TabuEnd}(\text{TestAdd}).$$

TestDrop is tabu-active when

$$\text{Iter} \leq \text{TabuEnd}(\text{TestDrop}).$$

This is a simpler representation than the one using *TabuStart*, and so, it is appealing when *TabuStart* is not also used for additional purposes (Also, *TabuEnd* can simply be initialized at 0 rather than at a large negative number).

As will be discussed more fully in the next section, the values of *TabuAddTenure* and *TabuDropTenure* (which are explicitly referenced in testing tabu-active status with *TabuStart* and implicitly referenced in testing this status with *TabuEnd*) are often preferably made variable rather than fixed. The fact that we use different tenures for added and dropped elements discloses that it can be useful to differentiate the tenures applied to elements of different classes. This type of differentiation can also be based on historical performance, as tracked by frequency-based measures. Consequently, tenures may be individually adjusted for different elements (as well as modified over time). Such adjustment can be quite effective in some settings. These basic considerations can be refined to create effective implementations and also can be extended to handle additional move structures, as shown in Glover and Laguna [31].

3.5 Tabu Tenure

In general, recency-based memory is managed by creating one or several tabu lists, which record the tabu-active attributes and implicitly or explicitly identify their current status. Tabu tenure can vary for different types or combinations of attributes and can also vary over different intervals of time or stages of the search. This varying tenure makes it possible to create different kinds of trade-offs between short-term and longer-term strategies. It also provides a dynamic and robust form of search.

The choice of appropriate types of tabu lists depends on the context. Although no single type of list is uniformly best for all applications, some guidelines can be formulated. If memory space is sufficient (as it often is) to store one piece of information (e.g., a single integer) for each solution attribute used to define the tabu-activation rule, it is usually advantageous to record the iteration number that identifies when the tabu-active status of an attribute starts or ends as illustrated by the add/drop data structure described in Sects. 3.3 and 3.4. This typically makes it possible to test the tabu status of a move in constant time. The necessary memory space depends on the attributes and neighborhood size, but it does not depend on the tabu tenure.

Depending on the size of the problem, it may not be feasible to implement the preceding memory structure in combination with certain types of attributes. In general, storing one piece of information for each attribute becomes unattractive when the problem size increases or attribute definition is complex. Sequential and circular tabu lists are used in this case, which store the identities of each tabu-active attribute and explicitly (or implicitly, by list position) record associated tabu tenures.

Effective tabu tenures have been empirically shown to depend on the size of the problem instance. However, no single rule has been designed to yield an effective tenure for all classes of problems. This is partly because an appropriate tabu tenure depends on the strength of the tabu-activation rule employed (where more restrictive rules are generally coupled with shorter tenures). Effective tabu tenures and tabu-activation rules can usually be determined quite easily for a given class of problems by a little experimentation. Tabu tenures that are too small can be recognized by periodically repeated objective function values or other function indicators, including those generated by hashing, that suggest the occurrence of cycling. Tenures that are too large can be recognized by a resulting deterioration in the quality of the solutions found (within reasonable time periods). Somewhere in between typically exists a robust range of tenures that provide good performance.

Once a good range of tenure values is located, first-level improvements generally result by selecting different values from this range on different iterations (A smaller subrange, or even more than one subrange, may be chosen for this purpose). Problem structures are sometimes encountered where performance for some individual fixed tenure values within a range can be unpredictably worse than for other values in the range, and the identity of the isolated poorer values can change from problem to problem. However, if the range is selected to be good overall, then a strategy that selects different tenure values from the range on different iterations typically performs at a level comparable to selecting one of the best values in the range, regardless of the problem instance.

Short-term memory refinements subsequently discussed, and longer-term considerations introduced in later sections, transform the method based on these constructions into one with considerable power. Still, it occasionally happens that even the initial short-term approach by itself leads to exceptionally high-quality solutions. Consequently, some of the TS literature has restricted itself only to this initial part of the method.

In general, short tabu tenures allow the exploration of solutions “close” to a local optimum, while long tenures can help to break free from the vicinity of a local optimum. These functions illustrate a special instance of the notions of *intensification* and *diversification* that will be explored in more detail later. Varying the tabu tenure during the search provides one way to induce a balance between closely examining one region and moving to different parts of the solution space.

In situations where a neighborhood may (periodically) become fairly small, or where a tabu tenure is chosen to be fairly large, it is entirely possible that iterations can occur when all available moves are classified tabu. In this case, an *aspiration-by-default* is used to allow a move with a “least tabu” status to be considered admissible. Such situations rarely occur for most problems, and even random selection is often an acceptable form of aspiration-by-default. When tabu status is translated into a modified evaluation criterion, by penalties and inducements, then of course aspiration-by-default is handled automatically, with no need to monitor the possibility that all moves are tabu.

There are several ways in which a *dynamic* tabu tenure can be implemented. These implementations may be classified into *random* and *systematic* dynamic tabu tenures.

3.5.1 Random Dynamic Tenure

Random dynamic tabu tenures are often given one of two forms. Both of these forms use a tenure range defined by parameters t_{\min} and t_{\max} . The tabu tenure t is randomly selected within this range, usually following a uniform distribution. In the first case, the chosen tenure is maintained constant for αt_{\max} iterations, and then a new tenure is selected by the same process. The second form draws a new t for every attribute that becomes tabu at a given iteration. The first form requires more bookkeeping than the second one, because one must remember the last time that the tabu tenure was modified.

Either of the two arrays *TabuStart* or *TabuEnd* discussed in Sect. 3.4 can be used to implement these forms of dynamic tabu tenure. For example, a 2-dimensional array *TabuEnd* can be created to control a dynamic recency-based memory for the sequencing problem introduced at the beginning of this section. As in the case of the Min k -Tree problem, such an array can be used to record the time (iteration number) at which a particular attribute will be released from its tabu status. Suppose, for example, that $t_{\min} = 5$ and $t_{\max} = 10$ and that swaps of jobs are used to move from one solution to another in the sequencing problem. Also, assume that *TabuEnd* (j, p) refers to the iteration that job j will be released from a tabu restriction that prevents it from being assigned to position p . Then, if at iteration 30, job 8 in position 2 is swapped with job 12 in position 25, we will want to make the attribute (8,2) and (12,25) tabu-active for some number of iterations to prevent a move that will return one or both of jobs 8 and 12 from reoccupying their preceding positions. If t is assigned a value of 7 from the range $t_{\min} = 5$ and $t_{\max} = 10$, then upon making the swap at iteration 30, we may set *TabuEnd* (8,2)=37 and *TabuEnd* (12,25)=37.

This is not the only kind of *TabuEnd* array that can be used for the sequencing problem, and we examine other alternatives and their implications in Sect. 4.

Nevertheless, we warn against a potential danger. An array $\text{TabuEnd}(i, j)$ that seeks to prevent jobs i and j from exchanging positions, without specifying what these positions are, does not truly refer to attributes of a sequencing solution and hence entails a risk if used to determine tabu status (The pair (i, j) here constitutes an attribute of a move, in a lose sense, but does not serve to distinguish one solution from another). Thus, if at iteration 30, we were to set $\text{TabuEnd}(8,12)=37$, in order to prevent jobs 8 and 12 from exchanging positions until after iteration 37, this still might not prevent job 8 from returning to position 2 and job 12 from returning to position 25. In fact, a sequence of swaps could be executed that could return to precisely the same solution visited before swapping jobs 8 and 12.

Evidently, the TabuEnd array can be used by selecting a different t from the interval (t_{\min}, t_{\max}) at every iteration. As remarked in the case of the Min k -Tree problem, it is also possible to select t differently for different solution attributes.

3.5.2 Systematic Dynamic Tenure

Dynamic tabu tenures based on a random scheme are attractive for their ease of implementation. However, relying on randomization may not be the best strategy when specific information about the context is available. In addition, certain diversity-inducing patterns can be achieved more effectively by not restricting consideration to random designs. A simple form of *systematic* dynamic tabu tenure consists of creating a sequence of tabu search tenure values in the range defined by t_{\min} and t_{\max} . This sequence is then used, instead of the uniform distribution, to assign the current tabu tenure value. Suppose it is desired to vary t so that its value alternately increases and decreases (Such a pattern induces a form of diversity that will rarely be achieved randomly). Then the following sequence can be used for the range defined above:

$$\{5, 8, 6, 9, 7, 10\}.$$

The sequence may be repeated as many times as necessary until the end of the search, where additional variation is introduced by progressively shifting and/or reversing the sequence before repeating it (In a combined random/systematic approach, the decision of the shift value and the forward or backward direction can itself be made random). Another variation is to retain a selected tenure value from the sequence for a variable number of iterations before selecting the next value. Different sequences can be created and identified as effective for particular classes of problems.

The foregoing range of values (from 5 to 10) may seem relatively small. However, some applications use even smaller ranges but adaptively increase and decrease the midpoint of the range for diversification and intensification purposes. Well-designed adaptive systems can significantly reduce or even eliminate the need to discover a best range of tenures by preliminary calibration. This is an important area of study.

These basic alternatives typically provide good starting tabu search implementations. In fact, most initial implementations apply only the simplest versions of these ideas.

3.6 Aspiration Criteria and Regional Dependencies

Aspiration criteria are introduced in tabu search to determine when tabu-activation rules can be overridden, thus removing a tabu classification otherwise applied to a move (The improved-best and aspiration-by-default criteria, as previously mentioned, are obvious simple instances). The appropriate use of such criteria can be very important for enabling a TS method to achieve its best performance levels. Early applications employed only a simple type of aspiration criterion, consisting of removing a tabu classification from a trial move when the move yields a solution better than the best obtained so far. This criterion remains widely used. However, other aspiration criteria can prove effective for improving the search.

A basis for one of these criteria arises by introducing the concept of *influence*, which measures the degree of change induced in solution structure or feasibility. This notion can be illustrated for the Min k -Tree problem as follows. Suppose that the current solution includes edges (1,2), (1,4), (4,7), and (6,7), as illustrated in Fig. 9, following. A high-influence move, which significantly changes the structure of the current solution, is exemplified by dropping edge (1,2) and replacing it by edge (6,9). A low-influence move, on the other hand, is exemplified by dropping edge (6,7) and adding edge (4,6). The weight difference of the edges in the high-influence move is 15, while the difference is 9 for the low-influence move. However, it is important to point out that differences on weight or cost are not the only – or even the primary – basis for distinguishing between moves of high and low influence. In the present example, the move we identify as a low-influence move creates a solution that consists of the same set of nodes included in the current solution, while the move we identified as a high-influence move includes a new

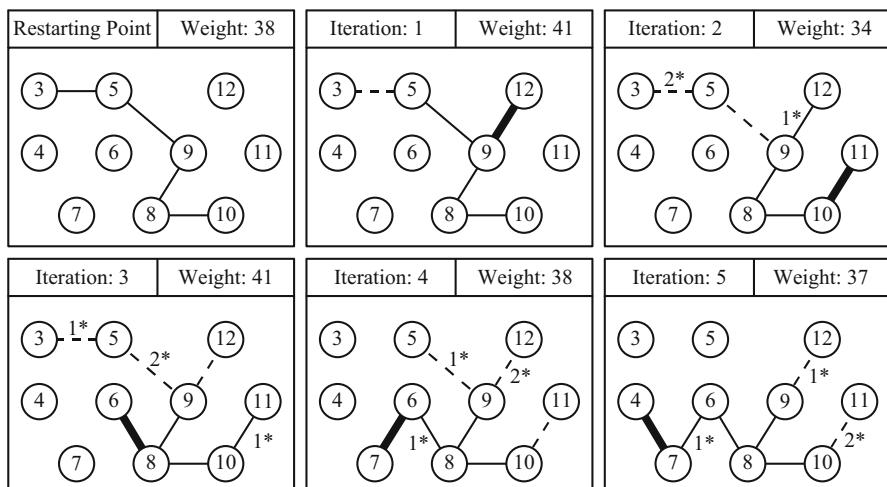

Fig. 9 Graphical representation of TS iterations after restarting

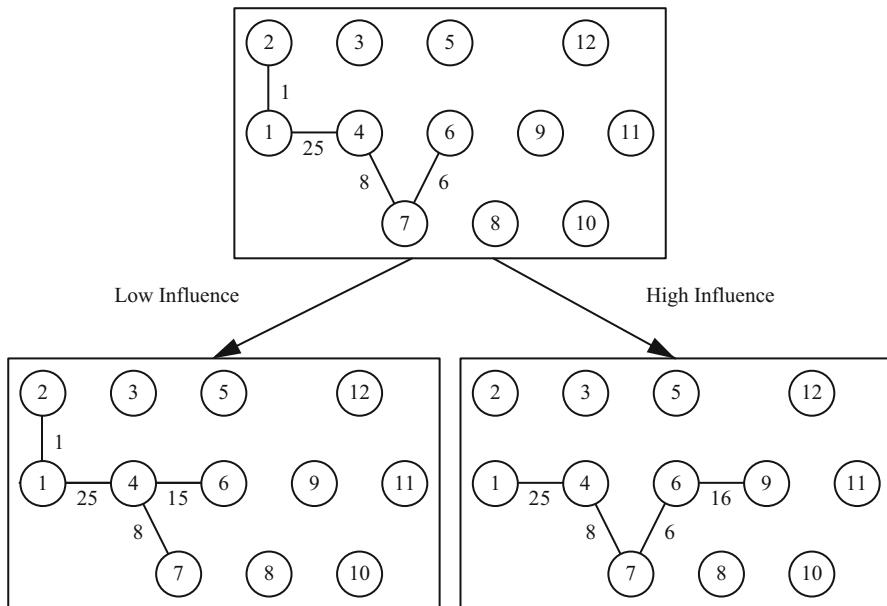

Fig. 10 Influence level of two moves

node (number 9) from which new edges can be examined (These moves correspond to those labeled static and dynamic in Fig. 5).

As illustrated here, high-influence moves may or may not improve the current solution, though they are less likely to yield an improvement when the current solution is relatively good. But high-influence moves are important, especially during intervals of breaking away from local optimality, because a series of moves that is confined to making only small structural change is unlikely to uncover a chance for significant improvement. Executing the high-influence move in Fig. 10, for example, allows the search to reach the optimal edges (8,9) and (9,12) in subsequent iterations. Of course, moves of much greater influence than those shown can be constructed by considering compound moves. Such considerations are treated in later sections.

Influence often is associated with the idea of move distance. Although important, move influence is only one of several elements that commonly underlie the determination of aspiration criteria. We illustrate a few of these elements in Table 7.

Aspirations such as those shown in Table 7 can be applied according to two implementation categories: aspiration by move and aspirations by attribute. A move aspiration, when satisfied, revokes the move's tabu classification. An attribute aspiration, when satisfied, revokes the attribute's tabu-active status. In the latter case, the move may or may not change its tabu classification, depending on whether the tabu-activation rule is triggered by more than one attribute. For example, in our sequencing problem, if the swap of jobs 3 and 6 is forbidden because a

Table 7 Illustrative aspiration criteria

Aspiration by	Description	Example
<i>Default</i>	If all available moves are classified tabu and are not rendered admissible by some other aspiration criteria, then a “least tabu” move is selected	Revoke the tabu status of all moves with minimum <i>TabuEnd</i> value
<i>Objective</i>	<i>Global</i> : A move aspiration is satisfied if the move yields a solution better than the best obtained so far <i>Regional</i> : A move aspiration is satisfied if the move yields a solution better than the best found in the region where the solution lies	<i>Global</i> : The best total tardiness found so far is 29. The current sequence is (4, 1, 5, 3, 6, 2) with $T = 39$. The move value of the tabu swap (5,2) is -20. Then, the tabu status of the swap is revoked and the search moves to the new best sequence (4, 1, 2, 3, 6, 5) with $T = 19$ <i>Regional</i> : The best sequence found in the region defined by all sequences (1, 2, 3, *, *, *) is (1, 2, 3, 6, 4, 5) with $T = 31$. The current solution is (1, 4, 3, 2, 6, 5) with $T = 23$. The swap (4, 2) with move value of 6 is tabu. The tabu status is revoked because a new regional best (1, 2, 3, 4, 6, 5) with $T = 29$ can be found
<i>Search direction</i>	An attribute can be added and dropped from a solution (regardless of its tabu status) if the direction of the search (improving or nonimproving) has not changed	For the Min k -Tree problem, the edge (11,12) has been recently dropped in the current improving phase making its addition a tabu-active attribute. The improving phase can continue if edge (11,12) is now added; therefore its tabu status may be revoked
<i>Influence</i>	The tabu status of a low-influence move may be revoked if a high-influence move has been performed since establishing the tabu status for the low-influence move	If the low-influence swap (1,4) described in Table 2.7 is classified tabu, its tabu status can be revoked after the high-influence swap (4,5) is performed

tabu-activation rule prevents job 3 from moving at all, then an attribute aspiration that revokes job 3's tabu-active status also revokes the move's tabu classification. However, if the swap (3,6) is classified tabu because both job 3 and job 6 are not allowed to move, then revoking job 3's tabu-active status does not result in overriding the tabu status of the entire move.

Different variants of the aspiration criteria presented in Table 7 are possible. For example, the regional aspiration by objective can be defined in terms of bounds on

the objective function value. These bounds determine the region being explored, and they are modified to reflect the discovery of better (or worse) regions. Another possibility is to define regions with respect to time. For example, one may record the best solution found during the recent past (defined as a number of iterations) and use this value as the aspiration level.

3.7 Concluding Observations for the Min k-Tree Example

Influence of Tabu Tenures

The tabu tenures used to illustrate the first-level TS approach for the Min k -Tree problem of course are very small. The risk of using such tenures can be demonstrated in this example from the fact that changing the weight of edge (3,6) in Fig. 4 from 20 to 17 will cause the illustrated TS approach with $\text{TabuAddTenure} = 2$ and $\text{TabuDropTenure} = 1$ to go into a cycle that will prevent the optimal solution from being found. The intuition that TabuDropTenure has a stronger influence than the TabuAddTenure for this problem is supported by the fact that the use of tenures of $\text{TabuAddTenure} = 1$ and $\text{TabuDropTenure} = 2$ in this case will avoid the cycling problem and allow an optimal solution to be found.

Alternative Neighborhoods

The relevance of considering alternative neighborhoods can be illustrated by reference to the following observation. For any given set of $k + 1$ nodes, an optimal (min weight) k -tree over these nodes can always be found by using the greedy constructive procedure illustrated in Table 2 to generate a starting solution (restricted to these nodes) or by beginning with an arbitrary tree on these nodes and performing a succession of static improving moves (which do not change the node set). The absence of a static-improving move signals that no better solution can be found on this set.

This suggests that tabu search might advantageously be used to guide the search over a “node-swap” neighborhood instead of an “edge-swap” neighborhood, where each move consists of adding a non-tree node i and dropping a tree node j , followed by finding a min weight solution on the resulting node set (Since the tree node j may not be a leaf node, and the reconnections may also not make node i a leaf node in the new tree, the possibilities are somewhat different than making a dynamic move in the edge-swap neighborhood). The tabu tenures may reasonably be defined over nodes added and dropped, rather than over edges added and dropped.

Critical Event Memory

The type of critical event memory used in the illustration of restarting the TS approach in Sect. 3.3.1 may not be best. Generally, it is reasonable to expect that the type of critical event memory used for restarting should be different from that used to continue the search from the current solution (when both are applied to drive the search into new regions). Nevertheless, a form that is popularly used in both situations consists of remembering *all* elements contained in solutions previously examined. One reason is that it is actually easier to maintain such memory than to keep track of elements that only occur in selected solutions. Also, instead of

keeping track only of which elements occur in past solution, critical event memory is more usually designed to monitor the frequency that elements have appeared in past solutions. Such considerations are amplified in [Sect. 5](#).

4 Additional Aspects of Short-Term Memory

We began the discussion of short-term memory for tabu search by contrasting the TS designs with those of memoryless strategies such as simple or iterated descent and by pointing out how candidate list strategies are especially important for applying TS in the most effective ways. We now describe types of candidate list strategies that often prove valuable in tabu search implementations. Then we examine the issues of logical restructuring, which provide important bridges to longer-term considerations.

4.1 Tabu Search and Candidate List Strategies

The aggressive aspect of TS is manifest in choice rules that seek the best available move that can be determined with an appropriate amount of effort. As addressed in [Sect. 3](#), the meaning of best in TS applications is customarily not limited to an objective function evaluation. Even where the objective function evaluation may appear on the surface to be the only reasonable criterion to determine the best move, the non-tabu move that yields a maximum improvement or least deterioration is not always the one that should be chosen. Rather, as we have noted, the definition of best should consider factors such as move influence, determined by the search history and the problem context.

For situations where $N^*(x)$ is large or its elements are expensive to evaluate, candidate list strategies are essential to restrict the number of solutions examined on a given iteration. In many practical settings, TS is used to control a search process that may involve the solution of relatively complex subproblems by way of linear programming or simulation. Because of the importance TS attaches to selecting elements judiciously, efficient rules for generating and evaluating good candidates are critical to the search process. The purpose of these values is to isolate regions of the neighborhood containing moves with desirable features and to put these moves on a list of candidates for current examination.

Before describing the kinds of candidate list strategies that are particularly useful in tabu search implementations, we note that the efficiency of implementing such strategies often can be enhanced by using relatively straightforward memory structures to give efficient updates of move evaluations from one iteration to another. Appropriately coordinated, such updates can appreciably reduce the effort of finding best or near-best moves.

In sequencing, for example, the move values often can be calculated without a full evaluation of the objective function. Intelligent updating can be useful even where candidate list strategies are not used. However, the inclusion of explicit

candidate list strategies, for problems that are large, can significantly magnify the resulting benefits. Not only search speed but also solution quality can be influenced by the use of appropriate candidate list strategies. Perhaps surprisingly, the importance of such approaches is often overlooked.

4.2 Some General Classes of Candidate List Strategies

Candidate lists can be constructed from context-related rules and from general strategies. In this section, we focus on rules for constructing candidate lists that are context-independent. We emphasize that the effectiveness of a candidate list strategy should not be measured in terms of the reduction of the computational effort in a single iteration. Instead, a preferable measure of performance for a given candidate list is the quality of the best solution found given a specified amount of computer time. For example, a candidate list strategy intended to replace an exhaustive neighborhood examination may result in more iterations per unit of time but may require many more iterations to match the solution quality of the original method. If the quality of the best solution found within a desirable time limit (or across a graduated series of such limits) does not improve, we conclude that the candidate list strategy is not effective.

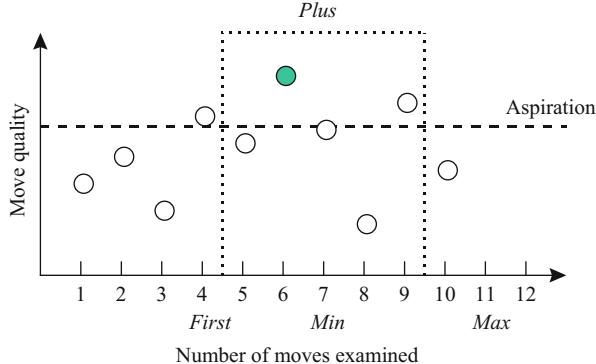

4.2.1 Aspiration Plus

The Aspiration Plus strategy establishes a threshold for the quality of a move, based on the history of the search pattern. The procedure operates by examining moves until finding one that satisfies this threshold. Upon reaching this point, additional moves are examined, equal in number to the selected value *Plus*, and the best move overall is selected.

To assure that neither too few nor too many moves are considered, this rule is qualified to require that at least *Min* moves and at most *Max* moves are examined, for chosen values of *Min* and *Max*. The interpretation of *Min* and *Max* is as follows. Let *First* denote the number of moves examined when the aspiration threshold is first satisfied. Then if *Min* and *Max* were not specified, the total number of moves examined would be *First* + *Plus*. However, if *First* + *Plus* < *Min*, then *Min* moves are examined while if *First* + *Plus* > *Max*, then *Max* moves are examined (This conditions may be viewed as imposing limits on the move that is “effectively” treated as the *First* move. For example, if as many as *Max* – *Plus* moves are examined without finding one that satisfies the aspiration threshold, then *First* effectively becomes the same as *Max* – *Plus*).

This strategy is graphically represented in Fig. 11. In this illustration, the fourth move examined satisfies the aspiration threshold and qualifies as *First*. The value of *Plus* has been selected to be 5, and so 9 moves are examined in total, selecting the best over this interval. The value of *Min*, set at 7, indicates that at least 7 moves will be examined even if *First* is so small that *First* + *Plus* < 7 (In this case, *Min* is not very restrictive, because it only applies if *First* < 2). Similarly, the value of *Max*, set at 11, indicates that at most 11 moves will be examined even if *First* is so large

Fig. 11 Aspiration Plus strategy

that $\text{First} + \text{Plus} > 11$ (Here, Max is strongly restrictive). The sixth move examined is the best found in this illustration.

The “Aspiration” line in this approach is an established threshold that can be dynamically adjusted during the search. For example, during a sequence of improving moves, the aspiration may specify that the next move chosen should likewise be improving, at a level based on other recent moves and the current objective function value. Similarly, the values of Min and Max can be modified as a function of the number of moves required to meet the threshold.

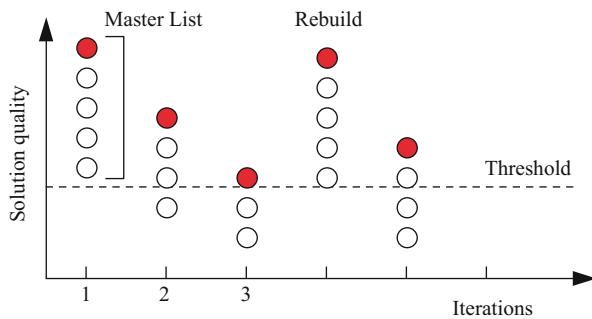

During a nonimproving sequence, the aspiration of the Aspiration Plus rule will typically be lower than during an improving phase but rise toward the improving level as the sequence lengthens. The quality of currently examined moves can shift the threshold, as by encountering moves that significantly surpass or that uniformly fall below the threshold. As an elementary option, the threshold can simply be a function of the quality of the initial Min moves examined on the current iteration.

The Aspiration Plus strategy includes several other strategies as special cases. For example, a *first-improving* strategy results by setting $\text{Plus} = 0$ and directing the aspiration threshold to accept moves that qualify as improving, while ignoring the values of Min and Max. Then *First* corresponds to the first move that improves the current value of the objective, if such a move can be found. A slightly more advanced strategy can allow *Plus* to be increased or decreased according to the variance in the quality of moves encountered from among some initial number examined. In general, in applying the Aspiration Plus strategy, it is important to assure on each iteration that new moves are examined which differ from those just reviewed. One way of achieving this is to create a circular list and start each new iteration where the previous examination left off.

4.2.2 Elite Candidate List

The elite candidate list approach first builds a Master List by examining all (or a relatively large number of) moves, selecting the k best moves encountered, where k is a parameter of the process. Then at each subsequent iteration, the current best move from the Master List is chosen to be executed, continuing until such a move

Fig. 12 Elite candidate list strategy

falls below a given quality threshold or until a given number of iterations have elapsed. Then a new Master List is constructed and the process repeats. This strategy is depicted in Fig. 12 below.

This technique is motivated by the assumption that a good move, if not performed at the present iteration, will still be a good move for some number of iterations. More precisely, after an iteration is performed, the nature of a recorded move implicitly may be transformed. The assumption is that a useful proportion of these transformed moves will inherit attractive properties from their antecedents.

The evaluation and precise identity of a given move on the list must be appropriately monitored, since one or both may change as result of executing other moves from the list. For example, in the Min k -Tree problem, the evaluations of many moves can remain unchanged from one iteration to the next. However, the identity and evaluation of specific moves will change as a result of deleting and adding particular edges, and these changes should be accounted for by appropriate updating (applied periodically if not at each iteration). An elite candidate list strategy can be advantageously extended by a variant of the Aspiration Plus strategy, allowing some additional number of moves outside the Master List to be examined at each iteration, where those of sufficiently high quality may replace elements of the Master List.

4.2.3 Successive Filter Strategy

Moves can often be broken into component operations, and the set of moves examined can be reduced by restricting consideration to those that yield high-quality outcomes for each operation separately. For example, the choice of an exchange move that includes an “add component” and a “drop component” may restrict attention only to exchanges created from a relatively small subset of “best add” and “best drop” components. The gain in efficiency can be considerable. If there are 100 add possibilities and 100 drop possibilities, the number of add/drop combinations is 10,000. However, by restricting attention to the 8 best add and drop moves, considered independently, the number of combinations to examine is only 64 (Values of 8 and even smaller have been found effective in some practical applications).

The evaluations of the separate components often will give only approximate information about their combined evaluation. Nevertheless, if this information is good enough to insure a significant number of the best complete moves will result by combining these apparently best components, then the approach can yield quite good outcomes. Improved information may be obtained by sequential evaluations, as where the evaluation of one component is conditional upon the prior (restricted) choices of another. Such strategies of subdividing compound moves into components, and then restricting consideration of complete compound moves only to those assembled from components that pass selected thresholds of quality, have proved quite effective in TS methods for partitioning problems and for telecommunication channel-balancing problems.

Conditional uses of component evaluations are also relevant for sequencing problems, where a measure can be defined to identify preferred attributes using information such as due dates, processing times, and delay penalties. If swap moves are being used, then some jobs are generally better candidates than others to move early or later in the sequence. The candidate list considers those swaps whose composition includes at least one of these preferred attributes.

In the context of the traveling salesman problem, good solutions are often primarily composed of edges that are among the 20–40 shortest edges meeting one of their endpoints (depending on various factors). Some studies have attempted to limit consideration entirely to tours constructed from such a collection of edges. The successive filter strategy, by contrast, offers greater flexibility by organizing moves that do not have to be entirely composed of such special elements, provided one or more of these elements is incorporated as part of the move. This approach can be frequently controlled to require little more time than the more restricted standard approach, while affording a more desirable set of alternatives to consider.

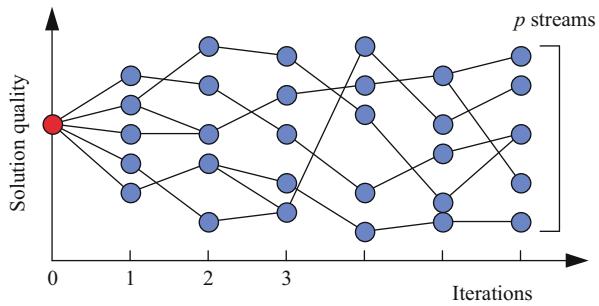

4.2.4 Sequential Fan Candidate List

A type of candidate list that is highly exploitable by parallel processing is the sequential fan candidate list. The basic idea is to generate some p best alternative moves at a given step and then to create a fan of solution streams, one for each alternative. The several best available moves for each stream are again examined, and only the p best moves overall (where many or no moves may be contributed by a given stream) provide the p new streams at the next step.

