Note that for weighted trees, the linear-cost subtree-transfer model is more general than the nni model in the sense that one can slide a subtree along an edge with subtree transfers. Such an operation is not realizable with nni moves.

3 Computing the nni Distance

In this section, the authors discuss the complexity of computing the nni distance between labeled or unlabeled trees, either exactly or approximately. The authors first discuss the case of unweighted trees and then consider the more general case of weighted trees.

Fig. 4 A linear tree with k leaves

3.1 Unweighted Trees: Computing nni Distance Exactly

The *nni* distance was introduced independently in [34, 36]. The complexity of computing the *nni* distance has been open for 25 years (since [36]). The problem is surprisingly subtle given the history of many erroneous results, disproved conjectures, and a faulty NP-completeness proof [4, 23, 24, 27, 28, 32, 46].²

Culik II and Wood [6] (improved later by [32]) proved that $n \log n + O(n)$ *nni* moves are sufficient to transform a tree of n leaves to any other tree with the same set of leaves. Sleator et al. [41] proved an $\Omega(n \log n)$ lower bound for most pairs of trees. A restricted version of the *nni* operation, known as the tree rotation operation (discussed in Sect. 6), was considered in [40], and a trivial approximation algorithm with approximation ratio of 2 was given. But given an individual pair of two trees (labeled or unlabeled), computing the *nni* distance between them (for either labeled or unlabeled trees) has been a long-standing open question until about a decade ago when this problem was settled (for both labeled and unlabeled trees) in [7, 8].

Theorem 1 *Computing the *nni* distance (between two labeled or unlabeled trees) is NP-hard.*

The authors provide a rough sketch of the proof of Theorem 1 for labeled trees (which is the more difficult case). The proof is by a reduction from Exact Cover by 3-Sets (X3C), which is known to be NP-complete [15], to our problem. Recall that, given an instance $S = \{s_1, \dots, s_m\}$, where $m = 3q$, and C_1, \dots, C_n , where $C_i = \{s_{i_1}, s_{i_2}, s_{i_3}\}$, the X3C problem is to find disjoint sets C_{i_1}, \dots, C_{i_q} such that $\bigcup_{j=1}^q C_{i_j} = S$. One will construct two trees T_1 and T_2 with unique leaf labels, such that transforming from T_1 into T_2 requires at most N (to be specified later) *nni* moves iff an exact cover of S exists.

Here is an outline of our reduction. One can perform sorting with *nni* moves and thus view *nni* as a special sorting problem. A sequence $x_1 \dots x_k$ can be represented as a linear tree as in Fig. 4. For convenience, such a linear tree will be simply called a sequence of length k . Sorting such a sequence means to transform it by *nni* operations to a linear tree whose leaves are in ascending order.

To construct the first tree T_1 , for each $s_i \in S$, a sequence S_i of leaves is created that takes a *large* number of *nni* moves to sort. One will make sure that S_i and S_j are *very different* permutations for each pair $i \neq j$, in the sense that one cannot hope to have the sequence S_i sorted *for free* while sorting the sequence S_j by *nni* moves and vice versa. Then for each set $C_i = \{s_{i_1}, s_{i_2}, s_{i_3}\}$, three sequences with

²In [27], the author reduced the partition problem to *nni* by constructing a tree of i nodes for a number i , in an attempt to prove the NP-hardness of computing *nni* distance between unlabeled trees.

the same permutations as the sequences $S_{i_1}, S_{i_2}, S_{i_3}$, respectively, are created but with distinct labels. Such n groups of sequences for C_1, \dots, C_n , each consisting of three sequences, will be placed *far away* from each other and from the m sequences S_1, \dots, S_m in tree T_1 . Tree T_2 has the same structure as T_1 except that all sequences are *sorted*.

Here is the connection between exactly covering S and transforming T_1 into T_2 by nni moves. To transform T_1 into T_2 , all one needs is to sort the sequences defined above. If there is an exact cover C_{i_1}, \dots, C_{i_q} of S , one can partition the m sequences S_1, \dots, S_m into $\frac{m}{3} = q$ groups, according to the cover. For each C_j ($j = i_1, \dots, i_q$) in the cover, one sends the corresponding group of sequences $S_{j_1}, S_{j_2}, S_{j_3}$ to their counterparts, merges the three pairs of sequences with identical permutations, sorts the three permutations, and then splits the pairs and transports the three sorted versions of $S_{j_1}, S_{j_2}, S_{j_3}$ back to their original locations in the tree. Thus, instead of sorting six sequences separately, one does three merges, three sortings, three splits, and a round trip transportation of three sequences. Our construction will guarantee that the latter is significantly cheaper. If there is no exact cover of S , then either some sequence S_i will be sorted separately or one will have to send at least $q + 1$ groups of sequences back and forth. The construction guarantees that both cases will cost significantly more than the previous case.

More details are now given. Apparently many difficult questions have to be answered: How can one find these m sequences S_1, \dots, S_m that are *hard* to sort by nni moves? How does one make sure that sorting one such sequence will never help to sort others? How can one ensure that it is most beneficial to bring the sequences $S_{j_1}, S_{j_2}, S_{j_3}$ to their counterparts defined for C_j to get sorted and not the other way?

One begins with the construction of the sequences S_1, \dots, S_m . Recall that each such sequence is actually a linear tree, as in Fig. 4. Intuitively, it would be a good idea to take a long and difficult-to-sort sequence and break it into m pieces of equal length. But this simple idea does not work for two reasons. First, such a sequence probably cannot be found in polynomial time. Second, even one finds such a sequence, because the upper bound in [6, 32] and the lower bound in [41] (see [32]) do not match, these pieces may still help each other in sorting possibly by merging, sorting together, and then splitting. The following lemma states that there exist two sequences of constant size that are hard to sort and do not help each other in sorting. One will build our m sequences using these two sequences.

Lemma 1 *For any positive constant $\epsilon > 0$, there exist infinitely many k for which there are a constant c and two sequences x and y of length k such that (i) each of them takes at least $(c - \epsilon)k \log k$ nni moves to sort, (ii) each of them takes at most $ck \log k$ nni moves to sort, and (iii) it takes at least $(1 - \epsilon)c(2k) \log(2k)$ nni moves to sort both of them together, i.e., the sequence xy .*

Proof Note that for any c, k, x, y , statements (ii) and (iii) imply statement (i). So it suffices to prove the existence of a constant c and an infinite number of k 's that satisfy conditions (ii) and (iii).

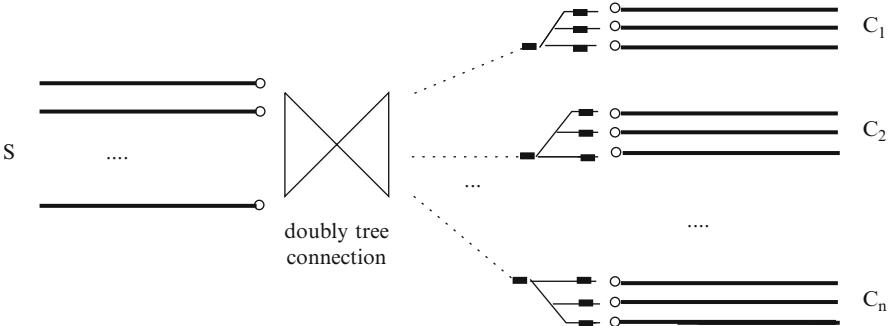

Fig. 5 Structure of tree T_1

From the results in [6, 32, 41], it is known that for each k , there exists a sequence of k leaves such that sorting the sequence takes at most $k \log k + O(k)$ nni moves and at least $\frac{1}{4}k \log k - O(k)$ nni moves. Let us define c_k , for any k , as the maximum number of nni steps to sort any sequence of length k , divided by $k \log k$. Since $\frac{1}{4} - o(1) \leq c_k \leq 1 + o(1)$, there must be infinitely many k satisfying $c_{2k} \geq c_k - \frac{\epsilon}{2}$. Taking x and y to be the two halves of a hardest sequence of length $2k$, for large enough such k , and taking $c = c_k$, one can see that conditions (ii) and (iii) are satisfied. \square

Let $\epsilon = 1/2$, k a sufficiently large integer satisfying Lemma 1 and c, x, y the corresponding constant and sequences. Next one uses x and y , each of length k , to construct m long sequences S_1, \dots, S_m . Choose m distinct binary sequences in $\{0, 1\}^{\lceil \log m \rceil}$. Replace each letter 0 with the sequence x^{m^3} and each letter 1 with the sequence y^{m^3} . Give each occurrence of x and y unique labels. Insert in front of every x and y block a *delimiter* sequence of length k^2 with unique labels. This results in sequences S_1, \dots, S_m , all with distinct labels. One can show that these sequences have the desired properties concerning sorting. The m sequences will have specific orientations in the tree; let us refer to one end as *head* and the other end as *tail*.

One is now ready to do the reduction. From sets $S = \{s_1, \dots, s_m\}$ and C_1, C_2, \dots, C_n , one constructs the two trees T_1 and T_2 as follows. For each element s_i , T_1 has a sequence S_i as defined above. For each set $C_i = \{s_{i_1}, s_{i_2}, s_{i_3}\}$, one creates three sequences $S_{i,i_1}, S_{i,i_2}, S_{i,i_3}$, with the same permutations as $S_{i_1}, S_{i_2}, S_{i_3}$, respectively, but with different and unique labels (one is not allowed to repeat labels).

Figure 5 outlines the structure of tree T_1 . Here a thick solid line represents a sequence S_i or $S_{i,j}$ with the circled end as head; a dotted line represents a toll sequence of m^2 uniquely labeled leaves; a small black rectangle represents a one-way circuit as illustrated in Fig. 6(i).

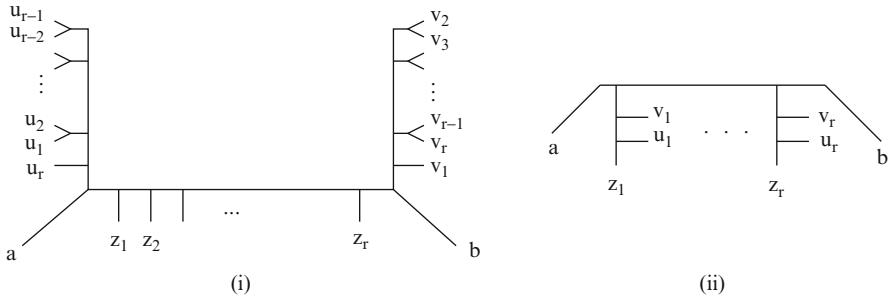

Fig. 6 One-way circuit

The heads of m sequences at the left of Fig. 5 are connected by two full binary trees connected root to root of depth $\log m + \log n$ to the n toll sequences, each leading to the *entrance* of a one-way circuit. The *exit* of each such one-way circuit is connected to the entrances of three one-way circuits leading finally to the three sequences corresponding to some set C_i .

A one-way circuit is designed for the purpose of giving free rides to subtrees moving first from a to b and then later from b to a while imposing a large extra cost for subtrees first moving from b to a and then from a to b . One will choose r so large (i.e., $r = m^4$) that it is not worthwhile to move any sequence $S_{i,j}$, corresponding to some C_i , to the left through the one-way circuits to sort and then move it back to its original location in T_1 . This can be seen as follows. The counterpart of the one-way circuit in T_2 is as shown in Fig. 6(ii).

In any optimal transformation of circuit (i) to (ii), the u 's are paired up with the z 's first, and then the v 's are paired with the u - z pairs. This requires u_r and v_1 to move up and out of the way. The pairing of the u 's essentially provides a shortcut for u_r to reach z_r in half as many steps and similarly for v_1 .

In the following, *sorting* a sequence S_i or $S_{i,j}$ means to have each of its x/y blocks sorted and then the whole sequence *flipped*. The tree T_2 has the same structure as T_1 except that:

- All sequences S_i and $S_{i,j}$ are sorted.
- Each circuit in Fig. 6(i) is changed to (ii).

Let M be the cost for sorting a sequence $S_{i,j}$ optimally (M can be computed easily). The following lemma completes the reduction and thus the proof of Theorem 1.

Lemma 2 *The set S has no exact cover iff $D_{\text{nni}}(T_1, T_2) \geq N + m^2/2$, where $N = q(\log m + \log n) + qm^2 + 28nm^4 - 28n + O(q) + 3nM + (k^2 + 6k)m^3 \log m + O(1)$.*

The authors provide an informal sketch of the proof of Lemma 2; the reader is referred to [7, 8] for more formal proofs. Assume that there is an exact cover for S . First, it is shown that the one-way circuit in Fig. 6 behaves as was claimed. This can be seen as follows. The counterpart of the one-way circuit in T_2 is as shown in Fig. 6(ii). Consider any optimal transformation of circuit (i) to (ii). A precise

breakdown of the cost is as follows: $(r - 3)/2$ steps to move u_r up, then $\frac{r-1}{2}$ times six steps to move each u pair down between the proper z 's and pair them up, and one final step to pair u_r . The exact same number of steps is needed for the symmetric pairing of v 's. Hence, assuming r is odd, in total one needs $2(\frac{r-3}{2} + 6\frac{r-1}{2} + 1) = 7r - 7$ nni moves. Note that a subtree situated at a can initially pair up with u_r in two steps and move together with it, spending three more steps to pop off just before u_r pairs with z_r , to end up at b . It can later spend another 5 steps to move together with v_1 ending up back at a . Going first from b to a and then back to b could only be done *for free* by pairing with v_1 first and with u_r later, since these are the only leaves to move away from b and a respectively, in an optimal transformation. But for v_1 to reach a with minimum cost requires collapsing all the v 's which imposes an extra cost on pairing u 's with z 's later. The least penalty for moving from b to a back to b is thus for v_1 not to take the shortcut which costs an extra $\frac{r}{2}$ steps.

In the following, *sorting* a sequence S_i or $S_{i,j}$ means to have each of its x/y blocks sorted and then the whole sequence *flipped*. In order to transform T_1 into T_2 , one needs to sort the sequences S_i and $S_{i,j}$ and convert each one-way circuit to the structure shown in Fig. 6(ii). If the set S has an exact cover C_{i_1}, \dots, C_{i_q} , one can do the transformation efficiently as follows. For each C_j , $j = i_1, \dots, i_q$, in the cover, one sends the three sequences $S_{j_1}, S_{j_2}, S_{j_3}$ to their counterparts $S_{j,j_1}, S_{j,j_2}, S_{j,j_3}$, merges each pair and sorts them together, and then moves the sorted $S_{j_1}, S_{j_2}, S_{j_3}$ sequences back. During this process, one also gets each one-way circuit involved into the correct shape. One then sorts the other sequences $S_{i,j}$ and get their leading one-way circuits into the correct shape.

The total cost N for this process is calculated as follows. Recall that one sends precisely q groups of sequences to the right.

1. The overhead for these q groups to cross the tree connection network: $q(\log m + \log n) + O(1)$ nni moves.
2. The cost of crossing the q toll sequences of length m^2 before the first batch of one-way circuits: qm^2 nni moves.
3. Converting each one-way circuit to the structure in Fig. 6(ii) costs $7r - 7$ nni's. Since one selects $r = m^4$ and there are in all $4n$ one-way circuits, the total cost is $28nm^4 - 28n$.
4. Moving a group of sequences across a one-way circuit and back costs $O(1)$ extra nni moves, for each of the q groups. The total cost is therefore $O(q)$.
5. Let M be the cost for sorting a sequence $S_{i,j}$ optimally. M can be computed easily, given optimal ways to sort an x block and a y block. Observe that the k^2 delimiter sequences inserted in front of each x/y block prevent the *folding* of any sequence $S_{i,j}$ in an optimal sorting procedure, i.e., it will not be beneficial for two blocks on the same sequence to be merged and sorted together because it costs at most $ck \log k$ nni moves to sort a block and k^2 nni moves to bring a block across a delimiter sequence. Similarly, shrinking any sequence $S_{i,j}$ does not help either. So totally one needs $3nM$ nni moves to sort the $3n$ sequences defined for C_1, \dots, C_n .
6. The extra cost of merging each sequence S_i with its counterpart $S_{j,i}$ while sorting the latter and splitting it out when the sorting is done. The process is as follows.

One sorts $S_{j,i}$ block by block from head to tail. Before processing each block, one first merges this block with the corresponding block of S_i . After sorting this pair of blocks, one splits out the sorted block of S_i and moves down to the next block of S_i , passing a delimiter path of length k^2 . So the extra cost to sorting $S_{j,i}$ is $(k^2 + 6k)m^3 \log m$. Observe that the above process automatically reverses $S_{j,i}$ and S_i .

Conversely, suppose that S has no exact cover. Then to transform T_1 into T_2 , either one has to send $q + 1$ groups to the right crossing the one-way circuits or some sequence S_i is sorted separately from $S_{j,i}$'s or some sequence S_i is sorted together with a *wrong* sequence $S_{j,h}$, where $h \neq i$. In the first case, the cost will be increased by m^2 nni moves, which is the cost of moving an extra group past a delimiter sequence of length m^2 . In the last case, at least one segment of m^3 x 's is sorted together with a segment of y 's. By Lemma 1 and the choice $\epsilon = 0.5$, this is not much better than sorting the two segments separately and costs at least $0.5 cm^3 k \log k - m^3 k$ more nni moves than sorting one such segment, which is larger than m^2 for sufficiently large k and m . The second case introduces an extra cost of $(0.5 cm^3 k \log k \log m) - m^3 k \log m - m^2$ by Lemma 1, which is again larger than m^2 for sufficiently large k and m .

Notice that in the above definition of N , the bounds in items 2,3,5,6 are all optimal. The bounds in items 1 and 4 are the worst case overheads and may not be optimal. But these two items only account for $O(m(\log m + \log n))$ nni moves, which is not sufficient to compensate for the extra cost m^2 given above. This completes the sketch of proof of Lemma 2.

In practice, however, the trees to be compared usually have small nni distances between them, and it is of interest to devise efficient algorithms for computing the optimal nni sequence when the nni distance is small, say d . An $n^{O(d)}$ algorithm for this problem is trivial. With careful inspection, one can derive an algorithm that runs in $O(n^{O(1)} \cdot d^{O(d^2)})$ time. It turns out that by using the results in [32, 41], one could improve this asymptotically to $O(n^2 \log n + n \cdot 2^{23d/2})$ time. To be precise, the following result was proved in [7, 8].

Theorem 2 Suppose that the nni distance between T_1 and T_2 is at most d . Then, an optimal sequence of nni operations transforming T_1 into T_2 can be computed in $O(n^2 \log n + n \cdot 2^{23d/2})$ time.

A sketch of proof of Theorem 2 is as follows. Let T_1 and T_2 be the two trees being compared. An edge $e_1 \in T_1$ is *good* if there is another edge $e_2 \in T_2$ such that e_1 and e_2 partition the leaf labels of T_1 and T_2 identically; e_1 is *bad* otherwise. It is easy to see that T_1 contains at least 1 and at most d bad edges. Moreover, assume that these bad edges form t connected components B_1, \dots, B_t ($1 \leq t \leq d$). As observed in [32], for an optimal nni transformation, sometimes one or more nni operations are needed across a good internal edge of T_1 . Consider the set of at most $d - 1$ good edges in T_1 across which at least one nni operation is performed in an optimal nni sequence. This set of good edges forms at most $d - 1$ connected components in T_1 . Consider any one such connected component S . Since good edges in T_1 and T_2

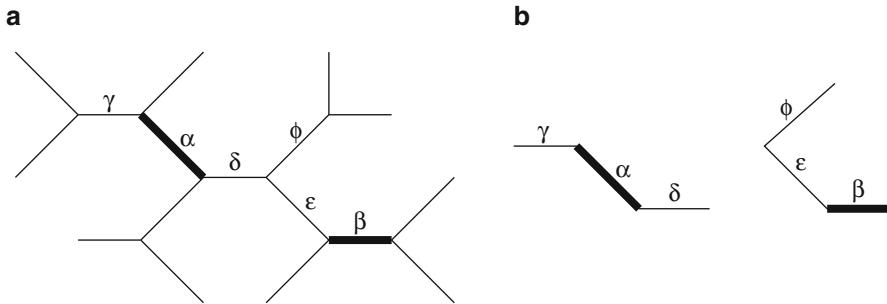

Fig. 7 Illustration of how algorithm NNI-d works ($d = 6, k_1 = k_2 = 3, t = 2$)

partition the trees in similar manner, it is very easy to see that there must be at least one connected component B_i sharing a vertex with S .

Using these observations, one can devise the algorithm shown in the next page. Figure 7 illustrates how the algorithm works. Figure 7a shows two bad edges α, β in T_1 (shown by thick lines) forming two connected components ($t = 2$). Figure 7b shows one choice of two subtrees containing k_1 and k_2 edges and including the edges α and β , respectively. For each subtree, algorithm NNI-d computes all possible nni sequences such that at most 3 nni are performed across edges of each subtree.

How fast does the algorithm run? There are at most $\binom{d+t-1}{d} < 2^{5d/2}$ choices for the integers k_1, \dots, k_t (using the fact that $\binom{n}{j} \leq (2.8n/j)^j$). Note that any subtree of k edges including a fixed edge can be represented by a rooted binary tree on $k+2$ nodes (the root corresponding to the middle of the fixed edge); hence, there are at most $C_{k+2} = \frac{1}{k+3} \binom{2k+4}{k+2} \leq 2^{2k}$ such trees. It follows that the total number of choices for the subtrees A_1, \dots, A_t (for any particular value of k_1, \dots, k_t) is at most $2^{\sum_{i=1}^t ((2k_i+1))} \leq 2^{3d}$. For each tree A_i , the number of sequences of k_i nni operations to consider is at most $3^{k_i-1} 2^{4k_i} < 2^{6k_i}$ by Lemma 1 of [32]. Combining everything, the number of trees one has to examine is at most $2^{5d/2} \cdot 2^{3d} \cdot 2^{6d} < 2^{23d/2}$. The set of all good edges of T_1 can be found in $O(n^2 \log n)$ time, and this time bound is also sufficient to find the connected components of good edges. Using the adjacency-list representation of trees, updating a tree during a single nni operation can easily be done in $O(1)$ time, and whether two trees are isomorphic can be easily checked in $O(n)$ time. Hence, this algorithm finds an optimal nni sequence in $O(n^2 \log n + n \cdot 2^{23d/2})$ time.

3.2 Unweighted Trees: Computing nni Distance Approximately

Since computing the nni distance is NP-hard, the next obvious question is the following: *can one get a good approximation of the distance?* The following result appeared in [32].

```

For every choice of integers  $k_1, \dots, k_t \geq 1$ ,  $\sum_{i=1}^t k_i \leq d$  do
  For every choice of subtrees  $A_1, \dots, A_t$  of  $T_1$  such that
     $A_i$  has at most  $k_i$  edges and contains the component  $B_i$  do
      Examine all sequence of nni transformations across edges
      of all  $A_i$ 's such that no more than  $k_i$  nni operations
      are performed across the edges of  $A_i$ 
    Among all sequences examined, select the one of shortest length that
    transforms  $T_1$  to  $T_2$ 

```

Algorithm NNI-d for the case when nni distance is bounded

Theorem 3 *The nni distance can be polynomial time approximated within a factor of $\log n + O(1)$.*

Proof Given two trees, T_1 and T_2 , one first identifies the bad edges in T_1 with respect to T_2 . These edges induce a subgraph of T_1 consisting of one or more components, each of which is a subtree of T_1 . Each bad-edge component links up the same set of neighboring shared-edge components in T_1 and T_2 , but it does so in different ways.

The algorithm transforms T_1 into T_2 by transforming each non-shared-edge component separately. Consider a component consisting of k non-shared edges in T_1 . This links up $k + 3$ shared-edge components, which one can consider as leaves for the purpose of linking them up differently. So one wants to transform C_0 into C_1 , where C_i is the $(k + 3)$ -tree corresponding to the component in T_i . By the *compression-method* of [6], the distance between C_0 and C_1 is at most $4(k + 3) \log(k + 3) + (4 - \log 3)(k + 3) - 12$. On the other hand, it is clear that any transformation from T_1 into T_2 must use at least one nni operation on every non-shared edge.

The approximation factor of this algorithm is at most

$$\frac{\sum 4(k + 3) \log(k + 3) + (4 - \log 3)(k + 3) - 12}{\sum k} \leq \frac{4n \log n + O(n)}{n - 3},$$

since $\sum k$ is at most the number of internal edges, which is $n - 3$. □

As is apparent from the previous two sections, the question of the computability of the nni distance measure, which will be denoted by d , has generated a lot of interest. Of course, a brute-force method can be employed which searches all (or a significant fraction of) trees in *exponential time and space* ([32] implemented a C program that uses $O(n)$ space to find the distance of any tree to a given one using a brute-force approach and could run it for trees up to size 11). In an attempt to improve efficiency, Waterman and Smith in [46] propose another distance measure, *closest partition*, which they conjecture is actually equal to d . The closest partition distance $c(T, S)$ for trees sharing a partition is defined recursively as the sum of the

two distances between the corresponding smaller parts resulting from splitting each tree into two. For trees T and S not sharing a partition, it is defined as $k + c(R, S)$, where k is the minimum number of nni operations required to transform a tree T into a tree R that shares a partition with tree S . Note that the nondeterminism in choosing R makes this measure somewhat ill-defined. They base their conjecture on what [9] aptly calls a *decomposability property* (DP) of nni. Informally, DP says that if two trees can each be split at some internal edge into identical subsets of leaves, then an optimal transformation of one into the other can be found in which no nni operation affects that internal edge. This claim appears in [46] as Theorem 4. Its proof however appeals to their Theorem 3, which was shown invalid in [24] with a 6-node counterexample. Consequently, [24] concludes that the status of Theorem 4 is unresolved and observes that Theorem 5 of [46] is a single step version of the Waterman and Smith's conjecture that $c = d$. This conjecture was shown to fail in [24] and [4] in a weak sense (for some choices that c allows) and shortly thereafter in [23] in a strong sense (for all choices in defining c). These papers also point out that computation of c appears to require exponential time as well, since there is no obvious bound on k in the definition of c . The work in [28] shows a logarithmic gap between measures c and d . Their example is a pair of trees, each on $n = 2^k$ nodes equidistant from the central internal edge. In one tree, the leaves can be drawn in normal order, while in the other, the leaves can be drawn in bit-reverse order (e.g., 0,4,2,6,1,5,2,7). For this pair of trees, one can show $d = \Theta(n)$, whereas $c = \Theta(n \log n)$ (in the weak sense at least). Finally, the following result was proved in [32], serving as a counterexample to all three theorems 3, 4, and 5 of [46].

Lemma 3 *There are trees T_1, T_2 sharing a partition which is not shared by any intermediate tree on a shortest path from T_1 to T_2 .*

3.3 Weighted Trees: Generalizing the nni Distance

In this section the authors discuss how to generalize the nni distance between two trees T_1 and T_2 when both T_1 and T_2 are weighted. The cost of an nni operation is now the weight of the edge across which two subtrees are swapped. As mentioned before, many phylogeny reconstruction methods produce weighted phylogenies. Hence, the weighted nni distance problem is also very important in computational molecular biology. NP-hardness of the (unweighted) nni distance problem (in Sect. 3.1) implies the NP-hardness of the weighted nni distance problem also.

The authors in [7, 8] present a polynomial-time algorithm with logarithmic approximation ratio for computing the nni distance on weighted phylogenies, generalizing the logarithmic ratio approximation algorithm in [32] (discussed in Sect. 3.2). The approximation for the weighted case is considerably more complex. Note that nni operations can be performed only across internal edges. For feasibility of weighted nni transformation between two given weighted trees T_1 and T_2 , one requires in this section that the following conditions are satisfied: (1) For each leaf

label a , the weight of the edge in T_1 incident on a is the same as the weight of the edge in T_2 incident on a ; (2) the multisets of weights of internal edges of T_1 and T_2 are the same.

Theorem 4 *Let T_1 and T_2 be two weighted phylogenies, each with n leaves. Then, $D_{\text{nni}}(T_1, T_2)$ can be approximated to within a factor of $6 + 6 \log n$ in $O(n^2 \log n)$ time.*

Note that the approximation ratio does not depend on the weights. Intuitively, the idea of the algorithm is as follows. One first identifies *bad* components in the tree that need a lot of nni moves in transformation process. Then, for each bad component, one puts things in correct order by first converting them into balanced shapes. But notice that one cannot afford to perform nni operations many times on heavy edges. Furthermore, not only the leaf nodes need to be moved to the right places, so do the weighted edges. The main contribution of our algorithm is the careful coordination of the transformations so that at most $O(\log n)$ nni operations are performed on each heavy edge.

4 Computing the Subtree-Transfer Distance

When *recombination* of DNA sequences occurs in an evolution, two sequences meet and generate a new sequence, consisting of genetic material taken left of the recombination point from the first sequence and right of the point from the second sequence [17, 18, 25]. From a phylogenetic viewpoint, before the recombination, the ancestral material on the present sequence was located on two sequences, one having all the material to the left of the recombination point and another having all the material to the right of the breaking point. The recombination makes the two evolutionary trees describing neighboring regions differ. However, two neighbor trees cannot be arbitrarily different; one must be obtainable from the other by a *subtree-transfer operation*. When more than one recombination occurs, one can describe an evolutionary history using a list of evolutionary trees; each corresponds to some region of the sequences, and each can be obtained by several subtree-transfer operations from its predecessor. The computation of subtree-transfer distance is useful in reconstructing such a list of trees based on parsimony [17, 18].

In this section, the authors show that computing the subtree-transfer distance between two evolutionary trees is NP-hard and give an approximation algorithm with performance ratio 3. Before one proves the results, it is again convenient to reformulate the problem. Let T_1 and T_2 be two evolutionary trees on set S . An *agreement forest* of T_1 and T_2 is any forest which can be obtained from both T_1 and T_2 by cutting k edges (in each tree) for some k and applying forced contractions in each resulting component trees. Define the size of a forest as the number of components it contains. Then the *maximum agreement forest* (MAF) problem is

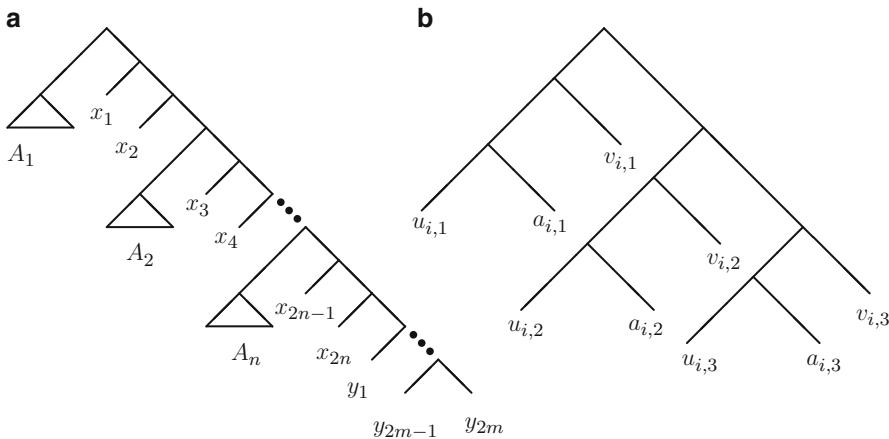

Fig. 8 (a) The tree T_1 . (b) The subtree A_i

to find an agreement forest with the *smallest* size. The following lemma shows that MAF is really equivalent to computing the subtree-transfer distance.

Lemma 4 *The size of an MAF of T_1 and T_2 is one more than their subtree-transfer distance.*

The lemma can be proven by a simple induction on the number of leaves. Intuitively, the lemma says that the transfer operations can be broken down into two stages: First one cuts off the subtrees to be transferred from the rest in T_1 (not worrying where to put them), and then one assembles them appropriately to obtain T_2 . This separation will simplify the proofs.

4.1 The NP-Hardness

Theorem 5 *It is NP-hard to compute the subtree-transfer distance between two binary trees.*

Proof (Sketch) The reduction is from Exact Cover by 3-Sets. Let $S = \{s_1, s_2, \dots, s_m\}$ be a set and C_1, \dots, C_n be an instance of this problem. Assume $m = 3q$.

The tree T_1 is formed by inserting n subtrees A_1, \dots, A_n into a chain containing $2n + 2m$ leaves $x_1, \dots, x_{2n}, y_1, \dots, y_{2m}$ uniformly (see Fig. 8a). Each A_i corresponds to $C_i = \{c_{i,1}, c_{i,2}, c_{i,3}\}$ and has 9 leaves, as shown in Fig. 8b. Suppose that $c_{j,j'}, c_{k,k'}$, and $c_{l,l'}$ are the three occurrences of an $s_i \in S$ in C . Then in T_2 , one has a subtree B_i , as shown in Fig. 9a. For each C_i , one also has a subtree D_i in T_2 , as shown in Fig. 9b. The subtrees are arranged as a linear chain, as shown in Fig. 9c.

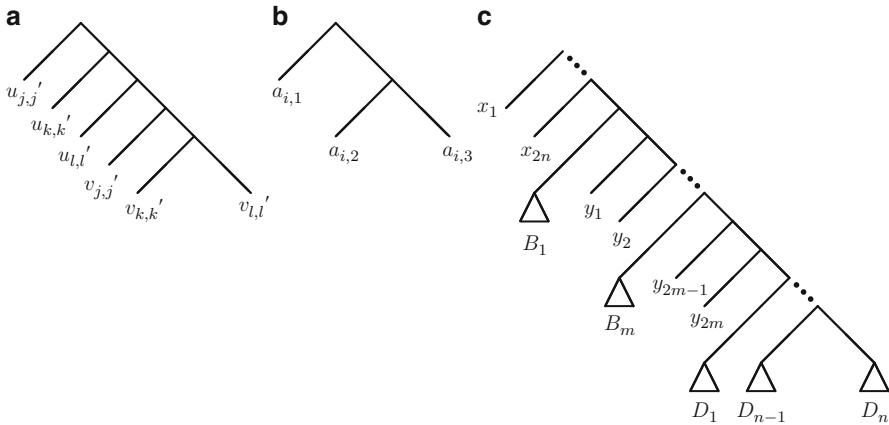

Fig. 9 (a) The subtree B_i . (b) The subtree D_i . (c) The tree T_2

Note that each adjacent pair of subtrees A_i and A_{i+1} in T_1 is separated by a chain of length 2 which also appears in T_2 . Thus, to form an MAF of T_1 and T_2 , our best strategy is clearly to cut off A_1, A_2, \dots, A_n in T_1 and similarly cut off B_1, B_2, \dots, B_m in T_2 . This then forces us to cut off D_1, D_2, \dots, D_n in T_2 . Now in each A_i , either one can cut off the leaves $u_{i,1}, v_{i,1}, u_{i,2}, v_{i,2}, u_{i,3}, v_{i,3}$ to form a subtree containing three leaves $a_{i,1}, a_{i,2}, a_{i,3}$ (yielding $6 + 1 = 7$ components totally) or one can cut off $a_{i,1}, a_{i,2}$, and $a_{i,3}$. In the second case, one will be forced to also cut links between the three subtrees containing leaves $\{u_{i,1}, v_{i,1}\}$, $\{u_{i,2}, v_{i,2}\}$, and $\{u_{i,3}, v_{i,3}\}$, respectively, as the B_i 's are already separated. Hence, in this case the best one can hope for is $3 + 3 = 6$ components (if one can keep all three 2-leaf subtrees in the agreement forest).

It can be shown that C has an exact cover of S if and only if T_1 and T_2 have an agreement forest of size $1 + 6q + 7(n - q) = 7n - q + 1$. \square

4.2 An Approximation Algorithm of Ratio 3

Our basic idea is to deal with a pair of sibling leaves a, b in the first tree T_1 at a time. If the pair a and b are siblings in the second tree T_2 , one replaces this pair with a new leaf labeled by (a, b) in both trees. Otherwise, one will cut T_2 until a and b become siblings or separated. Eventually both trees will be cut into the same forest. Five cases need be considered. Figure 10 illustrates the first four cases. The last case [case (v)] is that a and b are also siblings in T_2 .

The approximation algorithm is given in Fig. 11. The variable N records the number of components (or the number of cuts plus 1).

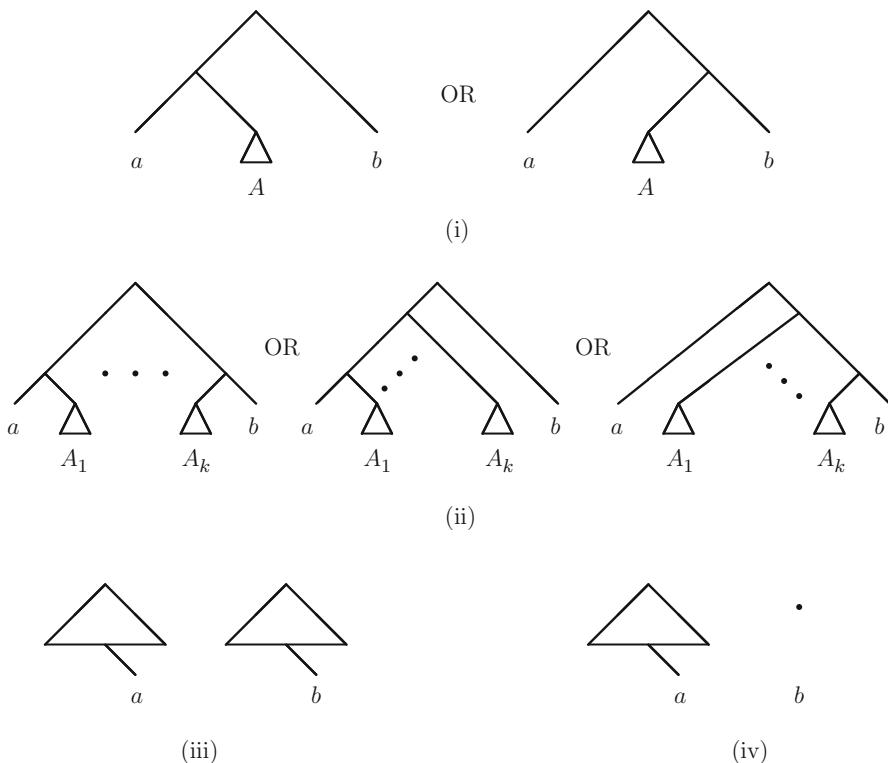

Fig. 10 The first four cases of a and b in T_2

Input: T_1 and T_2 .

0. $N := 1$;
 1. For a pair of sibling leaves a, b in T_1 , consider how they appear in T_2 and cut the trees:
 - Case (i):* Cut off the middle subtree A in T_2 ; $N := N + 1$;
 - Case (ii):* Cut off a and b in both T_1 and T_2 ; $N := N + 2$;
 - Case (iii):* Cut off a and b in both T_1 and T_2 ; $N := N + 2$;
 - Case (iv):* Cut off b in T_1 ;
 - Case (v):* Replace this pair with a new leaf labeled (a, b) in both T_1 and T_2
 2. If some component in the forest for T_1 has size larger than 1, repeat Step 1.
- Output: The forest and N .

Fig. 11 The approximation algorithm of ratio 3

Theorem 6 *The approximation ratio of the algorithm in Fig. 11 is 3, i.e., it always produces an agreement forest of size at most three times the size of an MAF for T_1 and T_2 .*

The NP-hardness proof can be easily strengthened to work for MAX-SNP-hardness. Thus there is no hope for a polynomial-time approximation scheme for this problem. Moreover, the small distance exact algorithm described in Sect. 3 for nni also works here.

5 Linear-Cost Subtree-Transfer Distance on Weighted Phylogenies

In this section the authors investigate the linear-cost subtree-transfer model on weighted phylogenies.

5.1 An NP-Hardness Result

It is open whether the linear-cost subtree-transfer problem is NP-hard for weighted phylogenies. However, one can show that the problem is NP-hard for weighted trees with nonuniquely labeled leaves.

Theorem 7 *Let T_1 and T_2 be two weighted trees with (not necessarily uniquely) labeled leaves. Then, computing $D_{st}(T_1, T_2)$ is NP-hard.*

Proof Our proof is by a reduction from the following *Exact Cover by 3-Sets* (X3C) problem that was used in the proof of Theorem 1. For the convenience of the reader, we state the X3C problem again below:

Instance: $S = \{s_1, \dots, s_m\}$, where $m = 3q$, and C_1, \dots, C_n , where $C_i = \{s_{i_1}, s_{i_2}, s_{i_3}\} \subseteq S$.

Question: Are there q disjoint sets C_{i_1}, \dots, C_{i_q} such that $\bigcup_{j=1}^q C_{i_j} = S$?

Given an instance of the X3C problem, one will construct two trees T_1 and T_2 with leaf labels (not necessarily unique), as shown in Fig. 12, such that transforming from T_1 into T_2 requires subtree transfers of total cost exactly 1 iff an exact cover of S exists.

T_1 has n long arms, $\alpha_1, \dots, \alpha_n$. T_2 has $n - q$ long arms, $\beta_1, \dots, \beta_{n-q}$, and m short arms, $\gamma_1, \dots, \gamma_m$. Each long (resp. short) arm consists of an edge of weight $\frac{1}{n}$ (resp. $\frac{1}{3n}$), with three leaves (resp. one leaf) labeled by the same label x ($x \notin S$), connected to it as shown in Fig. 12. For notational convenience, let e_{α_i} (resp. $e_{\beta_i}, e_{\gamma_i}$) denote the edge of nonzero weight in the long arm α_i (resp. in the long arm β_i , in the

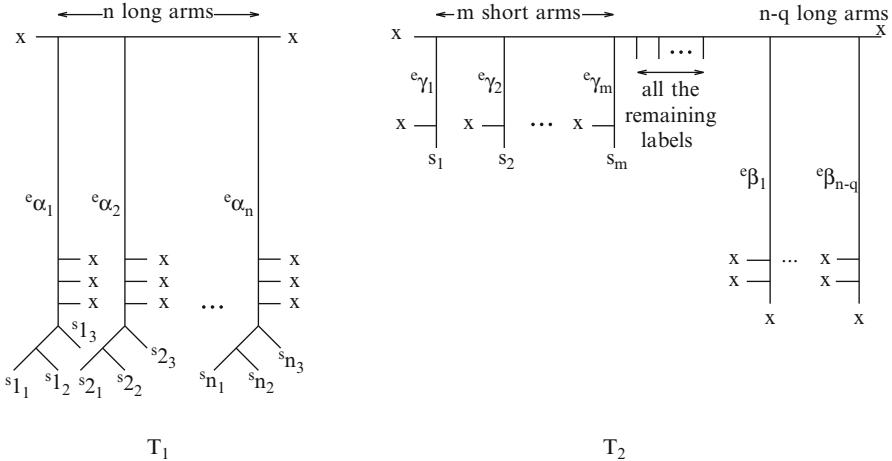

Fig. 12 Trees T_1 and T_2 used in the proof of Theorem 7. The leaf labels are shown beside the corresponding leaves. The notations for some of the internal edges are shown beside the corresponding edges. The edge weights are as follows: $w(e_{\alpha_1}) = w(e_{\alpha_2}) = \dots = w(e_{\alpha_n}) = w(e_{\beta_1}) = w(e_{\beta_2}) = \dots = w(e_{\beta_{n-q}}) = \frac{1}{n}$, $w(e_{\gamma_1}) = w(e_{\gamma_2}) = \dots = w(e_{\gamma_m}) = \frac{1}{3n}$, and all other edges have zero weights

short arm γ_i). In T_1 , at the bottom of the i th long arm α_i , one attaches a subtree t_i consisting of three leaves, as shown in Fig. 12, labeled by the three elements s_{i1}, s_{i2} , and s_{i3} of C_i . At the bottom of each long arm of T_2 , there are no additional subtrees attached. The labeling of the remaining leaves of T_2 is as follows:

- At the bottom of the i th short arm γ_i , one attaches a leaf labeled by s_i .
- The remaining $3n - m$ leaf labels (each leaf label is an element of S) are associated (in any order) with the $3n - m$ leaves in the middle of T_2 between the long and the short arms.

Note that the trees T_1 and T_2 are not uniquely labeled. The following claim proves the correctness of the NP-hardness reduction:

$$D_{st}(T_1, T_2) = 1 \text{ iff there is a solution of the X3C problem.}$$

A proof of the above claim can be found in [8]. □

5.2 An Approximation Algorithm

In this section, the authors present an approximation algorithm for computing the linear-cost subtree-transfer distance on weighted trees. First, the authors introduce some notations and a lower bound on the subtree-transfer distance which will be useful in subsequent proofs. For any tree T , let $E(T)$ (resp. $V(T)$) denote the edge set (resp. node set) of T and $L(T)$ denote the set of leaf nodes of T . An external

edge of T incident on a leaf node a is denoted by $e_T(a)$. Let $E_{\text{int}}(T)$ and $E_{\text{ext}}(T)$ denote the set of internal and external edges of T , respectively. For a subset $E' \subseteq E(T)$, define $w(E') = \sum_{e \in E'} w(e)$. Define $W_{\text{int}}(T) = w(E_{\text{int}}(T))$ and $W_{\text{ext}}(T) = w(E_{\text{ext}}(T))$. Partition $E_{\text{ext}}(T_1)$ into three subsets as follows:

$$\begin{aligned} E_{\text{ext}, T_1 > T_2}(T_1) &= \{e_{T_1}(a) \mid w(e_{T_1}(a)) > w(e_{T_2}(a))\} \\ E_{\text{ext}, T_1 = T_2}(T_1) &= \{e_{T_1}(a) \mid w(e_{T_1}(a)) = w(e_{T_2}(a))\} \\ E_{\text{ext}, T_1 < T_2}(T_1) &= \{e_{T_1}(a) \mid w(e_{T_1}(a)) < w(e_{T_2}(a))\} \\ W_{\text{ext}, T_1 > T_2}(T_1) &= \sum_{e_{T_1}(a) \in E_{\text{ext}, T_1 > T_2}(T_1)} w(e_{T_1}(a)) - w(e_{T_2}(a)). \end{aligned}$$

Similarly, $E_{\text{ext}}(T_2)$ can be partitioned into $E_{\text{ext}, T_1 > T_2}(T_2)$, $E_{\text{ext}, T_1 = T_2}(T_2)$, and $E_{\text{ext}, T_1 < T_2}(T_2)$. $W_{\text{ext}, T_1 < T_2}(T_2)$ is defined analogously. The following lemma is easy to prove.

Lemma 5 $W_{\text{int}}(T_1) + W_{\text{ext}, T_1 > T_2}(T_1) = W_{\text{int}}(T_2) + W_{\text{ext}, T_1 < T_2}(T_2)$.

Proof Since $w(E_{\text{ext}, T_1 > T_2}(T_1)) = w(E_{\text{ext}, T_1 > T_2}(T_2)) + W_{\text{ext}, T_1 > T_2}(T_1)$, one has

$$W_{\text{int}}(T_1) + w(E_{\text{ext}, T_1 = T_2}(T_1)) + w(E_{\text{ext}, T_1 < T_2}(T_1)) + w(E_{\text{ext}, T_1 > T_2}(T_2)) + W_{\text{ext}, T_1 > T_2}(T_1) = w(T_1) = 1.$$

Similarly, one has

$$W_{\text{int}}(T_2) + w(E_{\text{ext}, T_1 = T_2}(T_2)) + w(E_{\text{ext}, T_1 > T_2}(T_2)) + w(E_{\text{ext}, T_1 < T_2}(T_1)) + W_{\text{ext}, T_1 < T_2}(T_2) = w(T_2) = 1.$$

Since $w(E_{\text{ext}, T_1 = T_2}(T_1)) = w(E_{\text{ext}, T_1 = T_2}(T_2))$, the lemma follows from the above two equations. \square

One next defines the notion of good edge pairs as follows:

Definition 1 Let $e_1 \in E_{\text{int}}(T_1)$ and $e_2 \in E_{\text{int}}(T_2)$. Let T'_1 and T''_1 be the two subtrees of T_1 partitioned by e_1 . Let T'_2 and T''_2 be the two subtrees of T_2 partitioned by e_2 . e_1 and e_2 are called a *good pair* of T_1 and T_2 iff the following two conditions hold:

1. $L(T'_1) = L(T'_2)$ and $L(T''_1) = L(T''_2)$.
2. One of the following two conditions holds:
 - a. $w(E(T'_1)) \leq w(E(T'_2)) < w(E(T'_1)) + w(e_1)$.
 - b. $w(E(T'_2)) \leq w(E(T'_1)) < w(E(T'_2)) + w(e_2)$.

Lemma 6 If T_1 and T_2 share no good edge pairs, then:

1. $D_{\text{st}}(T_1, T_2) \geq W_{\text{int}}(T_1) + W_{\text{ext}, T_1 > T_2}(T_1)$.
2. $D_{\text{st}}(T_1, T_2) \geq W_{\text{int}}(T_2) + W_{\text{ext}, T_1 < T_2}(T_2)$.

Proof The authors only prove (1). The proof of (2) follows from (1) and Lemma 5. For each edge $e \in E(T_1)$, one determines the minimum portion of e over which some subtrees of T_1 must be transferred in order to transform T_1 to T_2 . First, consider an edge $e_1 \in E_{\text{int}}(T_1)$. By the assumption of the lemma, there is no edge e_2 in T_2 such that e_1 and e_2 are a good pair. There are two cases:

Case 1. The partition of $L(T_1)$ induced by e_1 is different from the partition of $L(T_2)$ induced by any edge in T_2 . Then, in order to transform T_1 to T_2 , some leaf nodes of T_1 must be transferred across the entire length of e_1 .

Case 2. The partition of $L(T_1)$ induced by e_1 is the same as the partition of $L(T_2)$ induced by an edge e_2 in T_2 . Let T'_1 and T''_1 be the two subtrees of T_1 partitioned by e_1 . Let T'_2 and T''_2 be the two subtrees of T_2 partitioned by e_2 , where $L(T'_1) = L(T'_2)$ and $L(T''_1) = L(T''_2)$.

Case 2.1. $w(E(T'_2)) \geq w(E(T'_1)) + w(e_1)$. In this case, in order to transform T'_1 to T'_2 , some subtree in T'_1 must be transferred across entire length of e_1 .

Case 2.2. $w(E(T'_1)) \geq w(E(T'_2)) + w(e_2)$. This implies $w(E(T''_1)) + w(e_1) \leq w(E(T''_2))$. In order to transform T''_1 to T''_2 , some subtree in T''_1 must be transferred across the entire length of e_1 .

In either case, some subtree of T_1 must be transferred across the entire length of e_1 with cost $w(e_1)$.

Next consider an edge $e_{T_1}(a) \in E_{\text{ext}, T_1 > T_2}(T_1)$. In order to transform $e_{T_1}(a)$ to $e_{T_2}(a)$, a subtree of T_1 must be transferred across a portion of $e_{T_1}(a)$ of length $w(e_{T_1}(a)) - w(e_{T_2}(a))$. Thus,

$$D_{\text{st}}(T_1, T_2) \geq \sum_{e \in E_{\text{int}}(T_1)} w(e) + \sum_{e \in E_{\text{ext}, T_1 > T_2}(T_1)} [w(e_{T_1}(a)) - w(e_{T_2}(a))]$$

$$= W_{\text{int}}(T_1) + W_{\text{ext}, T_1 > T_2}(T_1).$$

□

Remark 1 Assume that the given trees T_1 and T_2 are not uniquely labeled (i.e., a label may appear in more than one leaf). Extend the definition of good pair of edges by treating $L(T)$ as the multiset of leaves for a tree T and considering the condition $L(T'_1) = L(T'_2)$ or $L(T''_1) = L(T''_2)$ to hold if the corresponding multisets are identical. Assume that all the leaves are incident on *zero-weight* edges (i.e., $W_{\text{int}}(T_1) = W_{\text{int}}(T_2)$ and $W_{\text{ext}}(T_1) = W_{\text{ext}}(T_2) = 0$) and that T_1 and T_2 share no good pair of edges. Then, in a manner very similar to the proof of Lemma 6, one can show that $D_{\text{st}}(T_1, T_2) \geq W_{\text{int}}(T_1)$ (and that some subtree is transferred over every internal edge of T_1 to transform T_1 to T_2).

One says that nodes connected by 0-weight edges are equivalent and calls the resulting equivalence classes *super-nodes*. Let e_1, \dots, e_k be all positive weight edges incident to a super-node o . With 0 cost, one can reconnect the edges e_1, \dots, e_k by any subtree, consisting of only 0 weight edges. In particular, the following observation will be useful in our subsequent descriptions.

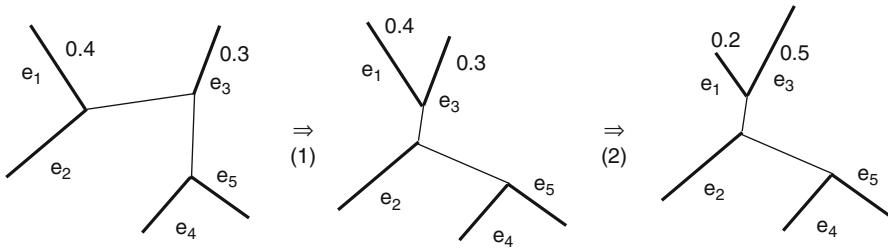

Fig. 13 The operation $\text{move}(e_1, 0.2, e_3)$. (1) e_2, e_4 , and e_5 are assembled into a tree S ; (2) S is moved along e_1 by a length of 0.2

Observation. Let o be a super-node of T . Let e_1, \dots, e_k be all positive weight edges incident on o . Pick any e_i and e_j . One can assemble $\{e_1, \dots, e_k\} - \{e_i, e_j\}$ into a single subtree S with 0 cost, and then transfer S along e_i by a distance $d \leq w(e_i)$. The effect of this operation is that the edges e_1, \dots, e_k are still incident on a super-node and a portion of e_i of length d is *moved* into e_j . The total cost of this operation is d . One denotes this operation by $\text{move}(e_i, d, e_j)$. This operation can be implemented in $O(k)$ time using the adjacency-list representation of the tree (where the weight of the edge is also stored in the adjacency list).

Figure 13 shows an example of this operation. In the figure, the thin lines denote 0 weight edges, and heavy lines denote positive weight edges.

A tree T is called a *superstar* if all of its internal edges have 0 weight. In other words, all external edges of a superstar T are incident to a single super-node.

In the rest of this section, the authors prove the following theorem.

Theorem 8 For any two weighted phylogenies T_1 and T_2 , $D_{\text{st}}(T_1, T_2)$ can be approximated to within a factor of 2 in $O(n^2 \log n)$ time.

First, the authors describe the algorithm DST which approximates $D_{\text{st}}(T_1, T_2)$ to within a factor of 2 for the special case when T_1 and T_2 do not have any good edge pairs. Then the authors will show how to apply the algorithm to the general case.

The algorithm transforms T_1 into a superstar T'_1 (by moving the weight of internal edges into external edges). Similarly, the algorithm transforms T_2 into a superstar T'_2 . The transformations are chosen to make T'_1 coincide with T'_2 . To transform T_1 to T_2 , one first transforms T_1 to $T'_1 (= T'_2)$ and then transforms this to T_2 . Let T'_1 (resp. T'_2) denote the tree during the transformation of T_1 (resp. T_2). T'_1 (resp. T'_2) is initialized to be T_1 (resp. T_2).

Algorithm DST

Step 0. Initialize $T'_1 = T_1$ and $T'_2 = T_2$.

Step 1. While T'_1 is not a superstar yet and there is an external edge $e_{T'_1}(a) = (a, u)$ in T'_1 such that $w(e_{T'_1}(a)) < w(e_{T'_2}(a))$, do:

- Let e_1 be any positive weight internal edge of T'_1 incident on the super-node containing u . Let $d = \min\{w(e_1), [w(e_{T'_2}(a)) - w(e_{T'_1}(a))]\}$.
- Perform the operation $\text{move}(e_1, d, e_{T'_1}(a))$ in T'_1 . (Note: after this move operation, either the entire length of e_1 is moved into $e_{T'_1}(a)$ or $w(e_{T'_1}(a)) = w(e_{T'_2}(a))$).

(Note: after the loop terminates, either T'_1 is a superstar or $w(e_{T'_1}(a)) \geq w(e_{T'_2}(a))$ for all leaf nodes a . Also one performs subtree transfer only on internal edges of T_1 .)

Step 2. Similar to Step 1, with the roles of T'_1 and T'_2 swapped.

Step 3. One transforms T'_1 and T'_2 into two superstars such that $w(e_{T'_1}(a)) = w(e_{T'_2}(a))$ for all leaf nodes a . There are two possible cases as follows:

Case 3.1. $w(e_{T'_1}(a)) = w(e_{T'_2}(a))$ for all leaf nodes a . Perform the following loop to transform both T'_1 and T'_2 into superstars. During the execution of the loop, one maintains the condition $w(e_{T'_1}(a)) = w(e_{T'_2}(a))$ for all leaf nodes a (this condition implies that T'_1 is a superstar iff T'_2 is a superstar).

Repeat

Pick any edge $e_{T'_1}(a) = (a, u_1)$ in T'_1 . Suppose that the corresponding edge $e_{T'_2}(a)$ in T'_2 is (a, u_2) . Let e_1 be any positive weight internal edge of T'_1 incident on the super-node containing u_1 . Let e_2 be any positive weight internal edge of T'_2 incident on the super-node containing u_2 . Let $d = \min\{w(e_1), w(e_2)\}$. In T'_1 , perform the operation $\text{move}(e_1, d, e_{T'_1}(a))$. In T'_2 , perform the operation $\text{move}(e_2, d, e_{T'_2}(a))$. (After this, one has moved the entire length of either e_1 or e_2 into external edges.)

Until both T'_1 and T'_2 are superstars.

(Note: during this step, one performs subtree transfer only on internal edges of T_1 and T_2 .)

Case 3.2. There exists a leaf node a such that $w(e_{T'_1}(a)) \neq w(e_{T'_2}(a))$. This can happen only if both T'_1 and T'_2 are superstars already. One needs to make $w(e_{T'_1}(a)) = w(e_{T'_2}(a))$ for all leaf nodes a . This is done as follows. Partition $L(T'_1)$ into three subsets A , B , and C as follows: A (resp. B , C) is the set of leaf nodes a (resp. b , c) such that $w(e_{T'_1}(a)) = w(e_{T'_2}(a))$ (resp. $w(e_{T'_1}(b)) < w(e_{T'_2}(b))$, $w(e_{T'_1}(c)) > w(e_{T'_2}(c))$).

Repeat

Pick any edge $e_{T'_1}(b)$ with $b \in B$ and $e_{T'_1}(c)$ with $c \in C$. Let $d = \min\{[w(e_{T'_1}(c)) - w(e_{T'_2}(c))], [w(e_{T'_2}(b)) - w(e_{T'_1}(b))]\}$. In T'_1 , perform $\text{move}(e_{T'_1}(c), d, e_{T'_1}(b))$. Then:

- If $d = w(e_{T'_2}(b)) - w(e_{T'_1}(b))$, remove b from B and put b into A .
- If $d = w(e_{T'_1}(c)) - w(e_{T'_2}(c))$, remove c from C and put c into A .
- If $d = w(e_{T'_1}(c)) - w(e_{T'_2}(c)) = w(e_{T'_2}(b)) - w(e_{T'_1}(b))$, remove b from B ; remove c from C ; put both b and c into A .

Until $B = C = \emptyset$.

Step 4. Now both T'_1 and T'_2 are superstars and $w(e_{T'_1}(a)) = w(e_{T'_2}(a))$ for all leaf nodes a . One adjusts the topology of the super-nodes of T'_1 and T'_2 so that T'_1 and T'_2 are identical.

Lemma 7 Assume that T_1 and T_2 do not share any good edge pairs. Then, algorithm DST approximates $D_{st}(T_1, T_2)$ to within a factor of 2 in $O(n^2)$ time.

Proof One analyzes the cost and running time of each step of the algorithm. One uses the adjacency-list representation of a tree. Steps 0 and 4 incur no costs and can easily be implemented in $O(n)$ time. During Steps 1, 2, and 3.1, one only transfers subtrees across internal edges of T_1 and T_2 . Over any portion of such an edge e , at most one subtree-transfer operation occurs. So the total cost of these steps is bounded above by $W_{int}(T_1) + W_{int}(T_2)$. Moreover, it is easy to see that at most $O(n)$ moves are performed during Steps 1, 2, and 3.1, and since each move operation can be implemented in $O(n)$ time, the total time for all these steps is at most $O(n^2)$.

Next, consider Step 3.2. Before the repeat loop is entered, for any $c \in C$, one has:

- $w(e_{T'_1}(c)) = w(e_{T_1}(c))$. (This is because no additional weight is moved to the edge $e_{T'_1}(c)$ during Steps 1 and 2.)
- $w(e_{T'_2}(c)) \geq w(e_{T_2}(c))$.

During Step 3.2, one only transfers subtrees across the edges $e_{T'_1}(c)$ for $c \in C$. Fix such an edge. Note that any portion of $e_{T'_1}(c)$ is traversed at most once during Step 3.2. Once the length of $e_{T'_1}(c)$ is reduced to $w(e_{T'_2}(c))$, c is removed from C . So the portion of $e_{T'_1}(c)$ traversed during Step 3.2 is $w(e_{T'_1}(c)) - w(e_{T'_2}(c)) = w(e_{T_1}(c)) - w(e_{T'_2}(c)) \leq w(e_{T_1}(c)) - w(e_{T_2}(c))$. So the total cost of Step 3.2 is at most $\sum_{c \in C} [w(e_{T'_1}(c)) - w(e_{T'_2}(c))] \leq \sum_{c \in C} [w(e_{T_1}(c)) - w(e_{T_2}(c))] \leq W_{ext,T_1>T_2}(T_1)$. Also, one performs at most $O(n)$ move operations during Step 3.2, and hence, this step can also be implemented in $O(n^2)$ time.

Thus the total cost of the algorithm is bounded above by $W_{int}(T_1) + W_{int}(T_2) + W_{ext,T_1>T_2}(T_1)$, which is at most $2D_{st}(T_1, T_2)$ by Lemma 6. \square

Next, one shows how to apply algorithm DST to achieve an approximation ratio of 2 when T_1 and T_2 may share some good edge pairs. One concentrates on the algorithm and omits implementation details. Let K be the number of good edge pairs in T_1 and T_2 . Our algorithm is by induction on K . If $K = 0$, algorithm DST works by Lemma 7. Suppose $K > 0$. Let $e_1 = (u_1, v_1) \in E(T_1)$ and $e_2 = (u_2, v_2) \in E(T_2)$ be a good pair. Let T'_1 and T''_1 be the two subtrees of T_1 partitioned by e_1 . Let T'_2 and T''_2 be the two subtrees of T_2 partitioned by e_2 , where $L(T'_1) = L(T'_2)$ and $L(T''_1) = L(T''_2)$.

Assume $w(E(T'_1)) \leq w(E(T'_2)) < w(E(T'_1)) + w(e_1)$. (The other case can be handled in a similar way.) Add a new edge (u_1, x) to T'_1 and assign $w((u_1, x)) = w(E(T'_2)) - w(E(T'_1))$. Add a new edge (x, v_1) to T''_1 and assign $w((x, v_1)) = w(e_1) - w((u_1, x))$. Add a new edge (u_2, x) to T'_2 and assign $w((u_2, x)) = 0$. Add a new edge (x, v_2) to T''_2 and assign $w((x, v_2)) = w(e_2)$ (see Fig. 14.) Note that the weights of all new edges are nonnegative.

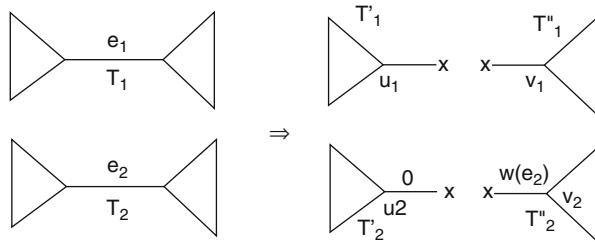

Fig. 14 Cut each of T_1 and T_2 into two smaller trees

Now one has $L(T'_1) = L(T'_2)$ and $w(T'_1) = w(T'_2)$. One can normalize the weights of T'_1 and T'_2 such that their sum is 1. By induction hypothesis, one can transform T'_1 to T'_2 with cost at most $2D_{st}(T'_1, T'_2)$. Similarly, one can transform T''_1 to T''_2 with cost at most $2D_{st}(T''_1, T''_2)$. Combining the two transfer sequences, one can transform T_1 to T_2 with cost at most $2D_{st}(T_1, T_2)$. The complete algorithm takes $O(n^2 \log n)$ time. This completes the proof of [Theorem 8](#).

6 The Rotation Distance

6.1 Rotation and Its Equivalences

A *rotation* is an operation that changes one rooted binary tree into another with the same size. [Figure 15](#) shows the general rotation rule. Note that the rotation is an invertible operation. If a tree T is changed into T' by a rotation, then T' can be changed back into T by another rotation. In a rooted binary tree of size n , there are $n - 1$ possible rotations, each corresponding a non-root node.

A *symmetric order* traversal of a rooted tree visits all of the nodes exactly once. The order can be described recursively as follows: For a node in the tree, traverse its left subtree (if there is one), visit the node itself, and then traverse its right subtree (if there is). A rotation maintains the symmetric order of the nodes.

The rotation on binary trees can be formulated with respect to different systems of combinatorial objects and their transformations. The diagonal-flip operation in triangulations is perhaps more intuitive and so supplies more insight.

Consider the standard convex $(n + 2)$ -gon. One chooses an edge of the polygon as a distinguished edge, called *root edge*, and labels its ends as 0 and $n + 1$. One also labels the other n vertices from 1 to n counterclockwise. Any triangulation of the $(n + 2)$ -gon has n triangles and $n - 1$ diagonals. From a triangulation of the $(n + 2)$ -gon, one derives a binary tree of size n by assigning a node for each triangle and connecting two nodes if the corresponding triangles sharing a common diagonal. The root of the tree corresponds to the triangle containing the root edge. It is not difficult to see that the i th node of the binary tree in symmetric order corresponds

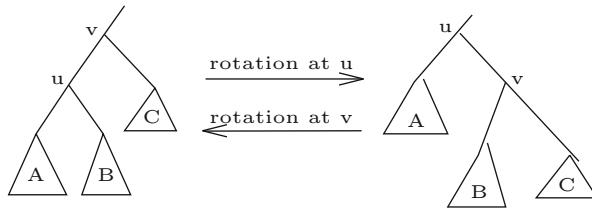

Fig. 15 The definition of rotation

Fig. 16 A triangulation and its corresponding n -node rooted binary tree

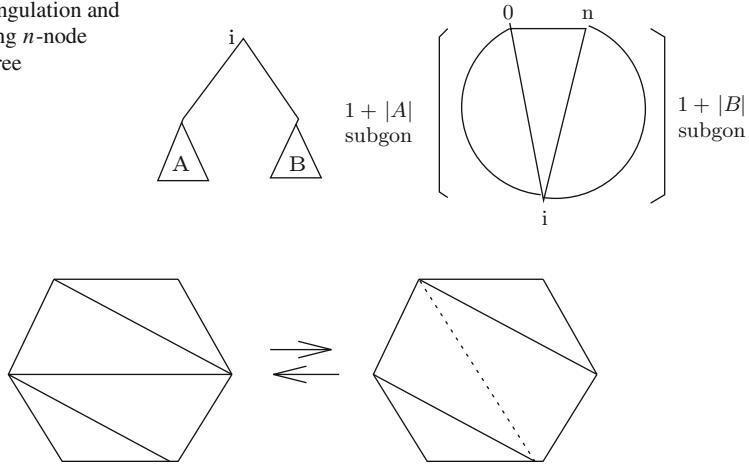

Fig. 17 A diagonal flip in a triangulation of the hexagon

to the triangle with vertices i , j , and k such that $j < i < k$. In this way, one obtains a 1–1 correspondence between n -node binary trees and triangulations of the $(n+2)$ -gon as illustrated in Fig. 16.

A *diagonal flip* is an operation that transforms one triangulation of a convex polygon into another, as shown in Fig. 17. A diagonal inside the polygon is removed, creating a quadrilateral. Then the opposite diagonal of this quadrilateral is inserted in place of the one removed, restoring a triangulation of the polygon. It is not difficult to see that diagonal flips in a triangulation correspond one-to-one to rotations in the corresponding binary tree.

Given a triangulation π of a polygon, one defines the *internal degree* of a vertex v as the number of diagonals adjacent to v , denoted by $\text{id}(v)$. Now let us see how $\text{id}(v)$ is reflected in the corresponding binary tree. In a rooted binary tree T , the *left* (*resp.* *right*) *path* is a maximal sequence of nodes that form a path starting at the root all of whose edges go in left (*resp.* right) direction. For a node $v \in T$, the left and right subtree rooted at v are denoted by LT_v and RT_v , respectively. Recall that all non-leaf nodes are *internal nodes* in a tree. The following result is of interest itself and has not appeared in literature to the best of the authors knowledge.

Theorem 9 ([33]) Suppose that the $(n + 2)$ -gon P is oriented by labeling its vertices from 0 to $n + 1$ and $(0, n + 1)$ is the root edge. Let π be a triangulation of P and T be the corresponding n -node rooted binary tree. Then:

1. The internal degree $\text{id}(0)$ of vertex 0 in P equals the number of internal nodes on the left path of T .
2. The internal degree $\text{id}(n + 1)$ of vertex $n + 1$ in P equals the number of internal nodes on the right path of T .
3. The internal degree $\text{id}(i)$ of vertex $i \in P$ ($0 < i < n + 1$) equals the number of subtrees at node i , which is at most 2, plus the number of internal nodes on the right path of the left subtree LT_i and the number of internal nodes on the left path of the right subtree RT_i .

Other interesting relationship between a triangulation of a convex polygon and its corresponding rooted binary tree can be found in a nice survey article [1].

6.2 Upper and Lower Bounds for the Rotation Distance

Any rooted binary tree of size n can be converted into any other with the same size by performing an appropriate sequence of rotations. Therefore, one can define the *rotation distance* between two trees as the minimum number of rotations required to convert one tree into the other. Let $\text{rt}(T_1, T_2)$ denote the rotation distance between two trees T_1 and T_2 . Define

$$\text{rt}(n) = \max\{\text{rt}(T_1, T_2) \mid |T_1| = |T_2| = n\}.$$

Similarly, one can define the *diagonal-flip* distance between two triangulations of the n -gon and denote the maximum distance between any pair of such triangulations by $\text{fd}(n)$. Obviously, $\text{rd}(n) = \text{fd}(n + 2)$.

Culik and Wood showed that $\text{rd}(n) \leq 2n - 2$ [6]. Sleator, Tarjan, and Thurston improved this bound to $2n - 6$ and showed that the bound is tight for all sufficiently large n using hyperbolic geometry.

Theorem 10 ([40]) $\text{rd}(n) = \text{fd}(n + 2) \leq 2n - 6$ for all $n > 10$. Furthermore, the equality holds for all sufficiently large n .

The exact values of $\text{rd}(n)$ for $n \leq 16$ are listed below [40]:

n	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
$\text{rd}(n)$	0	1	2	4	5	7	9	11	12	15	16	18	20	22	24	26

However, little is known about the lower bound for the rotation distance $\text{rd}(T_1, T_2)$ of two given trees T_1 and T_2 . The following two theorems are the only known lower bounds, which are presented in terms of the diagonal-flip distance for simplicity. The first one is a variant of Lemma 3 in [40].

Theorem 11 Let π_1 and π_2 be two triangulations of the n -gon. If π_1 and π_2 have k different diagonals, then $\text{fd}(\pi_1, \pi_2) \geq k$.

Let π_1 and π_2 be two triangulations of the n -gon. Consider a sequence Π of diagonal flips that transforms π_1 into π_2 . A diagonal flip $(ab, cd) \in \Pi$ is *auxiliary* if $cd \notin \pi_2$. One also says that the flip (ab, cd) *touches* the vertices a, b, c, d . Let $A(\Pi)$ denote the set of all auxiliary diagonal flips in S . Let $|\Pi|$ denote the number of flips in Π . Then

$$|\Pi| \geq |A(\Pi)| + n - 3. \quad (1)$$

Finally, a triangle of a triangulation is said to be *internal* if it contains three diagonals of the triangulation.

Theorem 12 ([33]) Let π_1 and π_2 be two triangulations of a convex polygon and let v be a vertex of the polygon. Suppose that the following conditions are satisfied:

- (a) v is an end of at least two diagonals in π_2 .
- (b) v is not a vertex of any internal triangles in π_1 or π_2 .
- (c) v is not connected by a π_2 -diagonal to any vertices of internal triangles in π_2 .
- (d) Flipping any π_1 -diagonal adjacent to v does not create a π_2 -diagonal.

Then, there is at least one auxiliary diagonal touching v in any sequence Π of diagonal flips that converts π_1 into π_2 .

As shown in the next subsection, [Theorem 12](#) is useful for estimating the diagonal-flip distance between two triangulations.

6.3 Approximating the Rotation and Diagonal-Flip Distances

Since the rotation and diagonal-flip distance are equivalent, the authors just state results in terms of the diagonal-flip distance.

Suppose that we are given two triangulations π_1 and π_2 with k different diagonals. Since every different π_1 -diagonal has to be flipped, any diagonal-flip transformation from one to another contains at least k flips. On the other hand, by [Theorem 10](#), $2k$ flips are enough to transform π_1 into π_2 . This implies an approximation with ratio 2.

Theorem 13 The diagonal-flip distance can be approximated with ratio 2 in polynomial time.

However, it is very hard to develop a polynomial approximation algorithm with constant ratio <2 for the distance. In what follows, the authors prove a slightly better approximation.

Theorem 14 ([33]) There is a polynomial approximation algorithm that, on the input of two triangulations π_1 and π_2 of the n -gon, outputs a diagonal-flip

Table 1 Transformation algorithm

Input: Two triangulations π_1 and π_2 ;

Do until the following “if” conditions fails

if there are isolated diagonals **then**

pick such an edge e ;

let e' be the unique diagonal that intersects e ;

if $e' \in \pi_1$ then $\pi_1 := \pi_1 + e - e'$ else $\pi_2 := \pi_2 + e - e'$;

Enddo

Let the resulting polygon triangulations have k cells $P_i (i \leq k)$, and let $\pi_j|_{P_i}$ denote the restriction of π_j on P_i for $j = 1, 2$ and $i \leq k$; assume P_i has n_i vertices.

For each cell P_i

pick a node v ;

transform $\pi_1|_{P_i}$ into the unique triangulation π all of whose

diagonals have one end at v using at most n_i steps;

transform π into $\pi_2|_{P_i}$ reversely.

Endfor

transformation of length at most $\left(2 - \frac{2}{4(d-1)(d+6)+1}\right) \text{fd}(\pi_1, \pi_2)$, where d is the maximum number of diagonals adjacent to a vertex in one of the given triangulations.

Proof Let e be a diagonal in π_1 or π_2 . The diagonal e is said to be *isolated* if there is only one diagonal (in the other triangulation) crossing e . Suppose that we are given two triangulations of the n -gon. They may have some diagonals in common in general. All the common diagonals divide the rest of diagonals into disjoint subclasses. Each disjoint subclass together with common diagonals around it is called a *cell*. A desired algorithm is presented in **Table 1**. Obviously, the algorithm takes polynomial time. One analyzes its approximation ratio as follows.

Without loss of generality, one assumes that π_1 and π_2 do not have common diagonals. Suppose that the do loop runs m_1 times for isolated diagonals. Then, after the do loop, π_1 and π_2 have been transformed into triangulations π'_1 and π'_2 which have m diagonals in common. Without loss of generality, one may assume that different diagonals in π'_1 and π'_2 form two triangulations of a convex $(n-m)$ -gon. Note that $\text{fd}(\pi_1, \pi_2) = m + \text{fd}(\pi'_1, \pi'_2)$.

A vertex $v \in P$ is *pure* with respect to π'_i , if it is only an end of π'_i -diagonals. Let V_1 and V_2 denote the sets of pure vertices with respect to π'_1 and π'_2 , respectively. One first proves that

$$\text{fd}(\pi'_1, \pi'_2) \geq (n-m) - 3 + |V_1|/4.$$

Consider a shortest sequence S of diagonal flips that transforms π'_1 into π'_2 . Since there are no isolated edges in both π'_1 and π'_2 , each vertex in V_1 is an end of at least two π_1 -diagonals. By [Theorem 12](#), for each node in V_1 , there is at least one auxiliary flip touching it. Since each auxiliary flip can touch at most 4 vertices, there are at most $|V_1|/4$ auxiliary flips in S . Hence, by Inequality ([Eq. 1](#)), $\text{fd}(\pi'_1, \pi'_2) \geq (n - m) - 3 + |V_1|/4$.

Similarly, by considering pure vertices with respect to π_2 , one is able to prove that $\text{fd}(\pi'_1, \pi'_2) \geq (n - m) - 3 + |V_2|/4$. Combining these two bounds together, one obtains that

$$\text{fd}(\pi_1, \pi_2) \geq (n - m) - 3 + \frac{|V_1| + |V_2|}{8}. \quad (2)$$

On the other hand, one can prove that there are at least $\frac{n-m}{d-1} - 3|V_1| - (d+2)|V_2|$ vertices satisfying the conditions in [Theorem 12](#). Thus, by Inequality ([Eq. 1](#)), $\text{fd}(\pi'_1, \pi'_2) \geq (n - m) - 3 + \frac{n-m}{4(d-1)} - \frac{3|V_1|}{4} - \frac{(d+2)|V_2|}{4}$. Similarly, one has $\text{fd}(\pi'_1, \pi'_2) \geq (n - m) - 3 + \frac{n-m}{4(d-1)} - \frac{3|V_2|}{4} - \frac{(d+2)|V_1|}{4}$. Combining these two inequalities together, one has

$$\text{fd}(\pi'_1, \pi'_2) \geq (n - m) - 3 + \frac{n - m}{4(d - 1)} - \frac{(d + 5)(|V_1| + |V_2|)}{8}. \quad (3)$$

By (2) and (3), $\text{fd}(\pi_1, \pi_2) = m + \text{fd}(\pi'_1, \pi'_2) \geq m + (n - m) \left(1 + \frac{1}{4(d-1)(d+6)}\right) - 3$.

The algorithm transforms π'_1 to π'_2 using at most $M = 2(n - m) + m = 2n - m$ flips, which is less than $\left(2 - \frac{2}{4(d-1)(d+6)+1}\right) \text{fd}(\pi_1, \pi_2)$. This finishes the proof. \square

Furthermore, [33] also presented a polynomial approximation algorithm with ratio 1.97 for the diagonal-flip transformation between two triangulations without internal triangle. Such a triangulation corresponds to a rooted binary tree without degree-3 internal nodes.

6.4 Miscellaneous Remarks

The diagonal-flip operation was early studied by Wagner [44] in the context of arbitrary triangulated planar graphs and by Dewdney [10] in the case of graphs of genus one. They showed that any such graph can be transformed to any other by diagonal flips. However, they did not try to accurately estimate how many flips are necessary. After [40] was published, the rotation and diagonal-flip operations have been studied in several aspects. Pallo [35] proposed a heuristic search algorithm to compute the rotation distance between two given trees. Hurtado et al. [22] studied diagonal flips in arbitrary polygons. Guibas and Hershberger [16] abstracted polygon morphing as a sequence of rotations on weighted binary trees, and Hershberger and Suri [20] proved that a weighted rooted binary tree can be converted into any other in at most $O(n \log n)$ rotations.

7 Open Questions

In this section, the authors list some open questions concerning the nni and subtree-transfer distances:

1. Give a constant ratio approximation algorithm for the nni distance on unweighted evolutionary trees or prove that the ratio $O(\log n)$ is the best possible.
2. Is the linear-cost subtree-transfer distance NP-hard to compute on weighted evolutionary trees?
3. Can one improve the approximation ratios for subtree-transfer distance on unweighted or weighted evolutionary trees?
4. Are there simple approximation algorithms for the rotation distance with non-trivial ratios?

8 Conclusion

In this chapter, we have surveyed a variety of results on some transformation based distances for evolutionary trees. Admitted, given the vast majority of topics in computational biology, these discussed topics constitute only a part of them. However, we hope that this survey article will inspire the readers for further study and research of these and other related topics.

Abstract

In a graph $G = (V, E)$, a subset C of vertices is called a Connected Dominating Set if every vertex is either in C or adjacent to a vertex in C , and in addition the subgraph induced by C is connected. Given a graph, finding the minimum Connected Dominating Set is a classical combinatorial optimization problem, existing in literature for a long time. Due to wide applications of the minimum Connected Dominating Set in wireless networks, Connected Dominating Sets attract many recent research efforts. In this chapter, those developments are surveyed.

1 Introduction

A few years ago, there was a news at *AP NewsBreak* “Airspeed systems failed on US planes” which contains the following statements:

On at least a dozen recent flights by U.S. jetliners, malfunctioning equipment made it impossible for pilots to know how fast they were flying, federal investigators have discovered. A similar breakdown is believed to have played a role in the Air France crash into the Atlantic that killed all 228 people aboard in June.

While a car's speedometer uses tire rotation to calculate speed, an airplane relies on sensors known as Pitot tubes to measure changing air pressure.

Like the fatal Air France flight, the newly discovered Northwest incidents and the two other malfunctions under investigation all involved planes with sensors made by the European electronics giant Thales Corp. The Air France crash called into question the reliability of the sensors and touched off a rush to replace them.

So, the 228 people were killed by failure of sensors which measure the spread of airplane. This surprising news made sensor an important issue in our life. Nowadays, the sensor is everywhere existing in our daily life. It is usually a small and not so expensive device with three functions, sensing, computation, and communication.

In this chapter, their communication will be studied. There are two types of communication: wired and wireless. This chapter will study wireless communication. There are many types of wireless network, such as wireless sensor network, wireless ad hoc network, and wireless mesh network.

“Wireless network” is a generic term to refer to a kind of network with a number of computing devices which can form an instant network using wireless communication links. Recently, several types of wireless networks including ad hoc network and sensor network have attracted much attention. The networks can be quickly deployed without any preexisting infrastructure and thus have a broad range of applications such as battlefield surveillance, disaster rescue, environmental monitoring, conferences, concert, exact farming, traffic control, and health applications [1, 26]. In the rest of this chapter, the infrastructureless wireless networks will be denoted as *wireless networks*.

The wireless network is widely used in battlefield, environmental monitoring, agriculture, health-care industry, and biological system and traffic control. The society is even under the benefits of wireless network in our daily life, such as WIFI in the public area and mobile phone.

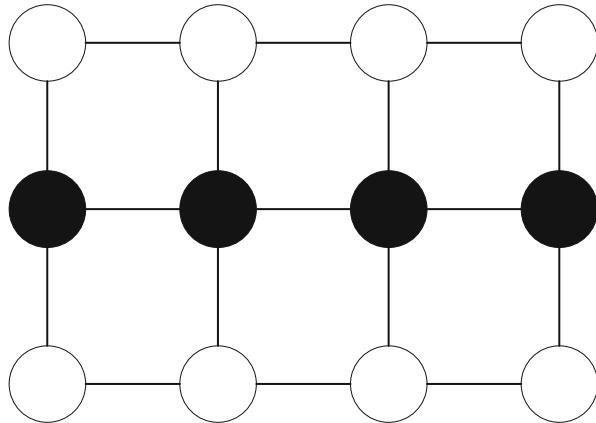

The sensors in the network are incorporated with integrated circuits to provide networking capability. The wireless sensor network essentially is an ad hoc wireless network which is composed of many sensors, also possibly many types of sensors. Usually, there is no central administration in the network, and the network is hardware-infrastructureless. In the wireless sensor network, each sensor is not only a mobile host but also a router. In other words, the sensors are able to forward the received data packages according to routing protocols.

Typically, each node (computing device) in a wireless network has a limited energy source such as a battery. The energy E consumed for transmitting a b bit message is roughly $E = b \cdot c \cdot d^\alpha$, where c is some constant and α is a value between 2 and 5. The equation implies that E increases superlinearly as the transmission distance d grows. As a result, the most dominating communication pattern in wireless network is short-distance multi-hop communication. However, multi-hop routing in a battery-operated wireless network is very challenging due to the dynamic of the network topology and the unique characteristics of wireless communication such as signal interference.

Although the wireless network is so different from the wired network and protocols in the wired network cannot be applied in the wireless network, some technologies of wired networks are still simulated by wireless networks in their developments. One of them is backbone [35], which can be used for reduction of communication overhead and increasing reliability. It is widely believed that Ephremides et al. first introduced an idea of constructing backbone-like structure in conventional wired networks such as the Internet, so-called virtual backbone (black nodes in Fig. 1), to wireless network [34]. In their scheme, a subset of nodes is selected such that (1) every node in a given network is either in the subset or adjacent to a node in the subset and (2) a subgraph induced by the subset is connected. Then, each node is required to communicate with another through the connected subset. This strategy has several apparent benefits for wireless network. Most of all, only the nodes in the structure are involved in routing. This narrows routing search space, reduces the amount of routing-related control messages, and helps a routing protocol to converge faster [71].

Clearly, the advantage of the structure can be magnified as the size of the subset becomes smaller. This motivated many people to investigate for computing smaller virtual backbones in wireless networks. Guha and Kuller modeled the problem of computing a smallest virtual backbone as the minimum Connected Dominating Set (CDS) problem [43]. However, the minimum CDS problem is a very well-known NP-Hard problem [42]. Thus, they introduced approximation algorithms for minimum CDS. Since then, extensive researches have been conducted on the problem of computing quality virtual backbone in wireless network.

Dominating Sets and Connected Dominating Sets are traditional research subjects in graph theory [69].

Fig. 1 Virtual backbone

Definition 1 (Dominating Set (DS)) Given a graph $G = (V, E)$, $V' \subseteq V$ is a DS of $G = (V, E)$ only if $\forall(u, v) \in E$, either $u \in V'$ or $v \in V'$ is true.

Definition 2 (Connected Dominating Set (CDS)) $C \subseteq V$ is a CDS of G if (1) C is a DS and (2) a graph induced by C is connected.

In graph theory, the minimum size of (Connected) Dominating Set in G is called the (*connected*) domination number of G . Determination of the domination number and the connected domination number in various graphs have attracted many research efforts [10, 16] since computing the dominating number and the connected dominating number in general graph is NP-hard [42].

Since Connected Dominating Set plays an important role of virtual backbone in wireless networks, computing the minimum Connected Dominating Set becomes a hot research topic in both theoretical computer science and computer network due to its impact in wireless networks.

In general graphs, several works have been studied in recent research literature. In [43], Guha and Khuller proposed two polynomial-time algorithms to construct a CDS in a general undirected graph G . These algorithms are greedy and centralized. The first one has a performance ratio of $2(H(\Delta) + 1)$ where H is a harmonic function. The idea of this algorithm is to build a spanning tree T rooted at the node with a maximum degree and grow T until all nodes are added to T . The non-leaf nodes in T form a CDS. In particular, all nodes in a given network are marked white initially. The greedy function that the algorithm uses to add nodes into T is the number of the white neighbors of each node or a pair of nodes. The one with the largest such number is marked in black, and its neighbors are marked in gray. These nodes (black and gray nodes) are then added to T . The algorithm stops when no white node exists in G . The second algorithm is an improvement of the first one. This algorithm consists of two phases. The first phase is to construct a Dominating Set and the second phase is to connect the Dominating Set using a Steiner tree algorithm. With such improvement, the second algorithm has a performance factor

of $H(\Delta) + 2$. These algorithms later were studied and implemented by Das et al. [7, 20, 72].

For the localized algorithms, Wu and Li [82] proposed a simple algorithm that can quickly determine a CDS based on the connectivity information within the 2-hop neighborhood. This approach uses a marking process. In particular, each node is marked true if it has two unconnected neighbors. All the marked nodes form a CDS. The authors also introduced some dominant pruning rules to reduce the size of the CDS. In [76], Wan et al. showed that the performance ratio of [82] is within a factor of $O(n)$, where n is the number of nodes in a network.

CDS algorithms can be divided into two types: one is 2-stage and the other one is 1-stage. The 2-stage algorithms can also be divided into two categories. The main idea of the first category is to construct a Dominating Set(DS) and add more nodes to connect DS into CDS. As a result, a CDS is constructed [12, 43, 61, 84]. The other category is to construct a redundant CDS first, then remove some nodes to get a smaller CDS [82]. The main idea of 1-stage algorithms aims to select a CDS directly, skipping the step of selection of a DS or a redundant CDS [43, 67].

Guha and Khuller [43] gave a two-stage greedy approximation within a factor of $3 + \ln \delta$ from optimal for the minimum Connected Dominating Set where δ is the maximum node degree of input graph. They also showed that this is almost the best possible, i.e., there is no polynomial-time approximation for the minimum Connected Dominating Set within a factor of $\rho \ln \delta$ from optimal for any $0 < \rho < 1$ unless $NP \subseteq DTIME(n^{O(\log \log n)})$. This lower bound result is obtained by a transformation from the result of Feige [37] on the set cover problem. Ruan et al. [67] improved upper bound from $3 + \ln \delta$ to $2 + \ln \delta$. Du et al. [29] showed a tight upper bound that the minimum Connected Dominating Set in general graph can be polynomial-time approximated within a factor of $\alpha(1 + \ln \delta)$ from optimal for any $0 < \alpha < 1$.

While virtual backbone in wireless networks becomes a very important topic, the computer science people pay their attention more and more on computing approximation solution for it. Because graph is usually used to represent the network model, minimizing the size of Dominating Set and Connected Dominating Set is much more important in the research of virtual backbone in wireless networks. Constructing DS and CDS is a real-world problem, people in combinatorics group are still finding the better solution for them. This area has many applications and some of them need other requirements, such as message optimal [3], distributed construction [76], strongly connected [28], weakly connected [11, 30], bounded diameter [51], minimum routing cost [23, 25], fault-tolerant [88], r -hop dominating [56], and shortest path condition [81, 82]. Those requirements give more potential research topics about Connected Dominating Set in unit disk graph in the future. In this article, those developments in the direction to approximation solution will be recalled, especially in graphs which are mathematical models of wireless networks. In Sect. 2, the general CDS construction will be introduced. CDS under constraints will also be recalled in Sect. 3. Strongly and Weakly Connected Dominating Set are shown in Sects. 4 and 5. Section 6 will introduce the fault-tolerant CDS construction in wireless networks.

2 General CDS Construction

2.1 Unit Disk Graphs

Usually, a graph is used to represent the network model of wireless networks. The simplest mathematical model is unit disk graph(UDG).