In the setting of tree search methods, such a sequential fanning process is sometimes called *beam search*. For use in the tabu search framework, TS memory and activation rules can be carried forward with each stream and hence inherited in the selected continuations. Since a chosen solution can be assigned to more than one stream, different streams can embody different missions in TS. Alternatively, when two streams merge into the same solution, other streams may be started by selecting a neighbor adjacent to one of the current streams.

The process is graphically represented in Fig. 13. Iteration 0 constructs an initial solution or alternatively may be viewed as the starting point for constructing a solution. That is, the sequential fan approach can be applied using one type of move to create a set of initial solutions and then can continue using another type

Fig. 13 Sequential fan candidate lis

of move to generate additional solutions (We thus allow a “solution” to be a partial solution as well as a complete solution). The best moves from this solution are used to generate p streams. Then at every subsequent iteration, the overall best moves are selected to lead the search to p different solutions. Note that since more than one move may lead the search to the same solution, more than p moves may be necessary to continue the exploration of p distinct streams.

A more intensive form of the sequential fan candidate list approach, which is potentially more powerful but requires more work, is to use the process illustrated in Fig. 13 as a “look-ahead” strategy. In this case, a limit is placed on the number of iterations that the streams are generated beyond iteration 0. Then the best outcome at this limiting iteration is used to identify a “best current move” (a single first branch) from iteration 0. Upon executing this move, the step shown as iteration 1 in Fig. 13 becomes the new iteration 0, that is, iteration 0 always corresponds to the current iteration. Then this solution becomes the source of p new streams, and the process repeats.

There are a number of possible variants of this sequential fan strategy. For example, instead of selecting a single best branch at the limiting iteration, the method can select a small number of best branches and thus give the method a handful of candidates from which to generate p streams at the new iteration 0.

The iteration limit that determines depth of the look ahead can be variable, and the value of p can change at various depths. Also the number of successors of a given solution that are examined to determine candidates for the p best continuations can be varied as by progressively reducing this number at greater depths.

The type of staging involved in successive solution runs of each stream may be viewed as a means of defining levels in the context of the Proximate Optimality Principle commonly associated with the strategic oscillation component of tabu search. Although we will study this principle in more detail later, we remark that the sequential fan candidate list has a form that is conveniently suited to exploit it.

4.2.5 Bounded Change Candidate List

A bounded change candidate list strategy is relevant in situations where an improved solution can be found by restricting the domain of choices so that no solution

component changes by more than a limited degree on any step. A bound on this degree, expressed by a distance metric appropriate to the context, is selected large enough to encompass possibilities considered strategically relevant. The metric may allow large changes along one dimension but limit the changes along another so that choices can be reduced and evaluated more quickly. Such an approach offers particular benefits as part of an intensification strategy based on decomposition, where the decomposition itself suggests the limits for bounding the changes considered.

4.3 Connections Between Candidate Lists, Tabu Status, and Aspiration Criteria

It is useful to summarize the short-term memory considerations embodied in the interaction between candidate lists, tabu status, and aspiration criteria. The operations of these TS short-term elements are shown in [Fig. 14](#). The representation of penalties in [Fig. 14](#) either as “large” or “very small” expresses a thresholding effect: Either the tabu status yields a greatly deteriorated evaluation or else it chiefly serves to break ties among solutions with highest evaluations. Such an effect of course can be modulated to shift evaluations across levels other than these extremes. If all moves currently available lead to solutions that are tabu (with evaluations that normally would exclude them from being selected), the penalties result in choosing a “least tabu” solution.

The sequence of the *tabu test* and the *aspiration test* in [Fig. 14](#) evidently can be reversed (i.e., by employing the tabu test only if the aspiration threshold is not satisfied). Also, the tabu evaluation can be modified by creating inducements based on the aspiration level, just as it is modified by creating penalties based on tabu status. In this sense, aspiration conditions and tabu conditions can be conceived roughly as “mirror images” of each other.

For convenience, [Fig. 14](#) expresses tabu restrictions solely in terms of penalized evaluations, although we have seen that tabu status is often permitted to serve as an all-or-none threshold, without explicit reference to penalties and inducements (by directly excluding tabu options from being selected, subject to the outcome of aspiration tests). Whether or not modified evaluations are explicitly used, the selected move may not be the one with the best objective function value, and consequently, the solution with the best objective function value encountered throughout the search history is recorded separately.

4.4 Logical Restructuring

Logical restructuring is an important element of adaptive memory solution approaches, which gives a connection between short- and long-term strategies. Logical restructuring is implicit in strategic oscillation and path relinking, which we examine in subsequent sections, but its role and significance in these strategies is

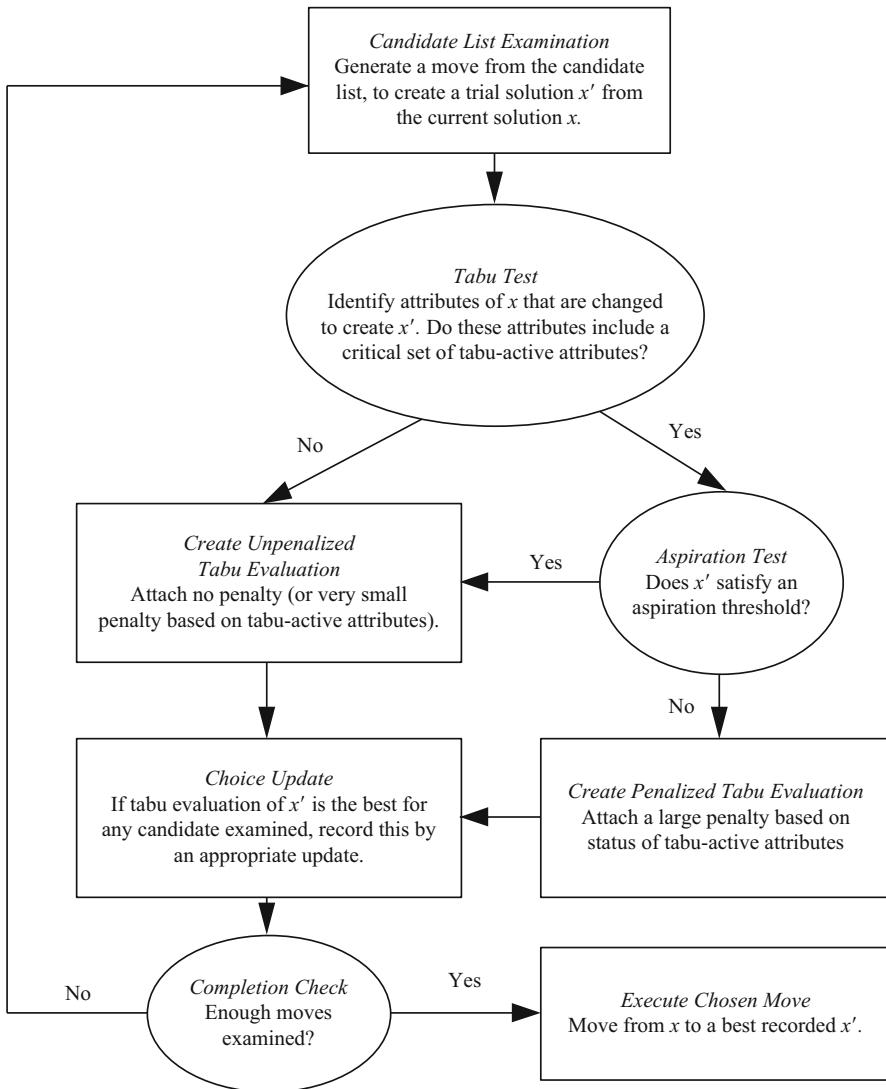

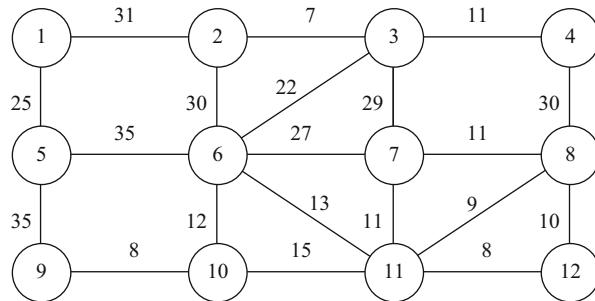

Fig. 14 Short-term memory operation

often overlooked. By extension, the general usefulness of logical restructuring is also often not clearly understood. We examine some of its principal features before delving into longer-term considerations and show how it can also be relevant for improving the designs of short-term strategies.

Logical restructuring emerges as a way to meet the combined concerns of quality and influence. Its goal is to exploit the ways in which influence (structural, local, and global) can uncover improved routes to high-quality solutions. For this purpose, a critical step is to redesign standard strategies to endow them with the

Fig. 15 Illustrative Min k -Tree problem

power to ferret out opportunities otherwise missed. This step particularly relies on integrating two elements: (1) the identification of changes that satisfy properties that are essential (and limiting) in order to achieve improvement, in contrast to changes that simply depart from what has previously been seen and (2) the use of anticipatory (“means-ends”) analysis to bring about such essential changes. Within the context of anticipatory analysis, logical restructuring seeks to answer the following questions: “What conditions assure the existence of a trajectory that will lead to an improved solution?” and “What intermediate moves can create such conditions?” The “intermediate moves” of the second question may be generated either by modifying the evaluations used to select transitions between solutions or by modifying the neighborhood structure that determines these transitions.

To illustrate the relevant considerations, we return again to the example of the Min k -Tree problem discussed in previous sections. We replace the previous graph by the one shown in Fig. 15 but continue to consider the case of $k = 4$.

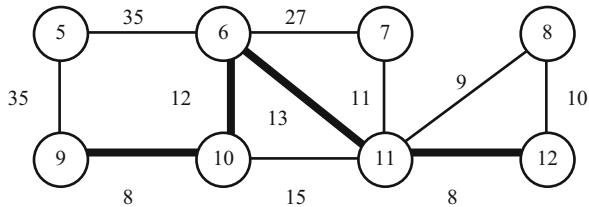

The same rules to execute a first-level tabu search approach as in our earlier illustrations (including the rules for generating a starting solution) produce a sequence of steps that quickly reaches the vicinity of the optimal solution but require some effort actually find this solution. In fact, it is readily verified that applying these rules will cause all edges of the optimal solution except one, edge (10,11), to be contained in the union of the two solutions obtained on iterations 4 and 5. Yet an optimal solution will not be found until iteration 11.

This delayed process of finding a route to an optimal solution (which can be greatly magnified for larger or more complex problems) can be substantially accelerated by means of logical restructuring. More generally, such restructuring can make it possible to uncover fertile options that can otherwise be missed entirely.

4.4.1 Restructuring by Changing Evaluations and Neighborhoods

The first type of logical restructuring we illustrate makes use both of modified evaluations and an amended neighborhood structure. As pointed out in Sect. 3.2 earlier, the swap moves we have employed for the Min k -Tree problem may be subdivided into two types: *static* swaps, which leave the nodes of the current tree unchanged, and *dynamic* swaps, which replace one of the nodes currently in the tree with another that is not in the tree. This terminology was chosen to reflect the effect that each swap type has on the nodes of the tree. Since dynamic swaps in a sense

Fig. 16 Solution and candidate edges to add to iteration 4 tree

are more influential, we give them special consideration. We observe that a dynamic swap can select an edge to be dropped only if it is a *terminal edge*, that is, one that meets a *leaf node* of the tree, which is a node that is met by only a single tree edge (the terminal edge).

Although it is usually advantageous to drop an edge with a relatively large weight, this may not be possible. Thus, we are prompted to consider an “anticipatory goal” of making moves that cause more heavily weighted edges to become terminal edges and hence eligible to be dropped. By this means, static swaps can be used to set up desirable conditions for dynamic swaps.

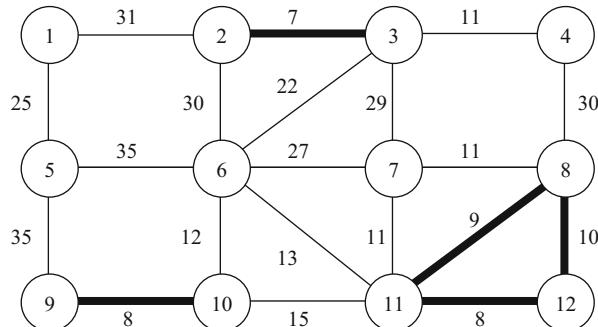

The solution obtained at iteration 4 of the process for solving the example problem of Fig. 15 gives a basis for showing what is involved. We clarify the situation by showing the current solution at this iteration in Fig. 16 (without bothering to identify the solutions obtained at other iterations), where edges contained in the current tree are shown as heavy edges and the candidate edges to add to the tree are shown as light edges.

The move that changes the tree at iteration 4 to that of iteration 5 – if the rules illustrated in Sect. 3 are used – is a dynamic swap that adds edge (8,11) with a weight of 9 and drops edge (9,10) with a weight of 8. We make use of information contained in this choice to construct a more powerful move using logical restructuring, as follows.

Having identified (8,11) as a candidate to be added, the associated anticipatory goal is to identify a static swap that will change a larger weight edge into a terminal edge. Specifically, the static swap that adds edge (10,11) and drops edge (6,10), with a move value of 3, produces a terminal edge from the relatively high weight edge (6,11) (which has a weight of 13). Since the candidate edge (8,11) to be added has a weight of 9, the result of joining the indicated static swap with the subsequent dynamic swap (that respectively adds and drops (8,11) and (6,11)) will be a net gain (The static move value of 3 is joined with the dynamic move value of -4, yielding a result of -1).

Effectively, such anticipatory analysis leads to a way to extract a fruitful outcome from a relatively complex set of options by focusing on a simple set of features. It would be possible to find the same outcome by a more ponderous approach that checks all sequences in which a dynamic move follows a static move. This requires a great deal of computational effort, in fact, considerably more than involved in the approach without logical restructuring that succeeded in finding an optimal solution at iteration 11 (considering the trade-off between number of iterations and work per iteration).

Fig. 17 Threshold generated components

By contrast, the use of logical restructuring allows the anticipatory analysis to achieve the benefits of a more massive exploration of alternatives but without incurring the burden of undue computational effort. In this example, the restructuring is accomplished directly as follows. First, it is only necessary to identify the two best edges to add for a dynamic swap (independent of matching them with an edge to drop), subject to requiring that these edges meet different nodes of the tree (In the tree of iteration 4, seen in Fig. 17, these two edges are (8,11) and (8,12)). Then at the next step, during the process of looking at candidate static swaps, a modified “anticipatory move value” is created for each swap that creates a terminal edge, by subtracting the weight of this edge from the standard move value.

This gives all that is needed to find (and evaluate) a best “combined move sequence” of the type we are looking for. In particular, every static move that generates a terminal edge can be combined with a dynamic move that drops this edge and then adds one of the two “best edges” identified in first of the two preceding steps. Hence, the restructuring is completed by adding the anticipatory move value to the weight of one of these two edges (appropriately identified) thereby determining a best combined move. The illustrated process therefore achieves restructuring in two ways: by modifying customary move values and by fusing certain sequences of moves into a single compound move.

Although this example appears on the surface to be highly problem specific, its basic features are shared by applications that arise in a variety of problem settings. Later, the reader will see how variants of logical restructuring embodied in this illustration are natural components of the strategies of path relinking and ejection chain constructions.

4.4.2 Threshold-Based Restructuring and Induced Decomposition

The second mode of logical restructuring that we illustrate by reference to the Min k -Tree problem example is more complex (in the sense of inducing a more radical restructuring) but relatively easy to sketch and also potentially more powerful.

Consider again the solution produced at iteration 4. This is a local optimum and also the best solution found up to the current stage of search. We seek to identify a property that will be satisfied by at least one solution that has a smaller weight than the weight of this solution (41) and which will impose useful limits

on the composition of such a solution. A property that in fact must be shared by all “better” solutions can be expressed as a threshold involving the average weight of the tree edges. This average weight must be less than the threshold value of 41/4 (i.e., 10 1/4). Since some of the edges in any improved solution must have weights less than this threshold, we are motivated to identify such “preferred” edges as a foundation for a restructured form of the solution approach. In this type of restructuring, we no longer confine attention to swap moves but look for ways to link the preferred edges to produce an improved solution (Such a restructuring can be based on threshold values derived from multiple criteria).

When the indicated strategy is applied to the present example, a large part of the graph is eliminated, leaving only 3 separate connected components: (a) the edge (2,3), (b) the edge (9,10), and (c) the three edges (8,11), (8,12), and (11,12). The graph that highlights these components is shown in Fig. 17. At this point, a natural approach is to link such components by shortest paths and then shave off terminal edges if the trees are too large, before returning to the swapping process. Such an approach will immediately find the optimal solution that previously was not found until iteration 11.

This second illustrated form of restructuring is a fundamental component of the strategic oscillation approach which we describe in more detail in the next section. A salient feature of this type of restructuring is its ability to create an *induced decomposition* of either the solution space or the problem space. This outcome, coupled with the goal of effectively joining the decomposed components to generate additional solution alternatives, is also a basic characteristic of path relinking, which is also examined in the next section. More particularly, the special instance of path relinking known as vocabulary building, which focuses on assembling fragments of solutions into larger units, offers a direct model for generalizing the “threshold decomposition” strategy illustrated here.

In some applications, specific theorems can be developed about the nature of optimal solutions and can be used to provide relevant designs for restructuring. The Min k -Tree problem is one for which such a theorem is available (Glover and Laguna, [31]). Interestingly, the second form of restructuring we have illustrated, which is quite basic, exploits several aspects of this theorem, although without “knowing” what the theorem is. In general, logical restructuring and the TS strategies such as path relinking and strategic oscillation which embody it appear to behave as if they similarly have a capacity to exploit underlying properties of optimal solutions in broader contexts, contexts whose features are not sufficiently uniform or easily characterized to permit the nature of optimal solutions to be expressed in the form of a theorem.

5 Longer-Term Memory

In some applications, the short-term TS memory components are sufficient to produce very high-quality solutions. However, in general, TS becomes significantly stronger by including longer-term memory and its associated strategies. In the longer-term TS strategies, the modified neighborhood produced by tabu search

may contain solutions not in the original one, generally consisting of selected elite solutions (high-quality local optima) encountered at various points in the solution process. Such elite solutions typically are identified as elements of a regional cluster in intensification strategies and as elements of different clusters in diversification strategies. In addition, elite solution components, in contrast to the solutions themselves, are included among the elements that can be retained and integrated to provide inputs to the search process.

Perhaps surprisingly, the use of longer-term memory does not require long solution runs before its benefits become visible. Often, its improvements begin to be manifest in a relatively modest length of time and can allow solution efforts to be terminated somewhat earlier than otherwise possible, due to finding very high-quality solutions within an economical time span. The fastest methods for some types of routing and scheduling problems, for example, are based on including longer-term TS memory. On the other hand, it is also true that the chance of finding still better solutions as time grows, in the case where an optimal solution is not already found, is enhanced by using longer-term TS memory in addition to short-term memory.

5.1 Frequency-Based Approach

Frequency-based memory provides a type of information that complements the information provided by recency-based memory, broadening the foundation for selecting preferred moves. Like recency, frequency often is weighted or decomposed into subclasses by taking account of the dimensions of solution quality and move influence. Also, frequency can be integrated with recency to provide a composite structure for creating penalties and inducements that modify move evaluations (Although recency-based memory is often used in the context of short-term memory, it can also be a foundation of longer-term forms of memory).

For our present purposes, we conceive frequencies to consist of ratios, whose numerators represent counts expressed in two different measures: a *transition measure*, the number of iterations where an attribute changes (enters or leaves) the solutions visited on a particular trajectory, and a *residence measure*, the number of iterations where an attribute belongs to solutions visited on a particular trajectory or the number of instances where an attribute belongs to solutions from a particular subset. The denominators generally represent one of three types of quantities: (1) the total number of occurrences of all events represented by the numerators (such as the total number of associated iterations), (2) the sum (or average) of the numerators, and (3) the maximum numerator value. In cases where the numerators represent weighted counts, some of which may be negative, denominator (3) is expressed as an absolute value and denominator (2) is expressed as a sum of absolute values (possibly shifted by a small constant to avoid a zero denominator). The ratios produce *transition frequencies* that keep track of how often attributes change and *residence frequencies* that keep track of how often attributes are members of solutions generated. In addition to referring to such frequencies, thresholds based on the numerators alone can be useful for indicating when phases of greater

diversification are appropriate (The thresholds for particular attributes can shift after a diversification phase is executed).

Residence frequencies and transition frequencies sometimes convey related information but in general carry different implications. They are sometimes confused (or treated identically) in the literature. A noteworthy distinction is that residence measures, by contrast to transition measures, are not concerned with the characteristics of a particular solution attribute or whether it is an attribute that changes in moving from one solution to another. For example, in the Min k -Tree problem, a residence measure may count the number of times edge (i, j) was part of the solution, while a transition measure may count the number of times edge (i, j) was added to the solution (More complex joint measures, such as the number of times edge (i, j) was accompanied in the solution by edge (k, l) or was deleted from the solution in favor of edge (k, l) , can also selectively be generated. Such frequencies relate to the issues of creating more complex attributes out of simpler ones and to the strategies of vocabulary building).

A high residence frequency may indicate that an attribute is highly attractive if the domain consists of high-quality solutions or may indicate the opposite if the domain consists of low quality solutions. On the other hand, a residence frequency that is high (or low) when the domain is chosen to include both high- and low-quality solutions may point to an entrenched (or excluded) attribute that causes the search space to be restricted and that needs to be jettisoned (or incorporated) to allow increased diversity. For example, an entrenched attribute may be a job that is scheduled in the same position during a sequence of iterations that include both low- and high quality-objective function evaluations.

As a further useful distinction, a high transition frequency, in contrast to a high residence frequency, may indicate an associated attribute and is a “crack filler” that shifts in and out of solutions to perform a fine-tuning function. In this context, a transition frequency may be interpreted as a measure of volatility. For example, the Min k -Tree problem instance in Fig. 4 of Sect. 3 contains a number of edges whose weight may give them the role of crack fillers. Specifically, edges (3,5) and (6,7) both have a weight of 6, which makes them attractive relative to other edges in the graph. Since these edges are not contained in an optimal solution, there is some likelihood that they may repeatedly enter and leave the current solution in a manner to lure the search away from the optimal region. In general, crack fillers are determined not simply by cost or quality but by structure, as in certain forms of connectivity (Hence, e.g., the edge (3,5) of Fig. 4 does not repeatedly enter and leave solutions in spite of its cost). Some subset of such elements is also likely to be a part of an optimal solution. This subset can typically be identified with much less difficulty once other elements are in place. On the other hand, a solution (full or partial) may contain the “right” crack fillers but offer little clue as to the identity of the other attributes that will transform the solution into one that is optimal.

We use a sequencing problem and the Min k -Tree problem as contexts to further illustrate both residence and transition frequencies. Only numerators are indicated, understanding that denominators are provided by the conditions (1)–(3) previously defined. The measures are given in Table 8.

Table 8 Example of frequency measures

<i>Problem</i>	<i>Residence measure</i>	<i>Transition measure</i>
Sequencing	Number of times job j has occupied position $\pi(j)$	Number of times job i has exchanged positions with job j
	Sum of tardiness of job j when this job occupies position $\pi(j)$	Number of times job j has been moved to an earlier position in the sequence
Min k -Tree problem	Number of times edge (i, j) has been part of the current solution	Number of times edge (i, j) has been deleted from the current solution when edge (k, l) has been added
	Sum of total solution weight when edge (i, j) is part of the solution	Number of times edge (i, j) has been added during improving moves

Attributes that have greater frequency measures, just as those that have greater recency measures (i.e., that occur in solutions or moves closer to the present), can trigger a tabu-activation rule if they are based on consecutive solutions that end with the current solution. However, frequency-based memory often finds its most productive use as part of a longer-term strategy, which employs incentives as well as restrictions to determine which moves are selected. In such a strategy, tabu-activation rules are translated into evaluation penalties, and incentives become evaluation enhancements, to alter the basis for qualifying moves as attractive or unattractive.

To illustrate, in a scheduling setting where a swap neighborhood is used, an attribute such as a job j with a high residence frequency in position $\pi(j)$ may be assigned a strong incentive (“profit”) to serve as a *swap attribute*, thus resulting in the choice of a move that yields a new sequence π' with $\pi'(j) \neq \pi(j)$. Such an incentive is particularly relevant in the case where the *TabuEnd* value of job j is small compared to the current iteration, since this value (minus the corresponding tabu tenure) identifies the latest iteration that job j was a *swap attribute*, and hence discloses that job j has occupied position $\pi(j)$ in every solution since.

Frequency-based memory therefore is usually applied by introducing graduated tabu states, as a foundation for defining penalty and incentive values to modify the evaluation of moves. A natural connection exists between this approach and the recency-based memory approach that creates tabu status as an all-or-none condition. If the tenure of an attribute in recency-based memory is conceived as a conditional threshold for applying a very large penalty, then the tabu classifications produced by such memory can be interpreted as the result of an evaluation that becomes strongly inferior when the penalties are activated. Conditional thresholds are also relevant to determining the values of penalties and incentives in longer-term strategies. Most applications at present, however, use a simple linear multiple of a frequency measure to create a penalty or incentive term. The multiplier is adjusted to create the right balance between the incentive or penalty and the cost (or profit) coefficients of the objective function.

5.2 Intensification Strategies

Intensification strategies are based on modifying choice rules to encourage move combinations and solution features historically found good. They may also initiate a return to attractive regions to search them more thoroughly. A simple instance of this second type of intensification strategy is shown in Fig. 18. The strategy for selecting elite solutions is italicized in Fig. 18 due to its importance. Two variants have proved quite successful. One introduces a diversification measure to assure the solutions recorded differ from each other by a desired degree and then erases all short-term memory before resuming from the best of the recorded solutions. A diversification measure may be related to the number of moves that are necessary to transform one solution into another. Or the measure may be defined independently from the move mechanism. For example, in sequencing, two solutions may be considered diverse if the number of swaps needed to move from one to the other is “large.” On the other hand, the diversification measure may be the number of jobs that occupy a different position in the two sequences being compared (This shows that intensification and diversification often work together, as elaborated in the next section).

The second variant that has also proved successful keeps a bounded length sequential list that adds a new solution at the end only if it is better than any previously seen. The current last member of the list is always the one chosen (and removed) as a basis for resuming search. However, TS short-term memory that accompanied this solution is also saved, and the first move also forbids the move previously taken from this solution, so that a new solution path will be launched.

A third variant of the approach of Fig. 18 is related to a strategy that resumes the search from unvisited neighbors of solutions previously generated. Such a strategy keeps track of the quality of these neighbors to select an elite set and restricts attention to specific types of solutions, such as neighbors of local optima or neighbors of solutions visited on steps immediately before reaching such local optima. This type of “unvisited neighbor” strategy has been little examined. It is noteworthy, however, that the two variants previously indicated have provided solutions of remarkably high quality.

Another type of intensification approach is *intensification by decomposition*, where restrictions may be imposed on parts of the problem or solution structure in order to generate a form of decomposition that allows a more concentrated focus on other parts of the structure. A classical example is provided by the traveling salesman problem, where edges that belong to the intersection of elite tours may be “locked into” the solution, in order to focus on manipulating other parts of the tour. The use of intersections is an extreme instance of a more general strategy for exploiting frequency information, by a process that seeks to identify and constrain the values of *strongly determined* and *consistent variables*. We discuss the identification and use of such variables in Sect. 4.4.1.

Intensification by decomposition also encompasses other types of strategic considerations, basing the decomposition not only on indicators of strength and consistency but also on opportunities for particular elements to interact productively.

Fig. 18 Simple TS intensification approach

```

Apply TS short term memory.
Apply an elite selection strategy.
do {
    Choose one of the elite solutions.
    Resume short term memory TS from chosen solution.
    Add new solutions to elite list when applicable.
} while (iterations < limit and list not empty)

```

Within the context of a permutation problem as in scheduling or routing, for example, where solutions may be depicted as selecting one or more sequences of edges in a graph, a decomposition may be based on identifying subchains of elite solution, where two or more subchains may be assigned to a common set if they contain nodes that are “strongly attracted” to be linked with nodes of other subchains in the set. An edge disjoint collection of subchains can be treated by an intensification process that operates in parallel on each set, subject to the restriction that the identity of the endpoints of the subchains will not be altered. As a result of the decomposition, the best new sets of subchains can be reassembled to create new solutions. Such a process can be applied to multiple alternative decompositions in broader forms of intensification by decomposition.

These ideas are lately finding favor in other procedures and may provide a bridge for interesting components of tabu search with components of other methodologies. We address the connections with these methodologies in Sect. 6.

5.3 Diversification Strategies

Search methods based on local optimization often rely on diversification strategies to increase their effectiveness in exploring the solution space defined by a combinatorial optimization problem. Some of these strategies are designed with the chief purpose of preventing searching processes from *cycling*, that is, from endlessly executing the same sequence of moves (or more generally, from endlessly and exclusively revisiting the same set of solutions). Others are introduced to impart additional robustness or vigor to the search. Genetic algorithms use randomization in component processes such as combining population elements and applying crossover (as well as occasional mutation), thus providing an approximate diversifying effect. Simulated annealing likewise incorporates randomization to make diversification a function of temperature, whose gradual reduction correspondingly diminishes the directional variation in the objective function trajectory of solutions generated. Diversification in GRASP (greedy randomized adaptive search procedures) is achieved in a certain sense within repeated construction phases by means of a random sampling over elements that pass a threshold of attractiveness by a greedy criterion.

In tabu search, diversification is created to some extent by short-term memory functions but is particularly reinforced by certain forms of longer-term memory. TS diversification strategies, as their name suggests, are designed to drive the search

into new regions. Often, they are based on modifying choice rules to bring attributes into the solution that are infrequently used. Alternatively, they may introduce such attributes by periodically applying methods that assemble subsets of these attributes into candidate solutions for continuing the search or by partially or fully restarting the solution process. Diversification strategies are particularly helpful when better solutions can be reached only by crossing barriers or “humps” in the solution space topology.

5.3.1 Modifying Choice Rules

Consider a TS method designed to solve a graph-partitioning problem which uses full and partial swap moves to explore the local neighborhood. The goal of this problem is to partition the nodes of the graph into two equal subsets so that the sum of the weights of the edges that join nodes in one subset to nodes in the other subset is minimized. Full swaps exchange two nodes that lie in two different sets of the partition. Partial swaps transfer a single node from one set to the other set. Since full swaps do not modify the number of nodes in the two sets of the partition, they maintain feasibility, while partial swaps do not. Therefore, under appropriate guidance, one approach to generate diversity is to periodically disallow the use of nonimproving full swaps for a chosen duration (after an initial period where the search “settles down”). The partial swaps must of course be coordinated to allow feasibility to be recovered after achieving various degrees of infeasibility (This relates to the approach of strategic oscillation, described in Sect. 5.4). Implemented appropriately, this strategy has the effect of intelligently perturbing the current solution, while escaping from a local optimum, to an extent that the search is directed to a region that is different than the one being currently explored. The implementation of this strategy as applied to experimental problems has resulted in significant improvements in problem-solving efficacy.

The incorporation of partial swaps in place of full swaps in the previous example can be moderated by using the following penalty function:

$$\text{MoveValue}' = \text{MoveValue} + d * \text{Penalty}.$$

This type of penalty approach is commonly used in TS, where the *Penalty* value is often a function of frequency measures such as those indicated in Table 8 and d is an adjustable diversification parameter. Larger d values correspond to a desire for more diversification (For example, nodes that change sets more frequently are penalized more heavily to encourage the choice of moves that incorporate other nodes. Negative penalties, or “inducements,” may also be used to encourage low-frequency elements). The penalty can be applied to classes of moves as well as to attributes of moves. Thus, during a phase where full swaps moves are excluded, all such moves receive a large penalty (with a value of d that is effectively infinite).

In some applications where d is used to inhibit the selection of “feasibility preserving” moves, the parameter can be viewed as the reciprocal of a Lagrangian multiplier in that “low” values result in nearly infinite costs for constraint violation, while “high” values allow searching through infeasible regions. The adjustment of

such a parameter can be done in a way to provide a strategic oscillation around the feasibility boundary, again as discussed in [Sect. 5.4](#). The parameter can also be used to control the amount of randomization in probabilistic versions of tabu search.

In TS methods that incorporate the simplex method of linear programming, as in “adjacent extreme point approaches” for solving certain nonlinear and mixed-integer programming problems, a diversification phase can be designed based on the number of times variables become basic. For example, a diversification step can give preference to bringing a nonbasic variable into the basis that has remained out of the basis for a relatively long period (cumulatively, or since its most recent inclusion, or a combination of the two). The number of successive iterations such steps are performed, and the frequency with which they are initiated, are design considerations of the type that can be addressed, for example, by the approach of target analysis (see [Sect. 6](#)).

5.3.2 Restarting

Frequency information can be used in different ways to design restarting mechanisms within tabu search. In a sequencing problem, for example, the overall frequency of jobs occupying certain positions can be used to bias a construction procedure and generate new restarting points.

In a TS method for a location/allocation problem, a diversification phase can be developed using frequency counts on the number of times a depot has changed its status (from open to closed or vice versa). The diversification phase can be started from the best solution found during the search. Based on the frequency information, d depots with the lowest counts are selected and their status is changed. The search starts from the new solution which differs from the best by exactly d components. To prevent a quick return to the best solution, the status of the d depots is also recorded in short-term memory (This is another case where residence frequency measures may provide useful alternatives or supplements to transition frequency measures).

Additional forms of memory functions are possible when a restarting mechanism is implemented. For example, in the location/allocation problem, it is possible to keep track of recent sets of depots that were selected for diversification and avoid the same selection in the next diversification phase. Similarly, in a sequencing problem, the positions occupied by jobs in recent starting points can be recorded to avoid future repetition. This may be viewed as a very simple form of the critical event memory discussed in [Sect. 3](#), and more elaborate forms will often yield greater benefits. The exploitation of such memory is very important in TS designs that are completely deterministic, since in these cases, a given starting point will always produce the same search path. Experience also shows, however, that uses of TS memory to guide probabilistic forms of restarting can likewise yield benefits [[14, 50, 64](#)].

Before concluding this section, it is appropriate to provide a word of background about the orientation underlying diversification strategies within the tabu search framework. Often there appears to be a hidden assumption that diversification is somehow tantamount to randomization. Certainly, the introduction of a random element to achieve a diversifying effect is a widespread theme among search

procedures and is fundamental to the operation of simulated annealing and genetic algorithms. From an abstract standpoint, there is clearly nothing wrong with equating randomization and diversification, but to the extent that diversity connotes differences among elements of a set and to the extent that establishing such differences is relevant to an effective search strategy, then the popular use of randomization is at best a convenient proxy (and at worst a haphazard substitute) for something quite different.

When randomization is used as part of a restarting mechanism, for example, frequency information can be employed to approximate probability distributions that bias the construction process. In this way, randomization is not a “blind” mechanism, but instead, it is guided by search history. We examine inappropriate roles of randomization in [Sect. 5.6](#), where we also explore the intensification/diversification distinction more thoroughly.

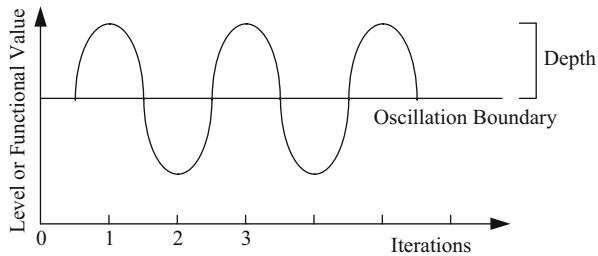

5.4 Strategic Oscillation

Strategic oscillation is closely linked to the origins of tabu search and provides a means to achieve an effective interplay between intensification and diversification over the intermediate to long term. The recurring usefulness of this approach documented in a variety of studies warrants a more detailed examination of its characteristics.

Strategic oscillation operates by orienting moves in relation to a critical level, as identified by a stage of construction or a chosen interval of functional values. Such a critical level or *oscillation boundary* often represents a point where the method would normally stop. Instead of stopping when this boundary is reached, however, the rules for selecting moves are modified to permit the region defined by the critical level to be crossed. The approach then proceeds for a specified depth beyond the oscillation boundary and turns around. The oscillation boundary again is approached and crossed, this time from the opposite direction, and the method proceeds to a new turning point (see [Fig. 19](#)).

The process of repeatedly approaching and crossing the critical level from different directions creates an oscillatory behavior, which gives the method its name. Control over this behavior is established by generating modified evaluations and rules of movement, depending on the region navigated and the direction of search. The possibility of retracing a prior trajectory is avoided by standard tabu search mechanisms, like those established by recency-based and frequency-based memory functions.

A simple example of this approach occurs for the multidimensional knapsack problem, where values of zero-one variables are changed from 0 to 1 until reaching the boundary of feasibility. The method then continues into the infeasible region using the same type of changes but with a modified evaluator. After a selected number of steps, the direction is reversed by choosing moves that change variables from 1 to 0. Evaluation criteria to drive toward improvement vary according to whether the movement occurs inside or outside the feasible region (and whether it is

Fig. 19 Strategic oscillation

directed toward or away from the boundary), accompanied by associated restrictions on admissible changes to values of variables. The turnaround toward feasibility can also be triggered by a maximum infeasibility value, which defines the depth of the oscillation beyond the critical level (i.e., the feasibility boundary).

A somewhat different type of application occurs for graph theory problems where the critical level represents a desired form of graph structure, capable of being generated by progressive additions (or insertions) of basic elements such as nodes, edges, or subgraphs. One type of strategic oscillation approach for this problem results by a constructive process of introducing elements until the critical level is reached and then introducing further elements to cross the boundary defined by the critical level. The current solution may change its structure once this boundary is crossed (as where a forest becomes transformed into a graph that contains loops), and hence, a different neighborhood may be required, yielding modified rules for selecting moves. The rules again change in order to proceed in the opposite direction, removing elements until again recovering the structure that defines the critical level.

In the Min k -Tree problem, for example, edges can be added beyond the critical level defined by k . Then a rule to delete edges must be applied. The rule to delete edges will typically be different in character from the one used for adding (i.e., will not simply be its “inverse”). In this case, all feasible solutions lie on the oscillation boundary, since any deviation from this level results in solutions with more or less than k edges.

Such rule changes are typical features of strategic oscillation and provide an enhanced heuristic vitality. The application of different rules may be accompanied by crossing a boundary to different depths on different sides. An option is to approach and retreat from the boundary while remaining on a single side, without crossing (i.e., electing a crossing of “zero depth”).

These examples constitute a constructive/destructive type of strategic oscillation, where constructive steps “add” elements (or set variables to 1) and destructive steps “drop” elements (or set variables to 0) (Types of TS memory structures for add/drop moves discussed in Sect. 3 are relevant for such procedures). One-sided oscillations (that remain on a single side of a critical boundary) are appropriate in a variety of scheduling and graph-related applications, where constructive processes are traditionally applied. The alternation with destructive processes that

strategically dismantle and then rebuild successive trial solutions affords a potent enhancement of more traditional procedures. In both one-sided and two-sided oscillation approaches, it is frequently important to spend additional search time in regions close to the critical level and especially to spend time at the critical level itself. This may be done by inducing a sequence of tight oscillations about the critical level, as a prelude to each larger oscillation that proceeds to a greater depth. Alternately, if greater effort is permitted for evaluating and executing each move, the method may use “exchange moves” (broadly interpreted) to stay at the critical level for longer periods. In the case of the Min k -Tree problem, for example, once the oscillation boundary has been reached, the search can stay on it by performing swap moves (either of nodes or edges). An option is to use such exchange moves to proceed to a local optimum each time the critical level is reached.

When the level or functional values in Fig. 19 refer to degrees of feasibility and infeasibility, a vector-valued function associated with a set of problem constraints can be used to control the oscillation. In this case, controlling the search by bounding this function can be viewed as manipulating a parameterization of the selected constraint set. A preferred alternative is often to make the function a Lagrangian or surrogate constraint penalty function, avoiding vector-valued functions and allowing trade-offs between degrees of violation of different component constraints.

Intensification processes can readily be embedded in strategic oscillation by altering choice rules to encourage the incorporation of particular attributes, or at the extreme, by locking such attributes into the solution for a period. Such processes can be viewed as designs for exploiting *strongly determined* and *consistent* variables. A strongly determined variable is one that cannot change its value in a given high-quality solution without seriously degrading quality or feasibility, while a consistent variable is one that frequently takes on a specific value (or a highly restricted range of values) in good solutions. The development of useful measures of “strength” and “consistency” is critical to exploiting these notions, particularly by accounting for trade-offs determined by context. However, straightforward uses of frequency-based memory for keeping track of consistency, sometimes weighted by elements of quality and influence, have produced methods with very good performance outcomes.

An example of where these kinds of approaches are also beginning to find favor in other settings occurs in recently developed variants of genetic algorithms for sequencing problems. The more venturesome of these approaches are coming to use special forms of “crossover” to assure offspring will receive attributes shared by good parents, thus incorporating a type of intensification based on consistency. Extensions of such procedures using TS ideas of identifying elements that qualify as consistent and strongly determined according to broader criteria, and making direct use of memory functions to establish this identification, provide an interesting area for investigation (Additional links to GA methods, and ways to go beyond current explorations of such methods, are discussed in Sect. 6).

Longer-term processes, following the type of progression customarily found beneficial in tabu search, may explicitly introduce supplemental diversification strategies into the oscillation pattern. When oscillation is based on constructive

and destructive processes, the repeated application of constructive phases (rather than moving to intermediate levels using destructive moves) embodies an extreme type of oscillation that is analogous to a restart method. In this instance, the restart point is always the same (i.e., a null state) instead of consisting of different initial solutions, and hence, it is important to use choice rule variations to assure appropriate diversification.

A connection can also be observed between an extreme version of strategic oscillation, in this case a relaxed version, and the class of procedures known as *perturbation* approaches. An example is the subclass known as “large-step simulated annealing” or “large-step Markov chain” methods [39, 52–54]. Such methods try to drive an SA procedure (or an iterated descent procedure) out of local optimality by propelling the solution a greater distance than usual from its current location.

Perturbation methods may be viewed as loosely structured procedures for inducing oscillation, without reference to intensification and diversification and their associated implementation strategies. Similarly, perturbation methods are not designed to exploit trade-offs created by parametric variations in elements such as different types of infeasibility and measures of displacement from different sides of boundaries. Nevertheless, at a first level of approximation, perturbation methods seek goals similar to those pursued by strategic oscillation.

5.5 Path Relinking

A useful integration of intensification and diversification strategies occurs in the approach called *path relinking*. This approach generates new solutions by exploring trajectories that connect elite solutions by starting from one of these solutions, called an *initiating solution*, and generating a path in the neighborhood space that leads toward the other solutions, called *guiding solutions*. This is accomplished by selecting moves that introduce attributes contained in the guiding solutions.

The approach may be viewed as an extreme (highly focused) instance of a strategy that seeks to incorporate attributes of high-quality solutions, by creating inducements to favor these attributes in the moves selected. However, instead of using an inducement that merely encourages the inclusion of such attributes, the path-relinking approach subordinates all other considerations to the goal of choosing moves that introduce the attributes of the guiding solutions, in order to create a “good attribute composition” in the current solution. The composition at each step is determined by choosing the best move, using customary choice criteria, from the restricted set of moves that incorporate a maximum number (or a maximum weighted value) of the attributes of the guiding solutions. As in other applications of TS, aspiration criteria can override this restriction to allow other moves of particularly high quality to be considered.

Specifically, upon identifying a collection of one or more elite solutions to guide the path of a given solution, the attributes of these guiding solutions are assigned preemptive weights as inducements to be selected. Larger weights are assigned to

attributes that occur in greater numbers of the guiding solutions, allowing bias to give increased emphasis to solutions with higher quality or with special features (e.g., complementing those of the solution that initiated the new trajectory).

More generally, it is not necessary for an attribute to occur in a guiding solution in order to have a favored status. In some settings, attributes can share degrees of similarity, and in this case, it can be useful to view a solution vector as providing “votes” to favor or discourage particular attributes. Usually, the strongest forms of aspiration criteria are relied upon to overcome this type of choice rule.

In a given collection of elite solutions, the role of initiating solution and guiding solutions can be alternated. The distinction between initiating solutions and guiding solutions effectively vanishes in such cases. For example, a set of current solutions may be generated simultaneously, extending different paths and allowing an initiating solution to be replaced (as a guiding solution for others) whenever its associated current solution satisfies a sufficiently strong aspiration criterion.

Because their roles are interchangeable, the initiating and guiding solutions are collectively called *reference solutions*. These reference solutions can have different interpretations depending on the solution framework under consideration. Reference points can be created by any of a number of different heuristics that result in high-quality solutions.

An idealized form of such a process is shown in Fig. 20. The chosen collection of reference solutions consists of the three members, A, B, and C. Paths are generated by allowing each to serve as initiating solution and by allowing either one or both of the other two solutions to operate as guiding solutions. Intermediate solutions encountered along the paths are not shown. The representation of the paths as straight lines of course is oversimplified, since choosing among available moves in a current neighborhood will generally produce a considerably more complex trajectory. Intensification can be achieved by generating paths from similar solutions, while diversification is obtained creating paths from dissimilar solutions. Appropriate aspiration criteria allow deviation from the paths at attractive neighbors.

As Fig. 20 indicates, at least one path continuation is allowed beyond each initiating/guiding solution. Such a continuation can be accomplished by penalizing the inclusion of attributes dropped during a trajectory, including attributes of guiding solutions that may be compelled to be dropped in order to continue the path (An initiating solution may also be repelled from the guiding solutions by penalizing the inclusion of their attributes from the outset). Probabilistic TS variants operate in the path-relinking setting, as they do in others, by translating evaluations for deterministic rules into probabilities of selection, strongly biased to favor higher evaluations.

Promising regions are searched more thoroughly in path relinking by modifying the weights attached to attributes of the guiding solutions and by altering the bias associated with solution quality and selected solution features. Figure 21 depicts the type of variation that can result, where the point X represents an initiating solution, the points A, B, and C represent guiding solutions, and the dashed, dotted, and solid lines are different searching paths. For appropriate choices of the reference points (and neighborhoods for generating paths from them), the notion called the *Principle*

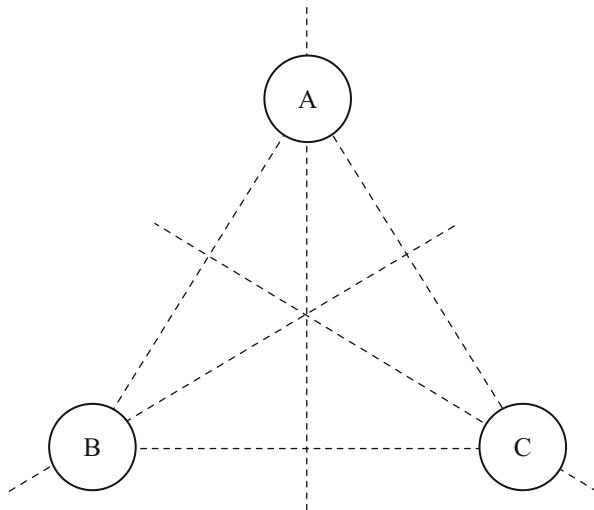

Fig. 20 Paths relinking in neighborhood space

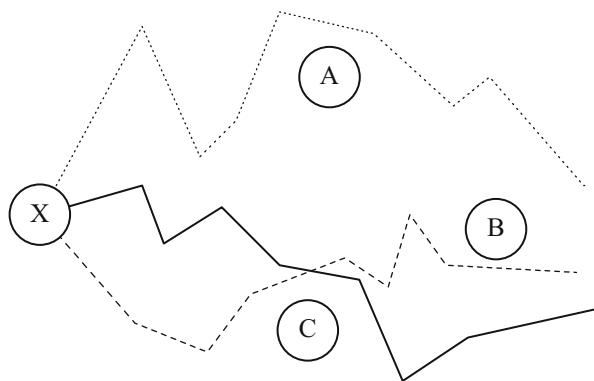

Fig. 21 Path relinking by attribute bias

of Proximate Optimality [31] suggests that additional elite points are likely to be found in the regions traversed by the paths, upon launching new searches from high quality points on these paths.

5.5.1 Roles in Intensification and Diversification

Path relinking, in common with strategic oscillation, gives a natural foundation for developing intensification and diversification strategies. Intensification strategies in this setting typically choose reference solutions to be elite solutions that lie in a common region or that share common features. Similarly, diversification strategies

based on path relinking characteristically select reference solutions that come from different regions or that exhibit contrasting features. Diversification strategies may also place more emphasis on paths that go beyond the reference points. Collections of reference points that embody such conditions can be usefully determined by clustering and conditional analysis methods.

These alternative forms of path relinking also offer a convenient basis for parallel processing, contributing to the approaches for incorporating intensification and diversification trade-offs into the design of parallel solution processes generally.

5.5.2 Incorporating Alternative Neighborhoods

Path-relinking strategies in tabu search can occasionally profit by employing different neighborhoods and attribute definitions than those used by the heuristics for generating the reference solutions. For example, it is sometimes convenient to use a constructive neighborhood for path relinking, that is, one that permits a solution to be built in a sequence of constructive steps (as in generating a sequence of jobs to be processed on specified machines using dispatching rules). In this case, the initiating solution can be used to give a beginning partial construction, by specifying particular attributes (such as jobs in particular relative or absolute sequence positions) as a basis for remaining constructive steps. Similarly, path relinking can make use of destructive neighborhoods, where an initial solution is “overloaded” with attributes donated by the guiding solutions, and such attributes are progressively stripped away or modified until reaching a set with an appropriate composition.

When path relinking is based on constructive neighborhoods, the guiding solution(s) provides the attribute relationships that give options for subsequent stages of construction. At an extreme, a full construction can be produced, by making the initiating solution a *null solution*. The destructive extreme starts from a “complete set” of solution elements. Constructive and destructive approaches differ from transition approaches by typically producing only a single new solution, rather than a sequence of solutions, on each path that leads from the initiating solution toward the others. In this case, the path will never reach the additional solutions unless a transition neighborhood is used to extend the constructive neighborhood.

Constructive neighborhoods can often be viewed as a special case of feasibility restoring neighborhoods, since a null or partially constructed solution does not satisfy all conditions to qualify as feasible. Similarly, destructive neighborhoods can also represent an instance of a feasibility restoring function, as where an excess of elements may violate explicit problem constraints. A variety of methods have been devised to restore infeasible solutions to feasibility, as exemplified by flow augmentation methods in network problems, subtour elimination methods in traveling salesman and vehicle routing problems, alternating chain processes in degree-constrained subgraph problems, and value incrementing and decrementing methods in covering and multidimensional knapsack problems. Using neighborhoods that permit restricted forms of infeasibilities to be generated, and then using associated neighborhoods to remove these infeasibilities, provides a form of path relinking with useful diversification features. Upon further introducing transition neighborhoods,

with the ability to generate successive solutions with changed attribute mixes, the mechanism of path relinking also gives a way to tunnel through infeasible regions. The following is a summary of the components of path relinking:

- Step 1. Identify the neighborhood structure and associated solution attributes for path relinking (possibly different from those of other TS strategies applied to the problem).
- Step 2. Select a collection of two or more reference solutions, and identify which members will serve as the initiating solution and the guiding solution(s) (Reference solutions can be infeasible, such as “incomplete” or “overloaded” solution components treated by constructive or destructive neighborhoods).
- Step 3. Move from the initiating solution toward (or beyond) the guiding solution(s), generating one or more intermediate solutions as candidates to initiate subsequent problem-solving efforts (If the first phase of this step creates an infeasible solution, apply an associated second phase with a feasibility restoring neighborhood).

In Sect. 6, we will see how the path-relinking strategy relates to a strategy called scatter search, which provides additional insights into the nature of both approaches.

5.6 The Intensification/Diversification Distinction

The relevance of the intensification/diversification distinction is supported by the usefulness of TS strategies that embody these notions. Although both operate in the short term as well as the long term, we have seen that longer-term strategies are generally the ones where these notions find their greatest application.

In some instances, we may conceive of intensification as having the function of an intermediate term strategy, while diversification applies to considerations that emerge in the longer run. This view comes from the observation that in human problem solving, once a short-term strategy has exhausted its efficacy, the first (intermediate term) response is often to focus on the events where the short-term approach produced the best outcomes and to try to capitalize on elements that may be common to those events. When this intensified focus on such events likewise begins to lose its power to uncover further improvement, more dramatic departures from a short-term strategy are undertaken (Psychologists do not usually differentiate between intermediate and longer-term memory, but the fact that memory for intensification and diversification can benefit from such differentiation suggests that there may be analogous physical or functional differences in human memory structures). Over the truly long term, however, intensification and diversification repeatedly come into play in ways where each depends on the other, not merely sequentially, but also simultaneously.

There has been some confusion between the terms intensification and diversification, as applied in tabu search, and the terms *exploitation* and *exploration*, as popularized in the literature of genetic algorithms. The differences between these

two sets of notions deserve to be clarified, because they have substantially different consequences for problem solving.

The exploitation/exploration distinction comes from control theory, where exploitation refers to following a particular recipe (traditionally memoryless) until it fails to be effective, and exploration then refers to instituting a series of random changes – typically via multiarmed bandit schemes – before reverting to the tactical recipe (The issue of exploitation versus exploration concerns how often and under what circumstances the randomized departures are launched).

By contrast, intensification and diversification in tabu search are both processes that take place when simpler exploitation designs play out and lose their effectiveness – although as we have noted, the incorporation of memory into search causes intensification and diversification also to be manifest in varying degrees even in the short range (Similarly, as we have noted, intensification and diversification are not opposed notions, for the best form of each contains aspects of the other, along a spectrum of alternatives).

Intensification and diversification are likewise different from the control theory notion of exploration. Diversification, which is sometimes confused with exploration, is not a recourse to a game of chance for shaking up the options invoked but is a collection of strategies – again taking advantage of memory – designed to move purposefully rather than randomly into uncharted territory.

The source of these differences is not hard to understand. Researchers and practitioners in the area of search methods have had an enduring love affair with randomization, perhaps influenced by the much publicized Heisenberg Uncertainty Principle in Quantum Mechanics. Einstein's belief that God does not roll dice is out of favor, and many find a special enchantment in miraculous events where blind purposelessness creates useful order (We are less often disposed to notice that this way of producing order requires an extravagant use of time and that order, once created, is considerably more effective than randomization in creating still higher order).

Our “scientific” reports of experiments with nature reflect our fascination with the role of chance. When apparently chaotic fluctuations are brought under control by random perturbations, we seize upon the random element as the key, while downplaying the importance of attendant restrictions on the setting in which randomization operates. The diligently concealed message is that under appropriate controls, *perturbation* is effective for creating desired patterned outcomes – and in fact, if the system and attendant controls are sufficiently constrained, perturbation works even when random (Instead of accentuating differences between workable and unworkable kinds of perturbation, in our quest to mold the universe to match our mystique, we portray the central consideration to be randomization versus nonrandomization).

The tabu search orientation evidently contrasts with this perspective. As manifest in the probabilistic TS variant, elements subjected to random influence are preferably to be strongly confined, and uses of randomization are preferably to be modulated through well differentiated probabilities. In short, the situations where randomization finds a place are very highly structured. From this point of view, God may play with dice, but beyond any question, the dice are *loaded*.

5.7 Some Basic Memory Structures for Longer-Term Strategies

To give a foundation for describing fundamental types of memory structures for longer-term strategies, we first briefly review the form of the recency-based memory structure introduced in Sect. 3 for handling add/drop moves. However, we slightly change the notation to provide a convenient way to refer to a variety of other types of moves.

5.7.1 Conventions

Let $S = \{1, 2, \dots, s\}$ denote an index set for a collection of solution attributes. For example, the indexes $i \in S$ may correspond to indexes of zero-one variables x_i , or they may be indexes of edges that may be added to or deleted from a graph, or the job indexes in a production scheduling problem. More precisely, by the attribute;element distinction discussed in Sect. 3, the attributes referenced by S in these cases consist of the specific values assigned to the variables, the specific add/drop states adopted by the edges, or positions occupied by the jobs. In general, to give a correspondence with developments of Sect. 4, an index $i \in S$ can summarize more detailed information, for example, by referring to an ordered pair (j, k) that summarizes a value assignment $x_j = k$ or the assignment of job j to position k . Hence, broadly speaking, the index i may be viewed as a notational convenience for representing a pair or a vector.

To keep our description at the simplest level, suppose that each $i \in S$ corresponds to a 0–1 variable x_i . As before, we let Iter denote the counter that identifies the current iteration, which starts at 0 and increases by 1 each time a move is made.

For recency-based memory, following the approach indicated in Sect. 3, when a move is executed that causes a variable x_i to change its value, we record $\text{TabuStart}(i) = \text{Iter}$ immediately after updating the iteration counter (This means that if the move has resulted in $x_i = 1$, then the attribute $x_i = 0$ becomes tabu-active at the iteration $\text{TabuStart}(i)$). Further, we let $\text{TabuTenure}(i)$ denote the number of iterations this attribute will remain tabu-active. Thus, by our previous design, the recency-based tabu criterion says that the previous value of x_i is tabu-active throughout all iterations such that

$$\text{TabuStart}(i) + \text{TabuTenure}(i) \leq \text{Iter}.$$

Similarly, in correspondence with earlier remarks, the value $\text{TabuStart}(i)$ can be set to 0 before initiating the method, as a convention to indicate no prior history exists. Then, we automatically avoid assigning a tabu-active status to any variable with $\text{TabuStart}(i) = 0$ (since the starting value for variable x_i has not yet been changed).

5.7.2 Frequency-Based Memory

By our foregoing conventions, allowing the set $S = \{1, \dots, s\}$ for illustration purposes to refer to indexes of 0–1 variables x_i , we may indicate structures to handle frequency-based memory as follows.

Transition frequency-based memory is by far the simplest to handle. A transition memory, $Transition(i)$, to record the number of times x_i changes its value, can be maintained simply in the form of a counter for x_i that is incremented at each move where such a change occurs. Since x_i is a zero-one variable, $Transition(i)$ also discloses the number of times x_i changes to and from each of its possible assigned values. In more complex situations, by the conventions already noted, a matrix memory $Transition(j, k)$ can be used to determine numbers of transitions involving assignments such as $x_j = k$. Similarly, a matrix memory may be used in the case of the sequencing problem where both the index of job j and position k may be of interest. In the context of the Min k -Tree problem, an array dimensioned by the number of edges can maintain a transition memory to keep track of the number of times that specific edges have been brought in and out of the solution. A matrix based on the edges can also identify conditional frequencies. For example, the matrix $Transition(j, k)$ can be used to count the number of times edge j replaced edge k . It should be kept in mind in using transition frequency memory that penalties and inducements are often based on *relative* numbers (rather than absolute numbers) of transitions, hence requiring that recorded transition values are divided by the total number of iterations (or the total number of transitions). As noted earlier, other options include dividing by the current maximum transition value. Raising transition values to a power, as by squaring, is often useful to accentuate the differences in relative frequencies.

Residence memory requires only slightly more effort to maintain than transition memory, by taking advantage of the recency-based memory stored in $TabuStart(i)$. The following approach can be used to track the number of solutions in which $x_i = 1$, thereby allowing the number of solutions in which $x_i = 0$ to be inferred from this. Start with $Residence(i) = 0$ for all i . Then, whenever x_i changes from 1 to 0, after updating $Iter$ but before updating $TabuStart(i)$, set

$$Residence(i) = Residence(i) + Iter - TabuStart(i).$$

Then, during iterations when $x_i = 0$, $Residence(i)$ correctly stores the number of earlier solutions in which $x_i = 1$. During iterations when $x_i = 1$, the true value of $Residence(i)$ is the right-hand side of the preceding assignment; however, the update only has to be made at the indicated points when x_i changes from 1 to 0. [Table 9](#) illustrates how this memory structure works when used to track the assignments of a variable x during 100 iterations. The variable is originally assigned to a value of zero by a construction procedure that generates an initial solution. In iteration 10, a move is made that changes the assignment of x from zero to one; however, the $Residence$ value remains at zero. $Residence$ is updated at iterations 22 and 73, when moves are made that change the assignment of x from 1 to 0. At iteration 65, for example, x has received a value of 1 for 27 iterations (i.e., $Residence + Iter - TabuStart = 12 + 65 - 50 = 27$), while at iteration 90, the count is 35 (i.e., the value of $Residence$).

As with transition memory, residence memory should be translated into a relative as a basis for creating penalties and inducements.

Table 9 Illustrative residence memory

<i>Iter</i>	<i>Assignment</i>	<i>Residence</i>
0	$x = 0$	0
10	$x = 1$	0
22	$x = 0$	$22 - 10 = 12$
50	$x = 1$	12
73	$x = 0$	$12 + 73 - 50 = 35$

The indicated memory structures can readily be applied to multivalued variables (or multistate attributes) by the extended designs illustrated in Sect. 4. In addition, the 0–1 format can be adapted to reference the number of times (and last time) a more general variable changed its value, which leads to more restrictive tabu conditions and more limiting (“stronger”) uses of frequency-based memory than by referring separately to each value the variable receives. As in the case of recency-based memory, the ability to affect larger numbers of alternative moves by these more aggregated forms of memory can be useful for larger problems, not only for conserving memory space but also for providing additional control over solutions generated.