Definition 3 (Unit disk graph (UDG)) $G = (V, E)$ is a UDG if $\forall u, v \in V$; there is a bidirectional edge between u and v if and only if $Eucdist(u, v) \leq 1$.

A *unit disk graph* is associated with a set of unit disks in the Euclidean plane. Each node represents the center of a unit disk. An edge exists between two nodes u and v if and only if the distance between u and v is at most one. Huson and Sen [48] presented the first paper to use UDG to abstract homogeneous (i.e., with the equivalent capabilities) wireless network. More detailed information on the graph theoretical characteristics of UDG can be found in [17].

When researchers study wireless networks, they assume all sensors have the same communication range, and two sensors are able to communicate each other if and only if their distance is within their communication range, which is a disk with certain radius. Therefore, it is isomorphic to a *unit disk graph*.

Computing the minimum Connected Dominating Set in *unit disk graph* has been proved as NP-hard [17]. Therefore, researchers usually design the approximation algorithms for minimum Connected Dominating Set (MCDS) problems. Fortunately, computing approximation solutions for MCDS in UDG is a little bit easier than in general graphs. The first polynomial-time constant approximation is obtained by Wan et al. [76]. The most important part of their work is the frame of their approximation solution. The detail of their method will be introduced in Sect. 2.1.1. Their work is followed later by almost all approximation solutions [9, 38, 39, 58, 61, 77] for the minimum Connected Dominating Set in unit disk graph with good performance which is provable in theory and comparable in computational experiments.

2.1.1 Maximal Independent Set Method

It is a popular way to construct a CDS by constructing a DS first, then connecting the DS into a CDS. For construction of a Dominating Set, the best-known easy way is to build a *maximal independent set (MIS)*. Therefore, the approximation ratio of minimum Connected Dominating Set problem would be determined by two facts. One is the ratio compared *maximal independent set* with *Connected Dominating Set*, and the other is how many nodes are required to connect MIS into a CDS. Clearly, an MIS of a graph is a DS of the graph. Computing a minimum DS is an NP-hard problem [49], and thus computing a minimum IS is NP-hard. An MIS of a graph G can be easily computed using the following graph coloring scheme: (1) initially, color all node white; (2) color one white node black, and its neighbors blue; and (3) repeat Step 2 until there is no white node. As a result, this coloring-based MIS computation strategy is frequently used to compute a DS.

Alzoubi et al. [2, 76] made a great improvement by proposing two 2-phase distributed algorithms. They first construct a spanning tree, then labeled each node in the tree either as a dominator or a dominatee. The algorithms obtained a constant performance ratio which is 8 in UDG. Alzoubi et al. [3] noticed that it is difficult to maintain their previous algorithms of constructing the CDS. Therefore, they designed a localized distributed 2-phase algorithm which can be maintained in general graphs easily. The new algorithm described as follows: first, generate an MIS in a distributed fashion without building a tree or selecting a leader. The node becomes a dominator if it has the smallest ID within its one-hop neighbors. After there are no more white nodes, the dominators will identify a path to connect all the dominators. This algorithm got the performance ratio of 192, and no network connectivity information is utilized in this algorithm. Another localized algorithm is proposed by Li et al. in [58], they reduced the performance ratio from 192 to 172. The localized algorithm in [58] only has one phase which is a node marks itself as a dominator if it can cover the most white nodes compared to its two-hop neighbors.

Definition 4 (Independent set (IS)) An IS I of $G = (V, E)$ is a subset of V such that $\forall u, v \in I, (u, v) \notin E$.

Definition 5 (Maximal independent set (MIS)) An IS I of $G = (V, E)$ is an MIS if $\forall v \in (V \setminus I), I \cup \{v\}$ is not an IS anymore.

Wan's et al. [76] frame also consists of two stages. They construct a Dominating Set in the first stage and connect the Dominating Set into a Connected Dominating Set in the second stage. Since using the maximal independent set method can build an approximation solution, estimating the size of a maximal independent set would be a very important part of analysis of this type of approximation. They consider a minimum Connected Dominating Set C^* . They construct a disk with center u and radius one, called *dominating disk* of u for each node $u \in C^*$. Then the set of dominating disks in C^* will contain all nodes in the graph because C^* is a Dominating Set. By the definition of MIS, all nodes in a maximal independent set are away from each other with the distance larger than one.

Order nodes in $C^* = \{a_1, a_2, \dots, a_{opt}\}$ in such way that every $C_j^* = \{a_1, \dots, a_j\}$ for $1 \leq j \leq opt$ induces a connected subgraph.

First, consider the dominating disk of u , how many independent nodes it can contain? Suppose a_1, \dots, a_k are independent nodes in the dominating disk of u as shown in Fig. 2. Then $\angle a_1ua_2 > 60^\circ, \angle a_2ua_3 > 60^\circ, \dots, \angle a_kua_1 > 60^\circ$. Therefore, $k \leq 5$.

Next, they consider the dominating disk of a_j for $j \geq 2$. How many independent nodes can be contained in the dominating disk of a_j , but not in the dominating disk of a_i for any $i = 1, 2, \dots, j-1$? Suppose b_1, b_2, \dots, b_k are those independent nodes. Since C_j^* induces a connected subgraph, there must exist $i, 1 \leq i \leq j-1$, such that a_i lies in the Dominating Set of a_j . Since b_1, b_2, \dots, b_k do not lie in the dominating disk of a_i . $a_i, b_1, b_2, \dots, b_k$ are independent nodes lying in the dominating disk of a_j . Therefore, $k \leq 4$. This concludes that the total number of independent nodes lying in the union of

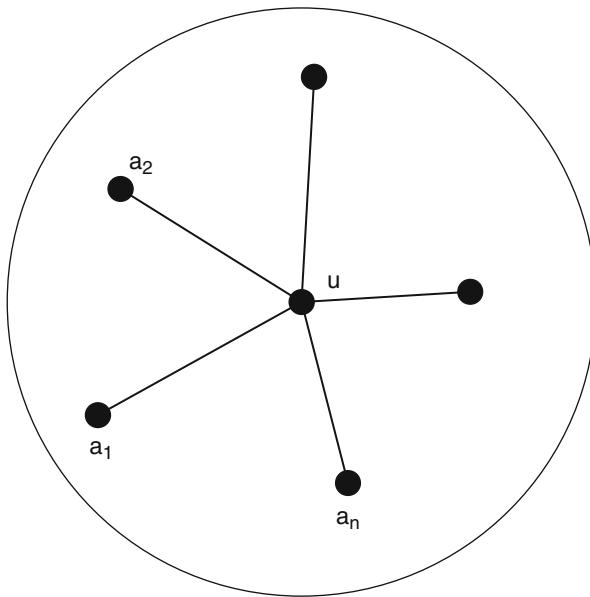

Fig. 2 Independent nodes in a dominating disk of u

dominating disk of nodes in C^* is at most $1 + 4 \text{ opt}$ where $\text{opt} = |C^*|$. This is a key lemma for Wan et al. [76] to show the constant performance ratio of their approximation.

Lemma 1 (Wan et al. [76]) Any maximal independent set has size at most $1 + 4 \text{ opt}$ where opt is the size of the minimum Connected Dominating Set.

2.1.2 Current Best Result For MIS Method

What is the possible best upper bound for the size of a maximal independent set? They have the following conjecture:

Open Problem 1 (Conjecture) In a unit disk graph, any maximal independent set has size $|mis| \leq 2 + 3 \cdot \text{opt}$ where opt is the size of the minimum Connected Dominating Set.

Several methods have established to attack this conjecture. The first method is based on new results on disk packing. Wu et al. [84] showed that:

1. Two dominating disks of u and v with distance at most one can contain at most eight independent nodes.
2. For any UDG, there exists a minimum spanning tree such that every vertex has degree at most five.
3. For every minimum spanning tree T with at least three vertices, it has a non-leaf vertex adjacent to at most one non-leaf vertex.

Based on these facts, they showed that the size of a maximal independent set is at most $3.8 \cdot opt + 1.2$. By the results of [9, 76], the performance ratio can be reduced to 7.8 from 8. Wan et al. [77] showed that for every connected UDG G with at least two nodes, if the dominating disk of u_0 contains u_1, u_2, u_3 , then the union of dominating disks of u_0, u_1, u_2, u_3 can contain at most 15 independent nodes and with this fact, further showed that $|mis| \leq 1 + 3\frac{2}{3} \cdot opt$. In another direction, Wan et al. [77] presented an example to show that $|mis| = 3 \cdot opt + 2$ is reachable.

A simple area argument was proposed by Funke et al. in [38]. They assumed that all nodes have an equal transmission range which is 2, and two nodes are adjacent if the two disks centered at the nodes have intersection. That means the inter distance of these two nodes is at most two. They use this definition instead of the commonly one to simplify their calculations. Then two adjacent nodes have at least $\frac{9}{2} \arccos \frac{1}{3} - \sqrt{2}$ area in common. Thus, there are at most

$$(opt - 1)(\pi 1.5^2 - \frac{9}{2} \arccos \frac{1}{3} + \sqrt{2}) + \pi 1.5^2$$

area in a minimum Connected Dominating Set. For every node y in a *maximal independent set*, draw a disk with center y and radius 0.5. All such disks are disjoint and lie in the adjacent areas of nodes in the minimum Connected Dominating Set. Therefore,

$$|mis| \leq \frac{(opt - 1) \left(\pi 1.5^2 - \frac{9}{2} \arccos \frac{1}{3} + \sqrt{2} \right) + \pi 1.5^2}{0.25\pi} \leq 3.748 \cdot opt + 9$$

Funke et al. [38] claimed a much better bound $|mis| \leq 3.453 \cdot opt + 8.291$ which can reduce the ratio to 6.91. However, the proof involves an unproved fact about disk packing. Therefore, this bound is not recognized as proved.

With a combinatorial method, Gao et al. [41] showed that $|mis| \leq 3.453 \cdot opt + 4.839$ by the comparison of area for MCDS and area for smallest Voronoi cell.

Definition 6 Let S be a set of n sites in Euclidean space. For each site p_i of S , the Voronoi cell $V(p_i)$ of p_i is the set of points that are closer to p_i than to other sites of S , say,

$$V(p_i) = \bigcap_{1 \leq j \leq n, j \neq i} \{p : |p - p_i| \leq |p - p_j|\}.$$

The Voronoi diagram $V(S)$ is the space partition induced by Voronoi cells.

Very recently, Li et al. [57] employed a geometry argument and push this bound further to $|mis| \leq 3.4306 \cdot opt + 4.8185$. They also tight the approximation ratio

of the algorithm in [77] to at most 6.075. They will introduce their main results in detail as follows:

Theorem 1 (Li et al. in [57]) *Let α and γ_c be the independence number and connected domination number of a connected UDG G . Then, $\alpha \leq 3.4306 \gamma_c + 4.8185$.*

They prove the above theorem by an integrated area and length argument. Let U be a minimum CDS of G , and define

$$\Omega = \cup_{u \in U} \text{disk}_{1.5}(u).$$

I is a maximum independent set of G . They used I to construct the Voronoi diagram. For each $o \in I$, its Voronoi cell is represented by V or (o) and the *truncated Voronoi cell* of o is represented by the set V or $(o) \cap \Omega$. It is easy to see that the total area of truncated Voronoi cells of all nodes in I is $|\Omega|$. They partition I into two subsets I_1 and I_2 defined by

$$\begin{aligned} I_1 &= \{o \in I : \text{disk}_{1/\sqrt{3}}(o) \subset \Omega\} \\ I_2 &= I \setminus I_1. \end{aligned}$$

α_1 and α_2 are the size of I_1 and I_2 , respectively. **Lemma 2** provides a lower bound on each truncated Voronoi cell.

Lemma 2 (Li et al. in [57]) *For each o in I_1 (respectively, I_2), the area of its truncated Voronoi cell is at least $\sqrt{3}/2$ (respectively, σ).*

Lemma 3 (Li et al. in [57]) *The length of $\vartheta\Omega'$ is at most $2(1 - 1/\sqrt{3})\alpha_2$, where $\vartheta\Omega'$ is the topological boundary of a set Ω' , and $\Omega' = \cup_{v \in U} \text{disk}_{1.5-1/\sqrt{3}}(v)$.*

By **Lemma 2**, they can get

$$|\Omega| \geq \frac{\sqrt{3}}{2}\alpha_1 + \sigma\alpha_2 = \frac{\sqrt{3}}{2}\alpha - \left(\frac{\sqrt{3}}{2} - \sigma\right)\alpha_2$$

which implies

$$\alpha \leq \frac{|\Omega|}{\frac{\sqrt{3}}{2}} + \left(1 - \frac{\sigma}{\frac{\sqrt{3}}{2}}\right)\alpha_2. \quad (1)$$

It is easy to prove by induction on γ_c that

$$|\Omega| \leq \frac{9}{2} \left((\gamma_c - 1) \left(\arcsin \frac{1}{3} + \frac{\sqrt{8}}{9} \right) + \frac{\pi}{2} \right), \quad (2)$$

and the length of $\vartheta \Omega'$ is at most

$$\begin{aligned} & 2 \left(3 - \frac{2}{\sqrt{3}} \right) \left((\gamma_c - 1) \arcsin \frac{1}{3 - \frac{2}{\sqrt{3}}} + \frac{\pi}{2} \right). \\ \alpha_2 & \leq \frac{2 \left(3 - \frac{2}{\sqrt{3}} \right) \left((\gamma_c - 1) \arcsin \frac{1}{3 - \frac{2}{\sqrt{3}}} + \frac{\pi}{2} \right)}{2 \left(1 - \frac{1}{\sqrt{3}} \right)} \\ & = \frac{\sqrt{3} + 7}{2} \left(\left((\gamma_c - 1) \arcsin \frac{1}{3 - \frac{2}{\sqrt{3}}} + \frac{\pi}{2} \right) \right). \end{aligned} \quad (3)$$

The three inequalities 1, 2, and 3 imply altogether that α is at most

$$\begin{aligned} & (\gamma_c - 1) \left(\sqrt{27} \left(\arcsin \frac{1}{3} - \frac{\sqrt{8}}{9} \right) + \frac{\left(1 - \frac{\sigma}{\frac{\sqrt{3}}{2}} \right) (\sqrt{3} + 7)}{2} \arcsin \frac{1}{3 - \frac{2}{\sqrt{3}}} \right) \\ & + \frac{\pi}{2} \left(\sqrt{27} + \left(1 - \frac{\sigma}{\frac{\sqrt{3}}{2}} \right) \frac{\sqrt{3} + 7}{2} \right) \\ & \approx 3.4305176\gamma_c + 4.8184688. \end{aligned}$$

Thus, Theorem 1 is proved.

2.1.3 Steiner Tree Method

The progress on the second stage is going quite fast when the research on Open Problem 1 is still quite active. A naive way to connect a Dominating Set into a connect Dominating Set is to construct a minimum spanning tree. This construction can be also combined with the construction of maximal independent set. Defer from the previous method, they choose a uncolored node adjacent to a gray node instead of making an arbitrary choice starting from the second iteration. Then there is only one gray node in each “edge” in a minimum spanning tree for black nodes. Thus, they need only $|mis| - 1$ gray nodes to connect all black nodes into a connect Dominating Set. This will form a Connected Dominating Set with size $2|mis| - 1 \leq 6.8612 \cdot opt + 8.637$.

- A popular strategy to compute a CDS of a graph with Steiner tree method is:
1. Compute an MIS I of the graph, which is also a DS.
 2. Add more nodes in $V \setminus I$ to I using a Steiner or spanning algorithm so that the I can be connected.

This strategy is initially introduced by Guha and Kuller [43], and nowadays it is the most common approach to find an approximate solution for the minimum CDS problem.

Of course, it is a better idea to employ the Steiner tree to do minimize the size of Connected Dominating Set.

Definition 7 (Steiner tree) A *Steiner tree* for a given subset of nodes, called *terminals*, in a graph is a tree interconnecting all terminals such that every leaf is a terminal.

Definition 8 (Steiner node) Every node other than terminals in the Steiner tree is called a *Steiner node*.

Clearly, they prefer to minimize the number of Steiner nodes instead of the total edge length for interconnecting Dominating Set. It is the objective in classic Steiner tree problems. This means that they need to study the following problem:

Definition 9 (Steiner tree with minimum number of Steiner nodes (ST-MSN)) Given a unit disk graph G and a Dominating Set D of nodes, compute a Steiner tree for D with the minimum number of Steiner nodes.

Although the ST-MSN problem in *unit disk graph* has not been studied very much, its geometric version in the Euclidean plane has been studied extensively [12, 27, 60]. However, some results cannot be extended to UDG. For example, two points with distance 2 can be connected with a Steiner point in the Euclidean plane. But, two nodes with distance 2 may not be able to be connected by a Steiner node because such a node may not exist. Fortunately, some results in the Euclidean plane can be extended to unit disk graph. By performing such an extension, Min et al. [61] obtained a polynomial-time 3-approximation for the ST-MSN problem which can be extended from the Euclidean plane to UDG with a quite different proof, which becomes a fundamental part in their approximation algorithm. They found that the size of optimal solution for the ST-MSN cannot exceed the size of the minimum Connected Dominating Set that is because the latter can also interconnect the maximal independent set. Therefore, at most $3opt$ Steiner nodes are used in the second step. Hence, they got the approximation solution for the minimum Connected Dominating Set which has size at most $6.8 \cdot opt$ based on the number bound for $|mis|$.

For the classical network Steiner tree problem, Li et al. [58] presented a greedy algorithm with performance ratio of $4.8 + \ln 5$; their algorithm can also be implemented as a distributed algorithm. Their algorithm also has two phases:

1. Find the MIS.
2. Use Steiner tree algorithm to connect the MIS.

The Steiner tree algorithm takes the property which is that there are at most five independent nodes adjacent to one node.

2.1.4 Current Best Result For Steiner Tree Method

Current best approximation is constructed by Robins et al. [66]. They used greedy strategy to present a new polynomial-time heuristic with an approximation ratio approaching $1 + \frac{\ln 3}{2} \approx 1.55$. They reduced result from the previously best-known approximation algorithm of [45] with performance ratio ≈ 1.59 . The same as Li et al. [58], they also use greedy algorithm to achieve the best performance for interconnecting Dominating Set. Actually, it is normal to use greedy algorithms to design this problem such as [39, 58, 77]. Li et al. [58] found that the greedy approximation in [77] has the performance ratio 6.075.

Almost all previous heuristics algorithms which have good approximation ratio choose appropriate full components and then prune them in the interest of keeping them for the overall solution. However, if they may find a better component later, they cannot abandon the previous component which they already selected. It is because two components disagree if they share at least two terminals.

In [66], Robins et al. proposed an algorithm called Loss-Contracting Algorithm ([Algorithm 1](#)). The algorithm will prune the full components and keep them as little as possible so that (a) a chosen full component may still participate into the overall solution but (b) not many other full components would be rejected. For example, if they delete $Loss(K)$, i.e., replace a full component K by $C[K]$, then (a) it will not cost anything to add a full component K in the overall solution and (b) they decrease the gain of full components which disagree with K by a small value such as the value is less than in the Berman-Ramayer algorithm [6] for large k and much smaller than in [50] for any k .

The algorithm first constructed a minimum spanning tree of G_S called $MST(G_S)$ then iteratively modified the terminal-spanning tree T which is originally $MST(G_S)$ by incorporating into T loss-contracted full components greedily chosen from G . The cost of the approximate solution lies between $mst = mst(G_S)$ and opt_k . The intuition behind the gain-over-loss objective ratio is as follows [66]:

1. If they accept a component K , then it increases the gap between mst and the cost of the approximation by gaining a K . Thus, the gain of K is our clear profit.
2. If K does not belong to OPT_k , then after accepting K they would no longer be able to reach Opt_k because they would need to pay for the connection of incorrectly chosen Steiner points. Therefore, the value of $loss(K)$, which is the connection cost of Steiner points of K to terminals, is an upper bound on the increase in the cost gap between opt_k and the best achievable solution after accepting K . Thus, $loss(K)$ is an estimate of our connection expense.
3. Maximizing the ratio of gain over loss is equivalent to maximizing the profit per unit expense.

Theorem 2 (Robins et al. [66]) *For any instance of the Steiner tree problem, the cost approx of the Steiner tree produced by algorithm k-LCA is at most*

$$Approx \leq loss_k \cdot \ln\left(1 + \frac{mst - opt_k}{loss_k}\right) + opt_k.$$

Algorithm 1 Loss-Contracting Algorithm ($k - LCA$) for Steiner Trees in Graphs (Robins et al. [66])

0: **Input:** A complete graph $G = (V, E, \text{cost})$ with *edge costs* satisfying the triangle inequality, a set of terminals $S \subset V$, and an integer $k \leq |S|$
Output: A k -restricted Steiner tree in G connecting all the terminals in S

- 1: $T = MST(G_S)$
- 2: $H = G_S$
- 3: **Repeat forever**
- 4: Find a k -restricted full component K with the maximum $r = gain_T(K)/loss(K)$
- 5: **If** $r \leq 0$ **then exit repeat**
- 6: $H = H \cup K$
- 7: $T = MST(T \cup C[K])$
- 8: **Output** the tree $MST(H)$

2.1.5 PTAS for MCDS in UDG

They might want to know whether there exists a lower bound for the performance ratio of polynomial-time approximation for the minimum Connected Dominating Set in unit disk graph. The truth is there is no such thing. Actually, Cheng et al. [14] already showed that there exists a PTAS (polynomial-time approximation scheme) for MCDS problem.

Definition 10 (PTAS) For any $\varepsilon > 0$, there exists a polynomial-time approximation within a factor of $1 + \varepsilon$ from optimal.

However, the running time of such an approximation is $O(n^{1/\varepsilon^2})$. It cannot be implemented to use in the real world. Therefore, they are still making efforts to look for approximations with a smaller performance ratio and a low-degree polynomial for running time.

Cheng et al. [14] designed a $(1 + 1/s)$ -approximation for the minimum Connected Dominating Set in unit disk graph. The running time is $n^{O((s \log s)^2)}$. There is an evidence [14] to show that currently existing implemented approximations have a large space for improvement. In this section, they will introduce their main results.

An algorithm \mathbb{A} is a PTAS for a minimization problem with optimal cost OPT if the following is true:

Given an instance I of the problem and a small positive error parameter ε :

1. The algorithm outputs a solution with cost at most $(1 + \varepsilon)OPT$.
2. When ε is fixed, the running time is bounded by a polynomial in the size of the instance I .

If there exists a PTAS for an optimization problem, the problem's instance can be approximated to any required degree.

To design a PTAS for MCDS in UDG, they quote the result from [13] which is:

Lemma 4 (Cheng et al. [13]) *There exists a polynomial-time approximation for the MCDS in unit disk graph, with performance ratio 8.*

The general picture of constructing the PTAS for the MCDS in UDG [14] is as follows:

1. Divide a space and make it contain all vertices of the input unit disk graph, into a grid of small cells. For each small cell, take the points h distance away from the boundary (the central area of the cell).
2. Optimally compute a minimum union of Connected Dominating Sets in each cell for connected components of the central area of the cell. The key lemma is to prove that the union of all such minimum unions is no more than the MCDS for the whole graph.
3. For vertices not in central areas, just use the part of an 8-approximation lying in boundary areas (within distance $h + 1$ away from the boundary, with some overlap with the central areas) to dominate them. This part, together with the above union, forms a Connected Dominating Set for the whole input unit disk graph.
4. Using the shifting argument (i.e., shift the grid around to get partitions at different coordinates) to make sure there are at least half good partitions having good approximations overall.

Corollary 1 (Cheng et al. [14]) *There is a $(1 + 1/s)$ -approximation for an MCDS in connected unit disk graphs, running in time $n^{O((s \log s)^2)}$.*

The proof of this corollary can be found in [14].

2.2 Node-Weighted Unit Disk Graph

In real world, different sensors do not have the same value. Therefore, when wireless sensor networks contain many types of sensors with the same transmission range but different costs, the mathematical model would be changed to the unit disk graph with node weight. For virtual backbone, they would prefer to have Connected Dominating Set with minimum total weight rather than Connected Dominating Set with minimum cardinality.

If they want to use the same construction method as unit disk graph, they should construct the minimum-weight Dominating Set first. However, they could not continue using the maximal independent set method, because, there is no efficient way for constructing a minimum-weight MIS unless $NP = P$ [42]. Actually, how to construct a constant-approximation algorithm for minimum-weight Dominating Set in UDG is still an open problem.

In 2006, Ambühl et al. [5] presented a 72-approximation algorithm for this problem by using the partition technique. Gao et al. [40] introduced a new technique, called *double partition* in 2008. They proposed an algorithm with performance ratio of $6 + \varepsilon$. A year later, Dai et al. [19] reduced the ratio to $5 + \varepsilon$. Zou et al. [90] further improved the performance ratio to $(4 + \varepsilon)$ in the same year.

For connecting the DS into minimum-weight Connected Dominating Set in unit disk graph, Ambühl et al. [5] spent $17opt$ to connect their previous solution and got an 89-approximation for minimum-weight Connected Dominating Set where opt is the object function value of an optimal solution which is the minimum total weight of Connected Dominating Set. Gao et al. [40] decreased the cost for interconnection to $4opt$. Zou et al. [92] further reduced the cost to $2.5\rho \cdot opt \approx 3.875opt$, where ρ is the best-known performance ratio for polynomial-time approximation of classical Steiner minimum tree problem in graphs. This result can be used to connect a Dominating Set by adding nodes of weight at most 2.5ρ times the weight of an optimal Connected Dominating Set, yielding the approximation ratio of 8.875 for MWCDS. Later Zou [90] and Erlebach et al. [36] both obtained $4 + \varepsilon$ -approximation for minimum-weight Dominating Set, and this result will maintain a 7.875-approximation for MWCDS, which improves the previously best approximation ratio of 8.875.

In [90], they used dynamic programming algorithm for the *min-weight chromatic disk cover* to propose a $(4 + \varepsilon)$ -approximation algorithm for **MWDS**. For a given set \mathbb{D} of unit disks, they assign positive weight to each disk by a function c and a set P of nodes in the plane. They colored each disk $D \in \mathbb{D}$ either red or blue. Assume there are $m + 1 \geq 2$ distinct horizontal lines $y = y_i$ for $0 \leq i \leq m$ from the top to the bottom, where m is a nonnegative integer constant. Therefore, the $m + 1$ lines separate the plane into $m + 2$ horizontal strips. A node $p \in P$ is chromatically covered by a red/blue disk $D \in \mathbb{D}$ if $p \in D$ and the center of D is above/below the strip which contains p . A *chromatic cover* of P is a subset $D \in \mathbb{D}$ which each node in P is chromatically covered by some disk in \mathbb{D}' . The *min-weight chromatic disk cover* (**MWCDC**) problem is to find a min-weight chromatic cover $D \in \mathbb{D}$ of P . They proved that there is a polynomial $(4\rho + \varepsilon)$ -approximation algorithm for the MWDS for any fixed ε by proposing a ρ -approximation algorithm for the **MWCDC**.

In [36], Erlebach et al. proposed a $(4 + \varepsilon)$ -approximation algorithm for **MWDS** in unit disk graph. Their algorithm is based on several ideas of previous constant-factor approximation algorithms for the problem [5, 47]. They first partitioned the plane into $K \times K$ areas where K is an arbitrary constant. They considered the following subproblem for each of these areas:

Find a minimum-weight set of disks that dominate all disks that have a center in the area.

The union of feasible solutions for each subproblem produces a Dominating Set for the original problem. For the shifting technique presented in [47], the loss in the approximation factor is only $(1 + O(1)/K)$. Therefore, the (best) combination of the solutions is a $(\rho + O(1)/K)$ -approximation for the original problem if the solution for every subproblem is a ρ -approximation by using the shifting technique.

Thus, they can set K such that the obtained solution is a $(\rho + \varepsilon)$ -approximation for any constant ε . They presented a 4-approximation algorithm for the subproblem. By using the shifting technique and setting K appropriately, the algorithm forms a $(4 + \varepsilon)$ -approximation algorithm.

2.2.1 2.5ρ Approximation Algorithm in [92]

The main idea of this algorithm is based on the classical Steiner tree problem. They first constructed an edge-weighted graph G'' with the same node and edge set as the original graph G . Then, they defined the weight of every edge in G'' as the half of the sum of its endpoints' weights in G . Finally, they used ρ -approximation algorithm to obtain a Steiner tree of G'' . From the Steiner tree of G'' , they can get a Steiner tree of G with approximation ratio $2.5\rho \approx 3.875$. In [Corollary 2](#), they obtained a $8.875 + \varepsilon$ algorithm for minimum-weight Connected Dominating Set in unit disk graph.

1. Preliminaries

In this section, they introduce some useful definitions and denotations in [\[92\]](#). For a node-weighted (or edge-weighted) graph G with weight function w and a subgraph H of G , they use $w(H)$ to represent the weight sum of all nodes (or edges) in H . For any two nodes u and v of G , $dist_G(u, v)$ is the weight of the shortest path between u and v , which is calculated as $\min \sum_{v_k \in P} w(v_k)$ among all the possible paths between u and v which v_k is the internal node on every possible path p . Given an edge-weighted graph G and a node subset S , they use $SMT(G, S)$ and $MST(G)$ to represent the ρ -approximation algorithm for Steiner minimum tree (SMT) and the algorithm for finding minimum spanning tree (MST).

2. 2.5ρ Approximation Algorithm (Zou et al. [\[92\]](#))

The idea of this algorithm is to convert the node-weighted Steiner tree problem to the classical Steiner tree problem. There are three steps:

- Construct an edge-weighted graph G'' from G as follows by initializing G'' with the same node set and edge set as G and an edge weight function w' . For every edge $e = (u, v)$ in G'' , let the edge weight $w'(u, v) = \frac{1}{2}(w(u) + w(v))$.
- Compute a Steiner tree T of G'' on S through the ρ -approximation algorithm.
- View T as the node-weighted Steiner tree of G on S and output it.

The pseudo-code of this algorithm is presented in [Algorithm 2](#).

Algorithm 2 $NWST(G = (V, E, w, S))$ (Zou et al. [\[92\]](#))

- Initialize an edge-weighted graph $G' = (V', E', w', S')$ by setting $V' = V, S' = S$ and $E' = E$
 - for** each edge (v_i, v_j) in graph G' **do**
 - Assign the weight of this edge $w'(v_i, v_j) = (w(v_i) + w(v_j))/2$
 - end for**
 - $T = SMT(G', S)$
 - Output T
-

Since G is a unit disk graph, for any terminal set S , there always exists a minimum Steiner tree with maximum degree no more than 5 [61]. The following lemma proves the relationship between the weight of the optimal SMT in graph G' and the weight of the optimal NWST they want.

Lemma 5 (Zou et al. [92]) Denote $T_{OPT_{SM}}$ as the optimal Steiner minimum tree for G'' on the set S and $T_{OPT_{NWS}}$ as the optimal node-weighted Steiner tree of G on the same terminal set S , respectively. Then $w'(T_{OPT_{SM}}) \leq 2.5w(T_{OPT_{NWS}})$ when G is a unit disk graph.

Proof (Zou et al. [92]) Consider $T_{OPT_{NWS}}$ as a Steiner tree on S of G'' . For convenience, denote T as $T_{OPT_{NWS}}$, V as $V(T_{OPT_{NWS}})$, E as $E(T_{OPT_{NWS}})$, and $d_T(u)$ as the degree of node u in tree T ; they have

$$\begin{aligned} w'(T_{OPT_{SM}}) &\leq w'(T_{OPT_{NWS}}) = \sum_{e=(u,v) \in E} \left(\frac{1}{2}(w(u) + w(v)) \right) \\ &= \sum_{u \in V} \frac{d_T(u)}{2} w(u) \leq \frac{5}{2} w(T). \end{aligned}$$

Hence, the lemma holds.

If they consider the Steiner tree T of G'' as a subgraph of G , they can get the following lemma:

Lemma 6 (Zou et al. [92]) For any Steiner tree T of G'' on terminal set S , if they view it as a subgraph G , then T is also a Steiner tree of G on set S and $w(T) \leq w'(T)$.

Proof (Zou et al. [92]) Since for any Steiner tree, the degree of each Steiner node is not less than 2 and all weight of nodes in terminal set is 0, the lemma holds.

Theorem 3 (Zou et al. [92]) Algorithm NWST is a 2.5ρ -approximation for node-weighted Steiner tree problem in unit disk graph.

Proof (Zou et al. [92]) Let T be the output of NWST. Denote $T_{OPT_{SM}}$ and $T_{OPT_{NWS}}$ as Lemma 5. By Lemmas 5 and 6, they have

$$w(T) \leq w'(T) \leq \rho w'(T_{OPT_{SM}}) \leq 2.5\rho w(T_{OPT_{NWS}}).$$

Since the node-weighted Steiner tree can be used in the MWCDS problem to interconnect all nodes of the CDS, they can obtain the following corollary:

Corollary 2 (Zou et al. [92]) *Using node-weighted Steiner tree to interconnect all nodes of the CDS produces $(9.875 + \varepsilon)$ -approximation for minimum-weight Connected Dominating Set in unit disk graph.*

Proof (Zou et al. [92]) For any node-weighted graph G and a terminal set S , denote T_{OPT} and $T_{OPT_{CDS}}$ be the optimal Steiner tree of G on S and optimal CDS of G , respectively. Since the induced graph $G[S \cup T_{OPT_{CDS}}]$ is connected, this graph contains a Steiner tree of G on S . Thus, $w(T_{OPT}) \leq w(T_{OPT_{CDS}})$. By Huang et al. [47], they can get a Dominating Set C of G with $w(C) \leq (6 + \varepsilon)w(T_{OPT_{CDS}})$. Then, using algorithm NWST for C , they can obtain a Steiner tree T with $w(T) \leq 2.5\rho w(T_{OPT})$. Clearly, $V(T)$ is a Connected Dominating Set of G and

$$\begin{aligned} w(V(T)) &= w(C) + w(T) \leq (6 + \varepsilon)w(T_{OPT_{CDS}}) + 2.5\rho w(T_{OPT}) \\ &\leq (9.875 + \varepsilon)w(T_{OPT_{CDS}}). \end{aligned}$$

2.2.2 PTAS for MCDS in Node-Weighted UDG

The same as the MCDS in UDG, they have the following question:

Open Problem 2 *Does the minimum-weight Dominating Set have a PTAS in unit disk graphs?*

Nieberg et al. [64] developed a technique, called the *local neighborhood-based scheme technique*. A PTAS for minimum Dominating Set in polynomial growth bounded graphs is constructed. Because the unit disk graph is also a polynomial growth-bounded graph, Wang et al. [80] tried to use the local neighborhood-based scheme technique to find a PTAS in node-weighted UDG. They are successful in some special case. However, it is still open in general.

Because the running time for all approximations constructed with partition techniques is very high, it is hard to implement for application in the real world. Therefore, the following open problem receives more attention:

Open Problem 3 *Can they construct a constant approximation for the minimum-weight (Connected) Dominating Set in unit disk graphs without using partition?*

2.3 Unit Ball Graph

In most cases, people studied the MCDS problem in homogeneous wireless networks. They also assumed that all nodes in the networks are on a two-dimensional space and used unit disk graph (UDG) to abstract the networks. However, sometimes, this assumption is very far from reality. Underwater sensor networks (USNs) is a good example. USN can be used for ocean sampling networks, undersea explorations, distributed tactical surveillance, disaster prevention, assisted navigation, ocean environmental monitoring, etc. In many applications of USNs, underwater sensor nodes are floating around water instead of staying on the bottom

of the ocean. In this case, the height of nodes becomes considerably important. Therefore, when identical sensors are deployed into a field which is not flat, the mathematical model would be the unit ball graph.

Definition 11 (Unit ball graph(UBG)) A graph is called a *unit ball graph* if all its nodes lie in the three-dimensional Euclidean space, and an edge (u, v) exists if and only if the distance between u and v is at most one.

In other words, if they let each node u associate a ball with center u and diameter one, called a *unit ball*, then edge (u, v) exists if and only if ball u and ball v intersect each other. Since MCDS problem in UDG is NP-hard, and UDG is a special case of UBG, MCDS problem in UBG is also NP-hard.

There are also two stages for constructing a Connected Dominating Set in unit ball graph. The same as in UDG, they construct a maximal independent set first. Therefore, they need to find an upper bound for the size of maximal independent set. To do this, they have to study the following sphere packing problems.

Call the ball at center u with radius one the *dominating ball* of node u . The following is the first packing problem that they would like to study:

How many independent nodes can lie in the dominating ball of a node?

This problem has a close relationship to Gregory-Newton Problem, a well-known packing problem as follows:

How many unit balls can touch a unit ball such that they do not touch each other?

Gregory-Newton Problem was proposed in 1694 and conjectured as 12. Hoppe in 1874 (see [86]) proved that the answer is 12. Actually, an icosahedron has 12 vertices and the distance from the center to a vertex is smaller than the edge length. Therefore, they have

Corollary 3 ([46]) *The maximum degree of a minimum spanning tree T in a UBG G is at most 12.*

Lemma 7 ([46]) *For any vertex u in a UBG G , the neighborhood $N_G(u)$ contains at most 12 independent vertices.*

Hence, they can simply obtain $|mis| \leq 11 \cdot opt + 1$ in unit ball graph by the argument similar to the proof for $|mis| \leq 4 \cdot opt + 1$ in unit disk graph. The result can be improved by study the following question:

Open Problem 4 *How many independent nodes can lie in the union of dominating balls of two nodes with distance at most one?*

There are only a few work that has been done for studying the approximation algorithms for minimum Connected Dominating Set problem in unit ball graph. Hansen and Schmutz studied the expected size of a CDS in a random UBG [44]. In 2007, Butenko et al. [8] presented a distributed algorithm for MCDS in UBG

and proved that the performance ratio of their algorithm is 22 which means there are at most 22 independent nodes that can lie in the union of dominating balls of two nodes with distance at most one. Zou et al. [91] introduced a centralized heuristic algorithm whose performance ratio is $13 + \ln 10 \approx 15.302$. Zhong et al. [89] proposed a distributed algorithm and claimed its approximation ratio to be 16. However, when Kim et al. [53] did the same work later, they found that Zhong et al.'s algorithm is flawed and the performance analysis is incorrect. Kim et al. [53] studied how to construct quality CDS in UBG in distributed environments and showed the performance ratio is 14.937 which is the current best result.

For the second stage of connecting a maximal independent set into a Connected Dominating Set, the minimum spanning tree [8] and greedy algorithms [93] can also be used. They are all simple extensions from the Euclidean plane to the three-dimensional Euclidean space.

2.3.1 Currently Best Result

Kim et al. proposed the current best result in 2010. The contributions they made can be summarized as follows:

1. They first figure out how many independent nodes can be contained in the union of two adjacent unit balls.

Lemma 8 (Kim et al. [53]) *The number of independent nodes in $(B_1 \cup B_2) \setminus (B_1 \cap B_2)$ is at most 20.*

Lemma 9 (Kim et al. [53]) *The number of independent nodes in the union of two adjacent unit balls is at most 22.*

By combining their new result with some existing one, they reduced the upper bound for the size of a maximal independent set in a UBG from $11OPT_{CDS} + 1$ in [8] to $10.917 OPT_{CDS} + 1.083$, where OPT_{CDS} is the size of an optimal CDS of the UBG.

Theorem 4 (Kim et al. [53]) *Let M be an MIS of a UBG G . Then $|M| \leq 10.917 OPT_{CDS} + 1.083$, where OPT_{CDS} is the number of vertices in an optimal CDS of G .*

2. Different from others, they first presented a centralized algorithm C-CDS-UBG. The reason they introduced C-CDS-UBG first is that it is both easier to show its performance ratio than for the distributed algorithm and simpler to understand its behavior. C-CDS-UBG has two stages:
 - (a) Compute an MIS.
 - (b) Connect MIS into CDS by using greedy strategy.
- They showed that the performance ratio of C-CDS-UBG is 14.937.
- Here are some notations in [Algorithm 3](#) :
- $N(u) = \{v | v \in V(G) \setminus \{u\}\}$.
 - $N[x] = N(x) \cup \{x\}$.

Algorithm 3 $C - CDS - UBG(G(V, E))$ (Kim et al. [53])

```

1: Set  $M_0 = \emptyset$ ,  $W = \emptyset$ ,  $V' = V$ 
2: Pick a root  $r \in V'$  with a maximum degree
3: Set  $M_0 = r$ ,  $W = N(r)$ , and  $V' = V' \setminus (r \cup N(r))$ .
4: while  $V' \neq \emptyset$  do
5:   Pick  $x \in N(W)$  such that  $|N(x) \cap V'|$  is maximized.
6:   Set  $M_0 = M_0 \cup x$ ,  $W = W \cup (N(x) \cap V')$ , and  $V' = V' \setminus (x \cup N(x))$ .
7: end while
8: Set  $C = r$  and  $M = M_0 - r$ .
9: while  $M \neq \emptyset$  do
10:   Pick a node  $v \in N(C)$  such that  $|M_{v,C}| = \max |M_{x,C}| \mid x \in N(C)$ 
11:   Set  $C = C \cup v \cup M_{v,C}$  and  $M = M \setminus M_{v,C}$ 
12: end while
13: return  $C$ 

```

- For a node set C , $N(C) = (\cup_{x \in C} N(x)) \setminus C$.
- $M_{v,C}$ is a set of MIS nodes adjacent with v and not in C .

Lemma 10 (Kim et al. [53]) After Algorithm 3 is finished, $|C \setminus M_0| \leq 4.02|OPT_{CDS}|$, where OPT_{CDS} is an optimal CDS of G .

Theorem 5 (Kim et al. [53]) The size of the node set C generated by Algorithm 3 is no more than $14.937|OPT_{CDS}| + 1.083$, where OPT_{CDS} is an optimal CDS of G .

Proof (Kim et al. [53]) By Theorem 4, $|M_0| \leq 10.917|OPT_{CDS}| + 1.083$, and by Lemma 10, Algorithm 3 adds at most $4.02|OPT_{CDS}|$ to connect the nodes in M_0 . Therefore,

$$\begin{aligned}
|C| &= \sum_{i=1}^t \sum_{x \in M_0 \cap S_i} w(x) + |M_0| \leq 4.02t + 10.917|OPT_{CDS}| + 1.083 \\
&\leq 14.937|OPT_{CDS}| + 1.083.
\end{aligned}$$

3. They introduce a distributed algorithm D-CDS-UBG which is referred from C-CDS-UBG. Therefore, the performance ratio is also 14.937.

2.3.2 PTAS in UBG

Not every technique used in the Euclidean plane can be used in the three-dimensional Euclidean space. For example, the technique for constructing PTAS for MCDS in UDG [14] does not work in three-dimensional Euclidean space, because Cheng et al.'s [14] proof depends on a geometrical property which holds in the plane but is not true in the space. Zhang et al. [87] discovered a new technique to overcome this difficulty and showed that in any Euclidean space, the minimum Connected Dominating Set in unit ball graph has PTAS. They introduced a new

Algorithm 4 PTAS for UBG(Zhang et al. [87])

Input: The geometric representation of a connected unit ball graph G and a positive real number $\varepsilon < 1$.

Output: A Connected Dominating Set D of G .

- 1: Let $m = \lceil 300\rho/\varepsilon \rceil$ where ρ is the performance ratio of a constant approximation for MCDS in UBG.
- 2: Use the ρ -approximation algorithm to compute a Connected Dominating Set D_0 of G . For each $a \in 0, 1, \dots, m - 1$, denote by $D_0(a)$ the set of vertices of D_0 lying in the boundary region of $P(a)$. Choose a^* with the minimum $|D_0(a)|$.
- 3: For each cell e of $P(a^*)$, denote by G_e the subgraph of G induced by the vertices in the central region C_e . Compute a minimum subset D_e of vertices in e , such that

$$\text{for each component } H \text{ of } G_e, G[D_e] \text{ has a connected component dominating } H. \quad (4)$$

- 4: Let $D = D_0(a^*) \cup \bigcup_{e \in P(a^*)} D_e$.
-

construction, which gave not only a PTAS for the minimum Connected Dominating Set in unit ball graph but also improved running time of PTAS for unit disk graph. In fact, their method can be used to compute CDS for any n-dimensional unit ball graph. In this section, they will introduce their main results.

Lemma 11 (Zhang et al. [87]) *The output D of the Algorithm 4 is a CDS of G*

Lemma 12 (Zhang et al. [87]) *The Algorithm 4 runs in time $n^{O(1/\varepsilon^2)}$*

Theorem 6 (Zhang et al. [87]) *The Algorithm 4 is a $(1 + \varepsilon)$ -approximation for CDS in UBG.*

The proof of Algorithm 4 is in [87].

3 Connected Dominating Set Under Constraints

Wireless network is always a hot topic in research community because of its wide military and civil use. Different from wired networks, there is no physical infrastructure in wireless networks. On-demand routing and table-driven protocols cannot be used in wireless networks [75]. Hence, the idea of virtual backbone [15] in wireless network is well acknowledged and widely studied. Virtual backbone can save searching time for routing and reduce routing table size.

A *Connected Dominating Set* (CDS) is regarded as a good option acting as a virtual backbone. CDS can also have applications in routing, broadcasting, coverage, etc.