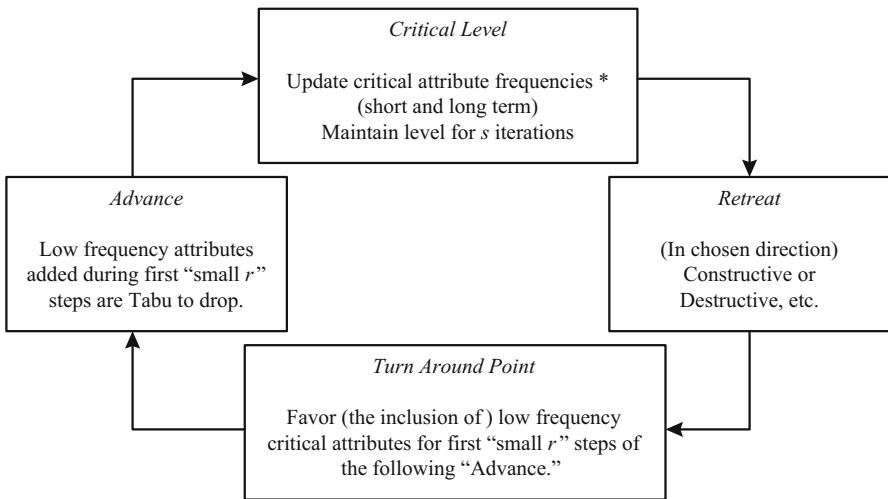

5.7.3 Critical Event Memory

Strategic oscillation offers an opportunity to make particular use of both short-term and long-term frequency-based memory. To illustrate, let $A(\text{Iter})$ denote a zero-one vector whose j th component has the value 1 if attribute j is present in the current solution and has the value 0 otherwise. The vector A can be treated “as if” it is the same as the solution vector for zero-one problems, though implicitly it is twice as large, since $x_j = 0$ is a different attribute from $x_j = 1$. This means that rules for operating on the full A must be reinterpreted for operating on the condensed form of A . The sum of the A vectors over the most recent t critical events provides a simple memory that combines recency and frequency considerations. To maintain the sum requires remembering $A(k)$, for k ranging over the last t iterations. Then the sum vector A^* can be updated quite easily by the incremental calculation:

$$A^* = A^* + A(\text{Iter}) - A(\text{Iter} - t + 1).$$

Associated frequency measures, as noted earlier, may be normalized, in this case, for example, by dividing A^* by the value of t . A long-term form of A^* does not require storing the $A(k)$ vectors but simply keeps a running sum. A^* can also be maintained by exponential smoothing.

Such frequency-based memory is useful in strategic oscillation where critical events are chosen to be those of generating a complete (feasible) construction or in general of reaching the targeted boundary (or a best point within a boundary region). Instead of using a customary recency-based TS memory at each step of an oscillating pattern, greater flexibility results by disregarding tabu restrictions until reaching the turning point, where the oscillation process alters its course to follow a path toward the boundary. At this point, assume a choice rule is applied to introduce an attribute that was not contained in any recent solution at the critical level. If this

* For selected part of critical level iterations: e.g., for first and best solutions of current block

Fig. 22 Strategic oscillation illustrative memory

attribute is maintained in the solution by making it tabu to be dropped, then upon eventually reaching the critical level, the solution will be different from any seen over the horizon of the last t critical events. Thus, instead of updating A^* at each step, the updating is done only for critical level solutions, while simultaneously enhancing the flexibility of making choices.

In general, the possibility occurs that no attribute exists that allows this process to be implemented in the form stated. That is, every attribute may already have a positive associated entry in A^* . Thus, at the turn-around point, the rule instead is to choose a move that introduces attributes which are least frequently used (Note that “infrequently used” can mean either “infrequently present” or “infrequently absent,” depending upon the current direction of oscillation). This again can be managed conveniently by using penalties and inducements. Such an approach has been found very effective for multidimensional knapsack problems and 0–1 quadratic optimization problems in [30, 33].

For greater diversification, this rule can be applied for r steps after reaching the turnaround point. Normally, r should be a small number, for example, with a baseline value of 1 or 2, which is periodically increased in a standard diversification pattern. Shifting from a short-term A^* to a long-term A^* creates a global diversification effect. A template for this approach is given in Fig. 22.

The approach of Fig. 22 is not symmetric. An alternative form of control is to seek immediately to introduce a low-frequency attribute upon leaving the critical level, to increase the likelihood that the solution at the next turn around will not duplicate a solution previously visited at that point. Such a control enhances diversity, though duplication at the turn around will already be inhibited by starting from different solutions at the critical level.

6 Connections, Hybrid Approaches, and Learning

Relationships between tabu search and other procedures like simulated annealing and genetic algorithms provide a basis for understanding similarities and contrasts in their philosophies and for creating potentially useful hybrid combinations of these approaches. We offer some speculation on preferable directions in this regard and also suggest how elements of tabu search can add a useful dimension to neural network approaches.

From the standpoint of evolutionary strategies, we trace connections between population-based models for combining solutions, as in genetic algorithms, and ideas that emerged from surrogate constraint approaches for exploiting optimization problems by combining constraints. We show how this provides the foundation for methods that give additional alternatives to genetic-based frameworks, specifically as embodied in the scatter search approach, which is the “primal complement” to the dual strategy of surrogate constraint approaches. Recent successes by integrating scatter search (and its path-relinking extensions) with tabu search disclose potential advantages for evolutionary strategies that incorporate adaptive memory.

Finally, we describe the learning approach called target analysis, which provides a way to determine decision parameters for deterministic and probabilistic strategies – and thus affords an opportunity to create enhanced solution methods.

6.1 Simulated Annealing

The contrasts between simulated annealing and tabu search are fairly conspicuous, though undoubtedly, the most prominent is the focus on exploiting memory in tabu search that is absent from simulated annealing. The introduction of this focus entails associated differences in search mechanisms and in the elements on which they operate. Accompanying the differences directly attributable to the focus on memory, and also magnifying them, several additional elements are fundamental for understanding the relationship between the methods. We consider three such elements in order of increasing importance.

First, tabu search emphasizes scouting successive neighborhoods to identify moves of high quality, as by candidate list approaches of the form described in Sect. 4. This contrasts with the simulated annealing approach of randomly sampling among these moves to apply an acceptance criterion that disregards the quality of other moves available (Such an acceptance criterion provides the sole basis for sorting the moves selected in the SA method). The relevance of this difference in orientation is accentuated for tabu search, since its neighborhoods include linkages based on history and therefore yield access to information for selecting moves that is not available in neighborhoods of the type used in simulated annealing.

Next, tabu search evaluates the relative attractiveness of moves not only in relation to objective function change but in relation to additional factors that represent quality, which are balanced over time with factors that represent influence. Both types of measures are affected by the differentiation among move attributes, as

embodied in tabu-activation rules and aspiration criteria, and in turn by relationships manifested in recency, frequency, and sequential interdependence (hence, again, involving recourse to memory). Other aspects of the state of search also affect these measures, as reflected in the altered evaluations of strategic oscillation, which depend on the direction of the current trajectory and the region visited.

Finally TS emphasizes guiding the search by reference to multiple thresholds, reflected in the tenures for tabu-active attributes and in the conditional stipulations of aspiration criteria. This may be contrasted to the simulated annealing reliance on guiding the search by reference to the single threshold implicit in the temperature parameter. The treatment of thresholds by the two methods compounds this difference between them. Tabu search varies its thresholds nonmonotonically, reflecting the conception that multidirectional parameter changes are essential to adapt to different conditions and to provide a basis for locating alternatives that might otherwise be missed. This contrasts with the simulated annealing philosophy of adhering to a temperature parameter that only changes monotonically.

Hybrids are now emerging that are taking preliminary steps to bridge some of these differences, particularly in the realm of transcending the simulated annealing reliance on a monotonic temperature parameter. A hybrid method that allows temperature to be strategically manipulated, rather than progressively diminished, has been shown to yield improved performance over standard SA approaches. A hybrid method that expands the SA basis for move evaluations also has been found to perform better than standard simulated annealing. Consideration of these findings invites the question of whether removing the memory scaffolding of tabu search and retaining its other features may yield a viable method in its own right. For example, experience cited in some of the studies reported in Glover and Laguna [31] suggests that, while a memoryless version of tabu search called tabu thresholding can outperform a variety of alternative heuristics, it generally does not match the performance of TS methods that appropriately exploit memory.

6.2 Genetic Algorithms

Genetic algorithms offer a somewhat different set of comparisons and contrasts with tabu search. GAs are based on selecting subsets (traditionally pairs) of solutions from a population, called parents, and combining them to produce new solutions called children. Rules of combination to yield children are based on the genetic notion of crossover, which in the classical form consists of interchanging solution values of particular variables, together with occasional operations such as random value changes. Children that pass a survivability test, probabilistically biased to favor those of superior quality, are then available to be chosen as parents of the next generation. The choice of parents to be matched in each generation is based on random or biased random sampling from the population (in some parallel versions executed over separate subpopulations whose best members are periodically exchanged or shared). Genetic terminology customarily refers to solutions as chromosomes, variables as genes, and values of variables as alleles.

By means of coding conventions, the genes of genetic algorithms may be compared to attributes in tabu search. Introducing memory in GAs to track the history of genes and their alleles over subpopulations would provide an immediate and natural way to create a hybrid with TS.

Some important differences between genes and attributes are worth noting, however. The implicit differentiation of attributes into *from* and *to* components, each having different memory functions, does not have a counterpart in genetic algorithms. A *from* attribute is one that is part of the current solution but is not included in the next solution once a move is made. A *to* attribute is one that is not part of the current solution but becomes part of the next solution once a move is made. The lack of this type of differentiation in GAs results because these approaches are organized to operate without reference to moves (although, strictly speaking, combination by crossover can be viewed as a special type of move).

A contrast to be noted between genetic algorithms and tabu search arises in the treatment of context, that is, in the consideration given to structure inherent in different problem classes. For tabu search, context is fundamental, embodied in the interplay of attribute definitions and the determination of move neighborhoods and in the choice of conditions to define tabu restrictions. Context is also implicit in the identification of amended evaluations created in association with longer-term memory and in the regionally dependent neighborhoods and evaluations of strategic oscillation.

At the opposite end of the spectrum, GA literature has traditionally stressed the freedom of its rules from the influence of context. Crossover, in particular, is supposedly a *context neutral* operation, which assumes no reliance on conditions that solutions must obey in a particular problem setting, just as genes make no reference to the environment as they follow their instructions for recombination (except, perhaps, in the case of mutation). Practical application, however, generally renders this an inconvenient assumption, making solutions of interest difficult to find. Consequently, a good deal of effort in GA implementation is devoted to developing “special crossover” operations that compensate for the difficulties created by context, effectively reintroducing it on a case-by-case basis.

The chief method by which modern genetic algorithms handle structure is by relegating its treatment to some other method. For example, genetic algorithms combine solutions by their parent-children processes at one level, and then a descent method may be introduced to operate on the resulting solutions to produce new solutions. These new solutions in turn are submitted to be recombined by the GA processes. In these versions, genetic algorithms already take the form of hybrid methods. Hence, there is a natural basis for marrying GA and TS procedures in such approaches. But genetic algorithms and tabu search also can be joined in a more fundamental way.

Specifically, tabu search strategies for intensification and diversification are based on the following question: How can information be extracted from a set of good solutions to help uncover additional (and better) solutions? From one point of view, GAs provide an approach for answering this question, consisting of putting solutions together and interchanging components (in some loosely defined sense,

if traditional crossover is not strictly enforced). Tabu search, by contrast, seeks an answer by utilizing processes that specifically incorporate neighborhood structures into their design.

Augmented by historical information, neighborhood structures are used as a basis for applying penalties and incentives to induce attributes of good solutions to become incorporated into current solutions. Consequently, although it may be meaningless to interchange or otherwise incorporate a set of attributes from one solution into another in a wholesale fashion, as attempted in traditional GA recombination operations, a stepwise approach to this goal through the use of neighborhood structures is entirely practicable. This observation provides a motive for creating *structured combinations* of solutions that embody desired characteristics such as feasibility – as is automatically achieved by the TS approach of path relinking discussed in Sect. 5. Instead of being compelled to create new types of crossover to remove deficiencies of standard operators upon being confronted by changing contexts, this approach addresses context directly and makes it an essential part of the design for generating combinations.

The current trend of genetic algorithms seems to be increasingly compatible with this perspective and could provide a basis for a useful hybrid combination of genetic algorithm and tabu search ideas. However, a fundamental question emerges, as posed in the development of the next sections, about whether there is any advantage to introducing genetic crossover-based ideas over introducing the apparently more flexible and exploitable path-relinking ideas.

6.2.1 Models of Nature: Beyond “Genetic Metaphors”

An aspect of tabu search that is often misunderstood concerns the relation between a subset of its strategies and certain approaches embodied in genetic algorithms. TS researchers have tended sometimes to overlook the part of the adaptive memory focus that is associated with strategies for combining sets of elite solutions. Complementing this, GA researchers have been largely unaware that such a collection of strategies outside their domain exists. This has quite possibly been due to the influence of the genetic metaphor, which on the one hand has helped to launch a number of useful problem-solving ideas and on the other hand has also sometimes obscured fertile connections to ideas that come from different foundations.

To understand the relevant ties, it is useful to go back in time to examine the origins of the GA framework and of an associated set of notions that became embodied in TS strategies. We will first sketch the original genetic algorithm design (see Fig. 23), as characterized in Holland [38]. Our description is purposely somewhat loose to be able to include approaches more general than the specific proposals that accompanied the introduction of GAs. Many variations and changes have come about over the years, as we subsequently observe.

A somewhat different model for combining elements of a population comes from a class of relaxation strategies in mathematical optimization known as surrogate constraint methods [19]. The goal of these approaches is to generate new constraints that capture information not contained in the original problem constraints taken independently, but which is implied by their union. We will see

Fig. 23 Genetic algorithm template

- 1) Begin with a population of binary vectors.
- 2) Operate repeatedly on the current generation of vectors, for a selected number of steps, choosing two “parent vectors” at random. Then mate the parents by exchanging certain of their components to produce offspring. (The exchange, called “crossover,” was originally designed to reflect the process by which chromosomes exchange components in genetic mating and, in common with the step of selecting parents themselves, was organized to rely heavily on randomization. In addition, a “mutation” operation is occasionally allowed to flip bits at random.)
- 3) Apply a measure of fitness to decide which offspring survive to become parents for the next generation. When the selected number of matings has been performed for the current generation, return to the start of Step 2 to initiate the mating of the resulting new set of parents.
- 4) Carry out the mating-and-survival operation of Steps 2 and 3 until the population becomes stable or until a chosen number of iterations has elapsed.

that some unexpected connections emerge between this development and that of genetic algorithms.

The information-capturing focus of the surrogate constraint framework has the aim of developing improved methods for solving difficult optimization problems by means of (a) providing better criteria for choice rules to guide a search for improved solutions and (b) inferring new bounds (constraints with special structures) to limit the space of solutions examined (The basic framework and strategies for exploiting it are given in Glover [19–21], Greenberg and Pierskalla [36,37], Karwan and Rardin [40,41], and Freville and Plateau [15,16]). Based on these objectives, the generation of new constraints proceeds as indicated in Fig. 24.

A natural first impression is that the surrogate constraint design is quite unrelated to the GA design, stemming from the fact that the concept of combining constraints seems inherently different from the concept of combining vectors. However, in many types of problem formulations, including those where surrogate constraints were first introduced, constraints are summarized by vectors. More particularly, over time, as the surrogate constraint approach became embedded in both exact and heuristic methods, variations led to the creation of a “primal counterpart” called *scatter search*. The scatter search approach combines solution vectors by rules patterned after those that govern the generation of new constraints and specifically inherits the strategy of exploiting linear combinations and inference [22].

6.3 Scatter Search

The scatter search process, building on the principles that underlie the surrogate constraint design, is organized to (1) capture information not contained separately

Fig. 24 Surrogate constraint template

- 1) Begin with an initial set of problem constraints (chosen to characterize all or a special part of the feasible region for the problem considered).
- 2) Create a measure of the relative influence of the constraints as basis for combining subsets to generate new constraints. The new (surrogate) constraints, are created from nonnegative linear combinations of other constraints, together with cutting planes inferred from such combinations. (The goal is to determine surrogate constraints that are most effective for guiding the solution process.)
- 3) Change the way the constraints are combined, based on the problem constraints that are not satisfied by trial solutions generated relative to the surrogate constraints, accounting for the degree to which different source constraints are violated. Then process the resulting new surrogate constraints to introduce additional inferred constraints obtained from bounds and cutting planes. (Weaker surrogate constraints and source constraints that are determined to be redundant are discarded.)
- 4) Change the way the constraints are combined, based on the problem constraints that are not satisfied by trial solutions generated relative to the surrogate constraints, accounting for the degree to which different source constraints are violated. Then process the resulting new surrogate constraints to introduce additional inferred constraints obtained from bounds and cutting planes. (Weaker surrogate constraints and source constraints that are determined to be redundant are discarded.)

in the original vectors and (2) take advantage of auxiliary heuristic solution methods to evaluate the combinations produced and to generate new vectors.

The original form of scatter search may be sketched as in Fig. 25.

Three particular features of scatter search deserve mention. First, the linear combinations are structured according to the goal of generating weighted centers of selected subregions, allowing for nonconvex combinations that project these centers into regions external to the original reference solutions. The dispersion pattern created by such centers and their external projections is particularly useful for mixed-integer optimization. Second, the strategies for selecting particular subsets of solutions to combine in Step 2 are designed to make use of clustering, which allows different types of strategic variation by generating new solutions “within clusters” and “across clusters.” Third, the method is organized to use supporting heuristics that are able to start from infeasible solutions and hence which remove the restriction that solutions selected as starting points for reapplying the heuristic processes must be feasible. In sum, scatter search is founded on the following premises.

- (P1) Useful information about the form (or location) of optimal solutions is typically contained in a suitably diverse collection of elite solutions.

Fig. 25 Scatter search procedure

- 1) Generate a starting set of solution vectors by heuristic processes designed for the problem considered, and designate a subset of the best vectors to be *reference solutions*. (Subsequent iterations of this step, transferring from Step 3 below, incorporate advanced starting solutions and best solutions from previous history as candidates for the reference solutions.)
- 2) Create new points consisting of linear combinations of subsets of the current reference solutions. The linear combinations are:
 - (a) chosen to produce points both inside and outside the convex regions spanned by the reference solutions.
 - (b) modified by generalized rounding processes to yield integer values for integer-constrained vector components.
- 3) Extract a collection of the best solutions generated in Step 2 to be used as starting points for a new application of the heuristic processes of Step 1. Repeat these steps until reaching a specified iteration limit.

- (P2) When solutions are combined as a strategy for exploiting such information, it is important to provide for combinations that can extrapolate beyond the regions spanned by the solutions considered and further to incorporate heuristic processes to map combined solutions into new points (This serves to provide both diversity and quality).
- (P3) Taking account of multiple solutions simultaneously, as a foundation for creating combinations, enhances the opportunity to exploit information contained in the union of elite solutions.

The fact that the heuristic processes of scatter search are not restricted to a single uniform design, but represent a varied collection of procedures, affords additional strategic possibilities. This theme also shares a link with the original surrogate constraint proposal, where heuristics for surrogate relaxations are introduced to improve the application of exact solution methods. In combination, the heuristics are used to generate strengthened surrogate constraints and, iteratively applied, to generate trial solutions for integer programming problems.

The catalog in Fig. 26 traces the links between the conceptions underlying scatter search and conceptions that have been introduced over time as amendments to the GA framework.

These innovations in the GA domain, which have subsequently been incorporated in a wide range of studies, are variously considered to be advances or heresies according to whether they are viewed from liberal or traditional perspectives. Significantly, their origins are somewhat diffuse, rather than integrated within a single framework.

It is clear that a number of the elements of the scatter search approach remain outside of the changes brought about by these proposals. A simple example is the approach of introducing adaptive rounding processes for mapping fractional

Fig. 26 Scatter search features (1977) incorporated into non-traditional GA approaches

- Introduction of “flexible crossover operations.” (Scatter search combinations include all possibilities generated by the early GA crossover operations, and also include all possibilities embedded in the more advanced “uniform” and “Bernoulli” crossovers (Ackley (1987), Spears and DeJong (1991)). Path relinking descendants of scatter search provide further possibilities, noted subsequently.)
- Use of heuristic methods to improve solutions generated from processes for combining vectors (Muhlenbein et al. (1988), Ulster et al. (1991)), (Whitley, Gordon and Mathias (1994)).
- Exploitation of vector representations that are not restricted to binary representations (Davis (1989), Eschelman and Schaffer (1992)).
- Introduction of special cases of linear combinations for operating on continuous vectors (Davis (1989), Wright (1990), Bäck et al. (1991), Michalewicz and Janikow (1991)).
- Use of combinations of more than two parents simultaneously to produce offspring (Eiben et al. (1994), Mühlenbein and Voigt (1996)).
- Introduction of strategies that subdivide the population into different groupings (Mühlenbein and Schlierkamp-Voosen (1994)).

components into integers. There also has conspicuously been no GA counterpart to the use of clustering to create strategic groupings of points, nor (as a result) to the notion of combining points according to distinctions between membership in different clusters (The closest approximation to this has been the use of “island populations” that evolve separately but without concern for analyzing or subdividing populations based on inference and clustering).

The most important distinction, however, is the link between scatter search and the theme of exploiting history. The prescriptions for combining solutions within scatter search are part of a larger design for taking advantage of information about characteristics of previously generated solutions to guide current search. In retrospect, it is perhaps not surprising that such a design should share an intimate association with the surrogate constraint framework, with its emphasis on extracting and coordinating information across different solution phases. This orientation, which takes account of elements such as the recency, frequency, and quality of particular value assignments, clearly shares a common foundation with notions incorporated within tabu search (The same reference on surrogate constraint strategies that is the starting point for scatter search is also often cited as a source of early TS conceptions). By this means, the link between tabu search and so-called “evolutionary” approaches also becomes apparent. The term *evolutionary* has undergone an interesting evolution of its own. By a novel turn, the term

“mutation” in the GA terminology has become reinterpreted to refer to any form of change, including the purposeful change produced by a heuristic process. As a result, all methods that apply heuristics to multiple solutions, whether or not they incorporate strategies for combining solutions, are now considered kindred to genetic algorithms, and the enlarged collection is labeled “evolutionary methods” (This terminology accordingly has acquired the distinction of embracing nearly every kind of method conceivable).

6.3.1 Modern Forms and Applications of Scatter Search

Recent implementations of scatter search (cited below) have taken advantage of the implicit learning capabilities provided by the tabu search framework, leading to refined methods for determining reference points and for generating new points. Current scatter search versions have also introduced more sophisticated mechanisms to map fractional values into integer values. This work is reinforced by new theorems about searches over spaces of zero-one integer variables. Special models have also been developed to allow both heuristic and exact methods to transform infeasible trial points into feasible points. Finally, scatter search is the source of the broader class of path-relinking methods, as described in [Sect. 5](#), which offer a wide range of mechanisms for creating productive combinations of reference solutions. A brief summary of some of these developments appears in [Fig. 27](#).

Implementation of various components of these extensions has provided advances for solving general nonlinear mixed discrete optimization problems with both linear and nonlinear constraints, as noted in the references cited under Recommended Reading.

- Tabu search memory is used to select current reference points from a historical pool (Glover, 1989, 1994a).
- Tabu search intensification and diversification strategies guide the generation of new points (Fleurent et al. 1996; Glover, Laguna and Marti, 2000).
- Solutions generated as “vector combinations” are further improved by explicit tabu search guidance (Trafalidis and Al-Harkan, 1995; Glover, Kelly and Laguna, 1996; Fleurent et al., 1996; Cung, et al. 1997).
- Directional rounding processes focus the search for feasible zero-one solutions allowing them to be mapped into convex subregions of hyperplanes produced by valid cutting plane inequalities (Glover, 1995a).
- Neural network learning is applied to filter out promising and unpromising points for further examination, and pattern analysis is used to predict the location of promising new solutions (Glover, Kelly and Laguna, 1996).
- Mixed integer programming models generate sets of diversified points, and yield refined procedures for mapping infeasible points into feasible points (Glover, Kelly and Laguna, 1996).
- Structured combinations of points take the role of linear combinations, to expand the range of alternatives generated (Glover, 1994a).

Fig. 27 Scatter search extensions

6.3.2 Scatter Search and Path-Relinking Interconnections

The relation between scatter search and path relinking sheds additional light on the character of these approaches. As already remarked, path relinking is a direct extension of scatter search. The way this extension comes about is as follows.

From a spatial orientation, the process of generating linear combinations of a set of reference points may be characterized as generating paths between and beyond these points (where points on such paths also serve as sources for generating additional points). This leads to a broader conception of the meaning of *combinations* of points. That is, by natural extension, we may conceive such combinations to arise by generating paths between and beyond selected points in neighborhood space, rather than in Euclidean space.

The form of these paths in neighborhood space is easily specified by reference to attribute-based memory, as used in tabu search. The path-relinking strategy thus emerges as a direct consequence. Just as scatter search encompasses the possibility to generate new solutions by weighting and combining more than two reference solutions at a time, path relinking includes the possibility to generate new solutions by multi-parent path constructions that incorporate attributes from a set of guiding solutions, where these attributes are weighted to determine which moves are given higher priority, as we have seen in Sect. 5. The name *path relinking* comes from the fact that the generation of such paths in neighborhood space characteristically “relinks” previous points in ways not achieved in the previous search history.

The relevance of these concepts as a foundation for evolutionary procedures is illustrated by recent applications of scatter search and path relinking which have disclosed the promise of these approaches for solving a variety of optimization problems. A sampling of such applications includes:

- Vehicle routing – Rochat and Taillard [64]; Taillard [66]
- Quadratic assignment – Cung et al. [7]
- Financial product design – Consiglio and Zenios [6]
- Neural network training – Kelly et al. [42]
- Job shop scheduling – Yamada and Nakano [71]
- Flow shop scheduling – Yamada and Reeves [72]
- Graph drawing – Laguna and Martí [46]
- Linear ordering – Laguna et al. [48]
- Unconstrained continuous optimization – Fleurent et al. [14]
- Bit representation – Rana and Whitley [62]
- Optimizing simulation – Glover et al. [32]
- Complex system optimization – Laguna [43]

It is additionally useful to note that reexpressing scatter search relative to neighborhood space – as done in path relinking – also leads to more general forms of scatter search in Euclidean space. The form of path relinking manifested in vocabulary building (which results by using constructive and destructive neighborhoods to create and reassemble components of solutions) also suggests the relevance of combining solutions in Euclidean space by allowing different linear combinations to be created for different solution components. The design considerations that underlie vocabulary building generally carry over to this particular instance (see [31]).

The broader conception of solution combinations provided by path relinking has useful implications for evolutionary procedures. The exploitation of neighborhood space and attribute-based memory gives specific, versatile mechanisms for achieving such combinations and provides a further interesting connection between tabu search proposals and genetic algorithm proposals. In particular, many recently developed “crossover operators,” which have no apparent relation between each other in the GA setting, can be shown to arise as special instances of path relinking, by restricting attention to two reference points (taken as parents in GAs) and by replacing the strategic neighborhood guidance of path relinking with a reliance on randomization. In short, the options afforded by path relinking for combining solutions are more unified, more systematic, and more encompassing than those provided by the “crossover” concept, which changes from instance to instance and offers no guidance for how to take advantage of any given context.

6.4 Greedy Randomized Adaptive Search Procedures (GRASP)

The GRASP methodology was developed in the late 1980s, and the acronym was coined by Tom Feo [13]. It was first used to solve computationally difficult set-covering problems [12]. Each GRASP iteration consists of constructing a trial solution and then applying an exchange procedure to find a local optimum (i.e., the final solution for that iteration). The construction phase is iterative, greedy, and adaptive. It is iterative because the initial solution is built considering one element at a time. It is greedy because the addition of each element is guided by a greedy function. It is adaptive because the element chosen at any iteration in a construction is a function of those previously chosen (That is, the method is adaptive in the sense of updating relevant information from iteration to iteration, as in most constructive procedures). The improvement phase typically consists of a local search procedure.

For illustration purposes, consider the design of a GRASP for the 2-partition problem (see, e.g., [44]). This problem consists of clustering the nodes of a weighted graph into two equal-sized sets such that the weight of the edges between the two sets is minimized. In this context, the iterative, greedy, and adaptive elements of the GRASP construction phase may be interpreted as follows. The initial solution is built considering one node at a time. The addition of each node is guided by a greedy function that minimizes the augmented weight of the partition. The node chosen at any iteration in the construction is a function of the adjacencies of previously chosen nodes. There is also a probabilistic component in GRASP that is applied to the selection of elements during the construction phase. After choosing the first node for one set, all nonadjacent nodes are of equal quality with respect to the given greedy function. If one of those nodes is chosen by some deterministic rule, then every GRASP iteration will repeat this selection. In such stages within a construction where there are multiple greedy choices, choosing any one of them will not compromise the greedy approach, yet each will often lead to a very different solution.

To generalize this strategy, consider forming a *candidate list* (at each stage of the construction) consisting of high-quality elements according to an adaptive greedy function. Then, the next element to be included in the initial solution is randomly selected from this list. A similar strategy has been categorized as a cardinality-based semi-greedy heuristic.

The solution generated by a greedy randomized adaptive construction can generally be improved by the application of an improvement phase following selected construction phases, as by using a descent method based on an exchange mechanism, since usually the result of the construction phase is not a local minimum with respect to simple exchange neighborhoods. There is an obvious computational trade-off between the construction and improving phases. An intelligent construction requires fewer improving exchanges to reach a local optimum, and therefore, it results in a reduction of the total CPU time required per GRASP iteration. The exchange mechanism can also be used as a basis for a hybrid method, as by incorporating elements of other methodologies such as simulated annealing or tabu search. In particular, given that the GRASP constructions inject a degree of diversification to the search process, the improvement phase may consist of a short-term memory tabu search that is fine-tuned for intensification purposes. Other connections may be established with methods such as scatter search or the path-relinking strategy of tabu search, by using the GRASP constructions (or their associated local optima) as reference points.

Performing multiple GRASP iterations may be interpreted as a means of strategically sampling the solution space. Based on empirical observations, it has been found that the sampling distribution generally has a mean value that is inferior to the one obtained by a deterministic construction, but the best over all trials dominates the deterministic solution with a high probability. The intuitive justification of this phenomenon is based on the ordering statistics of sampling. GRASP implementations are generally robust in the sense that it is difficult to find or devise pathological instances for which the method will perform arbitrarily bad. The robustness of this method has been well documented in applications to production, flight scheduling, equipment and tool selection, location, and maximum independent sets.

An interesting connection exists between GRASP and probabilistic tabu search (PTS). If PTS is implemented in a memoryless form and restricted to operate only in the constructive phase of a multistart procedure (stripping away memory, and even probabilistic choice, from the improving phase), then a procedure resembling GRASP results. The chief difference is that the probabilities used in PTS are rarely chosen to be uniform over members of the candidate list, but generally seek to capture variations in the evaluations, whenever these variations reflect anticipated differences in the effective quality of the moves considered.

This connection raises the question of whether a multistart variant of probabilistic tabu search may offer a useful alternative to memoryless multistart approaches like GRASP. A study of this issue for the quadratic assignment problem, where GRASP has been reported to perform well, was conducted by Fleurent and Glover [14]. To provide a basis for comparison, the improving phases of the PTS multistart

method excluded the use of TS memory and guidance strategies and were restricted to employ a standard descent procedure. Probabilistic tabu search mechanisms were used in the constructive phases, incorporating frequency-based intensification to improve the effectiveness of successive constructions. The resulting multistart method proved significantly superior to other multistart approaches previously reported for the quadratic assignment problem. However, it also turned out to be not as effective as the leading tabu search methods that use memory in the improving phases as well as (or instead of) in the constructive phases. Nevertheless, it seems reasonable to conjecture that classes of problems exist where increased reliance on restarting will prove advantageous and where the best results may be obtained from appropriately designed multistart strategies such as based on greedy randomized search and multistart variants of PTS.

6.5 Neural Networks

Neural networks have a somewhat different set of goals than tabu search, although some overlaps exist. We indicate how tabu search can be used to extend certain neural net conceptions, yielding a hybrid that may have both hardware and software implications. The basic transferable insight from tabu search is that memory components with dimensions such as recency and frequency can increase the efficacy of a system designed to evolve toward a desired state. We suggest the merit of fusing neural network memory with tabu search memory as follows (A rudimentary acquaintance with neural network ideas is assumed).

Recency-based considerations can be introduced from tabu search into neural networks by a *time-delay feedback loop* from a given neuron back to itself (or from a given synapse back to itself, by the device of interposing additional neurons). This permits firing rules and synapse weights to be changed only after a certain time threshold, determined by the length of the feedback loop. Aspiration thresholds of the form conceived in tabu search can be embodied in inputs transmitted on a secondary level, giving the ability to override the time delay for altering firing thresholds and synaptic weights. Frequency-based effects employed in tabu search similarly may be incorporated by introducing a form of cumulative averaged feedback.

Time-delay feedback mechanisms for creating recency and frequency effects also can have other functions. In a problem-solving context, for example, it may be convenient to disregard one set of options to concentrate on another, while retaining the ability to recover the suppressed options after an interval. This familiar type of human activity is not a customary part of neural network design, but can be introduced by the time-dependent functions previously indicated. In addition, a threshold can be created to allow a suppressed option to “go unnoticed” if current activity levels fall in a certain range, effectively altering the interval before the option reemerges for consideration. Neural network designs to incorporate those features may directly make use of the TS ideas that have made these elements effective in the problem-solving domain.

Tabu search strategies that introduce longer-term intensification and diversification concerns are also relevant to neural network processes. As a foundation for blending these approaches, it is useful to adopt an orientation where a collection of neurons linked by synapses with various activation weights is treated as a set of attribute variables which can be assigned alternative values. Then the condition that synapse j (from a specified origin neuron to a specified destination neuron) is assigned an activation weight in interval p can be coded by the assignment $y_j = p$, where y_j is a component of an attribute vector y as identified in the discussion of attribute creation processes in connection with vocabulary building. A similar coding identifies the condition under which a neuron fires (or does not fire) to activate its associated synapses. As a neural network process evolves, a sequence of these attribute vectors is produced over time. The association between successive vectors may be imagined to operate by reference to a neighborhood structure implicit in the neural architecture and associated connection weights. There also may be an implicit association with some (unknown) optimization problem or a more explicit association with a known problem and set of constraints. In the latter case, attribute assignments (neuron firings and synapse activation) can be evaluated for efficacy by transformation into a vector x , to be checked for feasibility by $x \in \mathbf{X}$ (We maintain a distinction between y and x since there may not be a one-one association between them).

Time records identifying the quality of outcomes produced by recent firings, and identifying the frequency particular attribute assignments produce the highest quality firing outcomes, yield a basis for delaying changes in certain weight assignments and for encouraging changes in others. The concept of influence, in the form introduced in tabu search, should be considered in parallel with quality of outcomes.

Early designs to incorporate tabu search into neural networks are provided in the work of de Werra and Hertz [9] and Beyer and Ogier [5]. These applications, which respectively treat visual pattern identification and nonconvex optimization, are reported to significantly reduce training times and increase the reliability of outcomes generated. More recent uses of tabu search to enhance the function of neural networks are provided by the studies reported in Glover and Laguna [31].

6.6 Target Analysis

Target analysis [29] links artificial intelligence and operation research perspectives to give heuristic or exact solution procedures the ability to learn what rules are best to solve a particular class of problems. Many existing solution methods have evolved by adopting, *a priori*, a somewhat limited characterization of appropriate rules for evaluating decisions. An illustration is provided by restricting the definition of a “best” move to be one that produces the most attractive objective function change. However, this strategy does not guarantee that the selected move will lead the search in the direction of the optimal solution. In fact, in some settings, it has been shown

that the merit of such a decision rule diminishes as the number of iterations increases during a solution attempt.

As seen earlier, the tabu search philosophy is to select a best admissible move (from a strategically controlled candidate list) at each iteration, interpreting best in a broad sense that goes beyond the use of objective function measures, and relies upon historical parameters to aid in composing an appropriate evaluation. Target analysis provides a means to exploit this broader view. For example, target analysis can be used to create a dynamic evaluation function that incorporates a systematic process for diversifying the search over the longer term.

A few examples of the types of questions that target analysis can be used to answer are:

1. Which decision rule from a collection of proposed alternatives should be selected to guide the search? (In an expanded setting, how should the rules from the collection be combined? By interpreting “decision rule” broadly, this encompasses the issue of selecting a neighborhood, or a combination of neighborhoods, as the source of a move at a given stage). Similarly, which parameter values should be chosen to provide effective instances of the decision rules?
2. What attributes are most relevant for determining tabu status, and what associated tabu restrictions, tabu tenures, and aspiration criteria should be used?
3. What weights should be assigned to create penalties or inducements (e.g., as a function of frequency-based memory), and what thresholds should govern their application?
4. Which measures of quality and influence are most appropriate, and which combinations of these lead to the best results in different search phases?
5. What features of the search trajectory disclose when to focus more strongly on intensification and when to focus more strongly on diversification? (In general, what is the best relative emphasis between intensification and diversification, and under what conditions should this emphasis change?)

Motivation for using target analysis to answer such questions is provided by contrasting target analysis with the way answers are normally determined. Typically, an experimenter begins with a set of alternative rules and decision criteria which are intended to capture the principal elements of a given method, often accompanied by ranges of associated parameters for implementing the rules. Then various combinations of options are tried to see how each one works for a preliminary set of test problems. However, even a modest number of rules and parameters may create a large number of possibilities in combination, and there is usually little hope of testing these with any degree of thoroughness. As a result, such testing for preferred alternatives generally amounts to a process of blind groping. Where methods boast the lack of optional parameters and rules, typically it is because the experimenter has already done the advance work to settle upon a particular combination that has been hardwired for the user, at best with some degree of adaptiveness built in, but the process that led to this hardwiring still raises the prospect that another set of options may be preferable.

More importantly, in an adaptive memory approach, where information from the history of the search is included among the inputs that determine current

choices, a trial-and-error testing of parameters may overlook key elements of timing and yield no insights about relationships to be exploited. Such a process affords no way to uncover or characterize the circumstances encountered during the search that may cause a given rule to perform well or badly and consequently gives no way to anticipate the nature of rules that may perform better than those originally envisioned. Target analysis replaces this by a systematic approach to create *hindsight before the fact* and then undertakes to “reverse engineer” the types of rules that will lead to good solutions.

6.6.1 Target Analysis Features

The main features of target analysis may briefly be sketched by viewing the approach as a five-phase procedure (see Fig. 28). *Phase 1* of target analysis is devoted to applying existing methods to determine optimal or exceptionally high-quality solutions to representative problems of a given class. In order to allow subsequent analysis to be carried out more conveniently, the problems are often selected to be relatively small, provided this can be done in a way to assure these problems will exhibit features expected to be encountered in hard problems from the class examined.

Although this phase is straightforward, the effort allotted to obtaining solutions of the specified quality will generally be somewhat greater than would be allotted during the normal operation of the existing solution procedures, in order to assure that the solutions have the quality sought (Such an effort may be circumvented in cases where optimal solutions to a particular testbed of problems are known in advance).

Phase 2 uses the solutions produced by Phase 1 as *targets*, which become the focus of a new set of solution passes. During these passes, each problem is solved again, this time scoring all available moves (or a high-ranking subset) on the basis of their ability to progress effectively toward the target solution. The scoring can be a simple classification, such as “good” or “bad,” or it may capture more refined gradations. In the case where multiple best or near-best solutions may reasonably qualify as targets, the scores may be based on the target that is “closest to” the current solution.

In some implementations, choices during Phase 2 are biased to select moves that have high scores, thereby leading to a target solution more quickly than the customary choice rules. In other implementations, the method is simply allowed to make its regular moves. In either case, the goal is to generate information during this solution effort which may be useful in inferring the solution scores. That is, the scores provide a basis for creating modified evaluations – and more generally, for creating new rules to generate such evaluations in order to more closely match them with the measures that represent “true goodness” (for reaching the targets).

In the case of tabu search intensification strategies such as elite solution recovery approaches, scores can be assigned to parameterized rules for determining the types of solutions to be saved. For example, such rules may take account of characteristics of clustering and dispersion among elite solutions. In environments where data bases can be maintained of solutions to related problems previously encountered, the

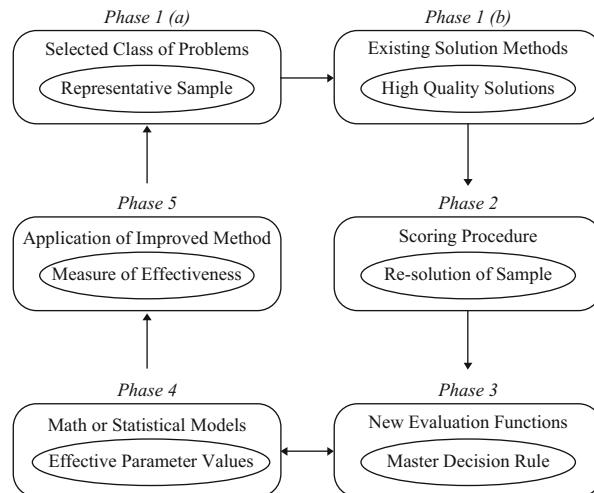

Fig. 28 Overview of the target analysis methodology

scores may be assigned to rules for recovering and exploiting particular instances of these past solutions and for determining which new solutions will be added to the data bases as additional problems are solved (The latter step, which is part of the target analysis and not part of the solution effort, can be performed “off line.”) An integration of target analysis with a generalized form of sensitivity analysis for these types of applications has been developed and implemented in financial planning and industrial engineering by Glover et al. [34]. Such designs are also relevant, for example, in applications of linear and nonlinear optimization based on simplex method subroutines, to identify sets of variables to provide crash-basis starting solution.

In path-relinking strategies, scores can be applied to rules for matching initiating solutions with guiding solutions. As with other types of decision rules produced by target analysis, these will preferably include reference to parameters that distinguish different problem instances. The parameter-based rules similarly can be used to select initiating and guiding solutions from preexisting solutions pools. Tunneling applications of path relinking, which allow traversal of infeasible regions, and strategic oscillation designs that purposely drive the search into and out of such regions, are natural accompaniments for handling recovered solutions that may be infeasible.

Phase 3 constructs parameterized functions of the information generated in *Phase 2*, with the goal of finding values of the parameters to create a *master decision rule*. This rule is designed to choose moves that score highly, in order to achieve the goal that underlies *Phase 2*. It should be noted that the parameters available for constructing a master decision rule depend on the search method employed. Thus, for example, tabu search may include parameters that embody various elements of recency-based and frequency-based memory, together with measures of influence

linked to different classes of attributes or to different regions from which elite solutions have been derived.

Phase 4 transforms the general design of the master decision rule into a specific design by applying a model to determine effective values for its parameters. This model can be a simple set of relationships based on intuition or can be a more rigorous formulation based on mathematics or statistics (such as a goal programming or discriminant analysis model, or even a “connectionist” model based on neural networks).

The components of phases 2, 3, and 4 are not entirely distinct and may be iterative. On the basis of the outcomes of these phases, the master decision rule becomes the rule that drives the solution method. In the case of tabu search, this rule may use feedback of outcomes obtained during the solution process to modify its parameters for the problem being solved.

Phase 5 concludes the process by applying the master decision rule to the original representative problems and to other problems from the chosen solution class to confirm its merit. The process can be repeated and nested to achieve further refinement.

Target analysis has an additional important function. On the basis of the information generated during its application, and particularly during its final confirmation phase, the method produces empirical frequency measures for the probabilities that choices with high evaluations will lead to an optimal (or near-optimal) solution within a certain number of steps. These decisions are not only at tactical levels but also at strategic levels, such as when to initiate alternative solution phases and which sources of information to use for guiding these phases (e.g., whether from processes for tracking solution trajectories or for recovering and analyzing solutions). By this means, target analysis can provide inferences concerning expected solution behavior, as a supplement to classical “worst case” complexity analysis. These inferences can aid the practitioner by indicating how long to run a solution method to achieve a solution desired quality, according to specified empirical probability.

One of the useful features of target analysis is its capacity for taking advantage of human interaction. The determination of key parameters, and the rules for connecting them, can draw directly on the insight of the observer as well as on supplementary analytical techniques. The ability to derive inferences from preestablished knowledge of optimal or near-optimal solutions, instead of manipulating parameters blindly (without information about the relation of decisions to targeted outcomes), can save significant investment in time and energy. The key, of course, is to coordinate the phases of solution and guided re-solution to obtain knowledge that has the greatest utility. Many potential applications of target analysis exist, and recent applications suggest the approach holds considerable promise for developing improved decision rules for difficult optimization problems.

6.6.2 Illustrative Application and Implications

An application of target analysis to a production scheduling problem [45] provides a basis for illustrating some of the relevant considerations of the approach. In this study, the moves consisted of a combination of swap and insert moves, and scores

were generated to identify the degree to which a move brought a solution closer to the target solution (which consisted of the best-known solution before improving the method by means of target analysis). In the case of a swap move, for example, a move might improve or worsen (or, by the measure used, leave unchanged) the “positional value” of each component of the swap, and by the simplification of assigning scores of 1, 0, or -1 to each component, a move could accordingly receive a score ranging from 2 to -2 . The application of target analysis then proceeded by tracking the scores of the 10 highest evaluation moves at each iteration, to determine the circumstances under which the highest evaluations tended to correspond to the highest scores. Both tabu and non-tabu moves were included in the analysis, to see whether tabu status was also appropriately defined.

At an early stage of the analysis, a surprising relationship emerged. Although the scores of the highest evaluation non-tabu moves ranged across both positive and negative values, the positive values were largely associated with moves that improved the schedule while the negative values were largely associated with moves that worsened the schedule. In short, the highest evaluations were significantly more “accurate” (corresponded more closely to high scores) during phases where the objective function value of the schedule improved than during phases when it deteriorated.

A simple diversification strategy was devised to exploit this discovery. Instead of relying on the original evaluations during “disimproving phases,” the strategy supplemented the evaluations over these intervals by assigning penalties to moves whose component jobs had been moved frequently in the past. The approach was initiated at a local optimum after the progress of the search began to slow (as measured by how often a new best solution was found) and was de-activated as soon as a move was executed that also was an improving move (to become reactivated the next time that all available moves were disimproving moves). The outcome was highly effective, producing new solutions that were often superior to the best previously found, especially for larger problems, and also finding the highest quality solutions more quickly.

The success of this application, in view of its clearly limited scope, provides an incentive for more thorough applications. For example, a more complete analysis would reasonably proceed by first seeking to isolate the high-scoring moves during the disimproving phases and to determine how frequency-based memory and other factors could be used to identify these moves more effectively. Comparisons between evaluations proposed in this manner and their associated move scores would then offer a foundation for identifying more intelligent choices. Classifications to segregate the moves based on criteria other than “improving” and “disimproving” could also be investigated. Additional relevant factors that may profitably be taken into account are examined in the illustration of the next subsection.

A Hypothetical Illustration. The following hypothetical example embodies a pattern related to the one uncovered in the scheduling application cited above. However, the pattern in this case is slightly more ambiguous and less clearly points to options that it may be exploited.

Table 10 Moves throughout the search history

Move rank	1	2	3	4	5
Percent of moves with “good” scores	22	14	10	20	16

Table 11 Moves during improving phases

Move rank	1	2	3	4	5
Percent of moves with “good” scores	34	21	9	14	7

Table 12 Moves during disimproving phases

Move rank	1	2	3	4	5
Percent of moves with “good” scores	8	7	11	26	25

For simplicity in this illustration, suppose that moves are scored to be either “good” or “bad” (If each move changes the value of a single 0-1 variable, for instance, a move may be judged good or bad depending on whether the assigned value is the same as in the target solution. More generally, a threshold can be used to differentiate the two classifications).

Table 10 indicates the percent of time each of the five highest evaluation moves, restricting attention in this case to those that are non-tabu, receives a good score during the search history (At a first stage of conducting the target analysis, this history could be for a single hard problem or for a small collection of such problems). The *move rank* in the table ranges from 1 to 5, corresponding to the highest evaluation move, the 2nd highest evaluation move, and so on to the fifth highest evaluation move.

The indicated percent values do not total 100 because good scores may also be assigned to moves with lower evaluations, whose ranks are not included among those shown. Also, it may be expected that some non-tabu moves will also receive good scores (A fuller analysis would similarly show ranks and scores for these moves).

At first glance, the table appears to suggest that the fourth- and fifth-ranked moves are almost as good as the first-ranked move, although the percent of moves that receives good scores is not particularly impressive for any of the ranks. Without further information, a strategy might be contemplated that allocates choices probabilistically among the first-, fourth-, and fifth-ranked moves (though such an approach would not be assured to do better than choosing the first ranked move at each step). **Tables 11** and **12** below provide more useful information about choices that are potentially favorable, by dividing the iterations into improving and disimproving phases as in the scheduling study previously discussed.

These tables are based on a hypothetical situation where improving and disimproving moves are roughly equal in number, so that the percent values shown in Table 9.1 are the average of the corresponding values in Tables 9.2 and 9.3 (For definiteness, moves that do not change the problem objective function may be assumed to be included in the improving phase, though a better analysis might treat them separately).

The foregoing outcomes to an extent resemble those found in the scheduling study, though with a lower success rate for the highest evaluation improving moves.

Clearly, [Tables 11](#) and [12](#) give information that is more exploitable than the information in [Table 10](#). According to these latter tables, it would be preferable to focus more strongly on choosing one of the two highest evaluation moves during an improving phase and one of the fourth or fifth highest evaluation moves during a disimproving phase. This conclusion is still weak in several respects, however, and we examine considerations that may lead to doing better.

Refining the Analysis. The approach of assigning scores to moves, as illustrated in [Tables 10–12](#), disregards the fact that some solution attributes (such as assignments of values to particular 0–1 variables) may be fairly easy to choose “correctly,” while others may be somewhat harder. Separate tables of the type illustrated should therefore be created for easy and hard attributes (as determined by how readily their evaluations lead to choices that would generate the target solution), since the preferred rules for evaluating moves may well differ depending on the types of attributes the moves contain. Likewise, an effective strategy may require that easy and hard attributes become the focus of different search phases. The question therefore arises as to how to identify such attributes.

As a first approximation, we may consider an easy attribute to be one that often generates an evaluation that keeps it out of the solution if it belongs out or that brings it into the solution if it belongs in. A hard attribute behaves oppositely. Thus, a comparison between frequency-based memory and move scores gives a straightforward way to differentiate these types of attributes. Both residence and transition frequencies are relevant, though residence measures are probably more usually appropriate. For example, an attribute that belongs to the current solution a high percentage of the time, and that also belongs to the target solution, would evidently qualify as easy. On the other hand, the number of times the attribute is accepted or rejected from the current solution may sometimes be less meaningful than how long it stays in or out. The fact that residence and transition frequencies are characteristically used in tabu search makes them conveniently available to assist in differentiations that can improve the effectiveness of target analysis.

6.6.3 Conditional Dependencies Among Attributes

[Tables 10–12](#) suggest that the search process that produced them is relatively unlikely to find the target solution. Even during improving phases, the highest evaluation move is almost twice as likely to be bad as good. However, this analysis is limited and discloses a limitation of the tables themselves. In spite of first appearances, it is entirely possible that these tables could be produced by a search process that successfully obtains the target solution (by a rule that chooses a highest evaluation move at each step). The reason is that the relation between scores and evaluations may change over time. While there may be fairly long intervals where choices are made poorly, there may be other shorter intervals where the choices are made more effectively – until eventually one of these shorter intervals succeeds in bringing all of the proper attributes into the solution.

Such behavior is likely to occur in situations where correctly choosing some attributes may pave the way for correctly choosing others. The interdependence

of easy and hard attributes previously discussed is carried a step farther by these conditional relationships, because an attribute that at one point deserves to be classified hard may later deserve to be classified easy, once the appropriate foundations are laid.

Instead of simply generating tables that summarize results over long periods of the search history, therefore, it can be important to look for blocks of iterations where the success rate of choosing good moves may differ appreciably from the success rate overall. These blocks provide clues about intermediate solution compositions that may transform hard attributes into easy ones and thus about preferred sequences for introducing attributes that may exploit conditional dependencies. The natural step then is to see which additional types of evaluation information may independently lead to identifying such sequences.

A simple instance of this type of effect occurs where the likelihood that a given attribute will correctly be selected (to enter or leave the solution) depends roughly on the number of attributes that already correctly belong to the solution. In such situations, the appropriate way to determine a “best choice” is therefore also likely to depend on this number of attributes correctly in solution. Even though such information will not generally be known during the search, it may be possible to estimate it and adjust the move evaluations accordingly. Such relationships, as well as the more general ones previously indicated, are therefore worth ferreting out by target analysis.

6.6.4 Differentiating Among Targets

In describing the steps of target analysis, it has already been noted that scores should not always be rigidly determined by only one specific target, but may account for alternative targets, and in general may be determined by the target that is closest to the current solution (by a metric that depends on the context). Acknowledging that there may be more than one good solution that is worth finding, such a differentiation among targets can prove useful. Yet even in the case where a particular solution is uniquely the one to be sought (as where its quality may be significantly better than that of all others known), alternative targets may still be valuable to consider in the role of intermediate solutions and may provide a springboard to finding additional solutions that are better. Making reference to intermediate targets is another way of accounting for the fact that conditional dependencies may exist among the attributes, as previously discussed. However, such dependencies in some cases may be more easily exploited by explicitly seeking constructions at particular stages that may progressively lead to a final destination.

Some elite solutions may provide better targets than others because they are easier to obtain – completely apart from developing strategies to reach ultimate targets by means of intermediate ones. However, some care is needed in making the decision to focus on such easier targets as a basis for developing choice rules. As in the study of Lokketangen and Glover [51], it may be that focusing instead on the harder targets will yield rules that likewise cause the easier targets to be found more readily, and these rules may apply to a wider spectrum of problems than those derived by focusing on easier targets.

6.6.5 Generating Rules by Optimization Models

Target analysis can use optimization models to generate decision rules by finding weights for various decision criteria to create a composite (master) rule. To illustrate, let G and B , respectively, denote index sets for good moves and bad moves, as determined from move scores, as in the classification embodied in [Tables 10–12](#). Incorporate the values of the different decision criteria in a vector A_i for $i \in G$ and $i \in B$; that is, the j th component a_{ij} of A_i is the value assigned to move i by the decision criterion j . These components need not be the result of rules, but can simply correspond to data considered relevant to constructing rules. In the tabu search setting, such data can include elements of recency-based and frequency-based memory. Then we may consider a master rule which is created by applying a weight vector w to each vector A_i to produce a composite decision value $A_i w = \sum_j a_{ij} w_j$. An ambitious objective is to find a vector w that yields

$$\begin{aligned} A_i w &> 0 \text{ for } i \in G \\ A_i w &\leq 0 \text{ for } i \in B. \end{aligned}$$

If such a weight vector w could be found, then all good moves would have higher evaluations by the composite criterion than all bad moves, which of course is normally too much to ask. A step toward formulating a more reasonable goal is as follows. Let $G(\text{iter})$ and $B(\text{iter})$ identify the sets G and B for a given iteration iter . Then an alternative objective is to find a w so that, at each such iteration, at least one $i \in G(\text{iter})$ would yield

$$A_i w > A_k w \text{ for all } k \in B(\text{iter})$$

or equivalently

$$\text{Max}\{A_i w : i \in G(\text{iter})\} > \text{Max}\{A_k w : k \in B(\text{iter})\}.$$

This outcome would insure that a highest evaluation move by the composite criterion will always be a good move. Naturally, this latter goal is still too optimistic. Nevertheless, it is possible to devise goal programming models (related to LP discriminant analysis models) that can be used to approximate this goal. A model of this type has proved to be effective for devising branching rules to solve a problem of refueling nuclear reactors [[17](#)].

A variety of opportunities exist for going farther in such strategies. For example, issues of creating nonlinear and discontinuous functions to achieve better master rules can be addressed by using trial functions to transform components of A_i vectors into new components, guided by LP sensitivity and postoptimality analysis. Target analysis ideas previously indicated can also be useful in this quest.

The range of possibilities for taking advantage of target analysis is considerable, and for the most part, only the most rudimentary applications of this learning approach have been initiated. The successes of these applications make further exploration of this approach attractive.

7 Neglected Tabu Search Strategies

We briefly review several key strategies in tabu search that are often neglected (especially in beginning studies) but which are important for producing the best results.

Our purpose is to call attention to the relevance of particular elements that are mutually reinforcing but which are not always discussed “side by side” in the literature and which deserve special emphasis. In addition, observations about useful directions for future research are included.

A comment regarding implementation is as follows: First steps do not have to include the most sophisticated variants of the ideas discussed in the following sections, but the difference between “some inclusion” and “no inclusion” can be significant. Implementations that incorporate simple instances of these ideas will often disclose the manner in which refined implementations can lead to improved performance.

The material that follows brings together ideas described in preceding sections to provide a perspective on how they interrelate. In the process, a number of additional observations are introduced.

7.1 Candidate List Strategies

Efficiency and quality can be greatly affected by using intelligent procedures for isolating effective candidate moves, rather than trying to evaluate every possible move in a current neighborhood of alternatives. This is particularly true when such a neighborhood is large or expensive to examine. The gains to be achieved by using candidate lists have been widely documented, yet many TS studies overlook their relevance.

Careful organization in applying candidate lists, as by saving evaluations from previous iterations and updating them efficiently, can also be valuable for reducing overall effort. Time saved in these ways allows a chance to devote more time to higher-level features of the search.

While the basic theme of candidate lists is straightforward, there are some subtleties in the ways candidate list strategies may be used. Considerable benefit can result by being aware of fundamental candidate list approaches, such as the *subdivision strategy*, the *Aspiration Plus strategy*, the *elite candidate list strategy*, the *bounded change strategy* and the *sequential fan strategy* (as discussed in Sect. 4).

An effective integration of a candidate list strategy with the rest of a tabu search method will typically benefit by using TS memory designs to facilitate functions to

be performed by the candidate lists. This applies especially to the use of frequency-based memory. A major mistake of some TS implementations, whether or not they make use of candidate lists, is to consider only the use of recency-based memory. Frequency-based memory – which itself takes different forms in intensification phases and diversification phases – cannot only have a dramatic impact on the performance of the search in general but also can often yield gains in the design of candidate list procedures. A useful way to meld different candidate list procedures is described in Glover [27].

7.2 Intensification Approaches

Intensification strategies, which are based on recording and exploiting elite solutions or, characteristically, specific features of these solutions, have proved very useful in a variety of applications. Some of the relevant forms of such strategies and considerations for implementing them are as follows.

7.2.1 Restarting with Elite Solutions

The simplest intensification approach is the strategy of recovering elite solutions in some order, each time the search progress slows, and then using these solutions as a basis for reinitiating the search. The list of solutions that are candidates to be recovered is generally limited in size, often in the range of 20–40 (although in parallel processing applications, the number is characteristically somewhat larger). The size chosen for the list in serial TS applications also corresponds roughly to the number of solution recoveries anticipated to be done during the search and so may be less or more depending on the setting. When an elite solution is recovered from the list, it is removed, and new elite solutions are allowed to replace less attractive previous solutions – usually dropping the worst of the current list members. However, if a new elite solution is highly similar to a solution presently recorded, instead of replacing the current worst solution, the new solution will compete directly with its similar counterpart to determine which solution is saved.

This approach has been applied very effectively in job shop and flow shop scheduling, in vehicle routing, and in telecommunication design problems. One of the best approaches for scheduling applications keeps the old TS memory associated with the solution but makes sure the first new move away from this solution goes to a different neighbor than the one visited after encountering this solution the first time. Another effective variant does not bother to save the old TS memory but uses a probabilistic TS choice design.

The most common strategy is to go through the list from best to worst, but in some cases, it has worked even better to go through the list in the other direction. In this approach, it appears effective to allow two passes of the list. On the first pass, when a new elite solution is found that falls below the quality of the solution currently recovered, but which is still better than the worst already examined on the list, the method still adds the new solution to the list and displaces the worst solution. Then a second pass, after reaching the top of the list, recovers any added solutions not previously recovered.

7.2.2 Frequency of Elite Solutions

Another primary intensification strategy is to examine elite solutions to determine the frequency in which particular solution attributes occur (where the frequency is typically weighted by the quality of the solutions in which the attributes are found).

This strategy was originally formulated in the context of identifying “consistent” and “strongly determined” variables – where, loosely speaking, consistent variables are those more frequently found in elite solutions, while strongly determined variables are those that would cause the greatest disruption by changing their values (as sometimes approximately measured by weighting the frequencies based on solution quality). The idea is to isolate the variables that qualify as more consistent and strongly determined (according to varying thresholds) and then to generate new solutions that give these variables their “preferred values.” This can be done either by rebuilding new solutions in a multistart approach or by modifying the choice rules of an ongoing solution effort to favor the inclusion of these value assignments.

Keeping track of the frequency that elite solutions include particular attributes (such as edges of tours, assignments of elements to positions, and narrow ranges of values taken on by variables), and then favoring the inclusion of the highest frequency elements effectively allows the search to concentrate on finding the best supporting uses and values of other elements. A simple variant is to “lock in” a small subset of the most attractive attributes (value assignments) – allowing this subset to change over time or on different passes.

A Relevant Concern: In the approach that starts from a current (good) solution and tries to bring in favored elements, it is important to introduce an element that yields a best outcome from among the current contenders (where, as always, best is defined to encompass considerations that are not solely restricted to objective function changes). If an attractive alternative move shows up during this process, which does not involve bringing in one of these elements, aspiration criteria may determine whether such a move should be taken instead. Under circumstances where the outcome of such a move appears sufficiently promising, the approach may be discontinued and allowed to enter an improving phase (reflecting a decision that enough intensification has been applied and it is time to return to searching by customary means).

Intensification of this form makes it possible to determine what percent of “good attributes” from prior solutions should be included in the solution currently generated. It also gives information about which subsets of these attributes should go together, since it is preferable not to choose attributes during this process that cause the solution to deteriorate compared to other choices. This type of intensification strategy has proved highly effective in the settings of vehicle routing and zero-one mixed-integer optimization.