CDS's construction will have a close relation to the performance of wireless networks. If the size of CDS is too large, then the cost of CDS-based broadcasting will increase since more nodes will be involved to help forward in the networks. Then more redundancy and interferences will be generated in the network too. Hence, a wireless network prefer small CDS. However, broadcasting is not the only operation in wireless network. Routing also happens very frequently in the network. If they reduce CDS size too much, routing cost will increase. In Fig. 3, nodes 4, 5, and 6 construct a minimum CDS. The hop distance between 1 and 3 is 2 and the shortest path between 1 and 3 is $p_{shortest} = \{1 - 2 - 3\}$. However, the routing path between 1 and 3 going through the CDS becomes $P^S = \{1 - 4 - 5 - 6 - 3\}$ of hop distance 4, twice of that of shortest path. Thus, when they construct a CDS, routing operation should also be taken into consideration and the size of the CDS is not the only criteria used to evaluate the performance of a CDS.

In [62], Mohammed et al. proposed the concept of *diameter* to evaluate the performance of a CDS. *Diameter* is defined as the length of the longest-shortest path of the graph, where shortest path between any pair of nodes is the path having the smallest hop count among all paths between the pair of nodes. Later, Kim et al. proposed a definition of Average Backbone Path Length (ABPL) which is used to evaluate the average routing path length in a graph in [51]. If the *diameter* and ABPL of the subgraph induced by a CDS is small, then the CDS is regarded as an efficient CDS. However, both [62] and [51] cannot provide guaranteed routing cost. In [23], MOC-CDS was proposed,

How to choose a CDS will determine backbone-based routing protocols' performance in wireless networks. If the size of the CDS is too large, it is difficult to maintain it and searching time and routing table size cannot be reduced significantly. If the size of the CDS is too small, some characteristics in original networks may not be preserved. For instance, in routing protocols, the length of routing path is an important factor. The smaller the length is, the fewer nodes will be involved in routing process. The benefit is that delivery delay, energy cost, and interference will be reduced since fewer nodes will participate in forwarding packets. In [62], Mohammed et al. also pointed out that in wireless networks, the probability of message transmission failure often increases when a packet is sent through a longer path. Therefore, when designing a routing protocol, they should take path length into consideration, which can be viewed as routing cost. The shorter the routing path is, the less the routing cost will be. That is why shortest path is applied to many routing protocols. However, most current CDS-based routing protocols only focus on how to reduce the size of CDS while sacrificing shortest path properties in original networks. For example, in Fig. 3a, the shortest path between A and C is $\{1, 2, 3\}$ with length of 2. However, through the chosen minimum CDS, the routing path between A and C will become $\{1, 4, 5, 6, 3\}$, with length twice as the original shortest path.

To achieve efficient CDS-based routing and broadcasting at the same time, in [22], the author studied a CDS problem – *Shortest Path Connected Dominating*

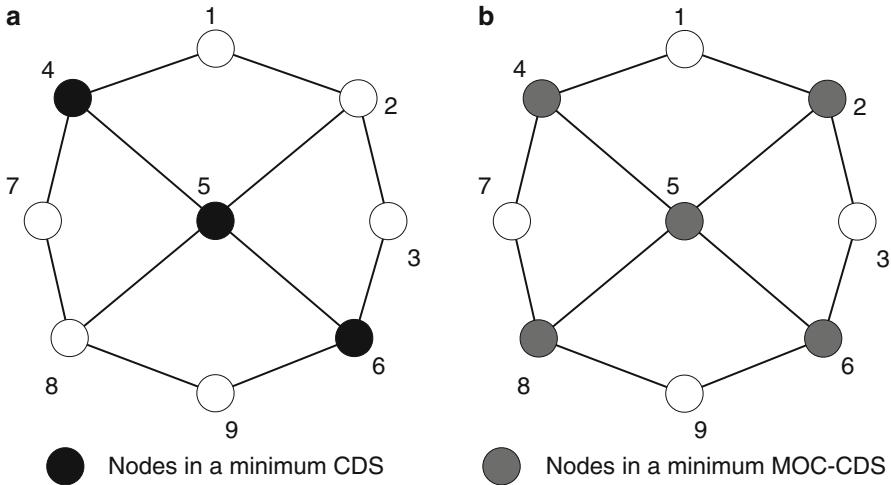

Fig. 3 Illustration of regular CDS and MOC-CDS. (a) A minimum regular CDS. (b) A minimum MOC-CDS

Set (SPCDS), which is a minimum node set including all intermediate nodes in every shortest path between any two nodes in the network. Due to this constraint, the length of path between any two nodes will not be increased even if the path is constructed through SPCDS. In [23], they study a special CDS problem – *Minimum rOuting Cost Connected Dominating Set* (MOC-CDS). First of all MOC-CDS is also a CDS. In addition, MOC-CDS has a constraint that between any pair of nodes, there exists at least one shortest path in the network, all of whose intermediate nodes must be included in MOC-CDS. Thus, packages can be delivered through MOC-CDS with the same routing cost as that in the original network. For example, in Fig. 3b, according to the constraints of MOC-CDS, node (2, 4, 5, 6, 8) are selected forming a minimum MOC-CDS. Hence, the shortest path between 1 and 3 will still be {1, 2, 3} with same length of 2 as that in the original network. However, the size of CDS will increase a lot when they put shortest constraint on CDS. To solve this problem, in [24], the shortest constraint is relaxed. The problem named as α *Minimum rOuting Cost Connected Dominating Set* (α -MOC-CDS) is studied. Besides all properties of regular CDS, α -MOC-CDS also has a special constraint – for any pair of nodes, there is at least one path all intermediate nodes on which belong to α -MOC-CDS, and the number of the intermediate nodes is smaller than α times of that on the shortest path in the original network. α -MOC-CDS is also studied in [32]. To save the energy in the unnecessary directions, directional antennas are used in [25] and MOC-DVB is studied.

In Sect. 3.1, they will recall the network models first. The details of the construction of the CDS under constraints will be introduced in Sect. 3.2.

3.1 Network Model

The network without directional antennas is modeled as a general graph when obstacles [65] exist or transmission radius are different in one network. If no obstacles exist and transmission ranges are same in one network, the network is modeled as a unit disk graph. When the directional antennas are used, the network is modeled as a directional graph where obstacles exist and transmission ranges are same.

3.1.1 General Graph

Two nodes can communicate when they satisfy two requirement.

The first one is transmission range constraint. In wireless networks, nodes may be from different providers. In one network, nodes may have different transmission ranges. In general graph model, two nodes can communicate with each other when they are in each other's transmission ranges. Two nodes cannot communicate when one is in the other one's transmission range but the other one is not in the "one's" transmission range.

The second one is non-obstacle constraint. Communications in wireless network are based on radio wave transmissions which are easily prevented by obstacles (like buildings, mountains). If two nodes satisfy the first constraint and there is no obstacle between them, then the two nodes can communicate. Otherwise, they cannot communicate even though they are physically close to each other enough.

In sum, two nodes can communicate when and only when they are close to each other and no obstacles exist between them. A general graph is denoted as $G = (V, E)$. V is a node set in the network. For each pair of nodes in the network, if there is a directed link between them in the network, then there exists an edge in E .

3.1.2 Unit Disk Graph

In unit disk graph (UDG) networks, it is assumed that all nodes in one network have the same transmission range and no obstacles are in the network. Any two nodes can communicate when and only when they satisfy the first constraint mentioned in Sect. 3.1.1. A UDG is denoted as $G = (V, E)$ where V is a node set and E is an edge set.

3.1.3 Directed Graph

In directed graph network, directional antennas are used. And you can choose the directions to forward messages through switching on antennas. In this kind of network, it is assumed that all nodes have the same transmission range and obstacles are there. There are two kinds of reception models – directional reception and omnidirectional reception. In their work, omnidirectional reception is used. Uniform and nonoverlapping directional antennas are used.

Directional antennas will divide one node's transmission range into uniform sectors. In Fig. 4, four uniform directional antennas are deployed on each node.

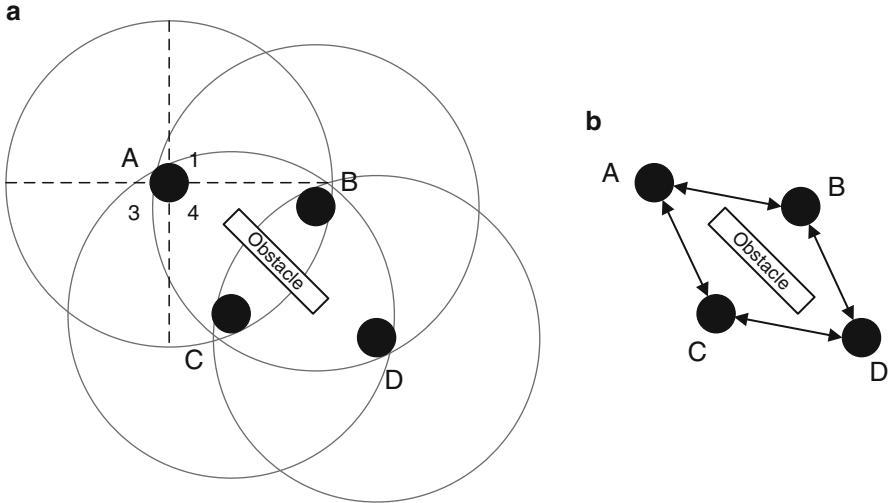

Fig. 4 Directed graph

Hence, each node's transmission range is divided to four sectors. Sector i of node u is denoted as u^i . In Fig. 4, the first sector of A is denoted as A^1 . Nodes B and C are in the fourth direction of A (A^4). If A^4 is switched off, then B and C cannot receive any messages from A , even though they are in A 's transmission range.

Thus, in directed graph network, if one node v wants to receive messages from node u , they must first satisfy two requirement in Sect. 3.1.1, and they also need to satisfy that u 's sector where v is switched on. Compared to the prior two models with node set and edge set, a directed graph has a direction set (sector set). Thus, one directed graph is denoted as $G = (V, E, S)$, where V is a node set, E is an edge set, and S is a sector set. In Fig. 4, $V = \{A, B, C, D\}$, $E = \{A^4 \rightarrow B, A^4 \rightarrow C, B^4 \rightarrow D, B^2 \rightarrow A, C^2 \rightarrow A, C^4 \rightarrow D, D^2 \rightarrow B, D^2 \rightarrow C\}$, $S = \{A^1, A^2, A^3, A^4, B^1, B^2, B^3, B^4, C^1, C^2, C^3, C^4, D^1, D^2, D^3, D^4\}$.

The three models are used in the following algorithms in Sect. 3.2. In every model, the length of a path is equal to the hop count of the path. And the distance of two nodes is the hop distance which is equal to the hop count on the shortest path between the two nodes.

3.2 Construction of CDS Under Constraints

To construct a CDS with guaranteed routing cost, many researches are done on this topic. In [82], Wu et al. proposed an algorithm to construct a CDS. The first step in [82] is to find a CDS including all intermediate nodes of all shortest path. Actually, this CDS in the first step can solve in polynomial time, which is studied in [22].

3.2.1 An Exact Algorithm to Construct SPCDS

SPCDS is a CDS. SPCDS also has another constraint that for each pair of nodes, the intermediate nodes on all shortest path should be in the SPCDS. To solve SPCDS, an equivalent problem 2PCDS is proposed in [22]. 2PCDS is a CDS firstly. 2PCDS also requires that all intermediate nodes on shortest path of distance 2. It is proved in [22] that SPCDS is equivalent to 2PCDS.

Lemma 13 *SPCDS and 2PCDS is equivalent to each other.*

Proof The first part is to prove that an SPCDS is a 2PCDS. In SPCDS, all shortest paths of any length will be considered. Thus, SPCDS also includes the shortest path of length 2. Thus, an SPCDS is also a 2PCDS.

The second part is to prove that a 2PCDS is also an SPCDS. Suppose there is a 2PCDS. For any pair of nodes u, v of distance bigger than or equal to 2, suppose that there is a shortest path between u and v denoted as $p_{u,v} = \{u, w_1, w_2, \dots, w_k, v\}$. From $p_{u,v}$, they know that the distance between u and w_2 should be of distance 2, then they can find a node w'_1 from the 2PCDS to replace w_1 . The distance between w'_1 and w_3 is 2, then they can find a node w'_2 to replace w_2 . Finally, they can find a replacement $p'_{u,v} = \{u, w'_1, w'_2, \dots, w'_k, v\}$, where all intermediate nodes are in 2PCDS. Thus, a 2PCDS is also a SPCDS. \square

The algorithm proposed in [22] is based on 2hop local information. The idea of algorithm in [22] is that for one node, if there exists a pair of nodes of distance 2, then the node will be added to 2PCDS. The check time is $O(\delta^2) \times O(n) = O(\delta^2 n)$, where δ is the maximum node degree in the network and n is the number of nodes in the network. Finally, a SPCDS is also constructed optimally in polynomial time.

3.2.2 MOC-CDS Problem

The size of SPCDS is relatively large, so in [23], MOC-CDS is proposed. Different from SPCDS, MOC-CDS does not require all nodes on the shortest path should be selected. MOC-CDS requires that for any pair of nodes, there exists at least one shortest path on all intermediate nodes that are in MOC-CDS. Thus, the size of MOC-CDS will be reduced greatly compared to that of SPCDS. Similar to SPCDS, another problem 2hop-CDS is proposed in [23] too. Referring to the proof of equivalence in [22], the equivalence between 2hop-CDS and MOC-CDS is proved in [23]. It is proved that MOC-CDS or 2hop-CDS is NP-hard in a general graph. The proof of NP-hard is based on the reduction of 2hop-CDS from set cover [37] problem.

Definition 12 (Set cover) Given a collection \mathcal{M} of subsets of a finite set X such that $\cup_{B \in \mathcal{M}} B = X$, find a minimum subcollection $\mathcal{B} \subseteq \mathcal{M}$ such that $\cup_{B \in \mathcal{B}} B = X$.

Decision version of 2hop-CDS: Given a positive integer k and a graph G , determine whether there is a 2hop-CDS of size at most k in G .

Decision version of set cover: Given a collection \mathcal{M} of subsets of a finite set X and a positive number h , determine whether there is a set cover \mathcal{M}' of at most h subsets in \mathcal{M} .

Theorem 7 *A minimum 2hop-CDS is NP-hard in a general graph.*

Proof Create a node a_B , $\forall B \in \mathcal{M}$. Create a node b_x , $\forall x \in X$. Two additional nodes will be created c and d . c and d are connected to all a_B 's, $\forall B \in \mathcal{M}$. Meanwhile d is also connected to all b_x , $\forall x \in X$. Edge between b_x and a_B represents that x is in B .

It is claimed that \mathcal{M} has a set cover \mathcal{B} of size at most k when and only when G has a 2hop-CDS of size at most $k + 1$. There are two parts of the proof.

The first one is to prove that a 2hop-CDS of size $k + 1$ can be constructed when $|\mathcal{B}| \leq k$. If there is a set cover \mathcal{B} of size at most k , then the corresponding nodes $\{d\} \cup \{a_B | B \in \mathcal{B}\}$ in G construct a 2hop-CDS of size at most $k + 1$.

c can be dominated by nodes in $\{a_B | B \in \mathcal{B}\}$. $\forall z \in \{b_x | x \in X\} \cup \{u_B | B \in \mathcal{B}\}$, z can be dominated by d . The node subset satisfies 2hop-CDS's characteristic of dominating.

Since d is connected to any other node in the node set, the node set is connected.

For any two nodes $e, f \in G$ of distance 2, $\{e, d, f\}$ must be a shortest path. For any two nodes c and $e \in G$ of distance 2, it is true that $e \in \{b_x | x \in X\} \cup \{d\}$. There should be a path $\{e, a_B, c\} \in G$ – a shortest path between e and c .

Therefore, the construction of the node set should be a 2hop-CDS of size at most $k + 1$.

The second part is to prove that if there is a 2hop-CDS of size at most $k + 1$, set cover has a solution of size at most k . The distance between c and any node e in $\{b_x | x \in X\}$ is 2. Any shortest path between c and e must pass a node a . Thus, the set cover is $\mathcal{B} = \{B | a_B \in \text{2hop-CDS and } B \in \mathcal{M}\}$. For any two different element $U, V \in \mathcal{M}$ of distance 2 in G , each shortest path must pass one node corresponding to element in \mathcal{M} . Thus, $|\mathcal{M}| \leq k$.

In summary, a minimum 2hop-CDS is NP-hard. □

Based on the above proof, it is trivial to conclude that a minimum MOC-CDS is NP-hard as well. Set cover does not have a solution of performance ratio of $\rho ln \gamma$, where γ is the maximum cardinality of element in \mathcal{M} and ρ is a nonnegative number smaller than 1, unless $NP \subseteq DTIME(n^{O(\log \log n)})$. Thus, there cannot be a solution to MOC-CDS with performance ratio of $\rho ln \delta$, where δ is the maximum node degree.

To construct a MOC-CDS, the distributed algorithm named FlagContest is proposed. For a given graph $G = (V, E)$, each node v is assigned a unique id, denoted as $id(v)$. id aims to solve the situation that more than one node can be selected at one time. The solution is to select the one having highest id . At the very beginning, each node will collect the pairs of neighbor nodes of distance 2. Each node having nonempty pair set will compute the times the node is acting as an intermediate node by counting the number of pairs in its pair set. Send the calculated

times to its neighbors. When one node receives times, it will choose one with the biggest times and send a flag to the selected one. If one node collect flags from all its neighbors, turn to black and send out its pair set 2 hops away. Nodes receiving the pair set will remove those pairs in the received pair sets from their own pair sets. Update the pair sets and recalculate the times acting as an intermediate node. The algorithm will stop when all nodes' pair sets are empty. The black nodes colored during the process will construct a 2hop-CDS.

The algorithm proposed in [23] is proved correct. Meanwhile, the performance ratio is proved – FlagContest produces approximation solution with performance ratio $H(\binom{\delta}{2})$, where H is the harmonic function and δ is the maximum node degree of input graph.

3.2.3 CDS Under Relaxed Constraints

The above CDS under shortest path constraint does achieve efficient routing; however, from their simulation results, the size of CDS will increase a lot compared to other CDS size. To reduce CDS size, [24] relaxed the shortest path constraint and proposed α Minimum rOuting Cost Connected Dominating Set (α -MOC-CDS). In α -MOC-CDS, the shortest path constraint is relaxed to that for any two nodes, there exists at least one path, and the number of intermediate nodes on this path is smaller than α times that of on the shortest path. Meanwhile, all intermediate nodes on this path must be in α -MOC-CDS. An equivalent problem α -2hop-CDS is proposed in [24] and the equivalence is proved too. Actually, MOC-CDS is a special case of α -MOC-CDS, when $\alpha = 1$. In [24], Ling et al. proposed a distributed localized algorithm to construct α -MOC-CDS which is introduced as follows.

The algorithm is based on the $\alpha + 1$ local topology information. The topology of the local information on each node v is denoted as $G(v) = (V_v, E_v)$. A weighted graph $G_w(v) = (V_w(v), E_w(v), W_w(v))$ can be induced by $G(v)$, where $V_w(v) = V(v)$, $E_w(v) = E(v)$, and $W_w(v)$ record the weight between any two nodes. For any two nodes, if there is an edge between them in $E(v)$, then the weight is 0. Otherwise, it is ∞ . For each node v , it will record a pair set which stores the pairs where distance of the two nodes in each pair is 2 in $G(v)$ and $G_w(v)$, there is two edges between v and the two nodes, and the total weight of the two edges should be smaller than α . Send out the pair set to its neighbors in $G(v)$. If one node receives all pair sets from its neighbors, it will order them based on their id and cardinality of the pair set. One node has higher rank when its cardinality is bigger. When two nodes have the same cardinality, the node that has higher *id* will have higher rank. After ordering all neighbors, one node will send flags to those nodes whose pair set has no intersection with any pair set of any node having higher rank. If one node receives all flags from its neighbors, it will turn black, send out its own pair set two hops away, and update its weighted graph. If node v turns black, then for any pair of nodes of distance 2 in $G_w(v)$ and there is a path in $G_w(v)$ of weight w , then edge between the two nodes in the pair should be added to $G_w(v)$ of weight $1 + w$. When one node receives the pair set, it will remove the pairs in the received pair set from its own pair set. The algorithm will stop when all pair sets are empty.

From the simulation results in [24], the size of CDS will reduce greatly, while the routing cost will not increase a lot when $\alpha = 3$. Thus, there is a tradeoff between CDS size and routing cost.

3.2.4 Du's Relaxation

In [32], Du et al. proposed a CDS with guaranteed routing cost named as GOC-MCDS. GOC-MCDS is also a α -MOC-CDS. In [24], Ling et al. propose a distributed algorithm; however, no performance ratio is given. In [32], one centralized and one distributed algorithms are proposed with performance ratio.

In the following two parts, the two algorithms will be recalled in details.

1. *GOC-MCDS-C* The centralized algorithm follows the steps of regular MCDS algorithms. The algorithm has two stages. In the first stage, a maximum independent set (MIS) is constructed. For any pair of MIS nodes of distance smaller than 4, find a shortest path and add all intermediate nodes on the path to the CDS. Finally, the selected MIS combined with the added nodes will construct a GOC-MCDS. The constructed GOC-MCDS will guarantee that for any pair of nodes, the length of the routing path through GOC-MCDS will be smaller five times that of the shortest path between the two nodes. And the size of the GOC-MCDS will be smaller than $|C| + |I| \leq 121 * |I| \leq 443\frac{2}{3} * opt_{GOC-MCDS} + 201\frac{2}{3}$, where $|C|$ is the number of added nodes in the second stage, $|I|$ is the size of the MIS in the first stage, and $opt_{GOC-MCDS}$ is the size of the optimal solution to GOC-CDS.
2. *GOC-MCDS-D* The distributed algorithm also has two stages. At the very beginning, the color of all nodes is white. During the algorithm, some nodes will keep white, some will change to black, and some will change to gray. All the black ones will construct a GOC-MCDS. Meanwhile, each node will be assigned a unique id . The algorithm will be introduced as follows.

The first stage is to find an MIS too. Each white node will send its own id to its neighbors. When one node receives all id 's from its neighbors and its own id is smaller than all id 's it receives, then the node will change to black and send the message “black” to its neighbors. Once a white node receives the “black,” turn to gray. When the algorithm stops, there are only black or gray nodes in the graph.

In the second stage, more nodes are added combining with black nodes in the first stage to form a GOC-MCDS. Every black node s will send its own $id(s)$ to its neighbors. When one node t receives $id(s)$, t will put its own $id(t)$ together with $id(s)$. t will send the pair $(id(s), id(t))$ to all its neighbors. For each node w with $id(w)$, when w receives a pair $(id(s), id(t))$ having $id(s) < id(t)$, w will send the tuple $(id(t), id(w), id(s))$ to the neighbor with $id(s)$. When w receives $(id(s), id(t))$ and $(id(s^*), id(t^*))$ and $id(s) < id(s^*)$, w will send a tuple $(id(s^*), id(t^*), id(w), id(s), id(t))$ to the neighbor with $id(t)$. When w receives $(id(s), id(t))$ and $id(s^*)$ and $id(s) < id(s^*)$, w will send a tuple $(id(s^*), id(w), id(t), id(s))$ to the neighbor with $id(t)$. Otherwise, w will send tuple $(id(s), id(t), id(w), id(s^*))$ to the neighbor with $id(s^*)$. When the node t receives a tuple $(id(s^*), id(t^*), id(w), id(s), id(t))$ or

$(id(s^*), id(w), id(t), id(s))$, t will send the tuple to its neighbors with $id(s)$. Each black node of $id(s)$ will have a tuple set \mathcal{M} storing tuples $(id(w_1), id(t), id(s))$, $(id(w_2), id(w_1), id(t), id(s))$, and $(id(w_3), id(w_2), id(w_1), id(t), id(s))$. Perform the policy of “computation on \mathcal{M} ” on each node. When a node $id(x)$ receives a tuple $(\dots, id(x-1), id(x), \dots)$, x will turn to black and pass the tuple to the node $id(x-1)$.

Computation on \mathcal{M} : Pick up $(id(h), \dots, id(2), id(1)) \in \mathcal{M}$ and send the tuple to the node of $id(2)$. Delete all tuple from \mathcal{M} starting with $id(h)$.

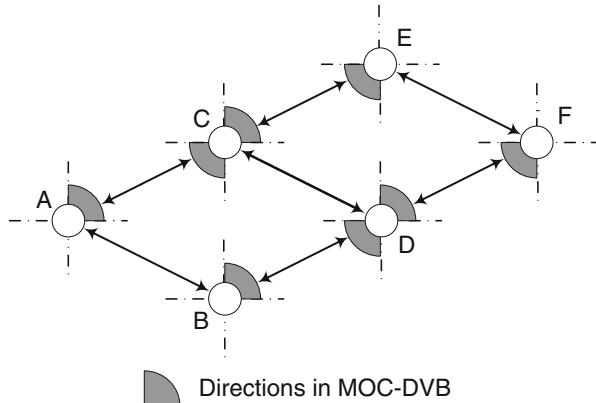

This distributed algorithm has the same performance ratio as the centralized one.

3.2.5 MOC-DVB

In wireless networks, saving energy is always the critical topic. In previous literature, directional antennas are used to help save energy in many operations, like broadcasting [21]. Thus, Ling et al. apply directional antennas to the wireless networks. The wireless networks with directional antennas are modeled as directed graphs. In such a wireless, *Minimum rOuting Cost Directional VB* (MOC-DVB) is studied in [25]. Fewer sectors selection will help save energy and reduce interference. MOC-DVB requires that if the source node initiates a message in omni-direction, then the message should be delivered by a shortest path on all intermediate directions that are in MOC-DVB. A MOC-DVB itself may be disconnected. For example, in Fig. 5, the gray sectors construct a minimum MOC-DVB. However, the MOC-DVB cannot induce a connected graph. Even though a connected subgraph of MOC-DVB, any messages can be successfully routed or broadcasted. If A has a message with destination F , the directional path should be $\{A \rightarrow B^1 \rightarrow D^1 \rightarrow F\}$ which means that A initiate a message in omnidirection, B use omni-reception and forward it to D through the first direction, D receive the message from B then forward it through the first sector of D , and lastly, D forward the message to F through the first direction of D . Meanwhile, it can go back from F to A through path $\{F \rightarrow E^3 \rightarrow C^3 \rightarrow A\}$. Originally, the directed graph is strongly connected.

In [25], Ling et al. prove that MOC-DVB is NP-hard. A distributed and greedy algorithm is proposed in [25]. For each direction u^i , a direction id is assigned, denoted as $d(u^i)$. For each direction w^i , it will compute a pair set which stores that the pair (u, v) of distance 2, u 's message can be delivered to v through direction w^i . Each direction will send out its times acting as an intermediate direction to its neighbors. When one node receives the times from all its neighbors, it will select the direction with the maximum times and send out a flag to the direction. When one direction collects flags from all the directions where it is, the direction will be added to MOC-DVB. The selected direction's pair set will be sent out 2 hops away. When one direction receives the pair set, it will remove the pair in the received pair set from its own pair set. The algorithm stops when all pair sets are empty.

Fig. 5 Comparison between CDS and MOC-DVB

3.2.6 PTAS for MCDS with Routing Cost Constraint [31]

Du et al. in [31] showed that $\alpha MOC - CDS$ has a PTAS for $\alpha \geq 5$. However, the problem is still open for $1 \leq \alpha < 5$. Actually, the main difficulty for $1 \leq \alpha < 5$ is how to connect a Dominating Set into a feasible solution for $\alpha MOC - CDS$. So far, there is no a good method to do that without increasing too much number of nodes. They will show some of their main results.

First, they use a square $[0, q] \times [0, q]$ to cover the whole graph $G = (V, E)$, then construct the other square called $P(0)$. $P(0)$ is divided into p^2 cells. Each cell is an $a \times a$ square called e . The side length for each cell a is equal to $2(\alpha + 2)k$, where $p = 1 + \lceil q/a \rceil$ and k is a positive integer. Note that all cells are disjoint, so they should ensure each cell only has left and lower boundary. The union of all cells covers the square $[0, q] \times [0, q]$.

For each cell e , construct two squares with the same center as e . The side length are $(a + 4) \times (a + 4)$ and $(a + 2\alpha + 4) \times (a + 2\alpha + 4)$. They use e^c to represent the *central area* which is the closed area bounded by the first square and e^b to represent the *boundary area* which is the area between the second square (exclude boundary) and cell e (include boundary). e^{cb} is the open area bounded by the second square which is $e^c \cup e^b$.

Now, for each cell e , they study the following problem:

- [Du et al. in [31]] LOCAL(e): Find the minimum subset D of nodes in $V \cap e^{cb}$ such that
1. D dominates all nodes in $V \cap e^c$.
 2. $m_D(u, v) \leq \alpha$ for any two nodes $u, v \in V \cap e^c$ with $m(u, v) = 1$ and $\{u, v\} \cap e \neq \emptyset$.

Let D_e denote the minimum solution for the LOCAL(e) problem. Define $D(0) = \cup_{e \in P(0)} D_e$ where $e \in P(0)$ means that e is over all cells in partition $P(0)$.

Lemma 14 (Du et al. in [31]) D_0 is a feasible solution of $\alpha MOC - CDS$ and D_0 can be computed in time $n^{O(\alpha^4)}$ where $n = |V|$.

Lemma 15 (Du et al. in [31]) $|D(0)| + |D(1)| + \dots + |D(k-1)| \leq (k+8)|D^*|$.

Algorithm 5 Algorithm PTAS(Du et al. in [31])

- 1: Compute $D(0), D(1), \dots, D(k - 1)$;
 - 2: Choose $i^*, 0 \leq i^* \leq k - 1$ such that
 - 3: $|D(i^*)| = \min(|D(0)|, |D(1)|, \dots, |D(k - 1)|)$;
 - 4: Output $D(i^*)$.
-

Theorem 8 (Du et al. in [31]) *Algorithm PTAS (Algorithm 5) produces an approximation solution for α MOC-CDS with size*

$$|D(i^*)| \leq (1 + \varepsilon)|D^*|$$

and runs in time $n^{O(1/\varepsilon^4)}$.

4 Strongly Connected Domination Set

In many scenarios, the communications in multi-hop wireless networks are asymmetric in real world. For example, nodes may have different transmission due to several reasons such as energy concern and cost. Therefore, it is possible to consider that node u can communicate with node v , but v cannot communicate with u . In such case, they need to model this kind of network to a directed graph $G = (V, E)$. In directed graph, they usually consider a strongly Connected Dominating Set (SCDS) as a virtual backbone. The problem minimum SCDS seeks an SCDS of the smallest cardinality in a specified digraph. Given a directed graph $G = (V, E)$, S is strongly connected if for every pair u and $v \in S$, there exists a directed path from u to v in the directed graph induced by S , i.e., $G(S)$. Formally, the SCDS problem can be defined as follows:

Definition 13 (Strongly Connected Domination Set) Given a directed disk graph $G = (V, E)$, find a subset $S \subset V$ with minimum size, such that the subgraph induced by S , called $G(S)$, is strongly connected and S forms a Dominating Set in G .

The SCDS problem is easy to be proved as an NP-hard problem because the MCDS problem in UDG is NP-hard and UDG is a special case of DG. Du et al. [28] consider the SCDS in directed graphs. Differ from undirected graph, an MIS is not necessary a DS in a directed graph. Therefore, they cannot find an MIS and connect it into a SCDS. Instead, they have to find a DS in the first stage, then connect it to a SCDS. Based on this approach, they present two constant-approximation algorithms for computing a minimum SCDS in DG if the transmission range is bounded which are Connected Dominating Set using the Breath First Search tree

(CDS-BFS) and Connected Dominating Set using the minimum nodes Steiner tree (CDS-MNS) algorithms. The main differences of these two algorithm are the second stage for connecting the obtained Dominating Set to an SCDS. They assume that G is a strongly connected graph in order to guarantee that the graph G has a solution for the SCDS problem.

In 2009, Li et al. [55] proposed another approximation algorithm for SCDS. In this section, they will introduce some of their main results.

They used $G = (V, E)$ to represent a digraph. A node in G is said to be a *internal* node if its out-degree is not zero and an *sink* node otherwise. $I(G)$ is the set of internal nodes in G . If a subgraph's vertex set is exactly V , they said that the subgraph is spanning. They call a subgraph of G an *arborescence* rooted at a node $s \in V$ if the in-degree of s is zero, and the in-degree of any other node is exactly one in this subgraph. An s -arborescence is also an arborescence rooted at s . For each node $v \in V$, $\delta^+(v)/\delta^-(v)$ is the out/in-degree of v in G , and $N^+(v)/N^-(v)$ is the set of out/in-neighbors of v in G . For any subset U of V , they denote by $G[U]$ the subgraph of G induced by U . G^R is the reverse of G which is a digraph obtained from G by reversing the direction of every arc. In other words, $G^R = (V, E^R)$ with

$$E^R = \{(u, v) | (v, u) \in E\}.$$

Lemma 16 (Li et al. [55]) *Let $G = (V, E)$ be a strongly connected digraph and s be an arbitrary node in V . Suppose that T_1 is a spanning s -arborescence in G , and T_2 is a spanning s -arborescence in G^R . Then $I(T_1) \cup I(T_2)$ is an SCDS of G .*

Theorem 9 (Li et al. [55]) *Suppose that \mathbb{A} is a ρ -approximation for SAFIN. Then Algorithm $SCDS(\mathbb{A})$ produces an SCDS of size at most $2\rho \cdot opt - 2\rho + 1$, where opt is the size of a minimum SCDS.*

By Lemma 16, they introduce the Spanning Arborescence with Fewest Internal Nodes (SAFIN) problem:

[Spanning Arborescence with Fewest Internal Nodes (SAFIN) problem] Given a digraph $G = (V, E)$ and a source node $s \in V$, compute a spanning s -arborescence T with minimum $|I(T) \setminus \{s\}|$.

It is easy to argue that SAFIN is at least as hard as minimum CDS. Therefore, they use SAFIN to find the minimum SCDS. Let \mathbb{A} be an arbitrary polynomial-time approximation for SAFIN. The Algorithm 6 described a polynomial-time approximation algorithm $SCDS(\mathbb{A})$ for minimum SCDS with the parametric \mathbb{A} as a subroutine. To reduce the running time, they selected a small subset S of candidates for the source node in the beginning. Specifically, let u be the node u which minimize satisfying that $\min(\delta^-(v), \delta^+(v))$ over all nodes $v \in V$. They said that S consists of u and all its out-neighbors if $\delta^-(u) > \delta^+(u)$. Otherwise, S consists of u and all

Algorithm 6 *SCDS(\mathbb{A})* (Li et al. [55])

```

1:  $u \leftarrow \arg \min_{v \in V} \min(\delta^-(v), \delta^+(v));$ 
2: If  $\delta^-(u) \leq \delta^+(u)$  then
3:    $S \leftarrow u \cup N^-(u);$ 
4: else
5:    $S \leftarrow u \cup N^+(u);$ 
6:  $U \leftarrow V;$ 
7: for each  $s \in S$ ,
8:    $T_1 \leftarrow$  spanning  $s$ -arborescence in  $G$  output by  $\mathbb{A}$ ;
9:    $T_2 \leftarrow$  spanning  $s$ -arborescence in  $G^R$  output by  $\mathbb{A}$ ;
10:  if  $|I(T_1) \cup I(T_2)| < |U|$  then
11:     $U \leftarrow I(T_1) \cup I(T_2);$ 
12: output  $U$ 

```

Algorithm 7 (\mathbb{A})

```

1:  $B \leftarrow s;$ 
2: while  $h(B) > 0$ ,
3:   construct  $\tau(B)$ ;
4:   find a cheapest  $T \in \tau(B)$ ;
5:    $B \leftarrow B \cup I(T);$ 
6: output a spanning  $s$ -arborescence of  $G\langle B \rangle$ 

```

its in-neighbors. Clearly, there must be at least one node in the selected S in every SCDS.

Next, they will show their $(1.5H(n - 1) - 0.5)$ -approximation algorithm \mathbb{A} ([Algorithm 7](#)) for SAFIN where H is the harmonic function. For such \mathbb{A} , the algorithm $SCDS\mathbb{A}$ is a $(3H(n-1)-1)$ -approximation algorithm for minimum SCDS by [Theorem 9](#).

They introduce some notations and terminologies for algorithm \mathbb{A} ([Algorithm 7](#)). They assigned each node a unique ID. And s is the source node. $G\langle B \rangle$ is the spanning subgraph of G whose arc set consists of all arcs of G leaving from the nodes in B for any $B \subset V$ containing s . If a strongly connected component of $G\langle B \rangle$ neither contains the source s nor has an incoming arc, it is an orphan with respect to B . The node with the smallest ID in this component is its head for each orphan component. The number of heads (equivalently, the number of orphans) with respect to B is denoted as $h(B)$. Clearly, a spanning s -arborescence is in $G\langle B \rangle$ if and only if $h(B) = 0$. They use $\tau(B)$ to denote the set of candidates. The construction of $\tau(B)$ is described can be found in [55].

Theorem 10 (Li et al. [55]) *The approximation ratio of the [Algorithm 7](#) for SAFIN is at most $1.5H(n - 1) - 0.5$.*

5 Weakly Connected Domination Set

In ad hoc networks, topology changes very often, and most of the changes are localized which means it is in a small area of the network. However, they do not want this kind of change effect the whole networks. Therefore, they need a new network structure such that the local changes will not be seen by the entire network which is *cluster*. Like the virtual backbone in wireless networks, they would like to control less nodes. In *cluster*, such node is called *clusterhead*. One method used in *cluster* is based on domination in graphs which they already introduced in the previous section. Of course, they wish to find the smallest number of *clusterhead* which is a minimum Dominating Set. So they can simplify the network structure as much as possible. Unfortunately, it is a NP-complete problem to find a minimum size Dominating Set in a general graph. In order to solve this problem, they can ensure that the clusterheads are adjacent to each other or at least reasonably close to each other. Hence, they can try to use CDS. However, minimum CDS problem in general graph is also NP-complete. Although a CDS provides an obvious routing, the connectivity requirement causes a very large number of *clusterhead*. Based on this, a Weakly Connected Dominating Set is proposed.

Definition 14 (Weakly Connected Domination Set (WCDS)) The subgraph weakly induced by W is $S_w = (N[W], E \cap (W \times N[W]))$, where $N[W]$ is a set of one-hop neighbor of W and W . The set W is a *Weakly Connected Dominating Set* (WCDS) if S_w is connected and W is a DS.

According to the definition of WCDS, the size of WCDS is less or equal to the size of CDS. Thus, they feel that WCDS is a better method for clustering. An approximation algorithm with ratio $O(\ln \Delta)$ was proposed by Chen [11], where Δ is the maximum degree of the input network. Alzoubi et al. [4] present two distributed algorithms with the ratio 5 and 122.5 in 2003. Dubhashi [33] gave another approximation algorithm with the same ratio as Chen's in 2003. Du et al. [30] proved that:

Theorem 11 (Du et al. [30]) *The least upper bound for the ratio of sizes between MIS and the minimum WCDS for UDG is five.*

To prove **Theorem 11**, they first proved that five is an upper bound. They considered an MIS M and a minimum WCDS D . For any vertex u , the disk with radius one and center u is called the *dominating disk* of u . Suppose $u \in D$ and the dominating disk of u contains n elements which is M, a_1, \dots, a_n , and order them in clockwise. Connect ua_1, ua_2, \dots, ua_n (Fig. 2). Because a_1, a_2, \dots, a_n are independent set, they have $|a_1a_2| > 1, \dots, |a_na_1| > 1$. Hence, they can get $\angle a_1ua_2 > \frac{\pi}{3}, \dots, \angle a_nua_1 > \frac{\pi}{3}$. Therefore, $n \leq 5$. So five is an upper bound is proven.

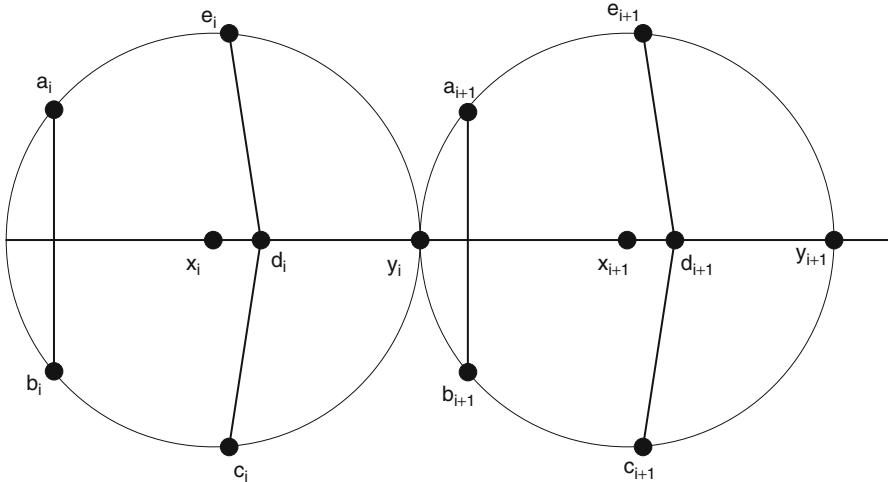

Fig. 6 An example for $|M| = 5|D|$

They constructed an example to show that five is the least upper bound. They showed that $|M| = 5|D|$ where M is an MIS and D is a minimum WCDS. They drawn the example as follows:

1. Construct a sequence of points $x_1, y_1, x_2, y_2, \dots, x_n, y_n$ on a line ℓ such that $|x_1y_1| = |y_1x_2| = |x_2y_2| = \dots = |x_ny_n| = 1$, as shown in (Fig. 6).
2. Construct four points a_i, b_i, c_i, e_i on the boundary of the dominating disk of each x_i such that segment $a_i b_i$ is perpendicular to line ℓ and $\angle e_i x_i a_i = \angle a_i x_i b_i = \angle b_i x_i c_i = \frac{\pi}{3} + \varepsilon$ where $\varepsilon > 0$ is a small constant.
3. Construct the fifth point d_i in dominating disk of x_i such that d_i is on line ℓ and at the middle between segments $a_i b_i$ and $a_{i+1} b_{i+1}$.

They study the UDG G with vertex set $\{a_i, b_i, c_i, d_i, e_i, x_i, y_i \mid i = 1, 2, \dots, n\}$. By calculating the distance of every pair of MIS, all the distance are larger than 1. Therefore, 5 is the least upper bound.

6 Fault-Tolerant Virtual Backbone in Wireless Network

Due to many factors such as mobility of nodes and limitation of energy supply, the topology of a wireless network is expected to be dynamic. However, most of the existing virtual backbone computation algorithms/protocols assume a static network topology. Naturally, even a slight topology change can make current virtual backbone structure obsolete. In such case, the backbone structure should be completely reconstructed. As a result, in a highly dynamic wireless network, those algorithms could work very inefficiently since they may need to reconstruct

virtual backbone very frequently. Motivated by this issue, the problem of computing fault-tolerant virtual backbone is introduced [18].

In graph theory, a graph is said to be *disconnected* only if there is a pair of nodes having no path between them in the graph. A graph is k -*connected* if the graph is still connected after removing any $k - 1$ nodes in the graph. They say a node dominates a set of nodes, if the node is adjacent to all of the nodes in the set in the graph. Similarly, a subset of the nodes in a graph dominates the other nodes outside the subset only if each of the nodes outside the subset has at least one neighbor in the subset. In addition, they say the subset m -dominates the nodes outside the subset only if each of the nodes outside the subset has at least m neighbors in the subset. Note that the CDS computation algorithms by Guha and Kuller and many conventional CDS computation algorithms are targeted to produce 1-connected 1-Dominating Set.

Let $G = (V, E)$ denote a connected graph representing a wireless network and C be a CDS of G , which can serve as a virtual backbone of the wireless network. In [79], the additional requirements for C to be a fault-tolerant virtual backbone is formally defined as follow:

- k -connectivity: C has to be k -connected so that the virtual backbone can survive after $k - 1$ backbone nodes fail.
- m -domination: each node $x \in (V \setminus C)$ has to adjacent to at least m nodes in C so that x can be connected even after $m - 1$ adjacent backbone nodes fail.

Here, k and m determine the level of fault tolerance. By enforcing the two new requirements on C , any pair of nodes can communicate with each other via the virtual backbone even after any $\min\{k, m\}$ nodes fails. The rest of this chapter is devoted to the survey of the recent advances in computing fault-tolerant CDS in wireless network.

6.1 Preliminaries

They first introduce several notations and definitions to simplify further discussion. $G = (V, E)$ is a connected graph. $V = V(G)$ and $E = E(G)$ are the set of vertices and edges in G , respectively. For a pair of nodes $u, v \in V(G)$, $Eucdist(u, v)$ is the Euclidean distance between them. Let $N(u)$ be the set of nodes adjacent to u , and $N[u] = \{u\} \cup N(u)$. There are two common graph models to abstract wireless network, unit disk graph (UDG) and disk graph (DG).

Unlike UDG, DG is used to abstract nonhomogeneous wireless network, in which nodes may have different maximum transmission range. As a result, DG has directional edges. Clearly, UDG is a special case of DG, and thus, every NP-hard problem in UDG is still NP-hard in DG. In addition, every algorithm working in DG also works in UDG.