7.2.3 Memory and Intensification

It is clearly somewhat more dangerous to hold elements “in” solution than to hold them “out” (considering that a solution normally is composed of a small fraction of available elements – as where a tree contains only a fraction of the edges of

a graph). However, there is an important exception, previously intimated. As part of a longer-term intensification strategy, elements may be selected very judiciously to be “locked in” on the basis of having occurred with high frequency in the best solutions found. In that case, choosing different mutually compatible (and mutually reinforcing) sets to lock in can be quite helpful. This creates a *combinatorial implosion* effect (opposite to a combinatorial explosion effect) that shrinks the solution space to a point where best solutions over the reduced space are likely to be found more readily.

The key to this type of intensification strategy naturally is to select an appropriate set of elements to lock in, but the chances appear empirically to be quite high that some subset of those with high frequencies in earlier best solutions will be correct. Varying the subsets selected gives a significant likelihood of picking a good one (More than one subset can be correct, because different subsets can still be part of the same complete set). Aspiration criteria make it possible to drop elements that are supposedly locked in, to give this approach more flexibility.

7.2.4 Relevance of Clustering for Intensification

A search process over a complex space is likely to produce clusters of elite solutions, where one group of solutions gives high frequencies for one set of attributes and another group gives high frequencies for a different set. It is important to recognize this situation when it arises. Otherwise, there is a danger that an intensification strategy may try to compel a solution to include attributes that work against each other. This is particularly true in a strategy that seeks to generate a solution by incorporating a collection of attributes “all at once,” rather than using a step-by-step evaluation process that is reapplied at each move through a neighborhood space (Stepping through a neighborhood has the disadvantage of being slower but may compensate by being more selective. Experimentation to determine the circumstances under which each of these alternative intensification approaches may be preferable would be quite valuable).

A strategy that incorporates a block of attributes together may yield benefits by varying both the size and composition of the subsets of high-frequency “attractive” attributes, even if these attributes are derived from solutions that lie in a common cluster, since the truly best solutions may not include them all. Threshold-based forms of logical restructuring, as discussed in Sect. 4, may additionally lead to identifying elements to integrate into solutions that may not necessarily belong to solutions previously encountered. The vocabulary building theme becomes important in this connection. The relevance of clustering analysis for logical restructuring and vocabulary building is reinforced by the use of a related conditional analysis, which is examined subsequently in Sect. 7.5.

7.3 Diversification Approaches

Diversification processes in tabu search are sometimes applied in ways that limit their effectiveness, due to overlooking the fact that diversification is not just

“random” or “impulsive” but depends on a purposeful blend of memory and strategy. As noted in Sect. 4, recency- and frequency-based memory are both relevant for diversification. Historically, these ideas stem in part from proposals for exploiting surrogate constraint methods. In this setting, the impetus is not simply to achieve diversification but to derive appropriate weights in order to assure that evaluations will lead to solutions that satisfy required conditions (see Sect. 6). Accordingly, it is important to account for elements such as how often, to what extent, and how recently particular constraints have been violated, in order to determine weights that produce more effective valuations.

The implicit *learning effects* that underlie such uses of recency, frequency, and influence are analogous to those that motivate the procedures used for diversification (and intensification) in tabu search. Early strategic oscillation approaches exploited this principle by driving the search to various depths outside (and inside) feasibility boundaries and then employing evaluations and directional search to move toward preferred regions.

In the same way that these early strategies bring diversification and intensification together as part of a continuously modulated process, it is important to stress that these two elements should be interwoven in general. A common mistake in many TS implementations is to apply diversification without regard for intensification. “Pure” diversification strategies are appropriate for truly long-term strategies, but over the intermediate term, diversification is generally more effective if it is applied by heeding information that is also incorporated in intensification strategies. In fact, intensification by itself can sometimes cause a form of diversification, because intensifying over part of the space allows a broader search of the rest of the space. A few relevant concerns are as follows.

7.3.1 Diversification and Intensification Links

A simple and natural diversification approach is to keep track of the frequency that attributes occur in nonelite solutions, as opposed to solutions encountered in general, and then to periodically discourage the incorporation of attributes that have modest to high frequencies (giving greater penalties to larger frequencies). The reference to nonelite solutions tends to avoid penalizing attributes that would be encouraged by an intensification strategy.

More generally, for a “first-level” balance, an intermediate-term memory matrix may be used, where the high-frequency items in elite solutions are not penalized by the long-term values, but may even be encouraged. The trade-offs involved in establishing the degree of encouragement, or the degree of reducing the penalties, represent an area where a small amount of preliminary testing can be valuable. This applies as well to picking thresholds to identify high-frequency items (Simple guesses about appropriate parameter values can often yield benefits, and tests of such initial guesses can build an understanding that leads to increasingly effective strategies).

By extension, if an element has never or rarely been in a solution generated, then it should be given a higher evaluation for being incorporated in a diversification approach if it was “almost chosen” in the past but did not make the grade.

This observation has not been widely heeded, but is not difficult to implement, and is relevant to intensification strategies as well. The relevant concerns are illustrated in the discussion of “Persistent Attractiveness” and “Persistent Voting” in Chap. 7 of Glover and Laguna [31].

7.3.2 Implicit Conflict and the Importance of Interactions

Current evaluations also should not be disregarded while diversification influences are activated. Otherwise, a diversification process may bring elements together that conflict with each other and make it harder rather than easier to find improved solutions.

For example, a design that gives high penalties to a wide range of elements, without considering interactions, may drive the solution to avoid good combinations of elements. Consequently, diversification – especially in intermediate term phases – should be carried out for a limited number of steps, accompanied by watching for and sidestepping situations where indiscriminately applying penalties would create incompatibilities or severe deterioration of quality. To repeat the theme, even in diversification, attention to quality is important. And as in “medical remedies,” sometimes small doses are better than large ones. Larger doses (i.e., more radical departures from previous solutions), which are normally applied less frequently, can still benefit by coordinating the elements of quality and change.

7.3.3 Reactive Tabu Search

An approach called reactive tabu search (RTS) developed by Battiti and Tecchiolli [3, 4] deserves additional consideration as a way to achieve a useful blend of intensification and diversification. RTS incorporates hashing in a highly effective manner to generate attributes that are very nearly able to differentiate among distinct solutions. That is, very few solutions contain the same hashed attribute, applying standard hash function techniques. Accompanying this, Battiti and Tecchiolli use an automated tabu tenure, which begins with the value of 1 (preventing a hashed attribute from being reinstated if this attribute gives the “signature” of the solution visited on the immediately preceding step). This tenure is then increased if examination shows the method is possibly cycling, as indicated by periodically generating solutions that produce the same hashed attribute.

The tabu tenure, which is the same for all attributes, is increased exponentially when repetitions are encountered and decreased gradually when repetitions disappear. Under circumstances where the search nevertheless encounters an excessive number of repetitions within a given span (i.e., where a moving frequency measure exceeds a certain threshold), a diversification step is activated, which consists of making a number of random moves proportional to a moving average of the cycle length.

The reported successes of this approach invite further investigations of its underlying ideas and related variants. As potential bases for generating such variants, attributes created by hashing may be viewed as *fine grain* attributes, which give them the ability to distinguish among different solutions. By contrast, “standard” solution attributes, which are the raw material for hashing, may be viewed as *coarse grain*

attributes, since each may be contained in (and hence provide a signature for) many different solutions. Experience has shown that tabu restrictions based on coarse grain attributes are often advantageous for giving increased vigor to the search (There can exist a variety of ways of defining and exploiting attributes, particularly at coarser levels, which complicates the issue somewhat). This raises the question of when particular degrees of granularity are more effective than others.

It seems reasonable to suspect that fine grain attributes may yield greater benefits if they are activated in the vicinity of elite solutions, thereby allowing the search to scour “high-quality terrain” more minutely. This effect may also be achieved by reducing tabu tenures for coarse grain attributes – or basing tabu restrictions on attribute conjunctions – and using more specialized aspiration criteria. Closer scouring of critical regions can also be brought about by using strongly focused candidate list strategies, such as a sequential fan candidate list strategy (Empirical comparisons of such alternatives to hashing clearly would be of interest). On the other hand, as documented by Nonobe and Ibaraki [59, 60], the use of “extra coarse grain” attributes (those that prohibit larger numbers of moves when embodied in tabu restrictions) can prove advantageous for solving large problems over a broadly defined problem domain.

Another type of alternative to hashing also exists, which is to create new attributes by processes that are not so uniform as hashing. A potential drawback of hashing is its inability to distinguish the relative importance (and appropriate influence) of the attributes that it seeks to map into others that are fine grained. A potential way to overcome this drawback is to make use of vocabulary building [31] and of conditional analysis ([Sect. 7.5](#)).

7.4 Strategic Oscillation

A considerable amount has been written on strategic oscillation and its advantages. However, one of the uses of this approach that is frequently overlooked involves the idea of oscillating among alternative choice rules and neighborhoods. As stressed in [Sect. 5](#), an important aspect of strategic oscillation is the fact that there naturally arise different types of moves and choice rules that are appropriate for negotiating different regions and different directions of search. Thus, for example, there are many constructive methods in graph and scheduling problems, but strategic oscillation further leads to the creation of complementary “destructive methods” which can operate together with their constructive counterparts. Different criteria emerge as relevant for selecting a move to take on a constructive step versus one to take on a destructive step. Similarly, different criteria apply according to whether moves are chosen within a feasible region or outside a feasible region (and whether the search is moving toward or away from a feasibility boundary).

The variation among moves and evaluations introduces an inherent vitality into the search that provides one of the sources underlying the success of strategic oscillation approaches. This reinforces the motivation to apply strategic oscillation to the choice of moves and evaluation criteria themselves, selecting moves from a

pool of possibilities according to rules for transitioning from one choice to another. In general, instead of picking a single rule, a process of invoking multiple rules provides a range of alternatives that run all the way from “strong diversification” to “strong intensification.”

This form of oscillation has much greater scope than may at first be apparent, because it invokes the possibility of simultaneously integrating decision rules and neighborhoods, rather than only visiting them in a strategically determined sequence.

Such concepts are beginning to find counterparts in investigations being launched by the computer science community. The “agent” terminology is being invoked in such applications to characterize different choice mechanisms and neighborhoods as representing different agents. Relying on this representation, different agents then are assigned to work on (or “attack”) the problem serially or in parallel. The CS community has begun to look upon this as a significant innovation – unaware of the literature where such ideas were introduced a decade or more ago – and the potential richness and variation of these ideas still seems not to be fully recognized. For example, there have not yet been any studies that consider the idea of “strategically sequencing” rules and neighborhoods, let alone those that envision the notion of parametric integration. The further incorporation of adaptive memory structures to enhance the application of such concepts also lies somewhat outside the purview of most current CS proposals. At the same time, however, TS research has also neglected to conduct empirical investigations of the broader possibilities. This is clearly an area that deserves fuller study.

7.5 Clustering and Conditional Analysis

To reinforce the theme of identifying opportunities for future research, we provide an illustration to clarify the relevance of clustering and conditional analysis, particularly as a basis for intensification and diversification strategies in tabu search.

An Example: Suppose 40 elite solutions have been saved during the search and each solution is characterized as a vector x of zero-one variables x_j , for $j \in N = \{1, \dots, n\}$. Assume the variables that receive positive values in at least one of the elite solutions are indexed x_1 to x_{30} (Commonly in such circumstances, n may be expected to be somewhat larger than the number of positive valued variables, e.g., in this case, reasonable values may be $n = 100$ or $1,000$).

For simplicity, we restrict attention to a simple weighted measure of consistency which is given by the frequency that the variables x_1 to x_{30} receive the value 1 in these elite solutions (We temporarily disregard weightings based on solution quality and other aspects of “strongly determined” assignments). Specifically, assume the frequency measures are as shown in [Table 13](#).

Since each of x_1 to x_{15} receives a value of 1 in 24 of the 40 solutions, these variables tie for giving “most frequent” assignments. An intensification strategy that favors the inclusion of some number of such assignments would give equal

Table 13 Frequency measures

Variables $x_j = 1$	Number of solutions
x_1 to x_{15}	24
x_{16} to x_{20}	21
x_{21} to x_{25}	17
x_{26} to x_{30}	12

Table 14 Frequency measures for two subsets

Subset 1 (20 solutions)		Subset 2 (20 solutions)	
Variables $x_j = 1$	No. of solutions	Variables $x_j = 1$	No. of solutions
x_{11} to x_{15}	20	x_{16} to x_{20}	20
x_{21} to x_{25}	16	x_6 to x_{10}	16
x_1 to x_5	12	x_1 to x_5	12
x_6 to x_{10}	8	x_{26} to x_{30}	8
x_{26} to x_{30}	4	x_{11} to x_{15}	4
x_{16} to x_{20}	1	x_{21} to x_{25}	1

bias to introducing each of x_1 to x_{15} at the value 1 (Such a bias would typically be administrated either by creating modified evaluations or by incorporating probabilities based on such evaluations).

To illustrate the relevance of clustering, suppose the collection of 40 elite solutions can be partitioned into two subsets of 20 solutions each, whose characteristics are summarized in Table 14.

A very different picture now emerges. The variables x_1 to x_{15} no longer appear to deserve equal status as “most favored” variables. Treating them with equal status may be a useful source of diversification, as opposed to intensification, but the clustered data provide more useful information for diversification concerns as well. In short, clustering gives a relevant contextual basis for determining the variables (and combinations of variables) that should be given special treatment.

7.5.1 Conditional Relationships

To go a step beyond the level of differentiation provided by cluster analysis, it is useful to sharpen the focus by referring explicitly to interactions among variables. Such interactions can often be identified in a very straightforward way and can form a basis for more effective clustering. In many types of problems, the number of value assignments (or the number of “critical attributes”) needed to specify a solution is relatively small compared to the total number of problem variables (For example, in routing, distribution, and telecommunication applications, the number of links contained in feasible constructions is typically a small fraction of those contained in the underlying graph). Using a 0–1 variable representation of possibilities, it is not unreasonable in such cases to create a *cross-reference* matrix, which identifies variables (or coded attributes) that simultaneously receive a value of 1 in a specific collection of elite solutions.

To illustrate, suppose the index set $P = \{1, \dots, p\}$ identifies the variables x_j that receive a value of 1 in at least r solutions from the collection of elite solutions under consideration (Apart from other strategic considerations, the parameter r can also be used to control the size of p , since larger values of r result in smaller values of p).

Then create a $p \times p$ symmetric matrix \mathbf{M} whose entries m_{ij} identify the number of solutions in which x_i and x_j are both 1 (Thus, row M_i of \mathbf{M} represents the sum of the solution vectors in which $x_i = 1$, restricted to components x_j for $j \in P$). The value m_{ii} identifies the total number of elite solutions in which $x_i = 1$, and the value m_{ij}/m_{ii} represents the “conditional probability” that $x_j = 1$ in this subset of solutions. Because p can be controlled to be of modest size, as by the choice of r and the number of solutions admitted to the elite set, the matrix \mathbf{M} is not generally highly expensive to create or maintain.

By means of the conditional probability interpretation, the entries of \mathbf{M} give a basis for a variety of analyses and choice rules for incorporating preferred attributes into new solutions. Once an assignment $x_j = 1$ is made in a solution currently under consideration (which may be either partly or completely constructed), an updated conditional matrix \mathbf{M} can be created by restricting attention to elite solution vectors for which $x_j = 1$ (Restricted updates of this form can also be used for look-ahead purposes). Weighted versions of \mathbf{M} , whose entries additionally reflect the quality of solutions in which specific assignments occur, likewise can be used.

Critical event memory provides a convenient mechanism to maintain appropriate variation when conditional influences are taken into account. The “critical solutions” associated with such memory in the present case are simply those constituting a selected subset of elite solutions. Frequency measures for value assignments can be obtained by summing these solution vectors for problems with 0–1 representations, and the critical event control mechanisms can then assure assignments are chosen to generate solutions that differ from those of previous elite solutions.

Conditional analysis, independent of such memory structures, can also be a useful foundation for generating solution fragments to be exploited by vocabulary-building processes.

7.6 Referent-Domain Optimization

Referent-domain optimization is based on introducing one or more optimization models to strategically restructure the problem or neighborhood, accompanied by auxiliary heuristic or algorithmic process to map the solutions back to the original problem space. The optimization models are characteristically devised to embody selected heuristic goals (e.g., of intensification, diversification, or both), within the context of particular classes of problems.

There are several ways to control the problem environment as a basis for applying referent-domain optimization. A natural control method is to limit the structure and range of parameters that define a neighborhood (or the rules used to navigate through a neighborhood) and to create an optimization model that operates under these restricted conditions.

The examples that follow assume the approach starts from a current trial solution, which may or may not be feasible. The steps described yield a new solution, and then the step is repeated, using tabu search as a master guiding strategy to avoid cycling and to incorporate intensification and diversification.

Example 1 A heuristic selects k variables to change values, holding other variables constant. An exact method determines the (conditionally) optimal new values of the k -selected variables.

Example 2 A heuristic identifies a set of restrictive bounds that bracket the values of the variables in the current trial solution (where the bounds may compel some variables to take on a single value). An exact method determines an optimal solution to the problem as modified to include these bounds.

Example 3 A heuristic selects a restructured and exploitable region around the current solution to search for an alternative solution. An exact method finds the best solution in this region.

Example 4 For add/drop neighborhoods, a heuristic chooses k elements to add (or to drop). For example, the heuristic may operate by both adding and dropping k -specific elements, as in k -opt moves for the TSP or k -swap moves for graph bipartitioning that add and drop k nodes. Then, attention is restricted to consider only the subset of elements added or the subset of elements dropped (and further restricted in the case of a bipartitioning problem to just one of the two sets). Then an exact method identifies the remaining k elements to drop (or to add) that will complete the move optimally.

Example 5 A heuristic chooses a modified problem formulation that also admits the current trial solution as a trial solution (For example, the heuristic may relax some part of the formulation and/or restrict another part). An exact method then finds an optimal solution to the modified formulation. An illustration occurs where a two-phase exact algorithm first finds an optimal solution to a relaxed portion of the problem and then finds an optimal solution to a restricted portion. Finally, a small part of the feasible region of the original problem close to or encompassing this latter solution is identified, and an exact solution method finds an optimal solution in this region.

Example 6 The use of specially constructed neighborhoods (and aggregations or partitions of integer variables) permits the application of mixed-integer programming (MIP) models to identify the best options from all moves of depth at most k (or from associated collections of at most k variables). When k is sufficiently small, such MIP models can be quite tractable and produce moves considerably more powerful than those provided by lower level heuristics.

Example 7 In problems with graph-related structures, the imposition of directionality or nonlooping conditions gives a basis for devising generalized shortest path (or

dynamic programming) models to generate moves that are optimal over a significant subclass of possibilities. This type of approach gives rise to a combinatorial leverage phenomenon, where a low-order effort (e.g., linear or quadratic) can yield solutions that dominate exponential numbers of alternatives (See, e.g., [24, 61, 63]).

Example 8 A broadly applicable control strategy, similar to that of a relaxation procedure but more flexible, is to create a proxy model that resembles the original problem of interest and which is easier to solve. Such an approach must be accompanied with a method to transform the solution to the proxy model into a trial solution for the original problem. A version of such an approach, which also induces special structure into the proxy model, can be patterned after layered surrogate/Lagrangian decomposition strategies for mixed-integer optimization.

Referent-domain optimization can also be applied in conjunction with target analysis to create more effective solution strategies. In this case, a first-stage learning model, based on controlled solution attempts, identifies a set of desired properties of good solutions, together with target solutions (or target regions) that embody these properties. Then a second-stage model is devised to generate neighborhoods and choice rules to take advantage of the outcomes of the learning model. Useful strategic possibilities are created by basing these two models on a proxy model for referent-domain optimization, to structure the outcomes so that they may be treated by one of the control methods indicated in the foregoing examples.

8 Conclusion

It is natural to be tempted to implement the most rudimentary forms of a method. More than a few papers on tabu search examine only a small portion of the elements of short-term memory and examine little or nothing at all of longer-term memory. Unfortunately, in some cases, these papers also present themselves as embodying the essence of tabu search.

A factor that has reinforced the tendency to examine a limited part of tabu search (aside from convenience, which can be sensible in early stages of an investigation) is that such a focus has sometimes produced very appealing results. When reasonably decent outcomes can be found without great effort, the motive to look further is diminished. The danger, of course, lies in failing to discover significant gains that are likely to be achieved by a more complete approach.

It is appropriate to acknowledge that attention may be given to a limited subset of ideas from an overall search framework for the following reasons:

1. Such a focus may help to uncover a better form for the strategies associated with this subset.
2. Weaknesses of this subset, when studied in isolation from other ideas, may stand out more clearly, thus yielding insights into the features of a more complete approach that are required to produce a better method.

3. For methods which are susceptible to highly “modular” implementations, as typically occurs for tabu search, simpler designs can readily be made a part of more complex designs.

Nevertheless, in many settings, tabu search implementations that incorporate a more comprehensive set of its basic strategies typically perform appreciably better than implementations that restrict consideration to a narrow set of such strategies.

A great deal remains to be learned about tabu search. Evidently, we also still know very little about how we ourselves use memory in our problem solving. It is not inconceivable that discoveries about effective uses of memory within our search methods will provide clues about strategies that humans are adept at employing – or may advantageously be taught to employ. The potential links between the areas of heuristic search and psychology have scarcely been examined. Unquestionably, in the realm of optimization, we have not yet investigated the strategic possibilities at a level that comes close to disclosing their full potential. The numerous successes of tabu search implementations provide encouragement that such issues are profitable to probe more fully. Some of the opportunities and challenges involved are discussed in Glover [28].

Recent fundamental advances in applications of tabu search have been assembled in a collection of “Tabu Search Vignettes” which can be accessed via the internet at <http://spot.colorado.edu/~glover>. These include summaries of key developments in a variety of areas, including:

Constraint Solving and Its Applications (Resource Assignment, Planning and Timetabling, Integer Programming Feasibility, Satisfiability, Mobile Network Frequency Assignment)

Chemical Industry Applications (Computer Aided Molecular Design (CAMD), Heat Exchanger Network (HEN) Synthesis, Phase Equilibrium Calculations, Gibbs Free Energy Minimization, Optimal Component Lumping Problems)

Classification

Feature Selection

Satellite Range Scheduling

Maritime Transportation for International Trade

Conservation Area Network Design

High Level Synthesis

Graph Coloring

Delivery

Routing with Loading and Inventory Constraints

Heterogeneous Routing and Scheduling

Capacitated Facility Location

Multi-period Forest Harvesting

Manpower Scheduling

DNA Sequencing

Airline Disruption Management

Internet Traffic Engineering

Matrix Bandwidth Minimization

Generalized Assignment

Constraint Satisfaction (Work Shift Scheduling, Set-Covering and Nurse Scheduling)
Resource-Constrained Project Scheduling
Dynamic Optimization (Trade Market Prediction, Meteorological Forecast, Robotics Motion Control)

Additional topics and references related to tabu search, including these vignettes, will also be featured in the website <http://www.tabusearch.info/> which is scheduled to debut in November 2012.

a neighbor of at least one vertex in S . In this chapter, we study three variants of domination: power domination, paired-domination, and total domination which were widely studied in recent years. We give a review of these variants of domination from complexity, approximation algorithm, polynomial algorithm, and bound.

1 Introduction

Domination is a central theme in graph theory. Domination and its variations in graphs have been extensively studied [17, 44, 45, 51]. The basic problem is as follows: given an undirected graph $G = (V, E)$, determine a minimum-size vertex set $S \subseteq V$ such that each vertex v is contained in S or v is a neighbor of at least one vertex in S .

Let $G = (V, E)$ be a graph with vertex set V and edge set E . A *dominating set*, abbreviated by DS, of G is a set S of vertices such that every vertex in $V \setminus S$ is adjacent to a vertex in S . The *domination number* of G , denoted by $\gamma(G)$, is the minimum cardinality of a DS. A dominating set of G of cardinality $\gamma(G)$ is called a γ -set of G (similar notation is used for the other domination parameters). An *independent dominating set* S of a graph G is a dominating set that no two vertices of S are connected by any edge of G . The *independent domination number* $i(G)$ is the minimum cardinality of an independent dominating set of G . A *connected dominating set* (CDS) of G is a set S of vertices of G such that S is a dominating set and the subgraph induced by S is connected. The *connected domination number* $\gamma_c(G)$ is the minimum cardinality of a connected dominating set of G . Equivalently, $\gamma_c(G) = |V(G)| - L$, where L is the maximum number of endpoints of a spanning tree of G [68]. A *total dominating set* (TDS) of G with no isolated vertex is a set S of vertices of G such that every vertex is adjacent to a vertex in S (other than itself). The *total domination number* of G , denoted by $\gamma_t(G)$, is the minimum cardinality of a total dominating set of G . A *matching* of G is a set of independent edges in G . The cardinality of a maximum matching in G is denoted by $\beta'(G)$. A *perfect matching* M in G is a matching in G such that every vertex of G is incident to a vertex in M .

In recent years paired-domination and power domination problems were widely studied. A *paired-dominating set* (PD) of G is a set S of vertices of G such that every vertex is adjacent to some vertex in S and the subgraph induced by S contains a perfect matching. The *paired-domination number* $\gamma_{pr}(G)$ is defined to be the minimum cardinality of a paired-dominating set in G . Every graph without isolated vertices has a paired-dominating set since the endvertices of any maximal matching form such a set. Clearly, $\gamma_t(G) \leq \gamma_{pr}(G)$ for any graph G without isolated vertices. Paired-domination was introduced by Haynes and Slater [43] as a model for assigning backups to guard for security purpose.

The power-domination problem was first studied in terms of graphs by Haynes et al. in [42]. Electric power companies need to continually monitor their system's state as defined by a set of state variable. One method of monitoring these variables is to place phase measurement units (PMUs) at selected locations in the system. Because of the high cost of a PMU, it is desirable to minimize the number of PMUs

while maintaining the ability to monitor (observe) the entire system. A system is said to be observed if all of the state variables of the system can be determined from a set of measurements.

Indeed, an electrical power network can be modeled by a graph where the vertices represent the electrical vertices and the edges are associated with the transmission lines joining two electrical vertices. This problem is of somehow different flavor than standard domination-type problems, since putting a phase measurement unit into a vertex of a graph can have global effects. For instance, if an electric power system can be modeled by a path, then a simple measurement unit suffices to monitor the system no matter how long the path.

Let G be a connected graph and S a subset of its vertices. Denote the *set monitored* by S with \mathcal{P}_S , and define it algorithmically as follows:

1. (*Domination*)

$$\mathcal{P}_S \leftarrow S \cup N(S).$$

2. (*Propagation*)

As long as there exists $v \in \mathcal{P}_S$ such that

$$N(v) \cap (V(G) - \mathcal{P}_S) = \{w\}$$

$$\text{set } \mathcal{P}_S \leftarrow \mathcal{P}_S \cup \{w\}.$$

In other words, the set \mathcal{P}_S is obtained from S as follows. First put into \mathcal{P}_S the vertices from the closed neighborhood of S . Then repeatedly add to \mathcal{P}_S vertices w that have a neighbor v in \mathcal{P}_S such that the other neighbors of v are already in \mathcal{P}_S . After no such vertex w exists, the set monitored by S has been constructed.

The set S is called a *power dominating set* (PDS) of G if $\mathcal{P}_S = V(G)$ and the *power domination number* $\gamma_P(G)$ is the minimum cardinality of a power dominating set in G .

A number of definitions are used in this chapter.

1.1 Graph Theory Terminology and Concepts

Let $G = (V, E)$ be a (nonempty) graph. Two vertices x, y of G are *adjacent*, or *neighbors*, if xy is an edge of G . The set of neighbors of a vertex v in G is denoted by $N_G(v)$, or briefly by $N(v)$. The *degree* of v in G , denoted by $d_G(v)$, is the number of edges of G incident with v . In particular, if G is a simple graph, $d_G(v)$ is equal to the number of neighbors of v in G . A vertex of degree 0 is called an *isolated vertex*. We denote by $\delta(G)$ and $\Delta(G)$ the *minimum* and *maximum degrees* of the vertices of G . If all the vertices of G have the same degree k , then G is *k -regular*, or simply *regular*. A regular 3-regular graph is called *cubic*.

A *star* is a graph $K_{1,a}$ composed of a central vertex c and a other vertices only adjacent to c . In the special case $a = 3$, the graph $K_{1,3}$ is called a *claw*. A *subdivided star* is a star whose edges are subdivided once, that is, each edge is replaced by a path of length 2 by adding a vertex of degree 2.

If G does not contain a graph F as an induced subgraph, then G is said to be F -*free*. As usual, K_n is the complete graph on n vertices. The graph $K_4 - e$ (with one edge removed from K_4) is called a *diamond*. In particular, we say a graph is *claw-free* if it is $K_{1,3}$ -free and *diamond-free* if it is $(K_4 - e)$ -free.

A graph is *bipartite* if its vertex set can be partitioned into two subsets X and Y so that every edge has one end in X and one end in Y . A graph which can be drawn in the plane in such a way that edges meet only at points corresponding to their common ends is called a *planar graph*, and such a drawing is called a planar embedding of the graph. A *split graph* is a graph in which the vertices can be partitioned into a clique and an independent set. For terminology and notation not given here, the reader is referred to [13].

A subset S of vertices in a graph G is a *packing* (respectively, an *open packing*) if the closed (respectively, open) neighborhoods of vertices in S are pairwise disjoint. The *packing number* $\rho(G)$ is the maximum cardinality of a packing in G , while the *open packing number* $\rho^o(G)$ is the maximum cardinality of an open packing in G .

A *tree decomposition* of G is a pair $\langle X_i \subseteq V(G) \mid i \in I, T = (I, F) \rangle$, where each X_i is a subset of $V(G)$, called a *bag*, and T is a tree with the elements of I as vertices. The following three properties must hold:

1. $\cup_{i \in I} X_i = V(G)$.
2. Every edge $uv \in E$ has both ends in some X_i .
3. For all $i, j, k \in I$, if j is on the unique path from i to k in T , then we have $X_i \cap X_k \subseteq X_j$.

The *width* of $\langle X_i \subseteq V \mid i \in I, T \rangle$ is $\max_{i \in I} |X_i| - 1$. The *treewidth* of G is defined as the minimum width over all tree decompositions of G .

MinRep Problem ([55])

In the MinRep [55] problem we are given a bipartite graph $G = (A, B, E)$ with a partition of A and B into equal-sized subsets, let q_A and q_B denote the number of sets in the partition of A and B , respectively. Let $A = A_1 \cup A_2 \dots \cup A_{q_A}$ denote the partition of A , and let $B = B_1 \cup B_2 \dots \cup B_{q_B}$ denote the partition of B . This partition naturally defines a superbipartite graph $H = (A, B, E)$. The supervertices of H are A_1, A_2, \dots, A_{q_A} and B_1, B_2, \dots, B_{q_B} . There is a superedge between supervertices A_i and B_j if there exists some $a \in A_i$ and $b \in B_j$ such that ab is an edge of G . We say that a superedge $A_i B_j$ is covered by vertices a, b if $a \in A_i, b \in B_j$, and if there is an edge between a and b in G . Given $S \subseteq A \cup B$, we say that the superedge $A_i B_j$ is covered by S if there exists $a, b \in S$ that covers $A_i B_j$. The goal in the *MinRep problem* is to pick a minimum-size set of vertices, $A' \cup B' \subseteq V(G)$, to cover all superedges in H .