Definition 15 (Disk Graphs(DG)) The nodes in V are located in the two-dimensional Euclidean plane, and each node $v_i \in V$ has a transmission range

$r_i \in [r_{\min}, r_{\max}]$. A directed edge $(v_i, v_j) \in E$ if and only if $d(v_i, v_j) \in E$, where $d(v_i, v_j)$ denotes the Euclidean distance between v_i and v_j . Such graphs are called disk graphs (DG).

An edge (v_i, v_j) is bidirectional if both (v_j, v_i) and (v_i, v_j) are in E , i.e., $d(v_i, v_j) \leq \min r_i, r_j$. Usually, they only study the CDS problem in disk graphs where all the edges in the network are bidirectional, called disk graphs with, bidirectional links (DGB). In this case, G is undirected.

Definition 16 (Disk graph with bidirectional links (DGB)) A DGB of a graph is a DG of the graph without all of its directional links.

Definition 17 (m -Dominating Set (m -DS)) $D \subseteq V$ is an m -Dominating Set (m -DS) of G if $\forall u \in (V \setminus D)$, u is adjacent to at least m nodes in D .

Definition 18 (k vertex connectivity) A graph G is k vertex connected if G is still connected after any $k - 1$ nodes are removed from G . In the rest of this section, they will use “ k vertex connected” and “ k -connected,” interchangeably.

Definition 19 (k -Connected m -Dominating Set ((k, m)-CDS)) C is a k -Connected m -Dominating Set, (k, m) -CDS, if (1) a graph induced by C is k -connected and (2) C is a m -DS. For simplicity, they will call (k, k) -CDS by k -CDS.

Definition 20 (Cut-vertex) A vertex $v \in V$ is a cut-vertex if and only if the induced graph by $V \setminus \{v\}$ is disconnected.

Definition 21 (Block) A subset $B \subseteq V$ is a block if and only if B is a maximal connected subgraph of $G = (V, E)$ without any cut-vertex.

Definition 22 (Leaf block) A block of G is called a leaf block if it contains only one cut-vertex.

6.2 Approximations for Computing (k, m) -CDS for $k \leq 3$ and $m \geq 1$

The minimum CDS problem, which is a problem of computing minimum (1,1)-CDS, of a graph, is a well-known NP-hard problem. Therefore, its generalized version, the problem of computing minimum (k, m) -CDS is also NP-hard. As a result, many researches have been conducted to find an approximation algorithm for this problem. In this section, they introduce approximation algorithms for computing (2, 1)-CDS, (1, m)-CDS, (2, m)-CDS, and (3, m)-CDS for any $m \geq 1$.

6.2.1 A Constant Approximation for (2, 1)-CDS

The CDS augmentation algorithm (CDSA) in [79] is the first approximation algorithm to compute multi-connected CDS. Given a 2-connected UDG G , CDSA first utilizes an existing approximation algorithm to compute 1-CDS of G , denoted by $C_{1,1}$. Once this is done, the algorithm augments $C_{1,1}$ to increase its connectivity and generate a (2,1)-CDS, denoted by $C_{2,1}$ as follows:

1. Let $L = \emptyset$ and $C = C_{1,1}$. Find every block in $C_{1,1}$ and put all of them in L .
2. Find a leaf block $B \in L$ and find the shortest path P from $v \in B$ to $u \in C_{1,1} \setminus B$ such that v and u are not cut-vertices. Add all nodes in P to C . If there is more than one block in L , repeat this step.

Figure 7 illustrates an example showing how this algorithm works. It is always true that there is at least one block in any 1-CDS of any graph with more than one vertex. Starting from a block of $C_{1,1}$ (a maximal 2-connected subgraph of $C_{1,1}$), the algorithm finds a shortest path P from a node u in the block to another node v in $C_{1,1}$, which is outside the block such that both of u and v are not cut-vertices in $C_{1,1}$. As a result, the union of the block, P , and some additional nodes from the original 1-CDS form a larger 2-connected subgraph C , which can be considered as a larger leaf block. By repeating such procedure until the subgraph includes all nodes in $C_{1,1}$, the subgraph, which is originally a 2-connected subgraph of $C_{1,1}$, grows into a (2, 1)-CDS.

Using geometry, the authors proved that each path P includes at most 8 new nodes. Also, each time P is added and a 2-connected subgraph is augmented, at least one node in the original $C_{1,1}$ joins to the augmented 2-connected subgraph. As a result, they have

$$2CDS = 1CDS + 8 \times 1CDS,$$

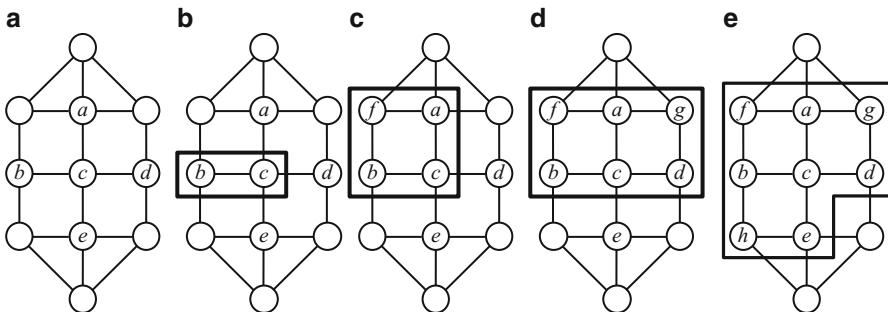

Fig. 7 These figures illustrate how a (2,1)-CDS is computed. In figure (a), the node set $\{a, b, c, d, e\}$ forms a 1-CDS, $C_{1,1}$. In figure (b), the node set $\{b, c\}$ is a leaf block of $C_{1,1}$. In figure (c), two blocks $\{b, c\}$ and $\{a, c\}$ sharing a cut-vertex c of $C_{1,1}$ are merged into a larger 2-connected subgraph $\{a, b, c, f\}$ by adding a path $\{b, f, a\}$. In figure (d), by adding a new path from node a in the 2-connected subgraph to another node d in $C_{1,1}$ outside the subgraph, they have a larger 2-connected subgraph, $\{a, b, c, d, f, g\}$. It is important that both a and d are not cut-vertices. In figure (e), one more node h is added to the subgraph, and finally the augmented subgraph contains $C_{1,1}$. Therefore, this subgraph is a (2,1)-CDS

where $2CDS$ is an output of CDSA, $1CDS$ is the original 1-CDS, and 8 is the maximum length of intermediate nodes in each path P . Based on the existence of a 6.91-approximation algorithm for the minimum CDS problem, the authors originally showed that the approximation ratio of the proposed algorithm is 62.19. Recently, a 6.075-approximation algorithm for the minimum CDS problem has been introduced [57]. By relying on this new result, it can be easily shown that the approximation ratio of CDSA is 54.675.

6.2.2 An Approximation for $(1, m)$ -CDS

In this section, they introduce an approximation algorithm to compute $(1, m)$ -CDS in [70, 74]. Roughly speaking, this method relies on an existing approximation algorithm for the minimum CDS problem. The algorithm consists of following three steps:

1. Compute a $C_{1,1}$ of $G = (V, E)$ using an existing approximation algorithm, which computes an MIS M_0 of G first and connects the nodes in M_0 by adding some nodes B in $V \setminus M_0$. Then, $C_{1,1} = M_0 \cup B$.
2. Set $C = C_{1,1}$. Repeat following from $i = 1$ to $m - 1$: compute an MIS M_i of $(V \setminus (B \cup M_0 \cup \dots \cup M_{i-1}))$ and add it to C .
3. Return C .

The correctness of this algorithm can be proven as follow. In the first step, a $C_{1,1}$ is computed. Then, each node in $V \setminus C_{1,1}$ must have at least one neighbor in $C_{1,1}$ since $C_{1,1}$ includes M_0 , which is an MIS of G and thus is also a DS of G . Similarly, after M_1 is computed, each node in $V \setminus (C_{1,1} \cup M_1)$ must have at least one neighbor in M_1 . This implies that each node in $V \setminus (C_{1,1} \cup M_1)$ must have at least two neighbors in $(C_{1,1} \cup M_1)$, at least one in $C_{1,1}$, and at least another in M_1 . Therefore, $C = C_{1,1} \cup M_1$ is a $(1,2)$ -CDS of G . As a result, the output $C = B \cup M_0 \cup M_1 \cup \dots \cup M_{m-1}$ of the algorithm is a $(1, m)$ -CDS, which is denoted by $C_{1,m}$. Now, they describe the approximation ratio analysis of this algorithm.

Lemma 17 ([70]) *Given $G = (V, E)$, $|M| \leq \max\{\frac{5}{m}, 1\}|D_m^*|$, where M is an MIS of G and D_m^* is a minimum m -DS of G .*

Theorem 12 ([70]) *The approximation ratio of the strategy in this section for the minimum $(1, m)$ -CDS problem is $(5 + \frac{5}{m})$ for $m \leq 5$ and 7 for $m > 5$.*

Proof Let $S_i = M_i \cap D_m^*$. In the algorithm, each $M_i \setminus S_i$ is an IS and $(M_i \setminus S_i) \cap D_m^* = \emptyset$. From Lemma 17, they have $|M_i \setminus S_i| \leq \frac{5}{m}|D_m^* \setminus S_i|$, and

$$\begin{aligned} |M_0 \cup \dots \cup M_{m-1}| &= \sum_{i=0}^{m-1} |S_i| + \sum_{i=0}^{m-1} |M_i \setminus S_i| \leq \sum_{i=0}^{m-1} |S_i| + \sum_{i=0}^{m-1} \frac{5}{m} |D_m^* \setminus S_i| \\ &= \sum_{i=0}^{m-1} |S_i| + \frac{5}{m} \sum_{i=0}^{m-1} (|D_m^*| - |S_i|) = (1 - \frac{5}{m}) \sum_{i=0}^{m-1} |S_i| + 5|D_m^*|. \end{aligned}$$

From this inequality, they can observe $|M_0 \cup \dots \cup M_{m-1}| \leq 5|D_m^*|$ for $m \leq 5$ and $|M_0 \cup \dots \cup M_{m-1}| \leq 6|D_m^*|$ for $m > 5$ since $\sum_{i=1}^m |S_i| \leq |D_m^*|$. In addition, from Lemma 17, they have

$$|B| \leq |M_0| \leq \max \left\{ \frac{5}{m}, 1 \right\} |D_m^*|,$$

since $|B| \leq |M_0|$ is clearly true if a coloring is used to find M_0 . Therefore, they can conclude that the size of $|C|$, which is an output of the algorithm, is bounded by $(5 + \frac{5}{m})|D_m^*|$ for $m \leq 5$ and $7|D_m^*|$ for $m > 5$, and this theorem is proved. \square

6.2.3 An Approximation for $(2, m)$ -CDS

In Sects. 6.2.1 and 6.2.2, they introduced two approximation algorithms, one for computing $(2, 1)$ -CDS and another for computing $(1, m)$ -CDS. In [70], an approximation for computing $(2, m)$ -CDS can be obtained by combining the two strategies as below:

1. Given a UDG G , compute a $C_{1,m}$ of G using an existing approximation algorithm for computing $(1, m)$ -CDS. Let $C = C_{1,m}$.
2. Apply a variation of Wang et al.'s strategy for $(2, 1)$ -CDS in Sect. 6.2.1 on C such that only a path P with length at most 3 will be identified and used to merge a leaf block with another block in $C_{1,m}$.
3. Return C .

It is easy to see that an output of this algorithm C is a $(2, m)$ -CDS. Now, they describe the approximation ratio analysis of this algorithm.

Theorem 13 ([70]) *The approximation ratio of the strategy for the minimum $(2, m)$ -CDS problem is $(5 + \frac{25}{m})$ for $2 \leq m \leq 5$ and 11 for $m > 5$.*

Proof Let $C_{1,m}^*$ and $C_{2,m}^*$ be a minimum $(1, m)$ -CDS of G and a minimum $(2, m)$ -CDS of G , respectively. Clearly, $|C_{1,m}^*| \leq |C_{2,m}^*|$. Largely, this proof depends on the following facts:

1. $C_{2,m}$, a $(2, m)$ -CDS of G , can be obtained from $C_{1,m}$, a $(1, m)$ -CDS, by adding at most $2|C_{1,m}|$ nodes from $V \setminus C_{1,m}$. This is possible based on following two facts:
 - Suppose they have an MIS M_0 of $G = (V, E)$ and a CDS $C = M_0 \cup B$ of G . Let D be a 2-connected subgraph of G which is a union of a subset of C and some other nodes from $V \setminus C$. Then, there has to be a path with length at most 3 from a node u in $D \cap M_0$ to another node v in $(C \setminus D) \cap M_0$ such that both of u and v are not cut-vertices of $C_{1,m}$. Otherwise, there has to be a node in V which is not dominated by any node in M_0 , which makes M_0 not maximal.
 - The number of blocks in $C_{1,m}$ is to at most $|C_{1,m}|$. Furthermore, each time they add a path with length at most 3 from u to v , at least one block will be merged into the 2-connected subgraph which is being augmented.
2. Due to its construction, $|C_{1,1}| = |M_0| + |B|$.

3. $|B| \leq |M_0|$ if coloring is for M_0 .
4. $|M_0| \leq \max\{\frac{5}{m}, 1\}|C_{1,1}^*|$ (from Lemma 17).

From the second and third facts, they have $|C_{1,1}| \leq 2|M_0|$, and by combining this inequality with the first and last ones, they can conclude

$$|C_{2,m}| \leq |C_{1,m}| + 2|C_{1,1}| \leq |C_{1,m}| + 4|M_0| \leq |C_{1,m}| + 4 \max\{\frac{5}{m}, 1\}|C_{1,1}^*|.$$

Finally, from Theorem 12, they have $|C_{2,m}| \leq (5 + \frac{25}{m})|C_{2,m}^*|$ for $2 \leq m \leq 5$ and $|C_{2,m}| \leq 11|C_{2,m}^*|$ for $m > 5$, and this theorem is proved. \square

6.2.4 An Approximation for $(3, m)$ -CDS

In [52], the authors introduced an approximation for computing $(3, m)$ -CDS. The core part of this work is about on how to approximate the minimum $(3, 3)$ -CDS problem. After proposing a constant-approximation algorithm $(3,3)$ -CDS, the authors also showed how to approximate $(3, m)$ -CDS for any $m \geq 1$. Now, they briefly explain how the algorithm works.

In the algorithm, each node u in a $(2,3)$ -CDS, $C_{2,3}$ is either (1) a *good-point* if $C_{2,3} \setminus \{u\}$ is still 2-connected or (2) a *bad-point* if $C_{2,3} \setminus \{u\}$ is 1-connected. Clearly, if all nodes in $C_{2,3}$ are good-points, then $C_{2,3}$ is a $(3, 3)$ -CDS. Note that some of two bad-points $u, v \in C_{2,3}$ can make $C_{2,3} \setminus \{u, v\}$ completely disconnected. Denote such node pair by a *separator* of $C_{2,3}$. A separator $\{u, v\}$ of $C_{2,3}$ can be easily identified using min-max flow algorithm and takes polynomial time.

Now, they introduce the concept of a *block graph* of a graph $G = (V, E)$: remind that a block is a maximal 2-connected subgraph, and a vertex $u \in V$ is a cut-vertex if $G \setminus \{u\}$ is disconnected. Then, a block graph G' is constructed as follows:

1. For each block B of G , there is a corresponding node v_B in G' .
2. For each cut-vertex u in G , there is a node u in G' .
3. At last, for each pair of v_B (representing a block in G) and u (representing a cut-vertex in G) in G' , establish an edge between them only if $u \in B$ in G , where B is a block represented by v_B in G' .

Suppose T_B is a block tree of $C_{2,3} \setminus \{u\}$ rooted at v . Then, v and a cut-vertex w of T_B forms a separator of $C_{2,3}$. Note that w is also a bad-point of $C_{2,3}$. Then, the algorithm adds a path P with a bounded length for w such that w becomes a good-point of $C_{2,3} \cup \{P\}$. Clearly, the number of paths that must be added to make all of the bad-points in $C_{2,3}$ to be good-points is bounded by the size of $C_{2,3}$ multiplied by the number of bad-points. In [52], the authors showed the approximation ratio of this approach is $\frac{520}{3}$ for $(3,3)$ -CDS.

6.3 Approximations for General (k, m) -CDS

So far, several approximation algorithms have been proposed for the minimum (k, m) -CDS problem [59, 74, 83, 85]. Recently, Kim et al. proved that each of them is flawed in a sense that either it does not produce a (k, m) -CDS or its

approximation ratio analysis is not correct [52]. As a result, it is still an open problem to approximate the minimum (k, m) -CDS problem for $k > 3$ and $m \geq 1$.

6.3.1 Centralized Approximation Algorithms for (k, m) -CDS

CDSAN [74] is an approximation algorithm for computing k -CDS. To calculate a k -CDS, CDSAN first computes a $(1, k)$ -CDS and gradually increases its connectivity using a strategy similar to Wang et al.'s in Sect. 6.2.1. In detail, for some l such that $1 < l < k$ and $C_{l,k}$ (note that $C_{1,k}$ can be computed using the algorithm in Sect. 6.2.2), CDSAN repeats (1) identifying a $(l + 1)$ -connected subgraph of $C_{l,k}$ (e.g., leaf block) and (2) adding a path, from a node of $C_{l,k}$ in the subgraph to another node of $C_{l,k}$ outside the subgraph, to the subgraph so that the $(l + 1)$ -connected subgraph can be augmented into a larger $(l + 1)$ -connected subgraph. This repeating is terminated once a $(l + 1)$ -connected subgraph contains $C_{l,k}$. By performing such augmentation for $l = 2, \dots, k - 1$, CDSAN generates a k -connected subgraph containing $C_{1,k}$.

CDSAN works well for computing $C_{2,k}$ since there is always a block (maximal 2-connected subgraph) in any $C_{1,k}$ if $|C_{1,k}| \geq 2$. However, it is possible that there is no 3-connected subgraph in some $C_{2,k}$ of G even though there exists a $(3, k)$ -CDS of G [52]. As a result, CDSAN will fail in some problem instances since it cannot find any $(l + 1)$ -connected subgraph in a (l, k) -CDS.

ICGA [83] is a centralized approximation algorithm to compute (k, m) -CDS in UDG. In the algorithm, a $(1, m)$ -CDS is computed and is evolved into a (k, m) -CDS using following lemma.

Lemma 18 *Given a k -connected subgraph H of $G = (V, E)$ and a connected subgraph F of G such that $H \cap F = \emptyset$ and F does k -dominate H (each node in F has k neighbors in H), the graph induced by $V(H) \cup V(F)$ is $(k + 1)$ -connected.*

Roughly speaking, ICGA first computes a $(1, m)$ -CDS, $C_{1,m}$. Then, it identifies (1) a 2-connected subgraph of $C_{1,m}$ and (2) a subset F which does k -dominate the subgraph. By the lemma, the union of the subgraph and F should be a larger 3-connected subgraph. If the lemma is true, by repeating the augmentation procedure, they may eventually have a (k, m) -CDS. However, the lemma is not always true since there is a 3-connected graph with no such H and F [52].

CSAA [59] is another centralized algorithm for (k, m) -CDS. In detail, given a $C = C_{1,m}$, CSAA first finds a set of i -cut $Sp_i = \{v_{x_1}, \dots, v_{x_i}\}$ such that $C \setminus Sp_i$ is disconnected, and adds more nodes to C to remove the i -cuts. However, it is likely to happen that C is a kind of complete graph, G_{k-1} , while they are looking for a (k, k) -CDS. Then, Sp_i will be an empty set, but C is not k -connected, and therefore this algorithm does not work any further.

6.3.2 Distributed Approximation Algorithms (k, m) -CDS

DDA [59, 85] is a distributed approximation algorithm to compute (k, m) -CDS in UDG and consists of following three steps:

1. Compute a $(1, 1)$ -CDS, $C_{1,1}$ using an existing distributed approximation [54].
2. Augment $C_{1,1}$ to a $(1, m)$ -CDS, $C_{1,m}$ by exploiting the strategy in Sect. 6.2.2.

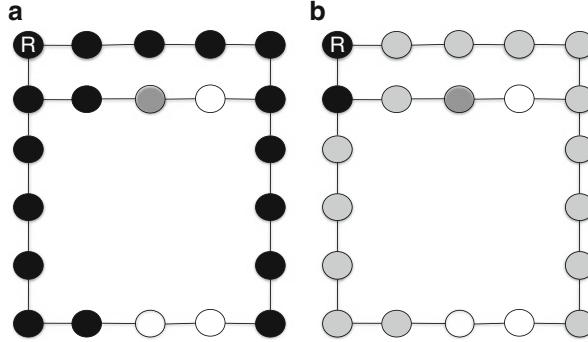

Fig. 8 These figures illustrate an example where DDA does not work correctly. Suppose they want to find a (2,1)-CDS. In figure (a), the set of *black nodes* forms a (1,1)-CDS. In figure (b), the root finds a 2-connected subgraph with its local information (the set of *black nodes*). Now, among the *gray nodes* (which is a member of the (1,1)-CDS other than the *black nodes*), there is no *gray node* which can have two vertex independent paths with length at most three from itself to a member of the 2-connected subgraph (one of the *black node*)

3. Augment $C_{1,m}$ into a (k,m) -CDS, $C_{k,m}$. This can be done by selecting a node using the well-known Expansion Lemma in Graph Theory (below) one by one.

Lemma 19 (Expansion Lemma) *Given a k -connected subgraph $H \subset V$ and $v \notin H$ such that v has at least k neighbors in H , $H' = H \cup \{v\}$ is a k -connected subgraph of $G = (V, E)$.*

Now, they describe an brief idea of Step 3. At the beginning of Step 3, DDA first selects a random root node r from $C_{1,m}$ and try to identify a 2-connected subgraph H of $C_{1,m}$ which consists of r and some or all of its two-hop neighbors. Then, it finds another node $v \in (C_{1,m} \setminus H)$ such that there is k vertex independent paths from v to H with length at most 3. The algorithm claims if they can find such paths the union of H , $\{v\}$, and the nodes on the paths will be a k -connected subgraph which includes H . As they can see in Fig. 8, there are some cases where DDA fails [52], which is also admitted by the authors of [59].

LDA [83] is a localized approximation algorithm for computing (k,m) -CDS in UDG and consists of following steps. Initially, the algorithm assumes that all nodes are colored white:

1. Compute a $C_{1,m}$ using an idea used in DDA and color all nodes in $C_{1,m}$ black.
2. $C_{1,1}$ in $C_{1,m}$ can be considered as a tree rooted at some node. For each parent and child pair $u, v \in C_{1,1} \subseteq C_{1,m}$, color its common neighbors black so that they can share at least k common black neighbors.
3. For each (black) node in $C_{1,1}$, it forms a local k -connected graph, which includes all the neighboring black nodes from Steps 1 and 2.

At the end of the steps, the union of all black nodes is a (k,m) -CDS. The main idea here is that if every parent and child pair in $C_{1,1}$ shares k black neighbors, then

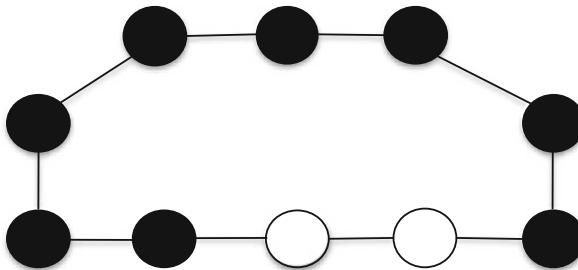

Fig. 9 An example where LDA fails. Suppose they are computing a (2,1)-CDS and the set of *black nodes* above is $C_{(1,1)}$. During the negotiation of each pair of neighboring *black node* u, v , no new *black node* will be introduced. At the end, the union of *black nodes* is still 1-connected. They can have a feasible solution, a (2,1)-CDS, by selecting all nodes

the union of them can be k -connected. However, there are some graph instances G (see Fig. 9), in which some node $u \in G_{1,1}$ of G cannot induce a local k -connected graph, and the union of the all black nodes is not k -connected, but G itself contains a feasible solution, a (k, m) -CDS, and therefore LDA fails [52].

Generally, finding a k -connected subgraph where $k \geq 2$ needs a global knowledge. Therefore, they believe that it will be very interesting and challenging question to design a localized distributed algorithm for a (k, m) -CDS where $k \geq 2$.

7 Conclusion

Virtual backbone can help reduce the searching space for the routing problem from the whole networks to the virtual backbones so that the routing path searching time will be reduced a lot. Due to the advantages of the virtual backbone, it is widely used in broadcasting and routing in wireless networks. Connected Dominating Set is a good choice for virtual backbone. In this book chapter, the previous literatures on Connected Dominating Set are recalled.

1 Introduction

Problems defined in a discrete space are, perhaps, the oldest mathematical problems. The birth and great development of infinitesimal analysis threw discrete problems somewhat into the shade. After the Second World War, due to the development of automatic computation and its wide applications, discrete problems have had a new life. In all these strong movements, one thing has remained almost stable: the fields of continuous and discrete problems have had a small intersection; this is true, in particular, for constrained extremum problems. There is a deep convincement that the two fields, which could be called “Continuous Structures of Mathematics” and “Discrete Structures of Mathematics,” should be considered explicitly and connected more and more.

The systematic study of such connections should by no way imply that one field can be reduced to the other; on the contrary, the more “spectacles” (of Galilean memory) one has to look at reality, the more insight one can achieve. The analysis of connections is meant in this light. In the last four decades of the last century, in the field of constrained extremum problems, most of the efforts have been devoted to transform discrete problems into continuous ones. Even though this activity has turned out to be useful, it has sometimes led to the wrong convincement that a continuous format be the final destination of every problem. Like every human activity, mathematical research is influenced by a sort of inertia: if a problem has been classified, since the beginning, as a continuous one, almost surely, it will be treated by the methods of continuous mathematics, independently of its deep nature.

For instance, the analysis of elastoplastic behavior of structures and materials has always been considered a continuous problem; a part of such an analysis leads to search for the minimum of a nonconvex function, which has several local, but not global, minima; this implies that, in the study of stationary points, one meets—without being ready—a combinatorial problem, which often leads the computation to quicksands.

This writing aims at surveying what has been done to analyze some connections between continuous and discrete extremum problems and related models, like generalized systems and variational inequalities. As concerns extremum problems, a first trace is contained in [64] and followed in [49]. Independently of [64], and in a slightly more general context, a first analysis of such connections has been faced in [38]. The idea expressed in [64] has been picked up in [36], where, however, the mathematical tools are independent of those in [64], inasmuch as the “ad hoc” analysis of linear algebraic problems is no longer valid for nonlinear ones; indeed, in [36], the equivalence is established between a nonlinear constrained extremum problem in a Euclidean space and a problem that is both a relaxation and a penalization of it; the equivalence between a continuous and a discrete problem is obtained as a corollary of it. The results of [36] stimulated some further research in the field; see, e.g., [2–5, 26, 29, 34, 35, 38, 44, 55–57, 61, 65].

The great development of the theory of constrained extrema and, more recently, of that of variational inequalities, has led to search for models that embody both theories. A possible answer is offered by the so-called generalized systems. Also such theories have received different and, sometimes, almost disjoint developments depending on the kind of space, where the problems have been defined. These kinds of problems will also be considered here.

Given a set X , a function $f : X \rightarrow \mathbb{R}$ and a subset S of X consider the problem:

$$\min f(x) \quad \text{s.t. } x \in S \tag{1}$$

Problem (1) is usually called a *combinatorial optimization problem* when S is finite and a *discrete optimization problem* when the points of S are isolated in some topology, i.e., every point of S has a neighborhood which does not contain other points of S . Obviously, all combinatorial optimization problems are also discrete optimization problems, but the converse is not true. A simple example is the problem of minimizing a function on the set of integer points contained in an unbounded polyhedron.

Even though some discrete and combinatorial optimization problems have been studied since ancient times, the increase of their importance and their development have been very fast only in the last few decades thanks to the possibility of practically solving them with modern computers and because of the several applications that they have found in many fields.

In most cases, discrete and combinatorial optimization problems can be formulated as linear or nonlinear integer programming problems and are solved by means of methods that exploit in a crucial way the finiteness or discreteness of the feasible region.

The linear programming formulation of most discrete and combinatorial optimization problems is typically based on the Fundamental Theorem of Linear Programming and on polyhedral theory. This subject, which is very well illustrated in the recent books [69] by Schrijver, is not covered here.

In the case where the feasible set S is defined by a family of equations and inequalities in \mathbb{R}^n and at least one of the constraints or objective functions is nonlinear, problem (1) is called a *nonlinear programming problem* or a *nonlinear program*. Problems of this kind have been studied for at least four centuries with tools that exploit the differential, geometric, and topological properties of the functions and sets involved.

Although the methods employed in integer and nonlinear programming are quite different in general, they can be complementary in several cases. In fact, it is often possible to restrict the search for a global solution of a nonlinear program to a finite set of points. On the other hand, most discrete optimization problems can be reformulated equivalently as nonlinear programs. Clearly, the restriction to a finite set of points or the nonlinear reformulation does not always lead to practical solution methods. Nevertheless, these approaches provide useful tools for many important classes of problems, as will be shown in the sequel.

This chapter is not meant to give an exhaustive survey of all connections between discrete optimization and nonlinear programming. The purpose here is to present the main tools that have been employed in the literature to transform a discrete problem into an *equivalent* nonlinear one and vice versa. This chapter does not cover, e.g., the many important continuous relaxations of discrete problems that lead to lower or upper bounds on the original problem without being equivalent to it.

2 Equivalence Through Relaxation–Penalization

2.1 General Results

This section contains general results about the equivalence of a constrained extremum problem with another one obtained from the former by enlarging the feasible region and penalizing the objective function. Several known and new results on the equivalence between mixed-integer and (continuous) nonlinear programming problems are derived as special cases of such general results.

More formally, one wishes to describe conditions that guarantee the equivalence of the problems

$$\min f(x) \quad \text{s.t. } x \in W, \tag{2}$$

and

$$\min[f(x) + \varphi(x; \epsilon)] \quad \text{s.t. } x \in X, \tag{3}$$

where $W \subseteq X \subset \mathbb{R}^n$, $f : \mathbb{R}^n \rightarrow \mathbb{R}$, and, for every $\epsilon \in \mathbb{R}_+$, $\varphi(\cdot; \epsilon) : \mathbb{R}^n \rightarrow \mathbb{R}$ is a suitable penalty function.

A recent general result in this direction is the following theorem, originally stated by Lucidi and Rinaldi with an unnecessary compactness assumption here omitted.

Theorem 1 (Lucidi and Rinaldi [56]) *Let $W \subseteq X \subset \mathbb{R}^n$, let $\|\cdot\|$ be any norm in \mathbb{R}^n , and make the following assumptions:*

(A1) *The function f is bounded on X and there exist an open set $\mathcal{A} \supset W$ and real numbers α , $L > 0$ such that, for any $x, y \in \mathcal{A}$,*

$$|f(x) - f(y)| \leq L \|x - y\|^\alpha; \quad (4)$$

The function $\varphi(\cdot; \epsilon)$ satisfies the following conditions:

(A2) *for every $x, y \in W$, and $\epsilon \in \mathbb{R}_+$,*

$$\varphi(x; \epsilon) = \varphi(y; \epsilon). \quad (5)$$

(A3) *There exists a value $\hat{\epsilon}$ such that, for every $z \in W$, there is a neighborhood $S(z)$ of z such that, for every $x \in S(z) \cap (X \setminus W)$ and $\epsilon \leq \hat{\epsilon}$,*

$$\varphi(x; \epsilon) - \varphi(z; \epsilon) \geq \hat{L} \|x - z\|^\alpha, \quad (6)$$

where $\hat{L} > L$. Furthermore, set $S := \cup_{z \in W} S(z)$ and suppose there is a point $\bar{x} \in X \setminus S$ such that

$$\lim_{\epsilon \rightarrow 0} \varphi(\bar{x}; \epsilon) - \varphi(z; \epsilon) = +\infty, \quad (7)$$

$$\varphi(x; \epsilon) \geq \varphi(\bar{x}; \epsilon), \quad \forall x \in X \setminus S. \quad (8)$$

Then, there exists a value $\tilde{\epsilon} > 0$ such that, for all $\epsilon < \tilde{\epsilon}$, (2) and (3) have the same minimum points.

Proof First, observe that a minimum point of (3) is also a minimum point of (2). Indeed, for all $\epsilon > 0$, if x^* is a minimum point of (3), then

$$f(x^*) + \varphi(x^*; \epsilon) \leq f(x) + \varphi(x; \epsilon), \quad \forall x \in X.$$

Since $W \subseteq X$, it follows that

$$f(x^*) + \varphi(x^*; \epsilon) \leq f(x) + \varphi(x; \epsilon), \quad \forall x \in W.$$

If $x^* \in W$, then Assumption (A2) ensures that

$$f(x^*) \leq f(z), \quad \forall z \in W,$$

which shows that x^* is a minimum point of (2). Now one can prove that there exists a value $\tilde{\epsilon}$ such that, for all $\epsilon > \tilde{\epsilon}$, every minimum point of (3) belongs to W . Let \bar{x} and S be, respectively, the point and the open set defined in Assumption (A3). Hence, by (7), there exists a value $\bar{\epsilon}$ such that, for $\epsilon > \bar{\epsilon}$, the following inequality holds:

$$\varphi(\bar{x}; \epsilon) - \varphi(z; \epsilon) > \sup_{x \in W} f(x) - \inf_{x \in (X \setminus S)} f(x). \quad (9)$$

Then, put

$$\tilde{\epsilon} := \max\{\bar{\epsilon}, \hat{\epsilon}\}, \quad (10)$$

where $\hat{\epsilon}$ is defined as in (A3). Ab absurdo, suppose there exists a $\epsilon > \tilde{\epsilon}$ such that x^* is a minimum point not in W . Consider two different cases:

Case 1: $x^* \in S$.

Without any loss of generality, consider $S \subset \mathcal{A}$. In this case, there exists $z \in W$ such that $x^* \in S(z)$. Using the definition of $\hat{\epsilon}$, Assumptions (A1) and (A3), one obtains

$$\begin{aligned} f(z) - f(x^*) &\leq L \|z - x^*\|^\alpha < \hat{L} \|z - x^*\|^\alpha \\ &\leq \varphi(x^*; \epsilon) - \varphi(z; \epsilon). \end{aligned}$$

Thus the contradiction

$$f(z) + \varphi(z; \epsilon) < f(x^*) + \varphi(x^*; \epsilon).$$

Case 2: $x^* \in X \setminus S$. In this case

$$f(x^*) + \varphi(x^*; \epsilon) \geq \inf_{x \in X \setminus S} f(x) + \varphi(x^*; \epsilon). \quad (11)$$

For all $z \in W$, one has $f(z) - \sup_{x \in W} f(x) \leq 0$; then

$$f(x^*) + \varphi(x^*; \epsilon) \geq f(z) - \sup_{x \in W} f(x) + \inf_{x \in X \setminus S} f(x) + \varphi(x^*; \epsilon). \quad (12)$$

By using (8) and Assumption (A3), one obtains

$$f(x^*) + \varphi(x^*; \epsilon) \geq f(z) - \sup_{x \in W} f(x) + \inf_{x \in X \setminus S} f(x) + \varphi(\bar{x}; \epsilon). \quad (13)$$

Adding and subtracting $\varphi(z; \mu)$ lead to

$$\begin{aligned} f(x^*) + \varphi(x^*; \epsilon) &\geq f(z) + \varphi(z; \epsilon) + \varphi(\bar{x}; \epsilon) - \varphi(z; \epsilon) \\ &\quad - \sup_{x \in W} f(x) + \inf_{x \in X \setminus S} f(x). \end{aligned}$$

Finally, recalling the definition of $\tilde{\epsilon}$ and exploiting (9), one obtains the contradiction

$$f(x^*) + \varphi(x^*; \epsilon) > f(z) + \varphi(z; \epsilon).$$

Now, one proves that, for all $\epsilon > \tilde{\epsilon}$, every minimum point of (2) is also a minimum point of (3). Ab absurdo, suppose that there is an $\epsilon > \tilde{\epsilon}$ such that

$$f(x^*) + \varphi(x^*; \epsilon) < f(z) + \varphi(z; \epsilon),$$

where z is a minimum point of (2) and x^* is a minimum point of (3). Recalling the first part of the proof, one obtains that, for every $\epsilon < \tilde{\epsilon}$, the point x^* is also a minimum point of (2); hence, using Assumption (A2), it follows that

$$f(x^*) < f(z),$$

which contradicts the fact that z is a minimum point of (2). \square

The previous theorem generalizes a similar result in [36] described below. In this case, the problem considered is

$$\min f(x) \text{ s.t. } x \in R \cap Z, \quad (14)$$

where Z and R are subsets of \mathbb{R}^n and $f : \mathbb{R}^n \rightarrow \mathbb{R}$; the result states conditions under which (14) is equivalent to

$$\min[f(x) + \mu\psi(x)] \text{ s.t. } x \in R \cap X, \quad (15)$$

where $X \supseteq Z$, $\psi : \mathbb{R}^n \rightarrow \mathbb{R}$ is a suitable penalty function and μ is a real parameter.

Theorem 2 (Giannessi and Niccolucci [36]) *Let $R \subseteq \mathbb{R}^n$ be closed, let $Z \subseteq X$ be compact, and let the following hypotheses hold:*

(H₁) *$f : X \rightarrow \mathbb{R}$ is bounded, and there exist an open set $\mathcal{A} \supset Z$ and real numbers α , $L > 0$, such that, for every $x, y \in \mathcal{A}$, f fulfills the following Hölder condition:*

$$|f(x) - f(y)| \leq L \|x - y\|^\alpha.$$

(H₂) *Let $\psi : \mathbb{R}^n \rightarrow \mathbb{R}$ be such that:*

- (i) *ψ is continuous on X .*
- (ii) *$\psi(x) = 0$, $\forall x \in Z$, $\psi(x) > 0$, $\forall x \in X \setminus Z$.*
- (iii) *$\forall z \in Z$, there exists a neighborhood $S(z)$ of z , and a real $\epsilon(z) > 0$ such that*

$$\psi(x) \geq \epsilon(z) \|x - z\|^\alpha, \quad \forall x \in S(z) \cap (X \setminus Z).$$

Then, a real μ_0 exists such that, for every $\mu > \mu_0$, (14) and (15) are equivalent.

Proof Apply [Theorem 1](#): now the sets W and X are, respectively, equal to $R \cap Z$ and $R \cap X$. Furthermore, the penalty function φ of (3) is given by $\varphi(x; \epsilon) = \psi(x)/\epsilon$. Then $(H_2)(ii)$ for ψ implies $(A2)$ for φ . Also, consider any \hat{L} with $\hat{L} > L$. Since Z is compact, there is a finite cover S of Z , $S = \cup_{i=1}^k S(z_i)$, where the neighborhoods $S(z_i)$ are those of $(H_2)(iii)$. Setting $\hat{\epsilon} := \min\{\frac{\epsilon(z_i)}{\hat{L}}, i = 1, \dots, k\}$, for all $\epsilon \leq \hat{\epsilon}$ and $x \in (S(z_i) \cap X) \setminus Z$, it holds that

$$\varphi(x; \epsilon) \geq \hat{L} \|x - z_i\|.$$

Since $(R \cap X) \setminus S$ is compact, the continuous function ψ has a minimum point \bar{x} on $(R \cap X) \setminus S$; thanks to $(H_2)(ii)$, $\psi(\bar{x}) > 0$, and then (7) and (8) hold. So thanks to [Theorem 1](#), there exists $\bar{\epsilon}$ such that, for $\epsilon < \bar{\epsilon}$, (14) and

$$\min[f(x) + \psi(x)/\epsilon] \text{ s.t. } x \in R \cap X$$

have the same minimum points. The thesis follows choosing $\mu_0 = 1/\bar{\epsilon}$ and $\mu = 1/\epsilon$. \square

2.2 Equivalence Between Mixed-Integer and Real Optimization

A special case of (14), which embraces most combinatorial problems, is that where

$$Z = \{0, 1\}^n, \quad R = \{x \in \mathbb{R}^n : g(x) \geq 0\},$$

with $g : \mathbb{R}^n \rightarrow \mathbb{R}^m$. Thus, problem (14) becomes

$$\min f(x) \text{ s.t. } x \in \{x \in \mathbb{R}^n : g(x) \geq 0\} \cap \{0, 1\}^n. \quad (16)$$

In this case, the set $X = X_Q := \{x \in \mathbb{R}^n : 0 \leq x_i \leq 1, i = 1, \dots, n\}$ is the natural relaxation of Z . In [36] the function ψ defined by

$$\psi(x) = \sum_{i=1}^n x_i(1 - x_i), \quad (17)$$

is introduced as a penalty function. In this way, (15) becomes

$$\min \left[f(x) + \mu \sum_{i=1}^n x_i(1 - x_i) \right] \text{ s.t. } x \in R \cap X_Q. \quad (18)$$

From [Theorem 2](#) one then derives the following result.

Theorem 3 ([36]) Let f be a Lipschitz function on X_Q . Then, there exists $\mu_0 \in \mathbb{R}$, such that, $\forall \mu > \mu_0$, problems (16) and (18) have the same set of global minimum points. Furthermore, if $f \in C^2(X_Q)$, then there exists $\mu_1 \in \mathbb{R}$ such that, $\forall \mu > \mu_1$, $f + \mu\psi$ is a strictly concave function.

Proof One only needs to prove that ψ of (17) satisfies Assumption (H_2) of Theorem 2 with $\alpha = 1$. Note that $(H_2)(i)$ and $(H_2)(ii)$ are trivially verified. For $\bar{\rho}$ in $]0, 1, [$ one can prove that ψ fulfills $(H_2)(iii)$, with $S(z) = \{x \in \mathbb{R}^n : \|x - z\| \leq \bar{\rho}\}$, $\epsilon(z) = 1 - \bar{\rho}$. Indeed, for $x \in S(z)$, put $\rho := \|x - z\|$ and $u := (x - z)/\rho$. Then

$$\psi(x) = \sum_{j=1}^n (\rho u_j + z_j)(1 - z_j - \rho u_j). \quad (19)$$

As $z + \rho u = x \in X_Q$, if $u_j > 0$, then $z_j = 0$; but if $u_j < 0$, then $z_j = 1$. From (19) it follows

$$\psi(x) = \sum_{u_j > 0} \rho u_j (1 - \rho u_j) + \sum_{u_j < 0} (1 + \rho u_j)(-\rho u_j) = \sum_{j=1}^n \rho |u_j| (1 - \rho |u_j|). \quad (20)$$

By construction $\|u\|^2 = 1$ and $\sum_j |u_j| \geq \|u\| = 1$; then, from (20), it follows that

$$\psi(x) = \rho \sum_{j=1}^n |u_j| - \rho^2 \geq \rho(1 - \bar{\rho}) = \epsilon(z) \|x - z\|.$$

Thus Assumption (H_2) of Theorem 2 is satisfied and the proof of equivalence of (16) and (18) follows. To prove strict concavity of $f + \mu\psi$, let $H(x)$ and $\hat{H}(x)$ denote the Hessian matrices of f and of $f + \mu\psi$, respectively. Then $\hat{H}(x) = H(x) - 2\mu I_n$. So $v(x)$ is an eigenvalue of $\hat{H}(x)$ if and only if $v(x) + 2\mu(x)$ is an eigenvalue of $H(x)$. The continuity of H implies that of the eigenvalues $\lambda_1, \dots, \lambda_n$ [25]. Thus, since X_Q is compact, one has

$$\tilde{\lambda} = \max_{i=1, \dots, n} \max_{x \in X} |\lambda_i(x)| \in \mathbb{R}.$$

Therefore, and $x \in X_Q$, one has $v(x) < 0$ for all eigenvalues $v(x)$ of $\hat{H}(x)$ so that $f + \mu\psi$ is strictly concave on X_Q . \square

It is interesting to observe that the second part of this theorem shows that every integer problem (16) with a sufficiently regular objective function can be transformed into a *concave* continuous problem, for which several solution methods have been developed (see, e.g., [11, 46, 62]).

For problem (16), in addition to the function $\psi(x) = \sum_{i=1}^n x_i(1-x_i)$ of [36], the following concave penalty functions $\varphi(\cdot; \epsilon) : \mathbb{R}^n \rightarrow \mathbb{R}$ have been proposed in [65]:

$$\varphi(x; \epsilon) = \sum_{i=1}^n \left(\log(x_i + \epsilon) + \log((1-x_i) + \epsilon) \right), \quad (21)$$

$$\varphi(x; \epsilon) = \sum_{i=1}^n \left(-(x_i + \epsilon)^{-p} - [(1-x_i) + \epsilon]^{-p} \right), \quad (22)$$

$$\varphi(x; \epsilon) = \frac{1}{\epsilon} \sum_{i=1}^n \left(\left[1 - e^{(-\alpha x_i)} \right] + \left[1 - e^{(-\alpha(1-x_i))} \right] \right), \quad (23)$$

$$\varphi(x; \epsilon) = \frac{1}{\epsilon} \sum_{i=1}^n \left([x_i + \epsilon]^q + [(1-x_i) + \epsilon]^q \right). \quad (24)$$

Furthermore, the following has been introduced in [56]:

$$\varphi(x; \epsilon) = \frac{1}{\epsilon} \sum_{i=1}^n \left([1 + e^{(-\alpha x_i)}]^{-1} + [1 + e^{(-\alpha(1-x_i))}]^{-1} \right), \quad (25)$$

where $\epsilon, \alpha, p > 0$, and $0 < q < 1$.