1.2 Hypergraph Terminology and Concepts

Hypergraphs are systems of sets which are conceived as natural extensions of graphs. A hypergraph $H = (V, E)$ is a finite set V of elements, called *vertices*, together with a finite multiset E of arbitrary subsets of V , called *hyperedges*. A *transversal* or *hitting set* in H is a subset of the vertices of H which has

a nonempty intersection with each hyperedge of H . The *transversal number* $\tau(H)$ of H is the minimum cardinality of a transversal in H . A transversal of H of cardinality $\tau(H)$ is called $\tau(H)$ -transversal. A k -uniform hypergraph is a hypergraph in which every hyperedge has size k . Graphs are special hypergraphs.

In this chapter, we will focus on three variants of domination: power domination, paired-domination and total domination which were widely studied in recent years.

2 Power Domination in Graphs

Power domination has been widely studied recently (see [9, 31, 32, 41, 43, 61, 62]). Given a graph G and a positive integer k , the power domination decision problem consists of deciding if the graph has a PDS of size at most k . The power domination decision problem has been proven to be NP-complete [42] even when the input graph is bipartite; Haynes et al. in [42] presented a linear-time algorithm to solve PDS optimally on trees. Kneis et al. [53] generalized this results to a linear-time algorithm that finds an optimal solution for PDS on graphs that have bounded treewidth, relying on earlier results of Courcelle et al. [31]. Guo et al. [41] developed a combinatorial algorithm based on dynamic programming for optimally solving the PDS problem on graphs of treewidth k . The running time of their algorithm is $O(c^{k^2} \cdot n)$, where c is a constant. Even for planar graphs, the dominating set problem (which is to determine a minimum dominating set in a graph G) is NP-hard [39], and the same holds for PDS [41]. Aazami and Stilp [1] gave an $O(\sqrt{n})$ -approximation algorithm for planar graphs and showed that their methods cannot improve on this approximation guarantee. Liao and Lee [61] proved that the PDS problem on split graphs is NP-complete, and they presented a polynomial-time algorithm for solving PDS optimally on interval graphs. Dorfling and Henning [36] computed the power domination number, that is, the size of an optimal power dominating set, for $n \times m$ grids. Zhao et al. [77] established a sharp upper bound on the power domination number of any connected graph G of order $n \geq 3$, and $\gamma_p(G) \leq n/4$ for any connected claw-free cubic graph G of order n and characterized the extremal cubic graphs attaining the bound.

2.1 Complexity Results

The dominating set problem is itself a classical NP-complete problem [39]. Haynes et al. [42] showed the NP-completeness of the PDS problem by giving a reduction from 3-SAT. What makes power dominating set seemingly harder to solve is its nonlocal structure: For dominating set, the placement of a dominating vertex cannot influence other parts in the graph that are away, while this is perfectly possible for power dominating set. A path of arbitrary length, for example, can be measured by a single vertex at one of its ends. Guo et al. [41] gave some first evident for this intuition. They showed that the PDS problem is at least as hard to solve as the DS problem by reducing the DS problem to the PDS problem.

Given a graph G , they constructed an augmented graph G' such that S is an optimal solution for the domination set problem on G if and only if it is an optimal solution for PDS on G' ; the G' is obtained from G by adding a new vertex v' for each vertex v in G and adding the edge vv' .

By reducing the DS problem to the PDS problem, Guo et al. [41] proved the following:

Theorem 1 ([41]) *The power dominating set problem is NP-complete in bipartite, chordal, circle, and planar graphs.*

Guo et al. [41] showed that the PDS problem is NP-complete in split graphs. The reduction is from the NP-complete vertex cover problem.

Theorem 2 ([41]) *The power dominating set problem is NP-complete in split graphs.*

The following table was given in [41], which compared the computational complexity of the PDS problem and the DS problem.

Aazami and Stilp [1] proved a result on the hardness of approximating the PDS problem by a reduction from the MinRep problem. They gave a gap preserving reduction from MinRep to the PDS problem. The hardness result showed that the PDS problem cannot be approximated within a factor of $2^{\log^{1-\epsilon} n}$ unless $\text{NP} \subseteq \text{DTIME}(n^{\text{polylog}(n)})$. This substantially improved the $\Omega(\log n)$ hardness result in [41, 53]; both papers gave a gap preserving reduction from the DS problem to the PDS problem.

Table 1 The computation complexity of the PDS problem and the DS problem [41]

Graph classes	Dominating set	Power dominating set
Bipartite	NP-complete	NP-complete
Chordal	NP-complete	NP-complete
Circle	NP-complete	NP-complete
Comparability	NP-complete	NP-complete
Planar	NP-complete	NP-complete
Split	NP-complete	NP-complete
AT-free	Poly. time	
Cocomparability	Poly. time	
Distance hereditary	Poly. time	
Dually chordal	Linear time	
Interval	Poly. time	Poly. time
k -Polygon ($k \geq 3$)	Poly. time	
Partial k -tree ($k \geq 1$)	Linear time	Linear time
Permutation	Linear time	
Strongly chordal	Poly. time	

Empty entries mean that this has not been studied yet

Theorem 3 ([1]) *The PDS problem cannot be approximated within ratio $2^{\log^{1-\epsilon} n}$ for any fixed $\epsilon > 0$, unless $NP \subseteq DTIME(n^{\text{polylog}(n)})$.*

Theorem 3 is proved by a reduction from the MinRep problem. The following result is due to Kortsarz [55].

Theorem 4 ([55]) *The MinRep problem cannot be approximated within ratio $2^{\log^{1-\epsilon} n}$, for any fixed $\epsilon > 0$, unless $NP \subseteq DTIME(n^{\text{polylog}(n)})$.*

Aazami and Stilp [1] created an instance $\hat{G} = (\hat{V}, \hat{E})$ of the PDS problem from a given instance $G = (A, B, E)$ of the MinRep problem. The idea is to replace each superedge with a “cover testing gadget.” Start with a copy of each vertex in $A \cup B$ in \hat{G} . Add a new vertex w^* to the graph \hat{G} and connect w^* to all vertices in $A \cup B$. Also add new vertices w_1^*, w_2^*, w_3^* and connect them to w^* (the vertices w_1^*, w_2^*, w_3^* are added to force w^* to be in any optimal solution). For all $i \in \{1, \dots, q_A\}$, $j \in \{1, \dots, q_B\}$, if $A_i B_j$ is a superedge, then do the following: Let E_{ij} denote the set of edges between A_i and B_j in G , and let l_{ij} denote $|E_{ij}|$. Denote the edges in E_{ij} by $e_1, e_2, \dots, e_k, \dots$. Let C_{ij} be a cycle of $3l_{ij}$ vertices. Sequentially label the vertices of C_{ij} as $u_1, v_1, w_1, u_2, v_2, w_2, \dots, u_k, v_k, w_k, \dots$. Make $\lambda = 4$ new copies of the graph C_{ij} . For each edge $e_k = a_k b_k \in E_{ij}$ and for each of the four copies of C_{ij} , add an edge from a_k to u_k and an edge from b_k to v_k . Let $\hat{G} = (\hat{V}, \hat{E})$ be the obtained graph. Let S be a feasible solution for the resulting PDS instance \hat{G} , and suppose $w^* \in S$.

The next lemma shows that the size of an optimal solution in PDS is exactly one more than the size of an optimal solution in MinRep. This will complete the proof of **Theorem 3** by showing that the above reduction is a gap preserving reduction from MinRep to the PDS problem with the same gap (hardness ratio) as the MinRep problem.

Lemma 1 ([1]) *$A^* \cup B^*$ is an optimal solution to the instance $G = (A, B, E)$ of the MinRep problem if and only if $S^* = A^* \cup B^* \cup \{w^*\} \subseteq V(\hat{G})$ is an optimal solution to the instance \hat{G} of the PDS problem.*

2.2 An Approximation Algorithm for the PDS Problem in Planar Graphs

Aazami and Stilp [1] described an $O(k)$ -approximation algorithm for the PDS problem in graphs with treewidth k ; the running time is $O(n^3)$, independent of k . This algorithm gives an $O(\sqrt{n})$ -approximation algorithm for the PDS problem in planar graphs. They showed that the analysis of the algorithm is tight on planar graphs.

Aazami and Stilp [1] introduced the notation of a strong region. For a graph $G = (V, E)$, a subset $R \subseteq V$ is called *strong* if every feasible solution to the

Algorithm 1 (see [1])

```

1: A tree decomposition  $\langle \{X_i | i \in I\}, T \rangle$  of  $G$  is given, where  $T$  is rooted at  $r$ .
2: Let  $I_l$  be the set of  $T$ -vertices at distance  $l$  from the root  $r$ , and let  $d$  be the maximum distance
   from  $r$  in  $T$ .
3:  $S \leftarrow \emptyset$ 
4: for  $i = d$  to 0 do
5:   Let  $I_i = \{r_1, \dots, r_{k_i}\}$  and denote by  $T_{r_j}$  the subtree in  $T$  rooted at  $r_j$ .
6:   Let  $Y_{r_j}$  be the union of bags corresponding to the  $T$ -vertices in  $T_{r_j}$ .
7:   for  $j = 1$  to  $k_i$  do
8:     if  $Y_{r_j}$  is an  $S$ -strong region, then
9:        $S \leftarrow S \cup X_{r_j}$ , where  $X_{r_j}$  is the bag corresponding to  $r_j$ .
10:    end if
11:   end for
12: end for
13: Output  $S_0 = S$ .

```

PDS problem has a vertex of R . The neighborhood of $R \subseteq V$ is defined as $\text{nbr}(R) = \{v \in V | \exists u \in R, v \in E, u \in R, v \notin R\}$, and the exterior of R is defined as $\text{ext}(R) = \text{nbr}(V \setminus R)$; that is, $\text{ext}(R)$ consists of the vertices in V that are adjacent to a vertex in $V \setminus R$.

Given a graph $G = (V, E)$ and a set $S \subseteq V$, the subset $R \subseteq V$ is called an *S -strong region* if $R \not\subseteq \mathcal{P}_{S \cup \text{nbr}(R)}$; otherwise, R is called an *S -weak region*. The region R is called *minimally S -strong* if it is an S -strong region, and for all $r \in R$, $R - r$ is an S -weak region.

It is easy to check from the definition that an S -strong region is also a strong region. Any feasible solution to the PDS problem needs to have at least one vertex from every strong region.

Lemma 2 ([2]) *For a graph $G = (V, E)$ and a subset $R \subseteq V$, the subset $R \subseteq V$ is an S -strong region if and only if for every feasible solution $S \cup S^*$ of G , we have $R \cap (S^* \setminus S) \neq \emptyset$.*

The following algorithm makes one level-by-level and bottom-to-top pass over the tree T of the tree decomposition of G and constructs a solution S for the PDS problem. At each vertex r_j of T , check whether the union of the bags in the subtree rooted at r_j forms an S -strong region; if yes, then the bag X_{r_j} of r_j is added to S ; otherwise, S is not updated.

Analysis of the Algorithm

To show that the solutions S_0 found by the algorithm is feasible, authors first got the following lemmas.

Lemma 3 ([1]) *Suppose Z is an S -weak region such that $\text{ext}(Z) \subseteq S$. Then we have $Z \subseteq \mathcal{P}_S$.*

Lemma 4 ([1]) *Let $Z \subseteq V$ be an S -strong region. Suppose that Y is a subset of V such that $Y \subseteq \mathcal{P}_S$ and $\text{ext}(Y) \subseteq S$. Then $Z \setminus Y$ is an S -strong region.*

For any vertex q of T , Y_q denotes the union of the bags corresponding to the T -vertices in the subtree rooted at q in T . Then $\text{ext}(Y_q) \subseteq X_q$. Using induction on the height of the subtree of T rooted at q and Lemmas 3 and 4, they proved that if Y_q is S^* -strong, then $Y_q \subseteq \mathcal{P}_{S^* \cup X_q}$, where S^* denotes the solution just before the algorithm examines Y_q .

The above statement implies that $V \subseteq \mathcal{P}_{S_0}$ when the algorithm examines the root r of T .

To show that the approximation guarantee is $(k + 1)$, they constructed a set Δ of pairwise disjoint strong regions R_1, R_2, \dots , such that there is a strong region R_j corresponding to each step of the algorithm that adds a nonempty bag X_{q_j} to S . Thus $|S_0| \leq (k + 1)|\Delta|$ since each bag has $\leq k + 1$ vertices, and $\text{Opt}(G) \geq \Delta$ because every feasible solution has size $\geq |\Delta|$ by Lemma 2. Hence $|S_0| \leq (k + 1)\text{opt}(G)$.

Theorem 5 ([1]) *Given a graph $G = (V, E)$ and a tree decomposition of G of width k as input, Algorithm 1 runs in time $O(n \cdot |E|)$ and achieves an approximation guarantee of $k + 1$.*

It is known that planar graphs have treewidth $O(\sqrt{n})$, and such a tree decomposition can be found in $O(n^{\frac{3}{2}})$ time [4]. This fact together with the above theorem proves the following theorem.

Theorem 6 ([1]) *Algorithm 1 achieves an approximation guarantee of $O(\sqrt{n})$ for the planar PDS problem.*

2.3 Polynomial Algorithms for the PDS Problem in Some Special Graphs

2.3.1 Power Domination in Trees

Haynes et al. [42] showed that the PDS problem is NP-complete even when the input graph is bipartite; they presented a linear-time algorithm to solve PDS optimally on trees. Guo et al. [41] presented simplified linear-time algorithm for the PDS problem in trees.

Without loss of generality, Guo et al. [41] assumed that the input is rooted at a degree-one vertex r and the *depth* of a vertex is defined as the length of the path between v and r . The algorithm follows a bottom-up strategy.

Analysis of the Algorithm

Based on an induction on the depth of the vertices u in T , they proved that the output P of Algorithm PDS-Trees is a power dominating set of T . The proof works top-down whereas the algorithm works bottom-up. Next, they proved the optimal of P by showing a more general statement.

Claim. Given a rooted tree $T = (V, E)$ with root r , Algorithm PDS-Trees outputs a power dominating set P such that $|P \cap V_u| \leq |G \cap V_u|$ for any optimal solution Q

PDS-Trees ([41])

Input: Rooted tree T with r denoting the root.

Output: Minimum power dominating set P .

```

1   Sort the inner vertices of  $T$  in a list  $L$  according to a post-order traversal of  $T$ ;
2   while  $L \neq \{r\}$  do
3      $v \leftarrow$  the first vertex in  $L$ ;  $L \leftarrow L \setminus \{v\}$ ;
4     if  $v$  has at least two unobserved children then
5        $P \leftarrow P \cup \{v\}$ ;
6     Exhaustively apply the two observation rules to  $T$  ;
7     end if
8   end while
9   if  $r$  is unobserved then
10   $P \leftarrow P \cup \{r\}$ ;
11 end if
12 return  $P$ .

```

of PDS for T and any tree vertex u , where V_u denotes the vertex set of the subtree of T rooted at u .

2.3.2 Power Domination in Graphs of Bounded Treewidth

Guo et al. [41] gave a linear-time algorithm for graphs of bounded treewidth; assuming that the corresponding tree decomposition is given, use basically the same strategy as the algorithms for DS [4, 5, 72], that is, bottom-up dynamic programming from the leaves to the root. There are two difficulties associated “propagation” that makes PDS “hard” than DS and which cannot be solved by a simple modification of algorithm for DS. Guo et al. [41] defined the orientations of graphs.

An *orientation* of an undirected graph $G = (V, E)$ is a graph $D = (V, E_1 \dot{\cup} E_2)$ such that, for each $\{u, v\} \in E$, there is either a directed edge (u, v) or (v, u) in E_1 or an undirected edge $\{u, v\}$ in E_2 . The indegree of a vertex v in D , denoted by $d^-(v)$, is defined as $|\{(u, v) : (u, v) \in E_1\}|$, and the outdegree of v , denoted by $d^+(v)$, as $|\{(v, u) : (v, u) \in E_1\}|$.

A *valid orientation* of $D = (V, E_1 \dot{\cup} E_2)$ of an undirected graph $G = (V, E)$ is an orientation such that:

1. For any $v \in V$: $(d^-(v) \leq 1)$ and $(d^-(v) = 1 \Rightarrow d^+(v) \leq 1)$.
2. And there is no dependent cycle in D .

The set of vertices with $d^-(v) = 0$ is called *origin* of D .

Valid Orientation with Minimum Origin (VOMO)

Input: An undirected graph $G = (V, E)$ and an integer $k \geq 0$.

Output: Is there a vertex subset $O \subseteq V$ with $|O| \leq k$ such that G has a valid orientation with O as origin?

Guo et al. [41] showed that orientation problem is a reformulation of the PDS problem.

Theorem 7 ([41]) *An undirected graph G has a power dominating set P if G has a valid orientation with P as origin.*

Guo et al. [41] described a dynamic programming procedure solving VOMO on graphs of bounded treewidth. As a consequence, they also arrived at a solution for the PDS problem.

Theorem 8 ([41]) *For a graph of order n with given width- k -tree decomposition, the PDS problem can be solved in $O(c^{k^2} \cdot n)$ time for a constant c .*

2.3.3 Power Domination in Block Graphs

A *block* of G is a maximal connected subgraph of G without a cut-vertex. A *block graph* is a connected graph whose blocks are complete graphs. Xu et al. [76] achieved a linear-time algorithm for block graphs. For block graphs, they first presented the following result.

Lemma 5 ([76]) *If G is a block graph, then there exists a minimum power dominating set in which every vertex is a cut-vertex of G .*

Based on Lemma 5, they gave PDS-BG Algorithm. The algorithm works on a treelike decomposition structure, named *refined cut-tree*, of a block graph. Let G be a block graph with h blocks BK_1, \dots, BK_h and p cut-vertices v_1, \dots, v_p . The cut-tree of G , denoted by $T^B(V^B, E^B)$, is defined as $V^B = \{BK_1, \dots, BK_h, v_1, \dots, v_p\}$ and $E^B = \{(BK_i, v_j) \mid v_j \in BK_i, 1 \leq i \leq h, 1 \leq j \leq p\}$. It is shown in [3] that the cut-tree of a block graph can be constructed in linear time by the depth-first-search method. For any block BK_i of G , define $B_i = \{v \in BK_i \mid v \text{ is not a cut-vertex}\}$, where $1 \leq i \leq h$. They can refine the cut-tree $T^B(V^B, E^B)$ as $V^B = \{B_1, \dots, B_h, v_1, \dots, v_p\}$ and $E^B = \{(B_i, v_j) \mid v_j \in BK_i, 1 \leq i \leq h, 1 \leq j \leq p\}$, and each B_i is called a *block-vertex*. It is shown that the cut-tree of a block graph can be constructed in linear time by the depth-first-search method.

PDS-BG Algorithm is presented actually as a color-marking process, and we give a brief overview on this algorithm. Let G be a connected block graph, and $T^B(V^B, E^B)$ the refined cut-tree of G . For notation convenience, set $T^B = T^B(V^B, E^B)$, and let $V_{v_j} = \{v \in V(G) \mid v \in BK_i, \text{ and } v_i^B \text{ is a vertex of } T_{v_j}^B\}$ for a cut-vertex v_j of G . Suppose $T^B(V^B, E^B)$ is a rooted tree with vertex set $\{v_1, v_2, \dots, v_n\}$ such that $l(v_i) \leq l(v_j)$ for $i > j$, and the root is a cut-vertex v_n (in G). Let H_i be the set of all vertices with level number i , and k be the largest level number. By the definition of $T^B(V^B, E^B)$, it is clear that $H_0 = \{v_n\}$ and H_i contains only either cut-vertices of G for even i or black-vertices for odd i . Clearly, k is odd. By Lemma 5, there exists a minimum power dominating set that contains only cut-vertices for a block graph G . PDS-BG Algorithm considers directly the cut-vertices in the rooted tree T^B . It starts from the largest even level of T^B and works upward to the root of the tree. Initially, all vertices of T^B are marked with white (which means all needed to be observed), and eventually, every white vertex will be marked with black or gray (except for the possibility that some will remain white and can also be observed by the rules of power observation). In the end of the algorithm, all black-vertices form a minimum PDS

of G , and each gray vertex is observed by some black cut-vertex. For a gray cut-vertex v , $\text{bound}(v) = 1$ means that v is bounded, that is, v itself is already observed and there exists unique white vertex which is adjacent to v in $G[V_v]$ (noting that such a white vertex can be observed by rules of power observation in $G[V_v]$); $\text{bound}(v) = 0$ means that there does not exist any white vertex adjacent to v in $G[V_v]$.

Theorem 9 ([76]) *Algorithm PDS-BG computes in linear time a minimum PDS of a given connected block graph G .*

2.3.4 Power Domination in Product Graphs

Given two graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$, the *Cartesian product* of G_1 and G_2 is the graph $G_1 \square G_2$ whose set of vertices is the Cartesian product of the sets V_1 and V_2 , so $V(G_1 \square G_2) = V_1 \times V_2$. Two vertices of $G_1 \square G_2$, say (v_1, v_2) and (u_1, u_2) , are adjacent if and only if $v_1 = u_1$ and v_2 is adjacent to u_2 in G_2 , or, alternatively, if v_1 is adjacent to u_1 in G_1 and $v_2 = u_2$. For particular pairs of graphs G_1 and G_2 , the Cartesian product provides well-known families of graphs. For example, the $n \times m$ grid can be obtained as the Cartesian product $P_n \square P_m$, where P_n and P_m , respectively, denote the paths with n and m vertices. Analogously, the $n \times m$ cylinder is the Cartesian product $P_n \square C_m$, where P_n denotes, as above, the path on n vertices and C_m stands for the cycle on m vertices. The $n \times m$ torus is the Cartesian product of two cycles, say C_n and C_m , respectively, having n and m vertices.

The *direct product* of G_1 and G_2 is the graph $G_1 \times G_2$, whose set of vertices is $V(G_1) \times V(G_2)$. Two vertices of $G_1 \times G_2$ are adjacent in $G_1 \times G_2$ if and only if they are adjacent in both coordinates. For any integers $m, n \geq 2$, the direct product $P_m \times P_n$ is not connected. If m or n is even, $P_m \times P_n$ consists of two isomorphic connected components; otherwise, it has two nonisomorphic connected components (see [75]).

A fundamental unsolved problem involving domination in graphs is to find the domination number of the $n \times m$ grid graph $P_n \square P_m$. Jacobson and Kinch [50] determined $\gamma(P_n \times P_m)$ for $n = 1, 2, 3, 4$ and all m , while Chang and Clark [19] determined $\gamma(P_n \square P_m)$ for $n = 5, 6$ and all m . For $n \geq 7$ and all m , the domination number of the grid $P_n \square P_m$ has yet to be determined. However, unlike the domination number of a grid graph, Dorfling and Henning [36] showed that the power domination number of an $n \times m$ grid graph can be completely determined.

Algorithm A (Dorfling and Henning's placement)

Input: An $n \times m$ grid with $m \geq n \geq 1$.

Output: A $\gamma_P(G)$ -set S .

1. $k \leftarrow \lfloor n/8 \rfloor$; $j \leftarrow n - 8k$; $S \leftarrow \bigcup_{i=0}^{k-1} \{(8i + 3, 2), (8i + 5, 3)\}$;
 2. **if** $j \in \{1, 2\}$ **then** $S \leftarrow S \cup \{(n, 1)\}$;
if $j = 3$ **then** $S \leftarrow S \cup \{(n - 1, 1)\}$;
if $j = 4$ **then** $S \leftarrow S \cup \{(n - 2, 1), (n - 1, 1)\}$;
if $j \in \{5, 6, 7\}$ **then** $S \leftarrow S \cup \{(n + 3 - j, 2), (n + 5 - j, 3)\}$;
-

Theorem 10 ([36]) *If G is an $n \times m$ grid, $m \geq n \geq 1$, then*

$$\gamma_P(G) = \begin{cases} \lceil \frac{n+1}{4} \rceil & \text{if } n \equiv 4 \pmod{8}, \\ \lceil \frac{n}{4} \rceil & \text{otherwise.} \end{cases}$$

By construction methods, Barrera and Ferrero [10] found upper bounds on the power domination number of some families of Cartesian products of graphs: the cylinders $P_n \square C_m$ for integers $n \geq 2, m \geq 3$ and the tori $C_n \square C_m$ for integers $n, m \geq 3$.

Theorem 11 ([10]) *The power domination number for the graph $P_n \square C_m$ is*

$$\gamma_P(P_n \square C_m) \leq \min\left\{\lceil \frac{m+1}{4} \rceil, \lceil \frac{n+1}{2} \rceil\right\}.$$

Theorem 12 ([10]) *The power domination number for the graph $G = C_n \square C_m$, $n \leq m$, is*

$$\gamma_P(G) \leq \begin{cases} \lceil \frac{n}{2} \rceil & \text{if } n \equiv 2 \pmod{4}, \\ \lceil \frac{n+1}{2} \rceil & \text{otherwise.} \end{cases}$$

Dorbec et al. [33] determined the power domination number for all direct products of paths except for the odd component of the direct product of two odd paths. They first presented a lower bound, then gave a construction that reaches it.

Theorem 13 ([36]) *For two positive integers m and n , let n be even and C a connected component of $P_m \times P_n$. If m is odd or $m \geq n$, then $\gamma_P(C) = \lceil \frac{n}{4} \rceil$.*

Theorem 14 ([36]) *For two positive integers m and n , if $m \leq n$ is odd and C is the even component of $P_m \times P_n$, then*

$$\gamma_P(C) = \max\left\{\lceil \frac{n}{4} \rceil, \lceil \frac{m+n}{6} \rceil\right\}.$$

Theorem 15 ([36]) *For two positive integers m and n , if $m \leq n$ is odd and C is the odd component of $P_m \times P_n$, then*

$$\gamma_P(C) \leq \max\left\{\lceil \frac{n-2}{4} \rceil, \lceil \frac{m+n-2}{6} \rceil\right\}.$$

2.4 Upper Bounds on the Power Domination Number in Graphs

Haynes et al. [43] proved that $\gamma_P(T) \leq n/3$ for a tree T of order n . Zhao et al. [77] further showed that $\gamma_P(G) \leq n/3$ for any connected graph of order n and this bound is tight. Furthermore, they also proved that $\gamma_P(G) \leq n/4$ for any connected

claw-free cubic graph G of order n and characterized extremal graphs attaining the upper bound.

Let Γ be the family of graphs obtained from connected graphs H by adding two new vertices v' and v'' to each vertex v of H and new edges vv' and vv'' , while $v'v''$ may be added or not.

Theorem 16 ([77]) *If $G = (V, E)$ is a connected graph of order $n \geq 3$, then $\gamma_P(G) \leq n/3$ with equality if and only if $G \in \Gamma \cup \{K_{3,3}\}$.*

The main idea of the proof is as follows. Among all these $\gamma_P(G)$ -sets, let S be chosen so that $\omega(G[S])$ is minimum. We claimed each vertex v in S has at least two external private neighbors, that is, $|pn(v, S) - S| \geq 2$. Therefore, G has at least $3|S|$ vertices; this implies that $\gamma_P(G) \leq n/3$.

Let D be a diamond. For each positive integer k , let D_k be the connected claw-free cubic graph formed from k disjoint copies of D by joining pairwise $2k$ vertices of degree two. Let $\Lambda = \{D_k | k \geq 1\}$.

Theorem 17 ([77]) *If $G = (V, E)$ is a connected claw-free cubic graph of order n , then $\gamma_P(G) \leq n/4$ with equality if and only if $G \in \Lambda$.*

The main idea of the proof is the following. Let S be a $\gamma_P(G)$ -set of G such that $G[S]$ has as few edges as possible and under this condition that $|N[S]|$ is as large as possible. They completed their proof by the following claims.

Claim 1 S is independent in G .

Claim 2 $N[x] \cap N[y] = \emptyset$ for any two distinct vertices x and y in S .

As each $N[v]$ has exactly four vertices, **Claim 2** implies that G has at least $4|S|$ vertices and so $\gamma_P(G) \leq n/4$.

3 Paired-Domination and Related Variations of Graphs

The decision problem to determine the paired-domination number of a graph is known to be NP-complete [43]. Hence it is of interest to determine upper bounds on the paired-domination number of a graph.

3.1 Upper Bounds on the Paired-Domination Number of Graphs

3.1.1 Upper Bounds on Paired-Domination Number of Graphs with Minimum Degree One

Haynes and Slater [43] obtained the following upper bound on the paired-domination number of a connected graph in terms of the order of the graph.

Theorem 18 ([43]) *If G is a connected graph of order $n \geq 3$, then $\gamma_{\text{pr}}(G) \leq n - 1$ with equality if and only if G is C_3 , C_5 or a subdivided star.*

Dorbec et al. [33] studied the upper bound on the paired-domination number in star-free graphs. They proved the following:

Theorem 19 ([36]) *For $a > 0$ an integer, if G is a connected $K_{1,a+2}$ -free graph of order $n \geq 2$, $\gamma_{\text{pr}}(G) \leq \frac{2(an+1)}{2a+1}$ and this bound is sharp.*

Considering claw-free or star-free graphs is a good way to avoid the critical cases; nevertheless, just a claw or a star is not really a problem for paired-domination. Dorbec and Gravier [35] considered graphs without the path P_5 on five vertices.

Theorem 20 ([35]) *Let G be a connected graph of order $n \geq 2$. If G is not C_5 and does not contain an induced P_5 , then*

$$\gamma_{\text{pr}}(G) \leq \frac{n}{2} + 1,$$

and this bound is sharp.

Concluding this study, Dorbec and Gravier [34] considered paired-domination in graphs containing no subdivided stars $K_{1,a+2}^*$ with $a \geq 1$. They proved the following result.

Theorem 21 ([34]) *Let G be a connected graph of order $n \geq 3$. If G contains no induced $K_{1,a+2}^*$ for some $a \geq 1$, then*

$$\gamma_{\text{pr}}(G) \leq \frac{2(an+1)}{2a+1}$$

and this bound is sharp.

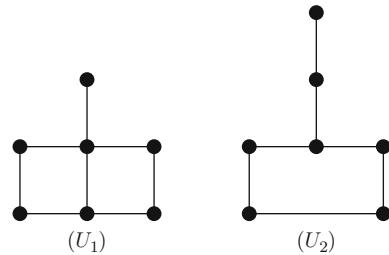

Observe that the bound here is exactly the same as the bound in [Theorem 19](#).

3.1.2 Upper Bounds on Paired-Domination Number of Graphs with Minimum Degree at Least Two

If we restrict the minimum degree to be at least two and the order to be at least six, then the upper bound in [Theorem 18](#) on the paired-domination number can be improved from one less than its order to two-thirds its order.

Theorem 22 ([43]) *If G is a connected graph of order $n \geq 6$ with $\delta(G) \geq 2$, then $\gamma_{\text{pr}}(G) \leq 2n/3$.*

The upper bound in [Theorem 22](#) can be improved slightly if the order of the graph is large.