Proposition 1 ([56]) *For every penalty term (21)–(25), there exists a value $\bar{\epsilon}$ such that, for any $\epsilon \in]0, \bar{\epsilon}[$, problems (16) and (18) have the same set of global minimum points.*

A penalty function for mixed-integer problems is introduced in [3]. More precisely, consider the mixed-integer problem:

$$\inf f(u, v) \quad \text{s.t. } (u, v) \in R, \quad (26)$$

where $f : \mathbb{R}^n \times \mathbb{R}^k \rightarrow \mathbb{R}$, $R := \{(u, v) \in \{0, 1\}^n \times \mathbb{R}^k : g(u, v) \in D\}$, $g : \mathbb{R}^n \times \mathbb{R}^k \rightarrow \mathbb{R}^m$, and $D \subseteq \mathbb{R}^m$.

For a closed convex set $A \subseteq \mathbb{R}^h$, let $\text{proj}_A : \mathbb{R}^h \rightarrow \mathbb{R}^h$ be the function defined by

$$\|x - \text{proj}_A(x)\| = \min_{y \in A} \|y - x\|;$$

let $\Pi : R^n \times \mathbb{R}^k \rightarrow \mathbb{R}^k$ be the canonical projection on \mathbb{R}^k :

$$\Pi(u, v) = v.$$

Proposition 2 (Antoni [3]) Suppose R is closed. If, for all $z \in \{0, 1\}^n$, the set $A_z = \{(u, v) : (u, v) \in R, u = z\}$ is a closed convex set, then the function $\Psi : \mathbb{R}^n \times \mathbb{R}^k \times \mathbb{R} \rightarrow \mathbb{R}$ defined by

$$\Psi(u, v; \epsilon) = \left[\sum_{i=1}^n u_i(1 - u_i) + \|v - \Pi(\text{proj}_R(u, v))\| \right] / \epsilon$$

satisfies Assumptions (A2) and (A3) of [Theorem 1](#).

When the equivalence between (16) and (18) holds, properties and methods valid for one of the two problems can be transferred to the other one. As an instance of this, consider the quadratic programming problem

$$\min \left[\langle c, x \rangle + \frac{1}{2} \langle x, Cx \rangle \right] \text{ s.t. } x \in \{Ax \geq b\} \cap \{0, 1\}^n, \quad (27)$$

where $b \in \mathbb{R}^m$, $c \in \mathbb{R}^n$, $A \in \mathbb{R}^{m \times n}$, and $C \in \mathbb{R}^{n \times n}$ is a symmetric matrix.

Theorem 4 ([36]) There is a real μ_2 such that, for all $\mu > \mu_2$, THE problem (27) and the linear complementarity problem

$$\min \langle \bar{c}, \xi \rangle \text{ s.t. } (\xi, \eta) \in D, \quad (28)$$

where

$$D := \{(\xi, \eta) \in \mathbb{R}^{2n+m} \times \mathbb{R}^{2n+m} : \bar{A}\xi + \eta = \bar{b}, \xi \geq 0, \eta \geq 0, \langle \xi, \eta \rangle = 0\}$$

$$\bar{A} = \begin{pmatrix} -C + 2\mu I_n & A^T & -I_n \\ A & 0 & 0 \\ I_n & 0 & 0 \end{pmatrix},$$

$$\bar{c}^T = (1/2)(c^T + \mu e^T + e^T, b^T, e^T), \quad \bar{b}^T = (c^T, b^T, e^T),$$

have the same set of global minimum points.

Proof Because of [Theorem 3](#), whose hypotheses are trivially satisfied, (27) is equivalent to the quadratic problem

$$\min \left[\langle c + \mu e, x \rangle + \frac{1}{2} \langle x, (C - 2\mu I_n)x \rangle \right] \text{ s.t. } x \in \{Ax \geq b\} \cap X_Q, \quad (29)$$

where $e = (1, \dots, 1) \in \mathbb{R}^n$, if μ is large enough. The well-known Karush–Kuhn–Tucker necessary condition for (29) is

$$\begin{aligned} c^T + \mu e^T + (C - 2\mu I_n)x - A^T y + t - u &= 0 \\ Ax - v = b; \quad x + w = e; \quad x, y, t, u, v, w \geq 0 \\ \langle x, u \rangle = \langle y, v \rangle = \langle t, w \rangle = 0, \end{aligned} \tag{30}$$

where y, t, u are vectors of multipliers associated to the inequalities $Ax \geq b, x \leq e$, and $x \geq 0$, respectively, and v, w are slack variables. Solving (29) is equivalent to finding, among the solutions of the complementarity system (30) (stationary points), those which minimize the function in square brackets of (29). Such a function, evaluated at the stationary points, becomes “linear”:

$$\frac{1}{2}[\langle c + \mu e, x \rangle + \langle b, y \rangle + \langle e, t \rangle].$$

Indeed, (30) implies

$$\begin{aligned} Cx - 2\mu x &= -(c + \mu e) + A^T y - t + u, \\ \langle x, u \rangle &= 0, \\ 0 &= \langle y, v \rangle = \langle y, b - Ax \rangle, \\ 0 &= \langle t, w \rangle = \langle t, e - x \rangle, \end{aligned}$$

and therefore

$$\begin{aligned} \langle y, b \rangle &= \langle y, Ax \rangle, \\ \langle t, e \rangle &= \langle t, x \rangle. \end{aligned}$$

Now, to achieve the thesis, it is sufficient to set

$$\xi^T := (x^T, y^T, t^T), \quad \eta^T := (u^T, v^T, w^T).$$

This completes the proof. \square

Note that no assumption has been made on the matrix C , so the convex case, as well the nonconvex one, has been considered. See also [61] for a reduction of a mixed-integer feasibility problem to a linear complementarity system.

2.3 On the Estimate of Penalization Parameters

For stability reasons, it is often useful to be able to choose a penalization parameter μ not too large. This section contains some theoretical results on the comparison between the parameters μ given in [36, 49]. More precisely, in [49] the following linear optimization problem is considered:

$$\min[-\langle c, x \rangle] \text{ s.t. } x \in R \cap Z, \quad (31)$$

where $x, c \in \mathbb{R}^n$, R is a polyhedron of \mathbb{R}^n , and $Z = \{0, 1\}^n$ is the set of vertices of the hypercube $X = \{x \in \mathbb{R}^n : 0 \leq x_i \leq 1\}$. Without any loss of generality, suppose c have nonnegative components.

Kalantari and Rosen [49] find a solution x_0 of

$$\min[-\langle c, x \rangle] \text{ s.t. } x \in R \cap X.$$

If $x_0 \in Z$, then x_0 solves (31). Otherwise, they consider the following maximization problem

$$\max g(x) \text{ s.t. } x \in \hat{F}, \quad (32)$$

where $g : \mathbb{R}^n \rightarrow \mathbb{R}$, $g(x) = \sum_{i=1}^n (x_i - 1/2)^2$, and \hat{F} denotes the set of the vertices of $R \cap X$ not in Z . Denoting by \bar{x} a solution of (32), they prove the equivalence between (31) and

$$\min[f(x) - \mu g(x)] \text{ s.t. } x \in R \cap X,$$

when

$$\mu > \mu_R := \frac{\langle c, x_0 \rangle}{n/4 - g(\bar{x})}.$$

Observe that the strictly concave function

$$\psi(x) = \sum_{i=1}^n x_i(1 - x_i) \quad (33)$$

is related to g by the relation

$$\psi(x) = n/4 - g(x).$$

So that the denominator of μ_R is $\psi(\bar{x})$.

The parameter μ_R is now compared with the parameter μ_G introduced in [36] and denoted by μ_0 in [Theorem 3](#), which establishes equivalence between (31) and

$$\min[-\langle c, x \rangle + \mu \psi(x)] \text{ s.t. } x \in R \cap X, \quad (34)$$

for $\mu > \mu_G = \mu_0$.

The following notation is adopted: $q := (1/2, \dots, 1/2) \in \mathbb{R}^n$; $d(x, A)$ denotes the distance between the vector x and the set A of \mathbb{R}^n ; $B(y, r) := \{x \in \mathbb{R}^n : d(x, y) < r\}$; for a subset A of \mathbb{R}^n , $cl A$ and A^c denote, respectively, the closure and the complement of A .

In order to verify the hypotheses of [Theorem 3](#), observe that the objective function $x \mapsto -\langle c, x \rangle$ is a Lipschitz function with constant $L = \|c\|$, and ψ satisfies the hypothesis (H_2) . Indeed, let ρ be a value of $]0, 1[$, and, for every $z_i \in R \cap Z$, let the set $S(z_i)$ be a neighborhood of z_i with $S(z_i) \subseteq B(z_i, \rho)$. Then, ψ satisfies (H_2) for $\alpha = 1$ and $\epsilon = 1 - \rho$. Recall the definition of parameter μ_G :

$$\mu_G := \max \left(\frac{\|c\|}{1 - \rho}, \frac{(\sup_{x \in R \cap X} [-\langle c, x \rangle]) - (\inf_{x \in R \cap X} [-\langle c, x \rangle])}{\min_{x \in X_{0,\rho}} \psi(x)} \right),$$

where

$$X_{0,\rho} := (X \cap R) \setminus \left(\cup_{i=1}^k S(z_i) \right).$$

Thanks to [Theorem 3](#), the equivalence between (31) and (34) holds for any $\mu > \mu_G$. Observe the dependence of μ_G on the radius ρ ; below, to highlight this dependence, the notation $\mu_{G,\rho}$ will be used instead of μ_G .

Before giving sufficient conditions to establish a comparison, observe the following:

Remark 1 The hypothesis (H_2) of [Theorem 3](#) and the continuity of ψ imply that $\rho < 1$.

For the sake of simplicity, put

$$\lambda_{0,\rho} := \frac{(\sup_{x \in R \cap X} [-\langle c, x \rangle]) - (\inf_{x \in R \cap X} [-\langle c, x \rangle])}{\min_{x \in X_{0,\rho}} \psi(x)}.$$

The following result gives sufficient conditions assuring that there exist a $\bar{\rho} > 0$ and a neighborhood $S(z_i) \subseteq B(z_i, \bar{\rho})$ such that

$$\mu_{G,\bar{\rho}} \leq \mu_R.$$

Theorem 5 ([5]) *Let \bar{x} be a solution of (32). Suppose that*

$$d(\bar{x}, q) \geq \frac{\sqrt{n-1}}{2}$$

and

$$\frac{\sup_{x \in R \cap X} \langle c, x \rangle}{\|c\|} \geq \frac{1}{2}. \quad (35)$$

Then, there exist $\bar{\rho} \in]0, 1[$ and, $\forall z_i \in Z$, a neighborhood $S(z_i) \subseteq B(z_i, \bar{\rho})$ such that

$$\mu_{G, \bar{\rho}} \leq \mu_R. \quad (36)$$

Proof Consider the one-dimensional face of X given by

$$F_1 := \{x \in \mathbb{R}^n : x = (x_1, 0, \dots, 0), x_1 \in [0, 1]\}.$$

Since $d(\bar{x}, q) \geq \sqrt{n-1}/2$ and $d(q, F_1) = \sqrt{n-1}/2$, necessarily the intersection $A := \text{cl } B(q, d(\bar{x}, q)) \cap F_1$ is nonempty. Put $\bar{\rho} = d(0, A)$ and denote by x^* the point of A at minimum distance from the origin of \mathbb{R}^n . Finally, let $S(z_i) := X \cap B(z_i, \bar{\rho})$. Since $X_{0, \bar{\rho}} = (X \cap R) \setminus \left(\bigcup_{i=1}^k S(z_i) \right)$, by construction,

$$X_{0, \bar{\rho}} \subseteq \text{cl } B(q, d(q, \bar{x})) = \{x \in \mathbb{R}^n : \psi(x) \geq \psi(\bar{x})\};$$

then one has

$$\min_{x \in X_{0, \bar{\rho}}} \psi(x) \geq \psi(\bar{x}),$$

so

$$\lambda_{0, \bar{\rho}} \leq \frac{(\sup_{x \in R \cap X} [-\langle c, x \rangle]) - (\inf_{x \in R \cap X} [-\langle c, x \rangle])}{\psi(\bar{x})}.$$

Moreover, obviously,

$$\frac{(\sup_{x \in R \cap X} [-\langle c, x \rangle]) - (\inf_{x \in R \cap X} [-\langle c, x \rangle])}{\psi(\bar{x})} \leq -(\inf_{x \in R \cap X} [-\langle c, x \rangle]) \psi(\bar{x}) = \mu_R;$$

thus

$$\lambda_{0, \bar{\rho}} \leq \mu_R. \quad (37)$$

Besides, the inequality

$$\frac{\|c\|}{1 - \bar{\rho}} \leq \mu_R \quad (38)$$

is equivalent to

$$\frac{\psi(\bar{x})}{1 - \bar{\rho}} \leq \frac{\sup_{x \in R \cap X} \langle c, x \rangle}{\|c\|}.$$

The last inequality is true because $\psi(\bar{x}) = \psi(x^*) = x_1^*(1 - x_1^*) = \bar{\rho}(1 - \bar{\rho})$, and thanks to the inequality in (35); indeed, one has

$$\frac{\psi(\bar{x})}{1 - \bar{\rho}} = \bar{\rho} \leq \frac{1}{2} \leq \frac{\sup_{x \in R \cap X} \langle c, x \rangle}{\|c\|}.$$

So (36) follows from (37) and (38) and the theorem is thus proved. \square

2.4 On the Equivalence of Lagrangian Duality and Penalization

Based on results by Larsen and Tind [55], it is shown here that the penalization approach to a constrained optimization problem described in [Theorem 1](#) can be interpreted in terms of Lagrangian duality with zero gap for an associated problem.

More precisely, consider the sets $W \subseteq X \subset \mathbb{R}^n$ and a (penalty) function $g : X \rightarrow \mathbb{R}$ such that $g(x) \geq 0$ for all $x \in X$ and $g(x) = 0$ for all $x \in W$. Then, problem [\(2\)](#) can be equivalently restated as

$$\min f(x) \text{ s.t. } x \in W = \{x \in X, g(x) \leq 0\}. \quad (39)$$

Its Lagrangian dual problem is

$$\sup w(\mu) \text{ s.t. } \mu \in \mathbb{R}_+, \quad (40)$$

where

$$w(\mu) = \min[f(x) + \mu g(x)] \text{ s.t. } x \in X. \quad (41)$$

Then, requiring the existence of a penalization parameter $\bar{\mu}$ such that, for all $\mu > \bar{\mu}$, problems [\(2\)](#) and [\(3\)](#) have the same solutions is equivalent to requiring that problem [\(39\)](#) has no duality gap and, more precisely, that for all $\mu > \bar{\mu}$ problem [\(41\)](#) has the same optimal solutions as [\(39\)](#). Thus any known result for zero duality gap can be immediately rephrased as an exact penalty result and vice versa. As an example, recall the following results by Larsen and Tind [55], rephrased in the current setting, with the notation $B(\bar{x}, \epsilon) := \{x \in \mathbb{R}^n : \| \bar{x} - x \| < \epsilon\}$.

Theorem 6 ([55]) *Let $W \subseteq X$ be nonempty compact sets in \mathbb{R}^n and let f and g be continuous functions on X such that $g(x) \geq 0$ for all $x \in X$ and $g(x) = 0$ for all $x \in W$. Assume that there exist constants $\epsilon > 0$ and $H > 0$ such that $f(\bar{x}) - f(x) \leq H g(x)$ for all solutions \bar{x} of [\(39\)](#) and for all $x \in B(\bar{x}, \epsilon) \cap (X \setminus W)$. Then, there exists $\mu_0 \geq 0$ such that, $\forall \mu \geq \mu_0$,*

$$\min_{x \in W} f(x) = w(\mu).$$

Consider, now, the following facial disjunctive special case of [\(39\)](#):

$$\min f(x) \text{ s.t. } x \in W = \{x \in X : \langle a_1^h, x \rangle \geq b_1^h \vee \langle a_2^h, x \rangle \leq b_2^h, h \in H\}, \quad (42)$$

where $a_1^h, a_2^h \in \mathbb{R}^n \setminus \{0\}$, $b_1^h, b_2^h \in \mathbb{R}$ for all $h \in H$, and H is a finite index set. According to Balas [10], the facial requirement for [\(42\)](#) is

$$(A) \quad \forall x \in X, \quad \langle a_1^h, x \rangle \leq b_1^h \wedge \langle a_2^h, x \rangle \geq b_2^h, \quad \forall h \in H.$$

Indeed, for the function

$$g(x) = \sum_{h \in H} (b_1^h - \langle a_1^h, x \rangle)((\langle a_2^h, x \rangle - b_2^h)), \quad (43)$$

one has $g(x) \geq 0$ for all $x \in X$ and $g(x) = 0$ for all $x \in W$. So the feasible set of (42) has the desired form $W = \{x \in X : g(x) \leq 0\}$ and g satisfies the assumptions of [Theorem 6](#).

On the feasible set W , the following further assumption is made:

$$(B) \quad \exists \delta > 0 \forall \bar{x} \in W \forall h \in H, \frac{b_1^h - \langle a_1^h, \bar{x} \rangle}{\|a_1^h\|} \geq \delta \text{ or } \frac{\langle a_2^h, \bar{x} \rangle - b_2^h}{\|a_2^h\|} \geq \delta.$$

Theorem 7 ([55]) *Let Assumptions (A) and (B) hold for the feasible set of (42) and choose $\rho \in]0, \delta[$. Then, the constraint function g in (43) satisfies, for all $\bar{x} \in W$ and $x \in B(\bar{x}, \rho) \cap (X \setminus W)$, the inequality*

$$g(x) \geq ((\delta - \rho)/\delta^2) \inf \left\{ \sum_{h \in H} |\langle a_1^h, u \rangle| |\langle a_2^h, u \rangle| : u \in U(\delta) \right\} \|x - \bar{x}\|,$$

where $U(\delta) := \{u \in \mathbb{R}^n : u = \delta(x - \bar{x})/\|x - \bar{x}\|, \bar{x} \in W, x \in X \setminus W\}$.

Now, the previous results are applied to the 0–1 problem given by

$$\min f(x) \text{ s.t. } x \in W = R \cap \{0, 1\}^n. \quad (44)$$

Obviously it holds that

$$W = R \cap [0, 1]^n \cap \left\{ \bigcap_{j=1}^n (\{x_j \geq 1\} \cup \{x_j \leq 0\}) \right\}.$$

Putting $X = R \cap [0, 1]^n$, (44) is a facial disjunctive program satisfying the facial requirement (A). Moreover it becomes the facial program

$$\min f(x) \text{ s.t. } x \in W = \{x \in R \cap [0, 1]^n, g(x) \leq 0\} \quad (45)$$

using the realization of g given by

$$g(x) = \sum_{j=1}^n x_j (1 - x_j).$$

Therefore the Lagrangian dual of (45) is

$$\sup_{M \geq 0} \min_{x \in R \cap [0, 1]^n} \left[f(x) + M \sum_{j=1}^n x_j (1 - x_j) \right]. \quad (46)$$

The next proposition, first proved in [36], can be stated as a direct application of [Theorem 6](#).

Theorem 8 ([55]) *Assume R and W are, respectively, a closed and a nonempty set of \mathbb{R}^n ; assume f is a Lipschitz continuous function on $R \cap [0, 1]^n$. Then the duality gap between (45) and (46) is closed with a finite dual multiplier.*

Proof Problem (44) is a facial disjunctive problem; Assumption (A) holds with $X = R \cap [0, 1]^n$; Assumption (B) holds with $\delta \leq 1$; finally, for all $u \in U(\delta)$, $\sum_{h \in H} |\langle a_1^h, u \rangle| |\langle a_2^h, u \rangle| = \delta^2$. Thus, [Theorem 7](#) implies the inequality $g(x) \geq (\delta - \rho) \|x - \bar{x}\|$ for all $x \in B(\bar{x}, \rho) \cap (X \setminus W)$ and $\bar{x} \in W$. Therefore [Theorem 6](#) can be applied. \square

3 Generalized Concavity and Extreme Point Minimizers

3.1 Global Minimizers at Extreme Points

In many cases it is possible to restrict the search for the global solution of a nonlinear program to a finite set of points. One way of doing this consists in considering only the set of points that satisfy some kind of first- or second-order necessary condition for local optimality. This set is often finite, but in general it is not practical to compute all its elements or to minimize the objective function over it. However, there are some interesting cases where this simple idea leads to useful connections between nonlinear and combinatorial problems.

This section describes another important case where the search for a solution of a nonlinear program can be restricted to a finite set, namely, when at least one global minimizer is guaranteed to be in the set of extreme points of a polyhedral feasible region.

The following definitions of extreme point and of concavity of a function in the general setting on nonconvex domains will be needed in the sequel.

Definition 1 (Extreme Point) Let X be a subset of \mathbb{R}^n . A point $x \in X$ is called an *extreme point* of X iff $y, z \in X$, $\alpha \in]0, 1[$, and $x = \alpha y + (1 - \alpha)z$ imply $y = z$. A point $x \in X$ is called a *convex hull extreme point* of X iff it is an extreme point of the *convex hull* (denoted by $\text{conv}(X)$) of X .

Note that the set of extreme points of a polyhedron is finite and coincides with the set of its vertices. Let $\mathcal{E}(X)$ denote the set of extreme points of a set X . Then the set of convex hull extreme points is given by $\mathcal{E}(\text{conv}(X))$. Since $X \subseteq \text{conv}(X)$, it follows from the above definition that $\mathcal{E}(\text{conv}(X)) \subseteq \mathcal{E}(X) \subseteq X$.

It is well known (see, e.g., [66]) that the convex hull of a compact set is compact. Furthermore, the Krein–Millman Theorem establishes the equality $X = \text{conv}(\mathcal{E}(X))$ for a nonempty convex compact set X . From this it easily follows that a nonempty compact set X has a nonempty set of convex hull extreme points and,

furthermore, that every extreme point of X is in the convex hull of the convex hull extreme points of X .

Proposition 3 *For a nonempty compact set X , one has*

$$\mathcal{E}(\text{conv}(X)) \neq \emptyset \quad \text{and} \quad \text{conv}(\mathcal{E}(\text{conv}(X))) = \text{conv}(\mathcal{E}(X)).$$

Proof The results follow from Krein–Millman Theorem and from the inclusions

$$\text{conv}(X) = \text{conv}(\mathcal{E}(\text{conv}(X))) \subseteq \text{conv}(\mathcal{E}(X)) \subseteq \text{conv}(X).$$

□

Definition 2 (Concavity on Nonconvex Sets) Let X be a subset of \mathbb{R}^n . A function $f : X \rightarrow \mathbb{R}$ is *concave* (resp., *quasi-concave*) on X iff, for every $x \in X$ and for every set of points $\{x^1, \dots, x^m\} \subseteq X$ and of coefficients $\alpha_1, \dots, \alpha_m \in]0, 1[$ such that $\sum_{i=1}^m \alpha_i = 1$ and $x = \sum_{i=1}^m \alpha_i x^i$, one has

$$f(x) \geq \sum_{i=1}^m \alpha_i f(x^i) \quad (\text{resp. } f(x) \geq \min_i f(x^i)). \quad (47)$$

A function is called *strictly concave* or *strictly quasi-concave* iff the above relations are satisfied with a strict inequality whenever $x^i \neq x$ for at least one index i .

Note that if the set X coincides with $\mathcal{E}(\text{conv}(X))$ (like, e.g., in the case of a circle), then every function is strictly concave on X with the above definition. However, when X is convex, **Definition 2** is equivalent to the standard definition of concavity and of strict concavity of a function.

Several conditions for the validity of the following property will be investigated in this section.

Property E

At least one (or all) global minimizer of f on a set X belongs to $\mathcal{E}(X)$.

The Fundamental Theorem of linear programming is the most popular result that guarantees the validity of Property E.

Theorem 9 (Fundamental Theorem of LP) *If a linear function f is bounded below on a polyhedron X , then at least one face of X of minimum dimension must be formed by global minimum points of f . In particular, whenever $\mathcal{E}(X) \neq \emptyset$, at least one global minimum point of f belongs to $\mathcal{E}(X)$.*

The Fundamental Theorem of LP establishes an important bridge between a (continuous) Linear Programming problem and many important combinatorial problems that can be viewed as problems of minimizing a linear function on the vertices of some polyhedron.

It is well known that Property E also holds for classes of feasible sets X and of objective functions f that are considerably larger than the classes of polyhedra and of linear functions. Notable examples are the cases where f is concave and X is a closed convex set, or where f is quasi-concave and X is a compact convex set (see, e.g., [45, 77]). Note, however, that Property E does not hold in general for quasi-concave functions on *unbounded* closed convex sets. A simple counterexample is provided by the quasi-concave (and convex) function $f : X = [0, +\infty[\rightarrow \mathbb{R}$ defined by $f(x) = -x$, for $x \in [0, 1]$, and $f(x) = -1$, for $x \in]1, +\infty[$.

3.2 The Case of Nonconvex Domains

It will now be shown that Property E still holds (and in a stronger form), for the minimization of concave or quasi-concave functions on nonconvex domains.

Definition 3 (Concave Envelope) Let X be a subset of \mathbb{R}^n . The *concave envelope* (or *concave hull*) of a function $f : X \rightarrow \mathbb{R}$, denoted f^{cv} , is the smallest concave function on $\text{conv}(X)$ which is minorized by f on X . The *convex envelope* (or *convex hull*) of f , denoted f^{cx} , is defined as the greatest convex function on $\text{conv}(X)$ which is majorized by f on X .

The convex and concave envelopes of f can be obtained as follows (see also [66]):

$$\begin{aligned} f^{cx}(x) &:= \inf\{y : (x, y) \in \text{conv}(\text{Epi } f)\}, \\ f^{cv}(x) &:= \sup\{y : (x, y) \in \text{conv}(\text{Hypo } f)\}, \end{aligned} \quad (48)$$

where $\text{Epi } f = \{(x, y) \in X \times \mathbb{R} : y \geq f(x)\}$ and $\text{Hypo } f = \{(x, y) \in X \times \mathbb{R} : y \leq f(x)\}$ denote the epigraph and the hypograph of f , respectively. The convex envelope of f satisfies the following properties (see, e.g., [52, 62]):

$$\inf_{x \in X} f(x) = \inf_{x \in \text{conv}(X)} f^{cx}(x) \quad \text{and} \quad \arg \min_{x \in X} f(x) \subseteq \arg \min_{x \in \text{conv}(X)} f^{cx}(x), \quad (49)$$

where $\arg \min_{x \in S} g(x)$ denotes the set of global minimum points of a function g on a set S . Thanks to properties (49), convex envelopes have been employed by several authors to develop algorithms for the minimization of some classes of nonconvex functions (see [19, Sect. 3.2] for a brief survey of these approaches).

When X is any subset of \mathbb{R}^n and f is a concave function on X , the *concave envelope* $f^{cv}(x)$ satisfies the same properties as the convex envelope.

Theorem 10 *Let X be a subset of \mathbb{R}^n and let $f : X \rightarrow \mathbb{R}$ be any real-valued function on X . Then*

$$f^{cv}(x) = f^{cx}(x) = f(x), \quad \forall x \in \mathcal{E}(\text{conv}(X)).$$

Furthermore, if f is concave on X , then

$$\begin{aligned} f^{\text{cv}}(x) &= f(x), \quad \forall x \in X, \\ \inf_{x \in X} f(x) &= \inf_{x \in \text{conv}(X)} f^{\text{cv}}(x), \\ \arg \min_{x \in X} f(x) &\subseteq \arg \min_{x \in \text{conv}(X)} f^{\text{cv}}(x). \end{aligned} \tag{50}$$

Proof Let $x \in \mathcal{E}(\text{conv}(X))$. Then, as observed earlier, $x \in X$. Furthermore, $f^{\text{cv}}(x) \leq f(x)$ by definition of f^{cv} . Assume, ab absurdo, that $f^{\text{cv}}(x) < f(x)$. Then, by (48), there exists a set of points $\{x^1, \dots, x^m\} \subseteq X$ and coefficients $\alpha_1, \dots, \alpha_m \in]0, 1[$ such that $\sum_{i=1}^m \alpha_i = 1$, $\sum_{i=1}^m \alpha_i x^i = x$, and $\sum_{i=1}^m \alpha_i f(x^i) < f(x)$. However, this contradicts the fact that x is a convex hull extreme point of X , which implies $x^1 = x^2 = \dots = x^m = x$. The proof of the equality $f^{\text{cv}}(x) = f(x)$, $\forall x \in \mathcal{E}(\text{conv}(X))$, is analogous.

Assume now that f is concave, and take any $x \in X$. From the concavity of f it follows that $f(x) \geq \sum_{i=1}^m \alpha_i f(x^i)$ for every set of points $\{x^1, \dots, x^m\} \subseteq X$ and coefficients $\alpha_1, \dots, \alpha_m \in]0, 1[$ such that $\sum_{i=1}^m \alpha_i = 1$ and $\sum_{i=1}^m \alpha_i x^i = x$. This clearly implies $f(x) \geq y$ for every y such that $(x, y) \in \text{conv}(\text{Hypo } f)$ and hence $f(x) \geq f^{\text{cv}}(x)$ by (48). Since $f(x) \leq f^{\text{cv}}(x)$ by definition, the equality $f(x) = f^{\text{cv}}(x)$ follows.

Let $m = \inf_{x \in X} f(x)$. If $m = -\infty$, then clearly $\inf_{x \in \text{conv}(X)} f^{\text{cv}}(x) = -\infty$ since $f(x) = f^{\text{cv}}(x)$ on X . If $m > -\infty$, consider the constant function $h(x) = m$ defined on X and note that $h^{\text{cv}}(x) = m$ for every $x \in \text{conv}(X)$. Furthermore, since $f(x) \geq h(x)$ for every $x \in X$, one has $f^{\text{cv}}(x) \geq h^{\text{cv}}(x)$ on $\text{conv}(X)$. Hence, it follows that $\inf_{x \in \text{conv}(X)} f^{\text{cv}}(x) = m = \inf_{x \in X} f(x)$.

The inclusion $\arg \min_{x \in X} f(x) \subseteq \arg \min_{x \in \text{conv}(X)} f^{\text{cv}}(x)$ is a trivial consequence of the equality $\inf_{x \in \text{conv}(X)} f^{\text{cv}}(x) = \inf_{x \in X} f(x)$ and of the coincidence of f and f^{cv} on X . \square

It is well known [45] that a concave function that achieves its minimum on a closed convex set X that contains no line has at least one global minimum point among the extreme points of X . This result can be extended to the case where X is not convex.

Theorem 11 *Let $X \subseteq \mathbb{R}^n$ and $f : X \rightarrow \mathbb{R}$.*

- (i) *If either $\text{conv}(X)$ is closed and contains no line and f is concave on X , or X is compact and f is quasi-concave on X , then*

$$\arg \min_{x \in X} f(x) \neq \emptyset \Leftrightarrow \arg \min_{x \in X} f(x) \cap \mathcal{E}(\text{conv}(X)) \neq \emptyset. \tag{51}$$

- (ii) *If either $\text{conv}(X)$ is closed and contains no line and f is strictly concave on X , or X is compact and f is strictly quasi-concave on X , then*

$$\arg \min_{x \in X} f(x) \subseteq \mathcal{E}(\text{conv}(X)). \tag{52}$$

Proof Note that, by Theorem 10, the concave envelope f^{cv} coincides with f on X and the minimum of f^{cv} on $\text{conv}(X)$ coincides with the minimum

f on X . Observe also that if X is compact, then $\text{conv}(X)$ is closed. Let x be any point in $X \subseteq \text{conv}(X)$. Then, by Theorem 18.5 in [66], x can be expressed as a convex combination of extreme points and extreme directions of $\text{conv}(X)$. Hence, there exist $y \in \mathcal{E}(\text{conv}(X))$, $z \in \mathbb{R}^n$, and $\lambda \geq 0$ such that $x = y + \lambda z$ and $y + \lambda z \in \text{conv}(X)$ for all $\lambda \geq 0$. Thus, taking $\beta = \frac{\lambda}{\lambda+1}$, one has $y + (\lambda+1)z \in \text{conv}(X)$ and $x = (1-\beta)y + \beta(y + (\lambda+1)z)$. Since $y \in \mathcal{E}(\text{conv}(X))$ and $y + (\lambda+1)z \in \text{conv}(X)$, this implies that x can be expressed as a convex combination of points $y^1, \dots, y^h \in \mathcal{E}(\text{conv}(X))$ and $w^1, \dots, w^k \in \text{conv}(X)$ with $h \geq 1$ and $k \geq 0$ ($k = 0$ if X is compact). Assume now that x is a global minimum point for f on X . Then:

- (i) If f is concave on X , then $f(y^1) = \dots = f(y^h) = f(w^1) = \dots = f(w^k) = f(x)$ and if f is quasi-concave on X , then $f(x) = \min\{f(y^1), \dots, f(y^h)\}$. Hence, at least one point in $\mathcal{E}(\text{conv}(X))$ is a global minimum point for f on X .
- (ii) If f is strictly concave or strictly quasi-concave on X , then one must have $h = 1$ and $k = 0$, i.e., x must belong to $\mathcal{E}(\text{conv}(X))$; otherwise a contradiction would arise. \square

3.3 The Case of Polyhedral Domains

In the remainder of this section, the attention is restricted to the minimization of a function on a polyhedron, and in order to avoid trivial cases, it is also assumed that all (unbounded) polyhedra contain no line and thus are *pointed*, i.e., they have at least one vertex.

It is easily seen that the class of quasi-concave functions is the most general class of functions for which Property E holds for *every* bounded polyhedron S . Indeed, by applying Property E to the special polyhedron that coincides with the line segment joining two points x^1 and x^2 , one trivially obtains the inequality defining quasi-concave functions.

For a given polyhedron, or class of polyhedra, it is however possible to find classes of functions that properly include quasi-concave functions and satisfy Property E. Several results of this type that have been obtained by Tardella [72, 73, 75, 76] and by Hwang and Rothblum [47] are described next.

One first needs to introduce some definitions and notation. The *affine hull* of a subset S of \mathbb{R}^n is the smallest affine manifold containing S . $\text{tng}(S)$ denotes the smallest linear subspace of \mathbb{R}^n containing $S - \{x^0\} = \{x - x^0 : x \in S\}$, where x^0 is any point of S . Note that $\text{tng}(S)$ coincides with the set $\{\alpha(x - y) : x, y \in S, \alpha \in \mathbb{R}\}$ and can also be viewed as the linear subspace obtained by translating in 0 the affine hull of S . The *relative interior* $\text{rint}(S)$ and the *relative boundary* $\text{rbd}(S)$ of S are the interior and the boundary of S for the topology relative to the affine hull of S , respectively.

Given a polyhedron P , a point x in P , and a direction $d \in \mathbb{R}^n \setminus \{0\}$, let F_x denote the face of P of minimum dimension containing x , and consider the set

$$P_d(x) := \{z \in P : z = x + \lambda d, \lambda \in \mathbb{R}\},$$

obtained intersecting P with the line passing through x with direction d . Since P is pointed, $P_d(x)$ is either a segment or a half line for every x and d .

Consider the following conditions:

$$P_d(x) \text{ is bounded and } f \text{ is quasi-concave on } P_d(x). \quad (53)$$

$$f \text{ is concave and bounded below on } P_d(x). \quad (54)$$

$$f \text{ is strictly quasi-concave on } P_d(x). \quad (55)$$

A face F of P is said to satisfy *Property A*, *B*, or *C*, if for every $x \in \text{rint } F$ there exists $d \in \text{tng}(F) \setminus \{0\}$, such that:

Property A: Condition (53) or (54) or (55) holds.

Property B: Condition (53) or (54) holds.

Property C: Condition (55) holds.

Let \mathcal{F}_A , \mathcal{F}_B , and \mathcal{F}_C denote the sets of all faces of P that *do not* satisfy Properties *A*, *B*, and *C*, respectively. By definition, each set \mathcal{F}_A , \mathcal{F}_B , and \mathcal{F}_C contains all the vertices V_P of P . Furthermore, if f is concave and bounded below on P , or if P is bounded and f is quasi-concave on P , then \mathcal{F}_A and \mathcal{F}_B contain *only* the vertices of P . If f is strictly quasi-concave on P , then \mathcal{F}_A and \mathcal{F}_C contain *only* the vertices of P . Note also that $\mathcal{F}_A \subseteq \mathcal{F}_B$ and $\mathcal{F}_A \subseteq \mathcal{F}_C$.

The following lemma shows that the faces in \mathcal{F}_B contain all the best candidate points for minimizing f over P .

Lemma 1 *If $x \in P \setminus \bigcup_{F \in \mathcal{F}_B} F$, then there exists $x' \in \bigcup_{F \in \mathcal{F}_B} F$ such that $f(x') \leq f(x)$. Furthermore, if T_1 is the time required to find a direction d satisfying condition (53) or (54) in a face $F \notin \mathcal{F}_B$, and T_2 is the time required to find the extreme points of $P_d(x)$ for x in F , then x' can be determined in $O(n(T_1 + T_2))$ time.*

Proof Let $x \in P \setminus \bigcup_{F \in \mathcal{F}_B} F$ and let F_x be the face of P of minimum dimension containing x . Then $x \in \text{rint } F_x$, and thus one can find, in T_1 time, a direction $d \in \text{tng}(F) \setminus \{0\}$ such that (53) or (54) holds. Note that, since $x \in \text{rint } F_x$, one has $x \in \text{rint } P_d(x)$. If $P_d(x)$ is bounded and y, z are its extreme points, then $y, z \in \text{rbd } F_x$ and $f(x) \geq \{f(y), f(z)\}$ by quasi-concavity of f on $P_d(x)$. On the other hand, if $P_d(x)$ is unbounded and y is its only extreme point, then $y \in \text{rbd } F_x$ and $f(x) \geq f(y)$. Indeed, if $f(x) < f(y)$ and f is concave on $P_d(x)$, then f must be unbounded on $P_d(x)$ contradicting (54). Thus, in both cases one can find, in T_2 time, a point $x^1 \in \text{rbd } F$ satisfying $f(x^1) \leq f(x)$. If $x \in \bigcup_{F \in \mathcal{F}_B} F$, then set $x' = x^1$ and stop. Otherwise, consider the face F_{x^1} of P of minimum dimension containing x^1 , and iterate. Since $\dim(F_{x^1}) < \dim(F_x) \leq n$ and $V_P \subseteq \mathcal{F}_B$, after at most n iterations, one must find a point $x' \in \bigcup_{F \in \mathcal{F}_B} F$ satisfying $f(x') \leq f(x)$. \square

The next theorem shows that the infimum of f on P coincides with the infimum over the union of the faces in \mathcal{F}_B , and if one infimum is attained, the other is also attained. Furthermore, if the infimum is attained, at least one global minimizer of f on P must belong to a face in \mathcal{F}_A . Finally, the set of all global minimizers of f on P must be contained in the union of the faces in \mathcal{F}_C .

Theorem 12 (Existence and Location of Minima)

$$\inf_{x \in P} f(x) = \min_{F \in \mathcal{F}_B} \inf_{x \in F} f(x), \quad (56)$$

where the first infimum is attained if and only if the second infimum is attained. If the infimum is attained, then

$$\min_{x \in P} f(x) = \min_{F \in \mathcal{F}_A} \min_{x \in F} f(x) \quad (57)$$

and

$$\arg \min_{x \in P} f(x) \subseteq \bigcup_{F \in \mathcal{F}_C} F. \quad (58)$$

Proof The inequality $\inf_{x \in P} f(x) \leq \min_{F \in \mathcal{F}_B} \inf_{x \in F} f(x)$ is trivial. The converse inequality follows easily from Lemma 1. Furthermore, if f attains its minimum at a point $x \in P$, then by Lemma 1 it also attains its minimum at a point $x' \in \bigcup_{F \in \mathcal{F}_B} F$.

Assume now that all global minimum points of f on P belong to $\bigcup_{F \in \mathcal{F}_B} F \setminus \bigcup_{F \in \mathcal{F}_A} F$, and let F' be a face of minimum dimension in $\mathcal{F}_B \setminus \mathcal{F}_A$ containing a minimum point \bar{x} for f on P . Since $F' \in \mathcal{F}_B \setminus \mathcal{F}_A$, condition (55) must hold at \bar{x} . Let $d \in \text{tng}(F') \setminus \{0\}$ be such that f is strictly quasi-concave on $P_d(\bar{x})$. Then \bar{x} must be an extreme point of $P_d(\bar{x})$. Otherwise, \bar{x} could be obtained as a convex combination of two points $x^1, x^2 \in P_d(\bar{x})$ so that $f(\bar{x}) > \min\{f(x^1), f(x^2)\}$, contradicting the minimality of \bar{x} . On the other hand, if \bar{x} is an extreme point of $P_d(\bar{x})$, then $\bar{x} \in \text{rbd } F'$, contradicting the minimality of the dimension of F' . Hence one must have $\bar{x} \in \bigcup_{F \in \mathcal{F}_A} F$, so that (57) holds.

Let x be a global minimum point of f on P and assume that $x \notin \bigcup_{F \in \mathcal{F}_C} F$. Let F_x be the face of P of minimum dimension containing x . Then $x \in \text{rint } F_x$ and hence $x \in \text{rint } P_d(x)$ for every $d \in \text{tng}(F_x) \setminus \{0\}$. Since $F_x \notin \mathcal{F}_C$, there is a direction $d \in \text{tng}(F_x) \setminus \{0\}$ such that f is strictly quasi-concave on $P_d(x)$. Furthermore, since $x \in \text{rint } P_d(x)$, there exist points $x^1, x^2 \in P_d(x)$ such that $x = \frac{1}{2}(x^1 + x^2)$. Hence, by strict quasi-concavity, $f(x) > f(x^1) + f(x^2)$, contradicting the minimality of $f(x)$. \square

A further extension of the class of functions that attain their minima on P at a point in $\bigcup_{F \in \mathcal{F}_A} F$ (and in particular at a vertex of P , when $\bigcup_{F \in \mathcal{F}_A} F = V_P$) can be obtained with the following simple result.

Theorem 13 Let $f, g : X \rightarrow \mathbb{R}$ and $Y \subseteq X$ satisfy $f(x) \leq g(x)$ for all x in X , and $f(x) = g(x)$ for all x in Y . Then, if f attains its minimum on X at a point of Y , also g attains its minimum on X at a point of Y .

Proof

$$\min_{x \in Y} f(x) = \min_{x \in Y} g(x) \geq \inf_{x \in X} g(x) \geq \min_{x \in X} f(x) = \min_{x \in Y} f(x). \quad \square$$

[Theorem 12](#) can be used to decompose the problem of minimizing a function f on a polyhedron P into two subproblems:

$$\varphi(F) = \min_{x \in F} f(x) \quad \text{and} \quad \min_{F \in \mathcal{F}_A} \varphi(F). \quad (59)$$

The first subproblem is similar to the main problem of minimizing f on P . However, such subproblem could be easier to solve due to additional structure of f on some faces of P (like, e.g., convexity). On the other hand, the second subproblem has a combinatorial nature. In [Sects. 3.4](#) and [3.6](#), it is shown that, in some interesting cases, one or both subproblems can be solved efficiently, thereby providing efficient (polynomial) methods for some classes of problems, or polynomial time reductions from a continuous formulation of a problem to a combinatorial one and vice versa.

Equality [\(57\)](#) can also be fruitfully applied in some cases to solve, exactly or approximately, the combinatorial problem $\min_{F \in \mathcal{F}_A} \varphi(F)$ by means of the continuous problem $\min_{x \in P} f(x)$. This approach will be used in [Sects. 3.4](#) and [3.6](#) to obtain continuous formulations for the maximum independent set problem, for the maximum clique problem, and for other combinatorial problems.

Besides the Fundamental Theorem of Linear Programming, [Theorem 12](#) extends several well-known results, which can be easily derived from it. A first example is the following existence result in indefinite Quadratic Programming due to Frank and Wolfe [\[30\]](#), for which a number of (more complex) alternative proofs and extensions are already available [\[12, 27, 50, 58, 63\]](#).

Theorem 14 ([30]) If f is a quadratic function that is bounded below on P , then f attains its minimum on P .

Indeed, from [Theorem 12](#), one easily derives the following common extension of the Frank–Wolfe Theorem and of the Fundamental Theorem of LP:

Theorem 15 If f is a quadratic function that is bounded below on P , then f attains its minimum on P at a point contained in a face of P where f is strictly convex.

Proof Note that, in this case, the family of faces \mathcal{F}_B defined above coincides with the family of faces of P where f is strictly convex. Furthermore, by coercivity, the

minimum of a strictly convex quadratic function on a closed set always exists. The conclusion then follows from [Theorem 12](#). \square

Note that when f is linear, the only faces of P where f is strictly convex are the vertices of P . Thus the Fundamental Theorem of LP is a special case of [Theorem 15](#).

One difficulty with the direct application of [Theorem 12](#) is due to the hardness of the determination of the classes \mathcal{F}_A , \mathcal{F}_B , and \mathcal{F}_C in general. However, in many cases it is sufficient to use some superclasses of \mathcal{F}_A , \mathcal{F}_B , and \mathcal{F}_C that can be determined more efficiently by using only the directions parallel to the edges of P , as described below.

Let D^B and D^U be two sets of vectors parallel to all the bounded edges and to all the extreme rays (unbounded edges) of P , respectively, and let $S^B \subseteq D^B$, $S^U \subseteq D^U$ and $S \subseteq D^B \cup D^U$.

Lemma 2 *Assume that, for every $x \in P$, f is quasi-concave on $P_d(x)$ for all $d \in S^B$ and concave or strictly quasi-concave on $P_d(x)$ for all $d \in S^U$. Then \mathcal{F}_A is contained in the set of faces of P that do not have any edge parallel to a vector in $S^B \cup S^U$. Furthermore, if, for every $x \in P$, f is strictly quasi-concave on $P_d(x)$ for all $d \in S$, then \mathcal{F}_C is contained in the set of faces of P that do not have any edge parallel to a vector in S .*

Proof The proof follows from the definition of \mathcal{F}_A and \mathcal{F}_C , and from the fact that for every face F of P and every vector d parallel to an edge of F (bounded or unbounded) one has $d \in \text{tng}(F) \setminus \{0\}$. \square

From [Lemma 2](#) and [Theorem 12](#) one can immediately deduce the following extensions of the Fundamental Theorem of Linear Programming.

Theorem 16 *Assume that, for every x in P , f is quasi-concave on $P_d(x)$ for all d in S^B and concave or strictly quasi-concave on $P_d(x)$ for all d in S^U . Then, if f attains its minimum on P , at least one global minimizer belongs to a face that does not have any edge parallel to a vector in $S^B \cup S^U$. Furthermore, if, for every x in P , f is strictly quasi-concave on $P_d(x)$ for all d in S , then all global minimizers belong to a face that does not have any edge parallel to a vector in S .*

Theorem 17 *Assume that, for every x in P , f is quasi-concave on $P_d(x)$ for all d in D^B :*

- (i) *If f is concave and bounded below on $P_d(x)$ for all x in P and d in D^U , then f attains its minimum on P at a vertex of P .*
- (ii) *If f attains its minimum on P , and f is concave or strictly quasi-concave on $P_d(x)$ for all x in P and d in D^U , then at least one global minimizer of f on P is in a vertex of P .*

Furthermore, if, for every x in P , f is strictly quasi-concave on $P_d(x)$ for all d in $D^B \cup D^U$, then every global minimizer of f on P is in a vertex of P .

Clearly, in order to apply [Theorems 16](#) and [17](#), one must have a list of vectors d parallel to some or all the edges of P . Furthermore, one should be able to check if f is concave or (strictly) quasi-concave on $P_d(x)$ for all x in P .

When the polyhedron P is described by a system of m inequalities in n variables, and both m and n are not too large, a list of vectors parallel to all its edges can be obtained computationally in a reasonable time (see, e.g., [8, 32] and references therein). On the other hand, if the polyhedron has a special structure, a list of vectors parallel to all its edges may be readily available or could be obtained by means of theoretical results. The next sections are concerned with optimization problems over some polyhedra for which the vectors parallel to the edges are known: rectangles, simplices, and polymatroids.

In the case where the function f is twice continuously differentiable, and, in particular, when it is a quadratic function, some simple necessary and sufficient conditions for its concavity on the sets $P_d(x)$ are described in the following Remark.

Remark 2 When f is twice continuously differentiable, the concavity of f on the sets $P_d(x)$ for all $x \in P$ is equivalent to $d^T H_f(x)d \leq 0$ for all $x \in P$, where $H_f(x)$ is the Hessian matrix of f at x . Furthermore, if $f(x) = \frac{1}{2}x^T Cx + q^T x$, then the (strict) quasi-concavity of f on $P_d(x)$ for all $x \in P$ is equivalent to requiring that at least one of the following conditions hold:

- (i) $d^T Cd \leq 0 (< 0)$.
- (ii) $\min_{x \in P} (Cx + q)^T d \geq 0 (> 0)$.
- (iii) $\max_{x \in P} (Cx + q)^T d \leq 0 (< 0)$.

The equivalence is justified by the property (see, e.g., [9]) that a function is (strictly) quasi-concave on a line if and only if it is either (strictly) monotone, or nondecreasing (increasing) up to a certain point and then nonincreasing (decreasing) on the half line starting that point.

When the edge directions of P are not explicitly known, one can still guarantee the validity of Property E by making some more restrictive assumptions on f .

Definition 4 Let f be a real function defined on a convex set $X \subset \mathbb{R}^n$ and let $m \leq n$. f is called *m-concave* (*m-quasi-concave*) on X iff

$$\begin{aligned} f(\alpha x^1 + (1 - \alpha)x^2)) &\geq \alpha f(x^1) + (1 - \alpha)f(x^2) \\ (\text{resp. } f(\alpha x^1 + (1 - \alpha)x^2)) &\geq \min\{f(x^1), f(x^2)\}, \end{aligned}$$

for every $\alpha \in [0, 1]$ and for every $x^1, x^2 \in X$ such that $x_i^1 = x_i^2$ for at least $n - m$ indices i in $\{1, \dots, n\}$.

Assume now that the polyhedron P is expressed in one of the following ways:

$$\begin{aligned} P &= \{x \in \mathbb{R}^n : Ax = b, \ell \leq x \leq u\} \\ \text{or} \\ P &= \{x \in \mathbb{R}^n : Ax \leq b, \ell \leq x \leq u\}, \end{aligned} \tag{60}$$

where $A \in \mathbb{R}^{m \times n}, b \in \mathbb{R}^m, \ell = (\ell_1, \dots, \ell_n), u = (u_1, \dots, u_n)$, $-\infty \leq \ell_i < u_i \leq +\infty$ and $\min\{|\ell_i|, |u_i|\} < +\infty$. Note that the assumptions on ℓ and u imply that, if $P \neq \emptyset$, then P has at least one vertex.

Theorem 18 *Let P be a polyhedron defined by (60) and assume that A has rank $m - 1$. If f is m -concave on P or f is m -quasi-concave on P and P is bounded, then Property E holds.*

Proof Let $s = (s_1, \dots, s_n)$ be any vector parallel to an edge of P . Observe that every edge of P lies in the intersection of $n - 1$ linearly independent hyperplanes taken from among those defining P in (60). Since $\text{rank}(A) = m - 1$, one has $s_i = 0$ for at least $n - m$ indices i . From the m -(quasi)-concavity of f one then derives that f is m -(quasi)-concave on the sets $P_s(x)$ for every $x \in P$. Hence, the conclusion follows from Theorem 17. \square

Some results concerning the location of global minimizers for strictly quasi-convex differentiable functions on a polytope are described next. From these results, one obtains new conditions for the existence of global minimizers at the vertices. It is interesting to observe that these conditions are obtained under assumptions of (quasi) convexity of f rather than concavity.

First, recall the following two results by Scozzari and Tardella [70] that establish the existence of a sequence of nested faces with interior minimizers for this type of problems.

Theorem 19 *Let f be a strictly quasi-convex differentiable function that attains its minimum on a polytope P at an interior point x^* of P . Then there exists a facet F of P such that the minimum of f on F is attained at a point in its relative interior.*

Corollary 1 *Let f be a strictly quasi-convex differentiable function that attains its minimum on a polytope P at an interior point x^* of P . Then there exists a nested sequence of faces $F^1 \subset F^2 \subset \dots \subset F^n$ such that $F^n = P$, $\dim(F^i) = i$, and $x_{F^i}^* \in \text{rint}(F^i)$ for $i = 1, \dots, n$.*

Using this result, one can easily derive conditions on the location of global minimizers and, in particular, conditions for the existence of vertex minimizers.

Theorem 20 *Let f be a strictly quasi-convex differentiable function, and let \mathcal{G} be a family of faces of P such that:*

- (i) *For every face F of P that is not strictly contained in a face of \mathcal{G} , and for every nested sequence of faces $F^1 \subset F^2 \subset \dots \subset F^k = F$ with $\dim(F^i) = i$, there is an index i for which $F^i \in \mathcal{G}$.*
- (ii) *For every face $G \in \mathcal{G}$, the restriction of f to G does not attain its minimum at a point in the relative interior of G .*

Then the global minimum of f over P is attained in the relative interior of a face that is strictly contained in a face of \mathcal{G} .

Proof Let x be the (unique) global minimizer of f over P . Clearly, x is in the relative interior of F_x , the smallest face of P containing x . Furthermore, by Corollary 1, there exists a nested sequence of faces $F^1 \subset F^2 \subset \dots \subset F^k$ such that $F^k = F_x$, $\dim(F^i) = i$, and the restriction of f to each F^i attains its minimum in the relative interior of F^i . Thus, by Assumptions (i) and (ii), F_x must be strictly contained in a face of \mathcal{G} . \square

When \mathcal{G} is the set of faces of dimension k , Assumption (i) in the previous theorem holds trivially. Thus one obtains the following consequence:

Corollary 2 *Let f be a strictly quasi-convex differentiable function. If the restriction of f to every face of dimension k does not attain its minimum in the relative interior of such face, then the global minimum of f on P is attained in a face of dimension less than k .*

In particular, for $k = 1$, vertex optimality follows.

Corollary 3 *Let f be a strictly quasi-convex differentiable function. If the restriction of f to every edge of P is minimized at one of its endpoints, then the global minimum of f on P is attained at a vertex of P .*

3.4 Pseudo-Boolean Optimization and Optimization with Box Constraints

A simple class of polyhedra to which Theorems 16 and 17 can be easily applied are the (generalized) rectangles (or *box constraints*) $R = [\ell, u] = \{x \in \mathbb{R}^n : \ell \leq x \leq u\}$, where one allows the values $\ell_i = -\infty$ or $u_i = +\infty$ (but not $\ell_i = -\infty$ and $u_i = +\infty$). In this case $D^B \cup D^U = \{e^1, \dots, e^n\}$. Furthermore, a function f is concave or (strictly) quasi-concave on $R_{e^i}(x)$ for all x in R , if and only if the function $f_i(t) = f(x + te^i)$ is concave or (strictly) quasi-concave on the interval $[\ell_i - x_i, u_i - x_i]$, respectively. This is equivalent to requiring that f is concave or (strictly) quasi-concave with respect to each variable. In particular, if f is twice continuously differentiable, then f is (strictly) quasi-concave on $R_{e^i}(x)$ if and only if there exists $\bar{t} \in [\ell_i - x_i, u_i - x_i]$ such that $f'_i(t) \geq 0$ (> 0) for all $t < \bar{t}$, and $f'_i(t) \leq 0$ (< 0) for all $t > \bar{t}$ (see, e.g., [9]). Furthermore, f is concave on $R_{e^i}(x)$ for all x in R if and only if the second partial derivative $f_{x_i x_i}(x)$ is nonpositive for every x in R .

When $f(x) = \frac{1}{2}x^T C x + q^T x$ is a quadratic function, these conditions can be stated as follows:

f is (strictly) concave on $R_{e^i}(x)$ for all $x \in R \Leftrightarrow c_{ii} \leq 0$ (< 0).

f is (strictly) quasi-concave on $R_{e^i}(x)$ for all $x \in R \Leftrightarrow c_{ii} \leq 0$ (< 0).

$\min_{x \in R} (C_i^T x + q_i) \geq 0$ (> 0), or $\max_{x \in R} (C_i^T x + q_i) \leq 0$ (< 0).

where C_i is the i th column vector of the matrix C . Note that

$$\min_{x \in R} (C_i^T x + q_i) = C_i^T x^{\min} + q_i \quad \text{and} \quad \max_{x \in R} (C_i^T x + q_i) = C_i^T x^{\max} + q_i,$$

where

$$x_j^{\min} = \begin{cases} \ell_j & \text{if } c_{ij} \geq 0 \\ u_j & \text{if } c_{ij} < 0 \end{cases} \quad \text{and} \quad x_j^{\max} = \begin{cases} \ell_j & \text{if } c_{ij} \leq 0 \\ u_j & \text{if } c_{ij} > 0 \end{cases}.$$

Let S^B denote the set of all unit vectors e^i such that ℓ_i and u_i are finite and f is quasi-concave on $R_{e^i}(x)$ for all x in R . Similarly, let S^U denote the set of all unit vectors e^i such that $\ell_i = -\infty$ or $u_i = +\infty$ and f is concave or strictly quasi-concave on $R_{e^i}(x)$ for all x in R . Let also $I = \{i : e^i \in S^B\}$, $J_\ell = \{i : e^i \in S^U \text{ and } u_i = +\infty\}$, $J_u = \{i : e^i \in S^U \text{ and } \ell_i = -\infty\}$, and $J = J_\ell \cup J_u$. For every $K \subseteq I$, set

$$R(K) := \{x \in R : x_i = \ell_i \text{ for } i \in J_\ell \cup K \text{ and } x_i = u_i \text{ for } i \in J_u \cup (I \setminus K)\},$$

$$\psi(K) := \min_{x \in R(K)} f(x). \quad (61)$$

Theorem 21 *If f attains its minimum on R , then*

$$\min_{x \in R} f(x) = \min_{K \subseteq I} \psi(K). \quad (62)$$

Proof The proof follows from [Theorem 16](#) by observing that the faces of R that do not have any edge parallel to a vector in $S^B \cup S^U$ are precisely the sets $R(K)$. \square

A *pseudo-Boolean function* is a real-valued function f on the Boolean hypercube $\mathbb{B}^n = \{0, 1\}^n$. By viewing every element of \mathbb{B}^n as the characteristic vector of a subset N of n elements, one can also view f as a function defined on the set 2^N of all subsets of N . The problem of minimizing a pseudo-Boolean function on \mathbb{B}^n , or on a subset thereof, has been extensively studied (see, e.g., [17] for a recent survey). The general problem is *NP*-complete, even in the quadratic case, but several polynomial classes of pseudo-Boolean optimization problems are known.

[Theorem 21](#) establishes the equivalence between the problem of minimizing a function f on R (minimization under box constraints) and the pseudo-Boolean problem of minimizing $\psi(K)$ on the subsets of I . In the special case where R is the *continuous* unit hypercube $[0, 1]^n$, [Theorems 17](#) and [21](#) can be specialized as follows (see also [72, 73]).

Corollary 4 *If f is (strictly) quasi-concave with respect to each variable on $[0, 1]^n$, then at least one (all) global minimum point of f on $[0, 1]^n$ belongs to the Boolean hypercube \mathbb{B}^n .*

[Corollary 4](#) provides a link between the pseudo-Boolean optimization problem of minimizing f on \mathbb{B}^n and the nonlinear problem of minimizing f on $[0, 1]^n$. This can be used to exploit nonlinear programming techniques to solve pseudo-Boolean optimization problems and vice versa. This link has also been used in control theory to efficiently perform a stability test for a system of linear differential equations with uncertain real parameters [33]. Later, [Corollary 4](#) is used to provide a continuous formulation for the maximum-weight independent set problem in a graph. The equivalence between minimization on the Boolean hypercube \mathbb{B}^n and on the continuous hypercube $[0, 1]^n$ had been already established by Rosenberg [67] for *multilinear* functions, i.e., functions that are linear with respect to each variable.

In the general case, the faces $R(K)$ of R are obtained by fixing the values of the variables with indices in $I \cup J$, and all have the same dimension $n - |I| - |J|$. Hence, the complexity of problem (61) decreases with $|I|$, while that of problem (62) increases. When f has some additional structure, problems (61) or (62) may be solved in polynomial time even if $|I|$ is small or large, respectively. For example, if a vector $x \in R$ is partitioned in the form $x = (x_M, x_{I \cup J})$ and f is convex with respect to x_M for every fixed value of $x_{I \cup J}$, then the minimum in (61) can be computed in polynomial time for every $K \subseteq I$. A case where problem (62) can be solved in polynomial time is described below.

Recall that a subset $S \subseteq \mathbb{R}^n$ is a sublattice of \mathbb{R}^n if, for all $x^1, x^2 \in S$, $x^1 \vee x^2 \in S$ and $x^1 \wedge x^2 \in S$, where $(x^1 \vee x^2)_i := \max\{x_i^1, x_i^2\}$ and $(x^1 \wedge x^2)_i := \min\{x_i^1, x_i^2\}$.

Note that a rectangle is trivially a sublattice of \mathbb{R}^n , and so is the Boolean hypercube \mathbb{B}^n . A real-valued function f is submodular on a sublattice S if

$$f(x^1 \vee x^2) + f(x^1 \wedge x^2) \leq f(x^1) + f(x^2),$$

for all $x^1, x^2 \in S$.

In the case where f is twice continuously differentiable, it is known [78] that f is submodular on a rectangle R if and only if the second-order mixed partial derivatives $f_{x_i x_j}(x)$ are nonpositive for all $x \in R$ and $i \neq j$.

Grötschel et al. [40] proved that the problem of minimizing a submodular function on \mathbb{B}^n (that is equivalent to the problem of minimizing a submodular function on the family of subsets of a set with n elements) can be solved in polynomial time (see also [48, 68] for *combinatorial* polynomial algorithms for this problem). Furthermore, if f is a submodular function on R , then a result of Topkis [78, Theorem 4.3] implies that $\varphi(K)$ is a submodular function on 2^I . This proves the following:

Theorem 22 *If f is a submodular function on $R = [\ell, u]$, and $\psi(K)$ can be evaluated in polynomial time for every $K \subseteq I$, then f can be minimized in polynomial time over R .*

This result can be specialized to the case where f is a quadratic function and R is bounded. Given an $n \times n$ matrix C , and a subset of indices $J \subseteq N = \{1, \dots, n\}$,

let C_{JJ} be the submatrix of C formed by the elements with row and column indices in J .

Corollary 5 Let $R = [\ell, u]$, with $\ell, u \in \mathbb{R}^n$, and let $f(x) = \frac{1}{2}x^T C x + q^T x$. Assume that $c_{ij} \leq 0$ for all $i \neq j$ that there exists a subset M of indices such that C_{MM} is positive semidefinite and that $c_{ii} \leq 0$ for all $i \in I = N \setminus M$. Then f can be minimized in polynomial time over R .

Proof Since C_{MM} is positive semidefinite, f is convex on all faces $R(K)$ for $K \subseteq I$. Hence, $\psi(K) = \min_{x \in R(K)} f(x)$ can be evaluated in polynomial time. Furthermore, f is submodular on R by the assumption $c_{ij} \leq 0$ for all $i \neq j$. Thus, the result follows from [Theorem 22](#). \square

[Corollary 4](#) can be used to provide a continuous formulation of the weighted maximum independent set problem in a graph. Such formulation includes as a special case the one proposed in [1] for the unweighted case.

Let $G = (V, E)$ be a simple undirected graph, where $V = \{1, \dots, n\}$ is the vertex set and E is the set of edges. A subset $S \subseteq V$ is an *independent set* if there is no edge joining vertices in S . Let w_i denote the weight of node i in V , and $w(S) = \sum_{i \in S} w_i$ denote the weight of the subset S of nodes. An independent set S has *maximum weight* if $w(S)$ is maximum among all independent sets.

Let $\alpha_1, \dots, \alpha_n$ and β_1, \dots, β_n be quasi-convex real-valued functions on $[0, 1]$ satisfying the following properties. For every $i = 1, \dots, n$,

$$\alpha_i(1) = \beta_i(0) = 0, \quad \alpha_i(0) = \beta_i(1) = 1, \quad \text{and } \alpha_i(x), \beta_i(x) > 0, \quad \text{for all } x \in (0, 1).$$

Consider the function $f : [0, 1]^n \rightarrow \mathbb{R}$ defined by

$$f(x) = \sum_{i \in V} w_i \alpha_i(x_i) \prod_{(i,j) \in E} \beta_j(x_j).$$

Note that for every $x \in \{0, 1\}^n$

$$f(x) = \sum_{i \in V} w_i (1 - x_i) \prod_{(i,j) \in E} x_j.$$

To every subset $S \subseteq V$ associate the point $x^S \in \{0, 1\}^n$ defined by $x_i^S = 0$ iff $i \in S$ (i.e., x^S is the complement of the characteristic vector of S).

Theorem 23 Let T be a maximum-weight independent set in G . Then

$$f(x^T) = w(T) = \max_{x \in [0, 1]^n} f(x) = \max_{x \in \{0, 1\}^n} f(x). \quad (63)$$

Proof Since f is quasi-convex with respect to each variable, the last equality in (63) follows directly from Corollary 4. If S is an independent set of G , then it can be easily verified that $f(x^S) = w(S)$. On the other hand, if S is any subset of V , then set $S_I = \{i \in S : (i, j) \in E \Rightarrow j \notin S\}$ is an independent set of G . Furthermore, if $i \in S \setminus S_I$, then $\prod_{(i,j) \in E} x_j^S = 0$. Thus, $f(x^S) = f(x_I^S)$ for every $S \subseteq V$. Therefore,

$$\max_{x \in \{0,1\}^n} f(x) = \max\{f(x^S) : S \text{ is an independent set of } G\} = w(T)$$

□

3.5 Convex–Concave Problems

Consider a problem of the form:

$$\min f(x, y) \quad \text{s.t. } (x, y) \in S \times T, \quad (64)$$

where $S, T \subset \mathbb{R}^n$ and $f : S \times T \rightarrow \mathbb{R}$.

When $f(x, y) = c^T x + x^T Q y + d^T y$, with $Q \in \mathbb{R}^{p \times q}$, $c, x \in \mathbb{R}^p$, $d, y \in \mathbb{R}^q$, and S and T are polyhedra, problem (64) is called a *bilinear programming problem*. This kind of problems, which can be reduced to concave minimization problems, have been studied by several authors (see, e.g., [19, 46, 62] and references therein). It is well known that at least one solution of a bilinear programming problem is achieved at a vertex of its feasible region. It is shown below that this property holds for a more general class of functions.

It is straightforward to prove that, if $\min_{x \in S} f(x, y)$ exists for every $y \in T$, then problem (64) is equivalent to the following:

$$\min_{y \in T} \varphi(y), \quad (65)$$

where $\varphi(y) := \min_{x \in S} f(x, y)$.

Hence, the solution of problem (64) may be reduced to the solution of the two subproblems $\min_{x \in S} f(x, y)$ and $\min_{y \in T} \varphi(y)$. In the case where T is a polyhedron, Theorem 17 can be applied to ensure that $\varphi(y)$ attains its minimum at one of the vertices of T .

Theorem 24 *If T is a polyhedron and the function $y \mapsto f(x, y)$ is quasi-concave on all directions parallel to bounded edges of T and concave or strictly quasi-concave on all directions parallel to unbounded edges of T , then, if the function $\varphi(y)$ attains its minimum on T , at least one global minimum point lies in a vertex of T .*

Proof It is sufficient to notice that, since $\varphi(y)$ is defined as a minimum of functions that are concave or quasi-concave on the directions parallel to the edges of T ,

φ shares the same properties of such functions and hence [Theorem 17](#) may be employed to complete the proof. \square

Clearly, if $\min_{x \in S} f(x, y)$ and $\min_{y \in T} \varphi(y)$ can be evaluated efficiently, then problem (64) can also be solved in an efficient manner. This is also the case for a special class of indefinite quadratic programs. Consider the problem

$$\begin{cases} \min f(x, y) = x^T Bx + x^T Cy + y^T Dy + c^T x + d^T y \\ x \in S = \{x : A_1 x \leq b_1\} \\ y \in T = \{y : A_2 y \leq b_2\}, \end{cases} \quad (66)$$

where $B \in \mathbb{R}^{p \times p}$, $C \in \mathbb{R}^{p \times q}$, $D \in \mathbb{R}^{q \times q}$, $A_1 \in \mathbb{R}^{m_1 \times p}$, $A_2 \in \mathbb{R}^{m_2 \times q}$, $c, x \in \mathbb{R}^p$, $d, y \in \mathbb{R}^q$, $b_1 \in \mathbb{R}^{m_1}$, and $b_2 \in \mathbb{R}^{m_2}$. Note that, if B is positive semidefinite, then $\varphi(y) = \min_{x \in S} f(x, y)$ can be evaluated in polynomial time [53] and, if $s^T D s \leq 0$ for all vectors s parallel to an edge of T , then $\varphi(y)$ achieves its minimum on a vertex of T . Hence, problem (66) can also be solved in polynomial time if the set V_T of vertices of T is small or if $\varphi(y)$ can be minimized in polynomial time over V_T . This is the case, e.g., if $T = \{y \in \mathbb{R}^n : \ell \leq y \leq u\}$ and $b_{ij} \leq 0$, $c_{ij} \leq 0$, $d_{ij} \leq 0$ for all $i \neq j$. In fact, these assumptions imply submodularity of $f(x, y)$ which in turn implies submodularity of $\varphi(y)$ by a result of Topkis [78]. This proves the following result:

Theorem 25 Problem (66) can be solved in polynomial time if $T = \{y \in \mathbb{R}^n : \ell \leq y \leq u\}$, B is positive semidefinite, $b_{ij}, d_{ij} \leq 0$ for all $i \neq j$, and $c_{ij} \leq 0$ for all i and j .

3.6 Max Clique and Optimization Over Simplices and Polymatroids

A polyhedron P is a k -dimensional simplex in \mathbb{R}^n if it is the convex hull of $k+1$ affinely independent vectors v^1, \dots, v^{k+1} . This is equivalent to requiring that P is k -dimensional and has $k+1$ vertices v^1, \dots, v^{k+1} , with $k \leq n$. The set D of directions parallel to all the edges of such simplex is $D = \{v^i - v^j : i, j = 1, \dots, k+1, i \neq j\}$. If f is a twice continuously differentiable function on P , and $d_{ij} = v^i - v^j \in D$, then concavity of f on all the segments $P_{d_{ij}}(x)$, for $x \in P$ is equivalent to

$$d_{ij}^T H_f(x) d_{ij} \leq 0, \text{ for all } x \in P, \quad (67)$$

where $H_f(x)$ is the Hessian matrix of f in x . If (67) holds for every $d_{ij} \in D$, then, by [Theorem 17](#), f attains its minimum at a vertex of P . Hence, in this case, the minimum of f on P can be trivially obtained by comparing the values of f at the vertices of P .

By means of an affine transformation, one can always reduce the problem of minimizing a function on a simplex to the standard form

$$\min f(x) \text{ s.t. } x \in \Delta, \quad (68)$$

where $\Delta = \{x \in \mathbb{R}^n : \sum_{i=1}^n x_i = 1, x_i \geq 0, i = 1, \dots, n\}$ is the *standard simplex* in \mathbb{R}^n . Hence, one can restrict the attention to the problem of minimizing a function on the standard simplex. In the special case where f is a quadratic function, problem (68) becomes the so-called *standard quadratic optimization problem*, an *NP-hard* problem with a number of applications which has been the object of several recent studies (see [13–16] and references therein).

When $P = \Delta$, condition (67) becomes

$$f_{x_i x_i}(x) + f_{x_j x_j}(x) - 2f_{x_i x_j}(x) \leq 0, \text{ for all } x \in P. \quad (69)$$

In particular, in the case where $f(x) = \frac{1}{2}x^T C x + q^T x$, condition (69) simplifies to

$$c_{ii} + c_{jj} - 2c_{ij} \leq 0. \quad (70)$$

Recall that a matrix M is a Monge matrix [18] if $m_{ih} + m_{jk} \leq m_{ik} + m_{jh}$ for all $i < j$ and $h < k$. Clearly a symmetric Monge matrix satisfies (70). Hence, the standard quadratic optimization problem can be trivially solved by comparing the values of f at the vertices of Δ when C is Monge.

Let us now return to the general minimization problem on the standard simplex (68). Let S be the set of all directions $d_{ij} = e^i - e^j$ in D such that (69) holds. Consider the graph $G = (V, E)$, where

$$V = \{1, \dots, n\} \text{ and } (i, j) \in E \Leftrightarrow d_{ij} \notin S. \quad (71)$$

To every subset Q of V associate the face $F_Q = \{x \in \Delta : \sum_{i \in Q} x_i = 1\}$ of Δ . Note that the mapping $Q \mapsto F_Q$ is a bijection between the subsets of V and the faces of Δ . Also consider the following weight function defined on the subsets Q of V :

$$W(Q) = \min\{f(x) : x \in F_Q\}.$$

Recall that a subset Q of V is a *clique* of G if every pair of nodes in Q is joined by an edge in E . A clique is *maximal* if it is not strictly contained in any larger clique. Let \mathcal{C} denote the set of all cliques of G and \mathcal{C}^M the set of all maximal cliques of G . Given a real-valued function $W(Q)$ on the subsets of V , a *maximum (minimum) weight clique* is a clique that maximizes (minimizes) $W(Q)$ on the set \mathcal{C} of all cliques of G . Note that there exists a maximum (minimum) weight clique that is also a maximal clique if the function W is *isotone (antitone)*, i.e., $W(Q) \leq W(Q')$ ($W(Q) \geq W(Q')$) whenever $Q \subseteq Q'$. In the classical maximum weight clique problem, the function W is modular, i.e., $W(Q) = \sum_{i \in Q} w_i$. The following result shows that the minimization problem on the standard simplex is equivalent to the minimum weight clique problem on the associated graph. Furthermore, one can restrict the search for the optimal solutions of (68) to the faces F_Q of Δ corresponding to maximal cliques Q of G .

Theorem 26

$$\min_{x \in \Delta} f(x) = \min\{f(x) : x \in \bigcup_{Q \in \mathcal{C}^M} F_Q\} = \min_{Q \in \mathcal{C}} W(Q) = \min_{Q \in \mathcal{C}^M} W(Q).$$

Proof First note that the function $W(Q)$ is antitone, since $Q \subseteq Q'$ implies $F_Q \subseteq F_{Q'}$. Thus, the proof follows easily from [Theorem 16](#) by observing that a face F_Q of Δ does not contain any edge parallel to a direction in S if and only if Q is a clique of G . \square

In view of [Theorem 26](#), one can solve problem (68) in polynomial time in those cases where all the maximal cliques of G can be listed in polynomial time (e.g., when G is sparse), and the weight function $W(Q)$ can also be evaluated in polynomial time for every $Q \in V$.

A well-known result of Motzkin and Straus [60] establishes the equivalence between the maximum clique problem and a special quadratic minimization problem on the standard simplex. This result has been extended to the maximum weight clique problem by Gibbons et al. [39]. A generalized version of the result of Gibbons et al. can be easily obtained as a special case of [Theorem 26](#).

Theorem 27 Let $f(x) = \frac{1}{2}x^T C x$ and let $G = (V, E)$ be defined as in (71) (i.e., $E = \{(i, j) : c_{ii} + c_{jj} - 2c_{ij} > 0\}$). Assume that $c_{ij} = 0$ for every $(i, j) \in E$. Then:

- (i) If $c_{ii} \leq 0$ for some index i , then $\min\{f(x) : x \in \Delta\} = c_{kk} = \min\{c_{ii} : i = 1, \dots, n\}$. Furthermore, a global minimum point for f on Δ is given by $x^* = e^k$.
- (ii) If $c_{ii} > 0$ for every $i \in V$, then

$$\min\{f(x) : x \in \Delta\} = \min_{Q \in \mathcal{C}} \left(\sum_{i \in Q} c_{ii}^{-1} \right)^{-1} = \left(\max_{Q \in \mathcal{C}} \sum_{i \in Q} c_{ii}^{-1} \right)^{-1}.$$

Furthermore, $x_i^* = c_{ii}^{-1} (\sum_{i \in Q} c_{ii}^{-1})^{-1}$ for $i \in Q$ and $x_i^* = 0$ for $i \notin Q$ is a global minimum point for f on Δ .

Proof Recall that $W(Q) = \min\{f(x) : x \in F_Q\}$. When Q is a clique of G one has

$$W(Q) = \min \left\{ \sum_{i \in Q} c_{ii} x_i^2 : \sum_{i \in Q} x_i = 1, x_i \geq 0, i = 1, \dots, n \right\}. \quad (72)$$

Hence, the optimal solution x^* of the minimization problem in (72) is given by $x^* = e^k$ with $k \in Q$ such that $c_{kk} = \min\{c_{ii} : i \in Q\}$, if $c_{kk} \leq 0$, and by $x_i^* = c_{ii}^{-1} (\sum_{i \in Q} c_{ii}^{-1})^{-1}$ for $i \in Q$ and $x_i^* = 0$ for $i \notin Q$, if $c_{kk} > 0$. In the first case $W(Q) = \min\{c_{ii} : i \in Q\}$, while in the second case $W(Q) = (\sum_{i \in Q} c_{ii}^{-1})^{-1}$. The proof then follows from [Theorem 26](#). \square

When all the c_{ii} are positive, this theorem transforms the problem of minimizing the special quadratic function f on Δ into a maximum weight clique problem. However, the transformation can also be applied in the reverse direction, as shown in the following corollary.

Corollary 6 ([39]) *Let $G = (V, E)$ be a simple graph with weight $w_i > 0$ associated to each node i in V , and let $W(Q) = \sum_{i \in Q} w_i$. Let C be any symmetric matrix satisfying $c_{ii} = w_i^{-1}$, for all $i \in V$, $c_{ij} = 0$ for all $(i, j) \in E$, and $c_{ii} + c_{jj} - 2c_{ij} \leq 0$ for all $(i, j) \notin E$. Then a clique of maximum weight in G is given by a subset Q of V such that the point $x_i^* = c_{ii}^{-1}(\sum_{i \in Q} c_{ii}^{-1})^{-1}$ for $i \in Q$ and $x_i^* = 0$ for $i \notin Q$ is a global minimum point of f on Δ . Furthermore,*

$$\left(\max_{Q \in \mathcal{C}} W(Q) \right)^{-1} = \min\{f(x) : x \in \Delta\}.$$

The maximum weight clique formulation for the standard quadratic optimization problem has been used by Scozzari and Tardella [70] to efficiently solve the latter problem by means of clique algorithms on the associated graph. This approach has led to the solution of problems of up to two orders of magnitude greater than those previously solved in the literature.

This section ends with the description of a class of polyhedra that includes both rectangles and simplices and still has a very small and simple set of directions parallel to all edges: polymatroids and base polyhedra.

Thus, in this class, one can still prove the existence of a vertex optimal solution by checking only a small number of fairly simple conditions.

A *polymatroid* is a polyhedron P in \mathbb{R}^n described by the following inequalities:

$$\begin{cases} \sum_{i \in I} x_i \leq g(I) & \text{for all } I \subseteq N = \{1, \dots, n\}, \\ x_i \geq 0 & \text{for all } i \in N, \end{cases}$$

where the function $g : 2^N \rightarrow \mathbb{R}$ is

Isotone: $g(S) \leq g(T)$ for all $S, T \subseteq N$.

Submodular: $g(S \cap T) + g(S \cup T) \leq g(S) + g(T)$ for all $S, T \subseteq N$.

Normalized: $g(\emptyset) = 0$.

A *base polyhedron* is the facet of a polymatroid determined by the additional constraint $\sum_{i \in N} x_i = g(N)$. It is well known from the characterization of adjacency of vertices in polymatroids and base polyhedra (see, e.g., [31, 79]) that every edge of a polymatroid is parallel to a vector of the set $\{e^i : i \in N\} \cup \{e^i - e^j : i, j \in N, i \neq j\}$, while every edge of a base polyhedron is parallel to a vector of the set $\{e^i - e^j : i, j \in N, i \neq j\}$.

Thus, a twice differentiable function f attains its minimum at a vertex of a base polyhedron P if

$$f_{x_i x_i}(x) + f_{x_j x_j}(x) - 2f_{x_i x_j}(x) \leq 0, \forall x \in P \text{ and } \forall i, j \in N, \text{ with } i \neq j.$$

For a polymatroid one must add the condition

$$f_{x_i x_i}(x) \leq 0, \forall x \in P \text{ and } \forall i \in N.$$

Note that the polyhedra described by nonnegativity constraints $x \geq 0$, upper bounds $x \leq u$, and a single knapsack constraint $\sum_i a_i x_i \leq b$ or $\sum_i a_i x_i = b$, with $a_i > 0$, $a_i u_i \leq b$ for all i , and $b \leq \sum_i a_i u_i$ can be transformed into polymatroids and base polyhedra by setting $y_i = a_i x_i$ and taking the submodular function g defined by $g(\emptyset) = 0$, $g(\{e^i\}) = a_i u_i$ for all i , and $g(S) = b$ for all other subsets $S \subseteq N$.

4 Piecewise Concavity and Applications

4.1 Piecewise Concavity

In this section the equivalence between some continuous and discrete optimization problems is established by exploiting another form of generalized concavity of the objective functions involved. More precisely, *piecewise concave* or *piecewise quasi-concave* functions are minimized on a set X . Such functions, which arise naturally from several applications, are required to be concave or quasi-concave on each element of a family of subsets of X whose union covers X . Some applications to location theory and to various types of minimax problems are described in the next sections. For piecewise concave functions, the search for a global minimum point can be restricted to a special subset of X that, under suitable assumptions, is guaranteed to be finite.

Let $X = \bigcup_{i \in I} X_i \subset \mathbb{R}^n$, where each X_i is a closed subset of \mathbb{R}^n . Consider a family $\{f_i\}_{i \in I}$ of functions with $f_i : X_i \rightarrow \mathbb{R}$ and $f_i(x) = f_j(x)$ for every $x \in X_i \cap X_j$ and for all $i, j \in I$. Let $g : X \rightarrow \mathbb{R}$ be defined by

$$g(x) := f_i(x), \quad \text{for } x \in X_i, i \in I. \quad (73)$$

The function g is called (*strictly*) *piecewise concave* or (*strictly*) *piecewise quasi-concave* iff all the functions f_i are (*strictly*) concave or (*strictly*) quasi-concave, respectively. Note that the sets X_i are not required to be convex and that the notions of concavity and quasi-concavity on X_i are those specified in [Definition 2](#). In fact, the sets X_i are not necessarily convex, e.g., in the important problem of minimizing a function defined as the maximum of a family of concave or quasi-concave functions on a convex set. Clearly, *piecewise convexity* and *piecewise quasi-convexity* of a function can be defined in a similar manner.

Consider the subset \mathcal{E} of X containing all the convex hull extreme points of all sets X_i , and let D be the subset of \mathcal{E} formed by those points that are convex hull extreme points of every set X_i to which they belong. More formally

$$\mathcal{E} = \bigcup_{i \in I} \mathcal{E}(\text{conv}(X_i)) \text{ and } D = \{x \in \mathcal{E} : x \in X_i \Rightarrow x \in \mathcal{E}(\text{conv}(X_i))\}. \quad (74)$$

Let X_{\min} be the set of global minimum points of g over X . The main result of this section, which generalizes and strengthens some well-known results for piecewise concave functions and for minimax problems [74] is the following:

Theorem 28 (i) If f_i is quasi-concave on X_i and X_i is compact for all $i \in I$, then

$$X_{\min} \neq \emptyset \Leftrightarrow X_{\min} \cap \mathcal{E} \neq \emptyset.$$

(ii) If f_i is strictly quasi-concave on X_i and X_i is compact for all $i \in I$, then

$$X_{\min} \neq \emptyset \Leftrightarrow X_{\min} \cap D \neq \emptyset.$$

(iii) If X is compact, g is lower semicontinuous on X and f_i is concave on X_i for all $i \in I$, then

$$X_{\min} \cap D \neq \emptyset \text{ and } \mathcal{E}(\text{conv}(X_{\min})) \subseteq D.$$

Proof (i) Let x^* be a global minimum point for g over X and assume that $x^* \in X_i$. Since X_i is compact, $\text{conv}(X_i)$ is also compact and hence $\text{conv}(X_i) = co(\mathcal{E}(\text{conv}(X_i)))$, by the Krein–Millman Theorem.

Thus $X_i \subseteq co(\mathcal{E}(\text{conv}(X_i)))$, so that there exist points $x^1, \dots, x^m \in \mathcal{E}(\text{conv}(X_i))$ and coefficients $\alpha_1, \dots, \alpha_m \in]0, 1[$ such that $x^* = \sum_{i=1}^m \alpha_i x^i$ and $\sum_{i=1}^m \alpha_i = 1$. Then, by the quasi-concavity of f_i , at least one of the points x^1, \dots, x^m must be a global minimum point for g .

- (ii) Let x^* be a global minimum point for g over X and assume that $x^* \in X_i$. Using an argument similar to the one employed in the proof of (i), for $x^* \notin \mathcal{E}(\text{conv}(X_i))$, there exist points $x^1, \dots, x^m \in \mathcal{E}(\text{conv}(X_i))$ such that $f_i(x^*) > \min\{f_i(x^1), \dots, f_i(x^m)\}$. This contradicts the minimality of x^* .
- (iii) First note that, by the lower semicontinuity of g , the set X_{\min} is nonempty, closed, and hence compact since it is contained in the compact set X . Hence, $\mathcal{E}(\text{conv}(X_{\min})) \neq \emptyset$ and, by the Krein–Millman Theorem, $\text{conv}(X_{\min}) = \text{conv}(\mathcal{E}(\text{conv}(X_{\min})))$. To complete the proof, it suffices to show that if $x^* \in \mathcal{E}(\text{conv}(X_{\min}))$, then $x^* \in \mathcal{E}(\text{conv}(X_i))$ for every i such that $x^* \in X_i$. Ab absurdo, if $x^* \in X_i \setminus \mathcal{E}(\text{conv}(X_i))$, then there exist $y, z \in \text{conv}(X_i)$ and $\lambda \in]0, 1[$ such that $x^* = \lambda y + (1-\lambda)z$. Then, by definition of $\text{conv}(X_i)$, there exist $y^1, \dots, y^{m_1}, z^1, \dots, z^{m_2}$ in X_i and coefficients $\alpha_1, \dots, \alpha_{m_1}, \beta_1, \dots, \beta_{m_2} \in]0, 1[$ such that $y = \sum_{i=1}^{m_1} \alpha_i y^i$, $z = \sum_{i=1}^{m_2} \beta_i z^i$, $\sum_{i=1}^{m_1} \alpha_i = 1$, and $\sum_{i=1}^{m_2} \beta_i = 1$. Setting $\gamma_i = \lambda \alpha_i$ for $i = 1, \dots, m_1$ and $\delta_i = (1-\lambda)\beta_i$ for $i = 1, \dots, m_2$, one has $x^* = \sum_{i=1}^{m_1} \gamma_i y^i + \sum_{i=1}^{m_2} \delta_i z^i$ and $\sum_{i=1}^{m_1} \gamma_i + \sum_{i=1}^{m_2} \delta_i = 1$. From the concavity of f_i , it then follows that $f_i(x^*) = f_i(y^i) = f_i(z^i)$ for all indices i . Hence, $g(x^*) = g(y) = g(z)$ and therefore $y, z \in X_{\min}$, contradicting $x^* \in \mathcal{E}(\text{conv}(X_{\min}))$.

□

Remark 3 Note that if $\text{conv}(X_i)$ is a polytope, then, taking into account [Theorem 17](#), the Assumption of (i) in [Theorem 28](#) can be weakened by requiring only quasi-concavity of f_i on all line segments in $\text{conv}(X_i)$ which are parallel to some edge of $\text{conv}(X_i)$.

Remark 4 The result of [Theorem 28\(i\)](#) holds also when some set X_i is an unbounded polyhedron. Also in this case, taking into account [Theorem 17](#), assumption (i) in [Theorem 28](#) can be replaced by the requirement of quasi-concavity of f_i on all line segments in X_i which are parallel to some bounded edge of X_i and concavity or strict quasi-concavity of f_i on all line segments in X_i which are parallel to some unbounded edge of X_i .

4.2 Minimax Problems

In several applications (see, e.g., [21, 23]) one has to solve minimax problems of the form

$$\min_{x \in X} \max_{i \in I} f_i(x), \quad (75)$$

where X is a compact subset of \mathbb{R}^n (often a polytope) and each f_i is (quasi-)concave on X . In this case, [Theorem 28](#) can be applied to the piecewise (quasi-)concave function $g(x) := \max_{i \in I} f_i(x)$ which is (quasi-)concave on the sets $X_i := \{x \in X : g(x) = f_i(x)\}$. Thus one obtains the following result first stated by Zangwill [80] for the concave case with a somewhat incomplete proof.

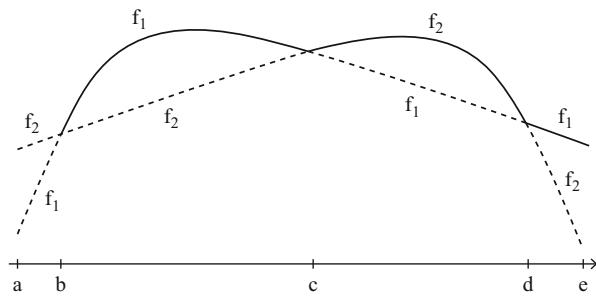

Theorem 29 *If X is a compact subset of \mathbb{R}^n and the functions $f_i : X \rightarrow \mathbb{R}$ are continuous and (quasi-)concave, then at least one solution of (75) belongs to the set D (resp. \mathcal{E}).*

Suppose now that X is a polytope described by a set of linear inequalities $a_j^T x \leq b_j$, $j \in J$ and, for every $x \in X$, define $I(x) = \{i \in I : g(x) = f_i(x)\}$ and $J(x) = \{j \in J : a_j^T x = b_j\}$. It can be easily verified that a point $x \in X$ is a vertex (extreme point) of X if $J(x)$ is maximal, i.e., there does not exist any $y \in X$ such that $J(x)$ is a proper subset of $J(y)$. Analogously, a point $x \in X$ is called a *g-vertex* of X iff $I(x) \cup J(x)$ is maximal. This notion has been introduced by Du and Hwang [22] (see also [21]) who also proved the following result that has been extended to the case of an infinite index set I by Du and Pardalos [24].