Fig. 1 The units U_1 and U_2 

Theorem 23 ([46]) *If G is a connected graph of order $n \geq 10$ with $\delta(G) \geq 2$, then $\gamma_{\text{pr}}(G) \leq 2(n - 1)/3$ and there are infinite families of graphs that achieve equality in this bound.*

A characterization of connected graphs with minimum degree at least 2 and order at least 14 that achieve the upper bound in [Theorem 23](#) is given in [46].

Chen et al. [21] proved the following result.

Theorem 24 ([21]) *If G is a cubic graph of order n , then $\gamma_{\text{pr}}(G) \leq 3n/5$.*

Later, Goddard and Henning [40] further provided a slightly simpler proof of [Theorem 24](#) and used the proof to characterize the cubic graphs that achieve equality in the bound of [Theorem 24](#).

Theorem 25 ([40]) *If G is a connected cubic graph of order n , then $\gamma_{\text{pr}}(G) \leq 3n/5$ with equality if and only if G is the Petersen graph.*

To improve this bound, Favaron and Henning studied paired-domination on claw-free cubic graphs in [37]. They proved the following theorem.

Theorem 26 ([37]) *If G is a connected claw-free cubic graph of order n , then $\gamma_{\text{pr}}(G) \leq n/2$.*

Henning [48] gave an upper bound on the paired-domination number in terms of the number of edges in the graphs. Henning [48] defined a *unit* to be a graph that is isomorphic to the graph U_1 or U_2 shown in [Fig. 1](#). The vertex named v in each unit in [Fig. 1](#) was called *link vertex* of the unit. For $i = 1, 2$, a unit isomorphic to the graph U_i was called a *type- i unit*.

For $n_1 + n_2 \geq 2$, let $F = F(n_1, n_2)$ be the graph obtained from the disjoint union of n_1 units of type 1 and n_2 units of type 2 by identifying the $n_1 + n_2$ link vertices, one from each unit, into one new vertex which are called the *identified vertex* of G . Let \mathcal{F} denote the family of all such graph F .

Theorem 27 ([48]) *Let G be a connected graph of size $m \geq 18$ with $\delta(G) \geq 2$. Then, $\gamma_{\text{pr}}(G) \leq 4m/7$ with equality if and only if G is a cycle C_{21} or if $G \in \mathcal{F}$.*

Chen et al. [22] presented some upper bounds on the paired-domination number of a graph with girth at least 6 in terms of its minimum degree, maximum degree, or girth.

Theorem 28 ([22]) *If G is a connected graph of order n with minimum degree $\delta(G) \geq 2$ and girth $g(G) \geq 6$, then $\gamma_{\text{pr}}(G) \leq \frac{2}{3} \left(n - \frac{(\delta(G)-1)(\delta(G)-2)}{2} \right)$.*

Theorem 29 ([22]) *If G is a connected graph of order n with minimum degree $\delta(G) \geq 2$ and girth $g(G) \geq 6$, then $\gamma_{\text{pr}}(G) \leq \frac{2}{3} (n + 1 - \Delta(G))$.*

Theorem 30 ([22]) *If G is a connected graph of order n with minimum degree $\delta(G) \geq 3$, then $\gamma_{\text{pr}}(G) \leq \frac{2n}{3} - \frac{g(G)}{6} + \frac{5}{6}$.*

3.2 Hardness Results and Approximation Algorithms for Paired-Domination in Graphs

It was proved that the paired-domination problem is NP-complete, even restricted to split graphs and bipartite graphs [17].

Chen et al. [23] investigated the approximation hardness of paired-domination in general graphs. By using a reduction from minimum set cover to minimum paired-dominating set, they got the following result.

Theorem 31 ([23]) *Let G be a graph of order n . If there is some $\varepsilon > 0$ such that a polynomial-time algorithm can approximate minimum paired-domination set within $(1 - \varepsilon) \ln n$ in G , then $NP \subseteq DTIME(n^{O(\log \log n)})$.*

Chen et al. [23] showed that the paired-domination problem is APX-complete, that is, there is no PATS, even if the degree of the graph is bounded by three. Given two NP optimization problem F and G and a polynomial-time transformation f from instances of F to instance of G , we say f is an L -reduction if there are positive constants α and β such that for every instance x of F :

1. $\text{opt}_G(f(x)) \leq \alpha \cdot \text{opt}_F(x)$.
2. (For every feasible solution y of $f(x)$ with objective value $m_G(f(x), y) = c_2$, we can in polynomial time find a solution y' of x with $m_F(x, y') = c_1$ such that $|\text{opt}_F(x) - c_1| \leq \beta \cdot |\text{opt}_G(f(x)) - c_2|$.

MIN VERTEX COVER-B

Instance: Graph $G = (V, E)$ of degree bounded by B .

Solution: A vertex cover of G , that is, a subset $V' \subseteq V$ such that for all $uv \in E$ at least one of u and v in V' .

Measure: Cardinality of the vertex cover.

MIN PAIRED-DOM SET-B

Instance: Graph $G = (V, E)$ without isolated vertices of degree bounded by B .

Solution: A paired-dominating set of G

Measure: Cardinality of the paired-dominating set.

Theorem 32 ([6]) *MIN VERTEX COVER-3 is APX-complete.*

By an L -reduction f from MIN VERTEX-COVER-3 to MIN PAIRED-DOM SET-7, Chen et al. [23] proved MIN PAIRED-DOM SET-7 is APX-complete. Then they gave an L -reduction f_1 from MIN PAIRED-DOM SET-7, which is APX-complete, to MIN PAIRED-DOM SET-4 and gave L -reduction f_2 from MIN PAIRED-DOM SET-4 to MIN PAIRED-DOM SET-3.

Theorem 33 ([6]) *MIN PAIRED-DOM SET-3 is APX-complete.*

Chen et al. [23] presented a greedy algorithm for finding a paired-dominating set in general graphs and proved the upper bound on the approximation ratio of this algorithm.

Theorem 34 ([6]) *The minimum paired-dominating set in any graph $G = (V, E)$ without isolated vertices can be approximated with an approximation ratio of $\ln(2\Delta(G)) + 1$.*

Algorithm GREEDY-PAIRED-DOM

Input: A graph $G = (V, E)$ without isolated vertices.

1. PD:= \emptyset ;
 2. $i = 0, S'_i := \emptyset$;
 3. While $(V - (S'_0 \cup \dots \cup S'_{i-1})) \neq \emptyset$ do
 4. $i := i + 1$
 5. Choose two vertices $u, v \in V - PD$ such that
 $uv \in E$ and $|N(u) \cup N(v) - (S'_0 \cup S'_1 \cup \dots \cup S'_{i-1})|$ is maximized;
 6. $S_i = N(u) \cup N(v)$;
 7. $S'_i = S_i - (S'_0 \cup \dots \cup S'_{i-1})$;
 8. PD:=PD $\cup \{u, v\}$;
 9. Output PD.
-

3.3 Paired-Domination in Special Graphs

Since the problem of determining the paired-domination number of an arbitrary graph is NP-hard, it is theoretically important to consider algorithm of the paired-domination number in special graphs.

3.3.1 Paired-Domination of Trees

Qiao et al. [65] first presented a linear-time algorithm computing the paired-domination number for trees. The algorithm first breaks the original tree T into

a collection of components, T_0 , where each component is a path. Then, for each path in T_0 , the minimum paired-dominating set is computed.

Observation 1 ([43]) For any graph G without isolated vertices, $\gamma(G) \leq \gamma_{\text{pr}}(G) \leq 2\beta'(G)$ and $\gamma_{\text{pr}}(G)$ is even, where $\beta'(G)$ denotes the size of a maximum independent set of edges.

Qiao et al. [65] characterized trees with equal domination and paired-domination numbers. To state the characterization, they introduced four types of operations that were used in constructing trees with equal domination and paired-domination numbers.

Type 1 operation: Attach a path P_1 to a vertex of a tree T , which is in a γ_{pr} -set of T .

Type 2 operation: Attach a P_5 to a vertex v of a tree T , where v is in a γ_{pr} -set of T , and for every γ -set X of T , there is no vertex u such that $PN(u, X) = v$ in T .

Type 3 operation: Attach a remote vertex of P_4 to a vertex v of a tree T , where v is a vertex such that for every γ -set X of T , there is no vertex u such that $PN(u, X) = v$ in T .

Type 4 operation: Attach a vertex u_0 of tree T_1 to a vertex of a tree T , where T_1 is a tree with $V(T_1) = \{u_0, u_1, u_2, u_3, u_4\}$ and $E(T_1) = \{u_0u_1, u_1u_2, u_1u_3, u_2u_4\}$.

Define the family F_p as

$F_p = \{T \mid T \text{ is obtained from } P_4 \text{ by a finite sequence of operations of Type 1, Type 2, Type 3, or Type 4}\}$.

Theorem 35 ([65]) For a tree T , $\gamma(T) = \gamma_{\text{pr}}(T)$ if and only if $T \in F_p$.

3.3.2 Paired-Domination on Permutation Graphs

Let $\pi = [\pi_1, \pi_2, \dots, \pi_n]$ be a permutation on the set $V_n = \{1, 2, \dots, n\}$. Then the *permutation graph* $G[\pi] = (V, E)$ is the undirected graph such that $V = V_n$ and $(i, j) \in E$ if and only if

$$(i - j)(\pi^{-1}(i) - \pi^{-1}(j)) < 0,$$

where $\pi^{-1}(i)$ is the position of i in π .

Cheng et al. [27] proposed an efficient $O(mn)$ algorithm for solving the minimum paired-dominating set on permutation graphs. The algorithm is based on a recursive formula by using the dynamic programming method.

For notational convenience, they introduce more notation as follows:

1. For any $1 \leq i, j \leq n$ and $V_i = \{\pi_1, \pi_2, \dots, \pi_i\}$, denote $V_{i,j}$ as the subset of V_i containing all elements smaller than or equal to j , that is, $V_{i,j} = \{\pi_k \in V_i, \pi_k \leq j\}$.
2. For any $i, 1 \leq i \leq n$, denote π_i^* as the minimum number over the suffix $\pi_i, \pi_{i+1}, \dots, \pi_n$, that is, $\pi_i^* = \min\{\pi_i, \pi_{i+1}, \dots, \pi_n\}$, and set $V_i^* = V_i \cup \{\pi_i^*\}$.

Algorithm: Finding an MPDS on a permutation graph.

Input: A permutation $\pi = [\pi_1, \pi_2, \dots, \pi_n]$.

Output: A minimum cardinality paired-dominating set of $G[\pi]$.

Step 1. Initialize $\text{PD}_{0,j} = \emptyset$.

$$\text{PD}_{i,j} = \begin{cases} \emptyset & \text{if } j < \pi_1; \\ \{1, \pi_1\} & \text{otherwise.} \end{cases}$$

for $j = 1, 2, \dots, n$.

Step 2. for $i \leftarrow 2$ to n do

Step 3. $\text{PD}_{\pi_i^*} = \text{Min}\{\text{PD}_{l-1, \pi_i^*} \cup \{\pi_i^*, \pi_l\} : \pi_l \in N(\pi_i^*), \pi_i^* \notin \text{PD}_{l-1, \pi_i^*}, l \leq i\}$

Step 4. for $j \leftarrow 1$ to n do

Step 5.

$$\text{PD}_{\max} = \begin{cases} \text{PD}_{i-1,j} \cup \{\pi_i^*, \max(V_i)\} & \text{if } \pi_i \neq \max(V_i); \\ V_i & \text{otherwise.} \end{cases}$$

Step 6.

$$\text{PD}_{i,j} = \begin{cases} \text{Min}(\{\text{PD}_{\pi_i^*}, \text{PD}_{\max}\}) & \text{if } j \geq \pi_i \text{ and } \max(\text{PD}_{i-1,j}) < \pi_i; \\ \text{Min}(\{\text{PD}_{\pi_i^*}, \text{PD}_{i-1,j}\}) & \text{otherwise.} \end{cases}$$

Step 7. End

Step 8. End

Step 9. Output $\text{PD}_{n,n}$.

3.3.3 Paired-Domination in Strongly Chordal Graphs

A vertex u is *simple* if $N_G[u] = \{u_1, u_2, \dots, u_k\}$, where $u = u_1$ satisfies $N_G[u_i] \subseteq N_G[u_j]$ for $1 \leq i \leq j \leq k$. A graph is *strongly chordal* if every induced subgraph has a simple vertex.

Starting with an end block and working recursive inward, Chen et al. [26] found a vertex ordering v_1, v_2, \dots, v_n in $O(n + m)$ time such that $v_i v_j \in E$ and $v_i v_k \in E$ imply that $v_j v_k \in E$ for $i < j < k \leq n$. They defined two labels on each vertex u , denoted by $(D(u), L(u))$. Based on labels, Chen et al. [26] gave algorithm MPDB to determine a minimum paired-dominating set in block graphs.

Theorem 36 ([26]) *Given a vertex ordering of a block graph G on n vertices and m edges, the algorithm MPDB can produce a minimum paired-dominating set of G in $O(m + n)$ time.*

Chen et al. [26] also employed the labeling technique to give a linear algorithm for finding a minimum paired-dominating set of an interval graph.

Chen et al. [24] presented a linear-time algorithm for the paired-domination problem in strongly chordal graphs, which generalized the algorithms in [26, 65].

$$D(v_i) = \begin{cases} 0 & \text{if } v_i \text{ is not dominated;} \\ 1 & \text{if } v_i \text{ is dominated.} \end{cases}$$

$$L(v_i) = \begin{cases} 0 & \text{if } v_i \text{ is not put into } \text{PD}(G); \\ 1 & \text{if } v_i \text{ is put into } \text{PD}(G), \text{ but it has no paired vertex in } \text{PD}(G); \\ 2 & \text{if } v_i \text{ is put into } \text{PD}(G), \text{ but it has a paired vertex in } \text{PD}(G). \end{cases}$$

Algorithm MPDS. Find a MPES in a strongly chordal graph without isolated vertices.

Input: A strongly chordal graph $G = (V, E)$ with a strong (elimination) ordering v_1, v_2, \dots, v_n ($n \leq 2$). Each vertex v_i has labels $(D(v_i), L(v_i)) = (0, 0)$, and $F(v_i) = v_j$ with $j = \max\{k \mid k \in M_i\}$.

Output: A minimum paired-dominating set PD of G .

Method

```

For  $i = 1$  to  $n$  do
    If  $(D(v_i) = 0 \text{ and } F(v_i) \neq v_i)$  then
         $L(F(v_i)) = 1;$ 
         $D(u) = 1$  for  $u \in N[F(v_i)]$ ;

    end if
end if
Output PD =  $\{v \mid L(v) = 2\}$ 
end
```

Theorem 37 ([24]) Let G be a strongly chordal graph on n vertices and m edges without isolated vertices. Algorithm MPDS can produce a minimum paired-dominating set of G in $O(m + n)$ time, if the strong (elimination) ordering of G is given in advance.

3.3.4 Paired-Domination in Inflated Graphs

The inflated graph G_I of the graph G without isolated vertices is obtained as follows: Each vertex x_i of degree $d(x_i)$ of G is replaced by a clique $X_i \cong K_{d(x_i)}$

and each edge (x_i, x_j) of G is replaced by an edge (u, v) in such a way that $u \in X_i, v \in X_j$, and two different edges of G are replaced by nonadjacent edges of G_I . An obvious consequence of the definition is that $|V(G_I)| = \sum_{x_i \in V(G)} d_G(x_i) = 2|E(G)|$, $\Delta(G_I) = \Delta(G)$, and $\delta(G_I) = \delta(G)$.

Kang et al. [52] gave some bounds on paired-domination number and presented a linear algorithm to compute a minimum paired-dominating set for an inflated tree.

Theorem 38 ([52]) *If G is a graph of order n with $\delta(G) \geq 2$, then $\gamma_{\text{pr}}(G_I) \geq n$ with equality if and only if G has a perfect matching.*

Theorem 39 ([52]) *If $\delta(G) \geq 2$, then $\gamma_{\text{pr}}(G_I) \leq 4|E(G)|/[\delta(G) + 1]$ and the bound is tight.*

3.4 Paired-Domination Subdivision Number of Graphs

For a vertex $v \in V(G)$, we denote by $N_2(v)$ the set of vertices of G at distance 2 from v and by $E_2(v)$ the set of edges of G with at least one endvertex in $N(v)$. A *leaf* is a vertex of degree one, and a *support vertex* is a vertex adjacent with a leaf. A support vertex is *strong* if it is adjacent with more than one leaf. We call the *core* of a graph and denote by $C(G)$ the set of vertices of G which are neither leaves nor support vertices. An edge $uv \in E(G)$ is *subdivided* if the edge uv is deleted, but a new vertex x is added, along with two new edges ux and vx . The vertex x is called a *subdivision vertex*. The *paired-domination subdivision number* $\text{sd}_{\gamma_{\text{pr}}}(G)$ of a graph G is the minimum number of edges that must be subdivided (where each edge in G can be subdivided at most once) in order to increase the paired-domination number. Similar definitions exist for the (connected, total) domination subdivision number $\text{sd}_\gamma(G)$. The first of these was introduced for the domination number in Velammal's thesis [74]. Favaron et al. [38] established upper bounds on the paired-domination subdivision number.

Theorem 40 ([38]) *Let G be a connected graph of order $n \geq 3$. If $C(G) = \emptyset$, then $\text{sd}_{\gamma_{\text{pr}}}(G) \leq 2$, and if $C(G) \neq \emptyset$, then $\text{sd}_{\gamma_{\text{pr}}}(G) \leq \min\{|E_2(v)| : v \in C(G)\}$.*

Theorem 41 ([38]) *Let $G = (V, E)$ be a connected graph of order $n \geq 3$ containing a vertex v such that $V = \{v\} \cup N(v) \cup N_2(v)$ and $N_2(v)$ is an independent set, and let F be the set of edges of G with exactly one endvertex in $N(v)$. Then $\text{sd}_{\gamma_{\text{pr}}}(G) \leq |F|$.*

Theorem 42 ([38]) *Let $G = (A \cup B, E)$ be a connected bipartite graph of order $n \geq 3$ containing a vertex v adjacent to every vertex of A and such that every vertex of A has a neighbor in $B \setminus \{v\}$. Then $\text{sd}_{\gamma_{\text{pr}}}(G) \leq n - 1$.*

Theorem 43 ([38]) *For every connected graph G on $n \geq 3$ vertices and m edges, $\text{sd}_{\gamma_{\text{pr}}}(G) = m$ if and only if G is a subdivided star.*

3.5 Distance Paired-Domination Numbers of Graphs

A set $D \subseteq V(G)$ is a k -distance dominating set of G if every vertex in $V(G) - D$ is within distance k of at least one vertex in D . The k -distance domination number $\gamma^k(G)$ of G equals the minimum cardinality among all k -distance dominating sets of G . A set D is a k -distance paired-dominating set of G if D is a k -distance dominating set of G and the induced subgraph $\langle D \rangle$ has a perfect matching. The k -distance paired-domination number $\gamma_p^k(G)$ is the minimum cardinality of a k -distance paired-dominating set of G .

3.5.1 Bounds on the k -Distance Paired-Domination Number of Graphs

Using a polynomial reduction from domination set, Raczek [66] proved that k -distance dominating set problem for bipartite graphs is NP-complete. Haynes and Slater [43] have proved that if G is a connected graph of order $n \geq 3$, then $\gamma_{pr}(G) \leq n - 1$ and characterized the extremal graphs. Raczek [66] generalized their result for k -distance paired-domination number of a graph.

Theorem 44 ([66]) *If T is a tree of order $n \geq k + 2$, then $\gamma_p^k(T) \leq 2\frac{n-1}{k+1}$.*

It is easily seen that $\gamma_p^k(G) \leq \gamma_p^k(T)$ for every spanning tree T of G .

Theorem 45 ([66]) *If G is a connected graph of order $n \geq k + 2$, then $\gamma_p^k(G) \leq 2\frac{n-1}{k+1}$.*

Raczek [66] characterized all trees for which $\gamma_p^k(T) = 2\frac{n-1}{k+1}$. For this purpose, the author defined \mathcal{R}^p to be the family of trees such that:

- (a) Each k -subdivide star $K_{1,t}^k$ belongs to \mathcal{R}^p .
- (b) Each tree T on $k + 2$ vertices belongs to \mathcal{R}^p .

Theorem 46 ([66]) *If T is a tree of order n , then*

$$\gamma_p^k(T) = 2\frac{n-1}{k+1}$$

if and only if T belongs to the family \mathcal{R}^p .

Raczek [66] characterized all connected graphs G for which $\gamma_p^k(G) = 2\frac{n-1}{k+1}$. For this purpose, a family \mathcal{R} of trees is defined as follows:

- (a) Each k -subdivided star $K_{1,t}^k$ belongs to \mathcal{R} .
- (b) Each connected graph G on $k + 2$ vertices belongs to \mathcal{R} .
- (c) The cycle C_{2k+3} belongs to \mathcal{R} .

Theorem 47 ([66]) *If G is a connected graph of order n , then $\gamma_p^k(G) = 2\frac{n-1}{k+1}$ if and only if G belongs to the family \mathcal{R} .*

Raczek [66] also gave a lower bound on the k -distance paired-domination number of tree in terms of order of T and the number of leaves in T and also characterized the extremal trees.

Theorem 48 ([66]) *If T is a tree of order $n \geq 2$, then*

$$(k + 1)\gamma_p^k(T) \geq n + 2k - kn_1(T),$$

where $n_1(T)$ is the number of leaves of T .

3.5.2 Distance Paired-Domination on Interval Graphs and Block Graphs

Chen et al. [25] presented two linear-time algorithms to find a minimum cardinality k -distance paired-dominating set in interval graphs and block graphs.

Let $G = (V, E)$ be an interval graph and its interval representation is I . For every vertex $u_i \in V$, I_i is the corresponding interval, and let a_i (b_i , respectively) denote the left endpoint (right endpoint, respectively) of interval I_i . We order the vertices of G by u_1, u_2, \dots, u_n in increasing order of their left endpoints.

Let $F(u_i) = u_j$ for $2 \leq i \leq n$, where $j = \min\{a | u_a u_i \in E \text{ and } a < i\}$. They define the notation $F^l(u)$ as follows:

$$F^l(u) = \begin{cases} F(u) & \text{if } l = 1; \\ F(F^{l-1}(u)) & \text{if } u \geq 2. \end{cases}$$

Algorithm k -MPDI. Find a minimum k -distance paired-dominating set of an interval graph.

Input: An interval graph $G = (V, E)$ with a vertex ordering u_1, u_2, \dots, u_n ordered by the increasing order of left endpoints, in which each vertex u_i has a label $D(u_i) = 0$.

Output: A minimum k -distance paired-dominating set kPD of G .

Method

```

 $kPD = \emptyset;$ 
For  $i = n$  to 1 do
    If  $(D(u_i) = 0)$  then
        If  $(F^k(u_i) \neq u_i \text{ and } F^{k+1}(u_i) \neq F^k(u_i))$  then
             $kPD = kPD \cup \{F^k(u_i), F^{k+1}(u_i)\};$ 
             $D(u) = 1 \text{ for every vertex } u \in N^k[F^k(u_i)] \cup N^k[F^{k+1}(u_i)];$ 
        else if  $(F^k(u_i) \neq u_i)$  then
             $kPD = kPD \cup \{u_1, u_2\};$ 
             $D(u) = 1 \text{ for every vertex } u \in N^k[u_1];$ 
        else
             $kPD = kPD \cup \{u_1, u_2\};$ 
             $D(u_i) = 1;$ 
        end if
    end if
end for

```

Chen et al. [25] presented the following algorithm for k -distance paired-domination problem in interval graphs.

Theorem 49 ([25]) *Given a vertex ordering ordered by the increasing order of left endpoints, the algorithm k-MPDI can produce a minimum k -distance paired-dominating set of an interval graph G on n vertices and m edges in $O(m + n)$.*

Using the similar labeling method, Chen et al. [25] presented a linear-time algorithm to finding a minimum k -distance paired-dominating set in block graphs.

4 Total Domination in Graphs

For a graph $G = (V, E)$, we denote by H_G the *open neighborhood hypergraph*, abbreviated by ONH, of G ; that is, $H_G = (V, C)$ is the hypergraph with vertex set $V(H_G) = V$ and with hyperedge set $E(H_G) = C$ consisting of the open neighborhood of vertices of V in G . The transversal number of the ONH of a graph is precisely the total domination number of the graph.

Observation 2 *If G is a graph with no isolated vertex and H_G is the ONH of G , then $\gamma_t(G) = \tau(H_G)$.*

It is easily seen that total domination in graphs can be translated to the problem of finding transversals in hypergraphs. The main advantage of considering hypergraphs rather than graphs is that the structure is easier to handle. This idea of using transversals in hypergraphs to obtain results on total domination in graphs first appeared in a paper by Thomassé and Yeo [71]. Subsequent to the Thomassé–Yeo paper, several results on total domination in graphs have been obtained using transversals in hypergraphs that appear very difficult to obtain using graph-theoretic techniques.

4.1 Complexity and Algorithmic Results on the Total Domination Problem

The basic complexity question concerning the decision for the total domination number takes the following form:

Total Domination Set

Instance: A graph $G = (V, E)$ and a positive integer k .

Question: Does G has a TDS of cardinality at most k ?

Table 2 [47] summarized the NP-completeness results for the total domination number with the corresponding citation.

Laskar et al. [60] constructed the first linear algorithm for computing the total domination number of a tree. Bertossi and Gori [12] constructed an $O(n \ln n)$ algorithm for the total domination number of an interval graph of order n . Kratsch and Stewart [56] constructed an $O(n^6)$ algorithm for computing the total domination number of a cocomparability graph of order n .

Table 2 NP-complete results for the total domination number

Graph classes	NP-completeness result	Citation
General graph	NP-complete	[64]

Distance-hereditary graph	P	[20, 58]
k -polygon graph (fixed $k \geq 3$)	P	[58]
Partial k -tree (fixed $k \geq 3$)	P	[8, 70]

4.2 Heuristics

Since total dominating set is NP-complete, it is important to develop efficient approximation algorithms for the TDS problem. Henning and Yeo [47, 49] gave a greedy approach to find a TDS in a graph G .

Let H_G be the ONH of G . Then, each hyperedge of H_G has size at least $\delta(G)$. Let H be obtained from H_G by shrinking all hyperedges of H_G , if necessary, to hyperedges of size $\delta(G)$. Then, H is a $\delta(G)$ -uniform hypergraph with n vertices and n hyperedges.

Heuristic Total Domination

Input: A graph $G = (V, E)$ with minimum degree $\delta(G) \geq 1$ and order n .

Output: A TDS of G .

- Step 1. Construct a hypergraph H where $V(H) = V$ and $E(H_G)$ consists of n hyperedges $N_x, x \in V$, where N_x is a set of $\delta(G)$ neighbors of x in G .
- Step 2. Compute the degrees of the vertices in H .
- Step 3. Initialize a hash table, L , of size n .
- Step 4. For each vertex, x , add it to the list $L(d(x))$ in L .
- Step 5. Set $T = \emptyset$.
- Step 6. If $L(k)$ is empty for all $k > 0$, then stop and output. Otherwise, go to Step 8.
- Step 7. Find the largest k such that $L(k)$ is not empty.

- Step 8. Put a vertex, x , from $L(k)$ to our set T and then delete it from $L(k)$.
 Step 9. For all y in $N(x)$ decrease the degree of y by 1 and move y from $L(i)$ to $L(i - 1)$ where i was the degree of y .
 Step 10. Return to Step 6.

By construction, the resulting set T hits every hyperedge of H and is therefore a transversal of H . It is known in [49] that $|H| \leq (\frac{1+\ln\delta}{\delta})n$ where $\delta = \delta(G)$. Every transversal of H is a transversal of H_G , and every transversal of H_G is a TDS of G . Hence the set T produced by this greedy algorithm is a TDS of G .

Theorem 50 ([49]) *If G is a graph with minimum degree $\delta \geq 2$ and order n , then heuristic total domination produces a TDS T in G satisfying*

$$|T| \leq \left(\frac{1 + \ln \delta}{\delta}\right)n.$$

The complexity of the algorithm is $O(n + \delta n)$.

For sufficiently large δ , the TDS T produced by heuristic total domination is essentially optimal, as can be deduced from the following result due to Thomasse and Yeo [71].

Theorem 51 ([71]) *For any $\epsilon > 0$ and for sufficiently large δ , there exists a δ -uniform hypergraph H with n vertices and n hyperedges satisfying*

$$\tau(H) > \left(\frac{(1 - \epsilon) \ln \delta}{\delta}\right)n.$$

4.3 Bounds on the Total Domination Number of Graphs

Any TDS must have a nonempty intersection with every open neighborhood. Hence if G is a graph with no isolated vertices, then $\gamma_t(G) \geq \rho^o(G)$.

4.3.1 Upper Bounds on the Total Domination Number of Graphs with Minimum Degree One

Cockayne et al. [29] obtained the following upper bound on the total domination number of a connected graph in terms of the graph.

Theorem 52 ([29]) *If G is a connected graph of order $n \geq 3$, then $\gamma_t(G) \leq 2n/3$.*

Brigham et al. [15] characterized the connected graphs of order at least 3 with total domination number exactly two-thirds their order.

Theorem 53 ([15]) *Let G be a connected graph of order $n \geq 3$. Then $\gamma_t(G) = 2n/3$ if and only if G is C_3 , C_6 or $H \circ P_2$ for some connected graph H .*

4.3.2 Upper Bounds on the Total Domination Number of Graphs with Minimum Degree at Least Two

Sun [69] showed that the upper bound in Theorem 52 can be improved if we restrict G to be connected graphs with the minimum degree two.

Theorem 54 ([69]) *If G is a connected graph of order n with $\delta(G) \geq 2$, then $\gamma_t(G) \leq \lfloor \frac{4}{7}(n+1) \rfloor$.*

Chvátal and McDiarmid [28] and Tuza [73] independently established the following results about transversals in hypergraphs (see also Thomassé and Yeo [71] for a short proof of this result).

Theorem 55 ([28, 73]) *Every hypergraph H where all hyperedges have size at least three on n vertices and m hyperedges has a transversal T such that $4|T| \leq m + n$.*

As an immediate consequence of Theorem 55, Henning [47] got that the total domination number of a graph with minimum degree at least three is at most one-half order. Archdeacon et al. [7] found an elegant proof of Theorem 56.

Theorem 56 ([7, 47]) *If G is a graph of order n with minimum degree $\delta(G) \geq 3$, then $\gamma_t(G) \leq n/2$.*

Thomasse and Yeo [71] further proved the following result.

Theorem 57 ([71]) *Every 4-uniform hypergraph on n vertices and m hyperedges has a transversal with no more than $(5n + 4m)/21$ vertices.*

As a consequence of Theorem 57, they have the following result.

Theorem 58 ([71]) *If G is a graph of order n with minimum degree $\delta(G) \geq 4$, then $\gamma_t(G) \leq 3n/7$.*

5 Conclusion

In this chapter, we study three variants of domination: power domination, paired-domination, and total domination which were widely studied in recent years. We give a review of these variants of domination from complexity, approximation algorithm, polynomial algorithm, and bound.