Theorem 30 *If X is a polytope in \mathbb{R}^n and the functions $f_i : X \rightarrow \mathbb{R}$ are continuous and concave, then at least one solution of (75) belongs to the set G of g-vertices of X .*

[Theorems 29](#) and [30](#) establish an interesting equivalence between the continuous problem (75) and the problem of minimizing $g(x)$ over the sets D , \mathcal{E} , or G which are often finite. Note however that [Theorem 29](#) provides a stronger restriction for

Fig. 1 Example for strict inclusions

global minimum points than [Theorem 30](#). Indeed, it is clear that $D \subseteq \mathcal{E}$, and it has been proved in [74] that $D \subseteq G$. Furthermore, simple examples like the following one show that there are cases where the inclusions $D \subset \mathcal{E} \subset G$ can be strict.

Example 1 Consider the interval $X = [a, e] \subset \mathbb{R}$ and the functions $f_1, f_2 : X \rightarrow \mathbb{R}$ illustrated in [Fig. 1](#). Then $X_1 = [a, b] \cup [c, d]$, $X_2 = [b, c] \cup [d, e]$, $D = \{a, e\}$, $\mathcal{E} = \{a, b, d, e\}$, and $G = \{a, b, c, d, e\}$.

4.3 Location Problems

Piecewise concavity has important applications in location theory. Consider, e.g., the rectilinear distance facility location problem, which consists in finding the coordinates of m new facilities x^1, \dots, x^m in an n -dimensional space so as to minimize a weighted sum of the rectilinear (or L^1) distances among them and between them and a set of p existing facilities located at the points a^1, \dots, a^p . Formally, one wants to minimize over $\mathbb{R}^{n \times m}$ the function

$$g(x^1, \dots, x^m) := \sum_{k=1}^n \sum_{i=1}^m \sum_{j=1}^m w_{ijk} |x_k^i - x_k^j| + \sum_{k=1}^n \sum_{i=1}^m \sum_{j=1}^p v_{ijk} |x_k^i - a_k^j|,$$

where w_{ijk} and v_{ijk} are nonnegative weights. Note that the function g is separable, i.e., it can be written in the form $g(x) = \sum_{k=1}^n g_k(x_k^1, \dots, x_k^m)$, where

$$g_k(x_k^1, \dots, x_k^m) = \sum_{i=1}^m \sum_{j=1}^m w_{ijk} |x_k^i - x_k^j| + \sum_{j=1}^p v_{ijk} |x_k^i - a_k^j|.$$

Hence, the problem of minimizing g over $\mathbb{R}^{n \times m}$ can be solved by minimizing each function g_k over \mathbb{R}^m separately. For this reason one can restrict the attention to the one-dimensional case where $x^i, a^i \in \mathbb{R}$. It is well known [20] that a global minimum point of g must be contained in the finite set $A := \{a^1, \dots, a^p\}^m$. One

can show that this is true also in a more general setting and that it is a consequence of the piecewise concavity of g .

Consider the function g defined by

$$g(x) = \sum_{i=1}^m \sum_{j=1}^m \varphi_{ij}(|x^i - x^j|) + \sum_{i=1}^m \sum_{j=1}^p \psi_{ij}(|x^i - a^j|), \quad (76)$$

where $\varphi_{ij}, \psi_{ij} : \mathbb{R}_+ \rightarrow \mathbb{R}$ are nondecreasing continuous concave functions satisfying $\varphi_{ij}(0) = \psi_{ij}(0) = 0$ and $\lim_{t \rightarrow +\infty} \psi_{ij}(t) = +\infty$ for all i and j . Assume, without loss of generality, that $a^1 < a^2 < \dots < a^p$. Let H denote the set of all bijective mappings (permutations) π from the set of indices $L = \{1, \dots, m+p\}$ into itself that verify $\pi^{-1}(i) < \pi^{-1}(i+1)$ for all $i = m+1, \dots, m+p-1$.

Lemma 3 *For every $i \in L$, define $y_i = x^i$ if $i \leq m$ and $y_i = a^{i-m}$ if $i > m$. Then for every $\pi \in H$ the function g defined in (76) is concave on $X_\pi := \{x \in \mathbb{R}^n : y_{\pi(i)} \leq y_{\pi(i+1)}, i = 1, \dots, m+p-1\}$.*

Proof Indeed, on X_π one has $|y_i - y_j| = y_i - y_j$ if $\pi^{-1}(i) < \pi^{-1}(j)$ and $|y_i - y_j| = y_j - y_i$ if $\pi^{-1}(i) > \pi^{-1}(j)$. Hence, on X_π the functions $\varphi_{ij}(|x^i - x^j|)$ and $\psi_{ij}(|x^i - a^j|)$ are concave for all i, j , since they are obtained as the composition of a concave and of a linear function. Therefore, the function g is concave on X_π because it is a sum of concave functions. \square

Theorem 31 *At least one global minimum point of g on \mathbb{R}^n is achieved at a point in A .*

Proof Note that the sets X_π are polyhedra with vertices in A and that $\mathbb{R}^n = \cup_{\pi \in H} X_\pi$. Furthermore, since g is continuous and $\lim_{t \rightarrow +\infty} \psi_{ij}(t) = +\infty$ for all i and j , there must be a global minimum point of g in a bounded neighborhood of 0. Hence, by Theorem 28, a global minimum point of g must be contained in A . \square

Another continuous location problem that can be solved by restricting the search to a finite set of candidate solutions is the problem of locating some undesirable facilities at locations $x^1, \dots, x^m \in \mathbb{R}^n$ in a way that minimizes the maximum of some decreasing nuisance cost functions of the distances among them and between them and a given set of points $b^1, \dots, b^p \in \mathbb{R}^n$ (see [28] for a survey on this type of problems). Formally, one wishes to minimize the function

$$g(x) = g(x^1, \dots, x^m) := \max\{\max_{i \in I, j \in J} \alpha_{ij}(\|x^i - b^j\|), \max_{i \neq j \in I} \beta_{ij}(\|x^i - x^j\|)\},$$

where α_{ij} and β_{ij} are continuous nonincreasing functions, $I = \{1, \dots, m\}$, $J = \{1, \dots, p\}$, and $\|\cdot\|$ is any norm in \mathbb{R}^n . In this case, the function g is piecewise

quasi-concave since it is the maximum of a finite family of continuous quasi-concave functions. Clearly, the infimum of g on $\mathbb{R}^{n \times m}$ is obtained when $\|x^i\| \rightarrow \infty$ for all i . Hence, this location problem becomes meaningful only when x is required to be in a compact set X . Under this assumption, [Theorem 29](#) can be applied to establish the following result.

Theorem 32 *At least one global minimum point of g on a compact set X is achieved in the set $\mathcal{E} = \bigcup_{i,j \in I} \mathcal{E}(\text{conv}(X_{ij})) \cup \bigcup_{i \in I, j \in J} \mathcal{E}(\text{conv}(Y_{ij}))$, where*

$$\begin{aligned} X_{ij} &:= \{x \in X : \alpha_{ij}(\|x^i - b^j\|) \\ &\geq \max\{\max_{h \in I, k \in J} \alpha_{hk}(\|x^h - b^k\|), \max_{h \neq k \in I} \beta_{hk}(\|x^h - x^k\|)\}\}, \\ Y_{ij} &:= \{x \in X : \beta_{ij}(\|x^i - x^j\|) \\ &\geq \max\{\max_{h \in I, k \in J} \alpha_{hk}(\|x^h - b^k\|), \max_{h \neq k \in I} \beta_{hk}(\|x^h - x^k\|)\}\}. \end{aligned}$$

When only one new undesirable facility has to be established, the objective function $g : \mathbb{R}^n \rightarrow \mathbb{R}$ becomes

$$g(x) = \max_{j \in J} \alpha_j(\|x - b^j\|).$$

In this case, [Theorem 32](#) implies that a global minimum point of g on a compact set X is attained at a point in $\mathcal{E} = \bigcup_{j \in J} \mathcal{E}(\text{conv}(X \cap X_j))$, where $X_j = \{x \in \mathbb{R}^n : \alpha_j(\|x - b^j\|) \leq \alpha_k(\|x - b^k\|) \text{ for all } k \neq j\}$. The family of sets X_j forms the (generalized) Voronoi diagram with respect to the functions $\alpha_j(\|x\|)$. This geometric structure has received much attention in recent years especially in the case where $\alpha_j(\|x\|) = \|x\|$ or $\alpha_j(\|x\|) = \lambda_j \|x\|$ and $\|\cdot\|$ is the Euclidean norm (see [6] and references therein). In particular, when $\alpha_j(\|x\|) = \|x\|$ and $\|\cdot\|$ is the Euclidean norm, the sets X_j are polyhedra described by

$$X_j = \left\{ x \in \mathbb{R}^n : (b^k - b^j)^T \left(x - \frac{b^j + b^k}{2} \right) \leq 0 \text{ for all } k \neq j \right\}.$$

In this case, the maximum number N of points in $\mathcal{E} = \bigcup_{j \in J} \mathcal{E}(X_j)$ satisfies the following bounds [51]:

$$n/2! p^{n/2} \leq N \leq 2(n/2! p^{n/2}) \text{ for } n \text{ even}$$

and

$$\frac{(\lceil n/2 \rceil - 1)!}{e} p^{\lceil n/2 \rceil} \leq N \leq 2(\lceil n/2 \rceil! p^{\lceil n/2 \rceil}) \text{ for } n \text{ odd.}$$

Furthermore, the points of \mathcal{E} can be computed in $O(p^{\lceil n/2 \rceil + 1})$ time in the general case [7], and in time $O(p \log p)$ for $n = 2$. Thus the minimum of g on a polyhedron X can be found by simple enumeration of all the vertices of the sets $X_i \cap X$. This yields a finite algorithm, while in [71] an algorithm is presented which requires some additional assumptions to solve the same problem in finitely many iterations.

Facility location on networks is an important field in location theory where much research has concentrated in identifying a *finite* set of points that necessarily contain an optimal solution. Good surveys on this topic are [43, 54, 59].

Location problems on networks can be formulated using some definitions and notation taken from [54]. An *edge* of length $\ell > 0$ is the image of an interval $[0, \ell]$ by a continuous mapping f from $[0, \ell]$ to \mathbb{R}^d such that $f(\theta) \neq f(\theta')$ for any $\theta \neq \theta'$ in $[0, \ell]$. A *network* is defined as a subset N of \mathbb{R}^d that satisfies the following conditions: (a) N is the union of a finite number of edges; (b) any two edges intersect at most at their extremities; (c) N is connected. The *vertices* of the network are the extremities of the edges defining N and are denoted by $V = \{v^1, \dots, v^n\}$. The set of edges defining the network is denoted by E . For every edge $[v^i, v^j] \in E$, let f_{ij} from $[0, \ell_{ij}]$ to \mathbb{R}^d be the defining mapping and denote by θ_{ij} the inverse of f_{ij} which maps $[v^i, v^j]$ into $[0, \ell_{ij}]$. Given two points $x^1, x^2 \in [v^i, v^j]$, the subset of points of $[v^i, v^j]$ between and including x^1, x^2 is a subedge $[x^1, x^2]$. The length of $[x^1, x^2]$ is given by $|\theta_{ij}(x^1) - \theta_{ij}(x^2)|$. A *path* joining two points $x^1 \in N$ and $x^2 \in N$ is a minimal connected subset of N containing x^1 and x^2 . The length of a path is equal to the sum of all its constituent edges and subedges. A metric d on N is defined by setting $d(x^1, x^2)$ equal to the length of a shortest path joining x^1 and x^2 .

For any point $z \in N$ consider the function on $[0, \ell_{ij}]$ defined by $d(z, f_{ij}(\theta))$. Note that, by the definition of the distance, one has

$$d(z, f_{ij}(\theta)) = \min\{d(z, v^i) + \theta, d(z, v^j) + \ell_{ij} - \theta\}.$$

Hence, $d(z, f_{ij}(\theta))$ is the minimum of two linear functions in θ . Therefore, the following properties hold [54]:

- (i) $d(z, f_{ij}(\theta))$ is continuous and concave on $[0, \ell_{ij}]$.
- (ii) $d(z, f_{ij}(\theta))$ is linearly increasing with slope $+1$ on $[0, \theta_{ij}(z)]$ and linearly decreasing with slope -1 on $[\theta_{ij}(z), \ell_{ij}]$, where $\theta_{ij}(z) = \frac{1}{2}[\ell_{ij} + d(z, v^j) - d(z, v^i)]$.

The (single) median problem on the network N consists of finding a point in N that minimizes the function

$$F(x) = \sum_{v^i \in V} w_i((d(v^i, x))),$$

where $w_i(t)$ are concave nondecreasing functions from \mathbb{R}_+ to \mathbb{R} . In 1964, Hakimi [41] showed that at least one solution of this problem belongs to V when $w_i(t) = \lambda_i t$ with $\lambda_i \geq 0$. This result was extended in [59] to the case where all $w_i(t)$ are concave nondecreasing functions. The proof is based on the remark that if $w_i(t)$ is

concave nondecreasing, then the function $w_i((d(v^i, f_{ij}(\theta))))$ is concave on $[0, \ell_{ij}]$ and hence $F(f_{ij}(\theta))$ is also concave on $[0, \ell_{ij}]$. Therefore, the global minimum of F must be attained at one of the points $f_{ij}(0)$ or $f_{ij}(\ell_{ij})$, i.e., at a vertex of N .

In the (single) center problem on the network N , one seeks to minimize the function

$$G(x) = \max_{v^i \in V} (d(v^i, x)).$$

In this case, the function $G(f_{ij}(\theta))$ is not concave on the whole segment $[0, \ell_{ij}]$, but only on subsegments thereof. However, the number of such subsegments is bounded by $|V|^2|E|$ and their extremities can be explicitly determined (see [54] for details). Hence, also the center problem on a network can be solved by enumerating a finite (and polynomially bounded) number of points.

5 Generalized Systems

5.1 Introduction

In the first half of the last century, there have been several important achievements: a great growth of the theory of extrema in the wake of the so-called Peano Function, the parallel development of the Theorems of the Alternative and of the Separation Theorems, the gathering of important results to form Convex Analysis, and a great development of the Calculus of Variations. Due to these achievements and also to some important problems arisen in Mathematical Physics, like the so-called Signorini Contact Problem, at the beginning of the second half of the last century, the theory of variational inequalities and, in parallel, that of Complementarity Systems have been formulated, the former mainly in infinite dimensional spaces, and the latter in finite dimensional spaces.

All these great developments have lead to search for models, which embody parallel theories. In particular, this has happened in the case of extremum problems, variational inequalities, and generalized systems. A possible unification has been found with the formulation of the so-called generalized systems. As concerns constrained extremum problems, the connection with a system is, nowadays, clear: while “optimization” is merely a language for looking at real problems, the mathematical core lies in stating whether or not a system be impossible.

The results contained in the following Sections are based on [2].

5.2 General Results

Given positive integers n and l , a convex cone $\mathcal{C} \subseteq \mathbb{R}^l$, sets $R, Z \subset \mathbb{R}^n$, and a vector-valued function $F : \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}^l$ consider the problem \mathcal{P} which consists in finding $y \in R \cap Z$ such that the system, in the unknown x ,

$$F(x; y) \in \mathcal{C}, \quad x \in R \cap Z \tag{77}$$

be impossible.

Given a set $X \subseteq \mathbb{R}^n$ such that $Z \subseteq X$, the replacement of $R \cap Z$ with $R \cap X$ represents a relaxation of the domain of (77); of course, this may change the set of solutions of \mathcal{P} . This drawback can be overcome through a suitable change of the system. To this end, consider a vector-valued function $\Phi : \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}^l$ and the family $\{\mathcal{P}(\mu)\}_{\mu \in \mathbb{R}}$ of problems where $\mathcal{P}(\mu)$ consists in finding $y \in R \cap X$ such that the system (in the unknown x)

$$F(x; y) + \mu \Phi(x; y) \in \mathcal{C}, \quad x \in R \cap X \quad (78)$$

be impossible. System (78) shows, with respect to (77), a relaxation of the domain and a penalization of F .

In [2] conditions are given under which \mathcal{P} and $\mathcal{P}(\mu)$ are equivalent in the sense that they have the same (possibly empty) set of solutions. To this end, one needs a preliminary proposition.

As concern notation, for every cone $\mathcal{C} \subset \mathbb{R}^l$ and for all $x, y \in \mathcal{C}$, let

$$\begin{aligned} x \geq_{\mathcal{C}} y &\iff x - y \in \mathcal{C}, \\ x \not\geq_{\mathcal{C}} y &\iff x - y \notin \mathcal{C}, \\ x >_{\mathcal{C}} y &\iff x - y \in \text{int } \mathcal{C}, \end{aligned}$$

where $\text{int } \mathcal{C}$ denotes the interior of \mathcal{C} . The notation \leq , $\not\leq$, and $<$ is defined in analogous way. Finally, for the sake of simplicity, and without any fear of confusion, $\|\cdot\|$ denotes either a norm in \mathbb{R}^l or in \mathbb{R}^n , or a matrix norm.

Lemma 4 Let $\mathcal{C}, \mathcal{C}^0 \subset \mathbb{R}^l$ be cones such that \mathcal{C}^0 be closed and $\{0\} \neq \mathcal{C}^0 \subseteq \text{int } \mathcal{C}$. Let $B_\rho = \{x \in \mathbb{R}^l : \|x\| \leq \rho\}$ with $\rho \geq 0$, and $U = \{x \in \mathbb{R}^l : \|x\| = 1\}$. Then, there exists η_0 such that

$$V_1 + \eta V_2 \in \text{int } \mathcal{C}, \quad \forall \eta > \eta_0, \quad \forall V_1 \in B_\rho, \quad \forall V_2 \in \mathcal{C}^0 \cap U \quad (79)$$

Proof Since $\|V_2\| = 1, \forall V_2 \in \mathcal{C}^0 \cap U, \forall \eta > \rho$, one has

$$1 \geq \frac{\langle V_1 + \eta V_2, V_2 \rangle}{\|V_1 + \eta V_2\|} \geq \frac{\langle V_1, V_2 \rangle + \eta \|V_2\|^2}{\|V_1\| \|V_2\| + \eta \|V_2\|} \geq \frac{-\rho + \eta}{\rho + \eta}.$$

Since the scalar product of vectors of unitary norm is 1 if and only if they coincide, passing to the limit as $\eta \rightarrow +\infty$, one obtains

$$\lim_{\eta \rightarrow +\infty} \frac{V_1 + \eta V_2}{\|V_1 + \eta V_2\|} = V_2.$$

Since $\mathcal{C}^0 \cap U$ is a compact set included in $\text{int } \mathcal{C}$, then $U \setminus \mathcal{C}$ and $\mathcal{C}^0 \cap U$ have positive distance (induced by the norm considered). Hence (79) follows. This completes the proof. \square

Note that, when $l = 1$, the assumptions of Lemma (4) are fulfilled only by $\mathcal{C} = \mathbb{R}_+$ and by $\mathcal{C} = \mathbb{R}_+ \setminus \{0\}$ (and, of course, by their opposites); in both cases $\mathcal{C}^0 = \mathbb{R}_+$ necessarily (or $\mathcal{C}^0 = \mathbb{R}_-$). In the sequel, $\forall x \in X$, $p(x)$ will denote a vector belonging to the set $\text{proj}_Z(x)$, where $\text{proj}_Z : X \rightarrow Z$ is the multivalued function which projects x on the compact set Z .

Theorem 33 *Let $R \subseteq \mathbb{R}^n$ be a closed set, $Z \subset X \subset \mathbb{R}^n$, Z and X be compact sets, and let $F, \Phi : X \times X \rightarrow \mathbb{R}^l$ satisfy the following assumptions:*

(H_1) *F is bounded on $X \times X$, and there exist positive reals L and α , and an open set $\Omega \supset Z$, such that*

$$\|F(p(x); x)\| \leq L \|x - p(x)\|^\alpha, \quad \forall x \in \Omega \cap X, \quad \forall p(x) \in \text{proj}_Z(x);$$

(H_2) (i) *Φ is continuous on $X \times X$.*

(ii) *$\forall x, y \in Z$, $\Phi(x, y) = 0$.*

(3i) *there exists a closed cone \mathcal{C}^+ with $\emptyset \neq (\mathcal{C}^+ \setminus \{0\}) \subseteq \text{int } \mathcal{C}$, such that*

$$\Phi(x, y) \in (\mathcal{C}^+ \setminus \{0\}), \quad \forall x \in Z, \quad \forall y \in X \setminus Z.$$

(4i) *$\forall z \in Z$ there exists a neighborhood $S(z)$ of z , and a real $\epsilon(z)$ such that*

$$\|\Phi(p(x); x)\| \geq \epsilon(z) \|x - p(x)\|, \quad \forall x \in S(z) \cap (X \setminus Z), \quad \forall p(x) \in \text{proj}_Z(x).$$

Then a real μ_1 exists, such that, $\forall \mu > \mu_1$, a solution of $\mathcal{P}(\mu)$ is a solution of \mathcal{P} .

Proof To prove the thesis it is sufficient to show that $\exists \mu_0 \in \mathbb{R}$ such that, $\forall \mu > \mu_0$, a solution of $\mathcal{P}(\mu)$ is achieved necessarily at point $z \in R \cap Z$. Because of (H_2)(i), this claim assures that a solution of $\mathcal{P}(\mu)$ is also a solution of \mathcal{P} . Consider the sets $\hat{X} = R \cap X$, $\hat{Z} = R \cap Z$, and $\hat{S}(z) = \Omega \cap S(z)$, where $S(z)$ is precisely that of (H_2)(4i). The family $\{\hat{S}(z), z \in \hat{Z}\}$ is obviously a cover of \hat{Z} . Since \hat{Z} is a closed subset of Z , there is a finite subcover, say $\{\hat{S}(z_i), i = 1, \dots, k\}$, of \hat{Z} . Set $S = \cup_{i=1}^k \hat{S}(z_i)$ and let $\rho = \max\{L/\epsilon(z_i), i = 1, \dots, k\}$. Because of (H_1) and (H_2)(4i), it holds

$$\frac{\|F(p(x); x)\|}{\|\Phi(p(x); x)\|} \leq \rho, \quad \forall x \in S \cap (\hat{X} \setminus \hat{Z}).$$

Consider the set $U = \{x \in \mathbb{R}^l : \|x\| = 1\}$; because of $(H_2)(3i)$ one has

$$\frac{\Phi(p(x); x)}{\|\Phi(p(x); x)\|} \in \mathcal{C}^+ \cap U, \quad \forall x \in \hat{X} \setminus \hat{Z}. \quad (80)$$

Apply [Lemma 4](#), where V_1 , V_2 , \mathcal{C}^0 , and \mathcal{C} are identified with $F(p(x); x)/\|\Phi(p(x); x)\|$, $\Phi(p(x); x)/\|\Phi(p(x); x)\|$, \mathcal{C}^+ , and \mathcal{C} , respectively. The assumptions of [Lemma 4](#) being fulfilled, one obtains the existence of a real η_1 , such that (79) holds, namely, for all $\eta > \eta_1$ and $x \in S \cap (\hat{X} \setminus \hat{Z})$

$$\frac{F(p(x); x)}{\|\Phi(p(x); x)\|} + \eta \frac{\Phi(p(x); x)}{\|\Phi(p(x); x)\|} \in \mathcal{C}. \quad (81)$$

It follows that, $\forall \mu > \eta_1$, $\mathcal{P}(\mu)$ cannot have solutions in $S \cap (\hat{X} \setminus \hat{Z})$.

Now, consider the compact set $X_0 = \hat{X} \setminus S$, and fix $\hat{z} \in \hat{Z}$. Because of $(H_2)(i, 3i)$, Φ is continuous and different from the null vector on the compact set $\{\hat{z}\} \times X_0$. Thus

$$M_\Phi = \min_{x \in X_0} \|\Phi(\hat{z}; x)\| > 0.$$

Apply again [Lemma 4](#), where $\rho = M_F/M_\Phi$, and V_1 , V_2 , \mathcal{C}^0 , and \mathcal{C} are identified with $F(\hat{z}; x)/\|\Phi(\hat{z}; x)\|$, $\Phi(\hat{z}; x)/\|\Phi(\hat{z}; x)\|$, \mathcal{C}^+ , and \mathcal{C} , respectively, and $M_F = \sup_{(x,y) \in X \times X} \|F(x; y)\|$. Then, the hypotheses of [Lemma 4](#) being satisfied, one obtains the existence of η_2 , such that, for all $\eta > \eta_2$ and $x \in X_0$,

$$\frac{F(\hat{z}; x)}{\|\Phi(\hat{z}; x)\|} + \eta \frac{\Phi(\hat{z}; x)}{\|\Phi(\hat{z}; x)\|} \in \mathcal{C}. \quad (82)$$

Hence, $\forall \mu > \eta_2$, $\mathcal{P}(\mu)$ cannot have solutions in X_0 . If $\mu > \mu_1 = \max\{\eta_1, \eta_2\}$, account taken of (81) and (82), $\mathcal{P}(\mu)$ cannot have solutions in $\hat{X} \setminus \hat{Z}$. This completes the proof. \square

Remark 5 Consider the special case where

$$F(x; y) = f(y) - f(x), \quad (83)$$

with $f : X \rightarrow \mathbb{R}^l$ bounded. It is trivial to check that, if f fulfills the Hölder condition on the set Ω , i.e., there exist $L, \alpha > 0$ such that

$$\|f(y) - f(x)\| \leq L \|x - y\|^\alpha, \quad \forall x, y \in \Omega \cap X, \quad (84)$$

then the function F defined in (83) satisfies (H_1) . The converse is not true, as shown by the [Example 2](#).

Note that, for F given by (83), y is a solution of \mathcal{P} if and only if f is a solution of the vector minimum problem

$$\min_{\mathcal{C}} f(x) \quad \text{s.t. } x \in R \cap Z, \quad (85)$$

where \mathcal{C} defines now the partial order and $\min_{\mathcal{C}}$ marks vector minimum: the impossibility of (77) defines y as a solution of (85); y is called vector minimum point, in short VMP.

Example 2 Let $n = l = 1$, $R = \mathbb{R}$, $Z = [0, 1]$, and $X = [-1, 1]$. Consider (83) with $f(x) = x \sin(1/x)$ if $x \neq 0$ and $f(0) = 0$. (H_1) is satisfied at $\alpha = 1$, $L = 1$, and $\Omega = [-2, 2]$. In fact, if $x \in Z$ so that $p(x) = x$, then $F(p(x); x) = 0$; if $x \in (\Omega \cap X) \setminus Z = [-1, 0[$, then $|F(0; x)| = |f(x)| = |x \sin(1/x)| \leq |x|$. Thus (H_1) holds. Obviously f does not fulfill (84).

Remark 6 Consider two special cases. For this, introduce $G : \mathbb{R}^n \rightarrow \mathbb{R}^{l \times n}$, and let $\langle G(u), v \rangle_l$ denote the vector whose i th component is the scalar product between the i th row of the matrix $G(u)$ and the vector v . The former special case is

$$F(x; y) = \langle G(y), y - x \rangle_l; \quad (86)$$

the second case is

$$F(x; y) = \langle G(x), y - x \rangle_l. \quad (87)$$

If G is bounded on \mathbb{R}^n , then both functions F in (86) and (87) fulfill (H_1) at $\alpha = 1$ and $L = \|G\| = \sup_{\|x\|=1} \|G(x)\|$, as it is easy to check. *Example 3* shows that the converse is not true.

Note that y is a solution of \mathcal{P} in case (86) (or (87)) if and only if it is a solution of the Vector Inequality of Stampacchia type [34]: find $y \in R \cap Z$ such that

$$\langle G(y), x - y \rangle_l \not\leq_C 0, \quad \forall x \in R \cap Z, \quad (88)$$

or of the vector variational inequality of Minty type [34]: find $y \in R \cap Z$ such that

$$\langle G(x), y - x \rangle_l \not\geq_C 0, \quad \forall x \in R \cap Z. \quad (89)$$

Example 3 Let $n = l = 1$, $\mathcal{C} = \mathbb{R}^+ \setminus \{0\}$, $R = \mathbb{R}$, $Z = [0, 1]$, and $X = [0, 2]$. Let F be defined by (86) with $G(y) = 1/\sqrt{|1-y|}$, with $y \neq 1$ and $G(1) = 0$; it holds

$$|F(p(x); x)| \leq |x - p(x)|^{1/2}, \quad \forall x \in]1, 2[;$$

indeed, if $x \in Z$, then $p(x) = x$ so that $F(p(x); x) = 0$; if $x \in]1, 2[$, then $p(x) = 1$ so that $|F(p(x); x)| = \sqrt{x-1}$.

Example 4 Let $F : \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{R}$, $F(x; y) = \sqrt{|x-y|}(x-1)$, $Z = [0, 1]$, and $X = [0, 2]$. In this case a constant L and an open set $\Omega \supset Z$ does not exist such that

$$|F(x; y)| \leq |x-y|, \quad \forall x \in \Omega \cap X, \quad \forall y \in Z.$$

However, the hypothesis (H_1) of [Theorem 33](#) holds with $\Omega = \mathbb{R}$, $L = \sqrt{2}$, and $\alpha = 3/2$.

Example 5 Let $n = l = 1$, $\mathcal{C} = \mathbb{R}^+ \setminus \{0\}$, $R = \mathbb{R}$, $Z = [0, 1]$ and $X = [0, 2]$, $F : X \times X \rightarrow \mathbb{R}$, and $F(x; y) = (x-y)^2(1-y)(x-1)$. Then F fulfills (H_1) with $\Omega =]-1, 2[$, $L = 1$, $\alpha = 2$. In fact, F is bounded; moreover, if $x \in]1, 2[$, $p(x) = 1$ and $F(1; x) = 0$; if $x \in Z$, $p(x) = x$ and $F(x; x) = 0$. Each $y \in [0, 1]$ is a solution of the following problem \mathcal{P} : find $y \in Z$ such that

$$F(x; y) \in \mathcal{C}, \quad x \in [0, 1]$$

be impossible.

Let $\Phi : X \times X \rightarrow \mathbb{R}$ be a penalty function defined as follows:

$$\Phi(x; y) = \begin{cases} -(1-x)^2, & \text{if } (x, y) \in]1, 2] \times [0, 1] \\ 0, & \text{if } (x, y) \in [0, 1] \times [0, 1] \\ (1-y)^2, & \text{if } (x, y) \in [0, 1] \times]1, 2[\\ -(x-y)^2, & \text{if } (x, y) \in]1, 2] \times]1, 2[, y \leq x \\ (x-y)^2, & \text{if } (x, y) \in]1, 2] \times]1, 2[, y > x \end{cases}$$

Then Φ fulfills condition (H_2) choosing $\mathcal{C}^+ = \mathbb{R}_+$, $\epsilon(z) = 1$, $\forall z \in Z$, $\alpha = 2$, and $L = 1$. Note that, $\forall \mu \in \mathbb{R}_+$, $y \in [0, 1]$ is not a solution for $\mathcal{P}(\mu)$. In fact, $\forall x \in]1, 2]$

$$F(x; y) + \mu \Phi(x; y) = (x-1)[(x-y)^2(1-y) - \mu(x-1)].$$

Observe that $\lim_{x \downarrow 1} (x-y)^2(1-y) - \mu(x-1) = (1-y)^3 > 0$. Thus $y \in [0, 1]$ is not a solution of $\mathcal{P}(\mu)$. Furthermore, F does not fulfill (H_3) of the following [Theorem 34](#) at $\alpha = 2$, $L = 1$. In fact, $p(x) = 1$ for $x \geq 1$ and the inequality

$$|F(p(x); y) - F(x; y)| \leq (x-1)^2, \quad \forall x \in X \cap \Omega, \text{ and } \forall p(x) \in \text{proj}_Z(x)$$

holds if and only if

$$(x-y)^2(1-y) \leq (x-1), \quad \forall x > 1, \quad \forall y \in [0, 1].$$

This is impossible for $x = 5/4$, $y = 1/4$.

Moreover, observe that $\mathcal{P}(\mu)$ has no solution: for each $y \in [1, 2]$, $x \in [0, 1]$, and $\mu > 0$

$$F(x; y) + \mu\Phi(x; y) \in \mathcal{C}.$$

If Z is finite, then the inequality in $(H_2)(4i)$ can be equivalently replaced (in the sense that the thesis of the [Theorem 33](#) is still valid and the class of the penalty functions Φ which satisfy it is nonempty) by the following condition:

$\forall z \in Z$ there exist a neighborhood $S(z)$ and a real $\epsilon(z) > 0$, such that

$$\|\Phi(z; x)\| \geq \epsilon(z) \|x - z\|, \quad \forall x \in S(z) \cap (X \setminus Z).$$

In fact, choosing a suitable neighborhood $S(z)$ of z , one has $p(x) = z$.

If Z is not finite, then the above condition might be in contrast with Assumptions $(H_2)(i, ii)$. In this case, the latter is replaced by the following one: $(H_2)'$ There exists a vector-valued function $\varphi : X \rightarrow \mathbb{R}^l$, such that:

- (i) φ is continuous on X .
- (ii) $\forall x \in Z$, $\varphi(x) = 0$.
- (3i) There exists a closed cone \mathcal{C}^+ with $\{0\} \neq \mathcal{C}^+ \subseteq \text{int } \mathcal{C}$, such that

$$\varphi(x) \in \mathcal{C}^+ \setminus \{0\}, \quad \forall x \in X \setminus Z.$$

(4i) $\forall z \in Z$; there exist a neighborhood $S(z)$ and a real $\epsilon(z) > 0$ such that

$$\|\varphi(x)\| \geq \epsilon(z) \|x - p(x)\|^\alpha, \quad \forall x \in S(z) \cap (X \setminus Z), \text{ and } \forall p(x) \in \text{proj}_Z(x).$$

Note that if $\Phi(x; y) = \varphi(x) - \varphi(y)$, $\forall x, y \in X$, then (H_2) of [Theorem 33](#) is fulfilled if $(H_2)'$ is fulfilled.

The following theorem deals with the special class of problem \mathcal{P} where the cone \mathcal{C} is equal to \mathbb{R}_+^l ; it gives a condition guaranteeing that a solution of \mathcal{P} is also a solution of a suitable problem $\mathcal{P}(\mu)$, for μ large enough.

Theorem 34 *Let $R \subseteq \mathbb{R}^n$ be a closed set, $Z \subset X \subset \mathbb{R}^n$, Z , and X be compact set, and let $F, \Phi : X \times X \rightarrow \mathbb{R}^l$ satisfy the following hypotheses:*

(H_3) *F is bounded on $X \times X$ and there exist positive reals L , α and an open set $\Omega \supset Z$, such that*

$$\|F(x; y) - F(p(x); y)\| \leq L \|x - p(x)\|^\alpha, \quad \forall x, y \in \Omega \cap X, \quad \forall p(x) \in \text{proj}_Z(x)$$

(H_4)

- (i) Φ is continuous on $X \times X$.
- (ii) $\forall x, y \in Z$, $\Phi(x; y) = 0$, $\forall x \in X$, $\Phi(x; \cdot)$ is constant on Z .
- (3i) There exists a closed cone \mathcal{C}^- , with $\{0\} \neq \mathcal{C}^- \subseteq \text{int } (-\mathcal{C})$, such that

$$\Phi(x; y) \in \mathcal{C}^- \setminus \{0\}, \quad \forall x \in X \setminus Z, \quad \forall y \in Z.$$

(4i) $\forall z \in Z$; there exists a neighborhood $S(z)$ of z and a positive real $\epsilon(z)$ such that

$$\|\Phi(x; p(x))\| \geq \epsilon(z) \|x - p(x)\|^\alpha, \quad \forall x, y \in S(z) \cap (X \setminus Z), \quad \forall p(x) \in \text{proj}_Z(x).$$

Then, there exists $\mu_2 \in \mathbb{R}$, such that, $\forall \mu > \mu_2$, a solution of \mathcal{P} is a solution of $\mathcal{P}(\mu)$.

Note that hypothesis (H_3) of [Theorem 34](#) can be weakened by replacing the requirement $x, y \in \Omega \cap X$ with $x \in \Omega \cap X, y \in Z$.

5.3 The Case of a Discrete Domain

This section deals with a special but very important case, namely, that of a discrete problem. More precisely, consider the case

$$Z = \mathbb{B}^n, \quad \mathcal{C} = \mathbb{R}_+^l \setminus \{0\}, \quad \mathcal{C}^+ = \{v \in \mathbb{R}_+^l : v_1 = \dots = v_l\}, \quad \mathcal{C}^- = -\mathcal{C}^+, \quad (90)$$

where $\mathbb{B} = \{0, 1\}$; the case where Z is a bounded subset of \mathbb{Z}^n can be reduced to the above one by well-known transformations [61].

The relaxation of $Z = \mathbb{B}^n$ is $X = X_Q = \{x \in \mathbb{R}^n : 0 \leq x_i \leq 1, i = 1, \dots, n\}$ and the penalty term $\Phi : X \times X \rightarrow \mathbb{R}^l$ is defined by

$$\Phi(x; y) = \begin{pmatrix} \varphi(y) - \varphi(x) \\ \vdots \\ \varphi(y) - \varphi(x) \end{pmatrix} \quad (91)$$

where $\varphi : \mathbb{R}^n \rightarrow \mathbb{R}$, $\varphi(x) = \langle x, e - x \rangle$, with $e = (1, \dots, 1) \in \mathbb{R}^n$. Under Assumptions (90), the function defined in (91) fulfills, with $\alpha = 1$, the conditions (H_2) of [Theorem 33](#) and (H_4) of [Theorem 34](#). In fact, $(H_2)(i)$, (ii) , $(3i)$, $(H_4)(i)$, (ii) , $(3i)$ are obvious. As concerns $(H_2)(4i)$ and $(H_4)(4i)$, note that if $S(z)$ is small enough so that $p(x) = z$, then, as proved in [36], φ satisfies the following conditions: $\forall z \in Z$ there is a neighborhood $S(z)$ of z and a real $\hat{\epsilon}(z)$, such that

$$\varphi(x) \geq \hat{\epsilon} \|x - z\|, \quad \forall x \in S(z) \cap (X \setminus Z).$$

Therefore for all $z \in Z$ and $x \in S(z) \cap (X \setminus Z)$

$$\|\Phi(p(x); x)\| = \|\Phi(x; p(x))\| = \begin{pmatrix} \varphi(x) \\ \vdots \\ \varphi(x) \end{pmatrix} = \sqrt{l}|\varphi(x)| \geq \sqrt{l}\hat{\epsilon}(z) \|x - z\|,$$

which proves $(H_2)(4i)$ and $(H_4)(4i)$ by setting $\epsilon(z) = \sqrt{l}\hat{\epsilon}(z)$. Hence, the following result has been established:

Theorem 35 *For the case (90)–(91), let the function F verify with $\alpha = 1$ the hypothesis (H_3) of Theorem 34, and assume that $F(x; x) = 0$ for all $x \in \Omega$. Then, there exists $\mu_3 \in \mathbb{R}$ such that, $\forall \mu > \mu_3$, \mathcal{P} and $\mathcal{P}(\mu)$ have the same set of solutions.*

Remark 7 Any function $F : X \times X \rightarrow \mathbb{R}^l$ of the form

$$F(x; y) = f(x) - f(y),$$

where $f : X \rightarrow \mathbb{R}^l$, or

$$F(x; y) = \langle G(y), y - x \rangle,$$

where $G : \mathbb{R}^n \rightarrow \mathbb{R}^{l \times n}$, fulfills the condition $F(x; x) = 0$ for all $x \in \Omega$.

In Theorem 35 the hypothesis (H_3) with $\alpha = 1$ was sufficient for the special Φ chosen. For $\alpha = 1$, the above theorem is still valid for all strictly concave functions $\varphi_1, \dots, \varphi_l : \mathbb{R}^n \rightarrow \mathbb{R}$ such that $\varphi_i(x) = 0$ for all $i = 1, \dots, l$ and $x \in Z$, and there exist a neighborhood $S_i(y)$ and a real constant $\epsilon_i(y)$ such that

$$|\varphi_i(x)| \geq \epsilon_i(y) \|x - y\|, \quad \forall x \in S_i(y) \cap (X \setminus Z).$$

Note that for $i = 1, \dots, l$, the above condition is a slight generalization of the condition on the function φ in [36], and it is equivalent to (H_2) of Theorem 33 when $l = 1$. Then one can put $h = (\varphi_1, \dots, \varphi_l)$, and, $\forall x, y \in X$,

$$\Phi(x; y) = h(y) - h(x). \tag{92}$$

Condition $(H_2)(4i)$ for Φ follows choosing $\forall z \in Z$, $S(z) = \cap_{i=1}^l S_i(z)$, and $\epsilon(z) = \sqrt{l} \min\{\epsilon_i(z), i = 1, \dots, l\}$.

The following theorem gives a condition which assures that, $\forall y \in X$; the function $F(\cdot; y) + \mu\Phi(\cdot; y)$ is component-wise strictly convex. This is a straightforward extension of Theorem 3.2 of [36] and Theorem 2 of [37].

Theorem 36 *In the case (90)–(91), let $F : X \times X \rightarrow \mathbb{R}^l$ fulfill the hypotheses of Theorem 35 with $\alpha = 1$. If $F \in \mathcal{C}^2(X \times X)$, then there exists a real μ_4 such that, $\forall \mu > \mu_4$, \mathcal{P} and $\mathcal{P}(\mu)$ have the same solutions, and $\forall y \in X$, the function $F(\cdot; y) + \mu\Phi(\cdot; y)$ is component-wise strictly convex.*

Proof $\forall y \in X$, let $H_i(x; y)$ and $\hat{H}_i(x; y)$ be the Hessian matrices at x , of the i -th component of $F(\cdot; y)$ and of $F(\cdot; y) + \mu\Phi(\cdot; y)$ respectively. Hence, for $i = 1, \dots, l$

$$\hat{H}_i(x; y) = H_i(x; y) + 2\mu I_n,$$

where I_n denotes the $n \times n$ identity matrix. $\forall i \in \{1, \dots, l\}$, $\forall r \in \{1, \dots, n\}$, let $\lambda_{ir} : X \times X \rightarrow \mathbb{R}$ be the function where $\lambda_{ir}(x; y)$, $r = 1, \dots, n$ are the eigenvalues of the Hessian $H_i(x; y)$. Because of the continuity of F , λ_{ir} is continuous. Hence

$$\eta_4 := \max_{i,r} \max_{X \times X} |\lambda_{ir}(x; y)| < +\infty.$$

Moreover, observe that, $\forall x, y$, $v_i(x; y)$ is an eigenvalue of $\hat{H}_i(x; y)$ if and only if $v_i(x; y) - 2\mu$ is an eigenvalue of $H_i(x; y)$. Then, if

$$\mu > \mu_4 = \frac{1}{2} \max\{\mu_1, \mu_2, \eta_4\}$$

it follows that, for all $(x, y) \in X \times X$, $v_{ir}(x; y) = \lambda_{ir}(x; y) + 2\mu$ is an eigenvalue of $\hat{H}_i(x; y)$ and it results $v_{ir}(x; y) > 0$. This completes the proof. \square

5.4 Discrete Vector Optimization and Variational Inequalities

In this section, equivalence results for vector optimization problems and vector variational inequalities are obtained as a direct application of the preceding theorems.

Indeed, consider the special case of (85), where $Z = \mathbb{B}^n$ and $\mathcal{C} = \mathbb{R}_+^l \setminus \{0\}$, namely, consider the vector minimization problem:

$$\min_{\mathcal{C}} f(x) \quad \text{s.t. } x \in R \cap \mathbb{B}^n. \quad (93)$$

It is well known that a point y is a solution of (93) if and only if the system

$$f(y) - f(x) \in \mathcal{C}, \quad x \in R \cap \mathbb{B}^n, \quad (94)$$

is impossible. (When $l = 1$ and $\mathcal{C} = (0, +\infty)$ the problem (93) becomes a scalar 0–1 optimization problem, and the impossibility of (94) becomes the impossibility of the inequality $f(y) - f(x) > 0$, $x \in R \cap \mathbb{B}^n$.)

Then, consider the vector minimum problem:

$$\min_{\mathcal{C}} [f(x) + \mu\psi(x)] \quad \text{s.t. } x \in R \cap X_Q, \quad (95)$$

where $\psi : \mathbb{R}^n \rightarrow \mathbb{R}^l$, $\psi = (\varphi, \dots, \varphi)$, $\varphi(x) = \langle x, e - x \rangle$, with $e = (1, \dots, 1)$, $\mu \in \mathbb{R}$, $X_Q = \{x \in \mathbb{R}^n : 0 \leq x_i \leq 1, i = 1, \dots, n\}$.

Corollary 7 *Let the following hypotheses be satisfied:*

(H_5) $f : \mathbb{R}^n \rightarrow \mathbb{R}^l$ is bounded on X_Q , and there exist a positive real L and an open set $\Omega \supset \mathbb{B}^n$ such that

$$|f_i(x) - f_i(y)| \leq L \|x - y\|, \quad \forall x, y \in \Omega \cap X_Q, \quad i = 1, \dots, l,$$

where f_i denotes the i -th component of f . Then, there exists a real $\mu_5 \in \mathbb{R}$, such that, $\forall \mu > \mu_5$, (93) and (95) have the same solutions. If, in addition, $f \in C^2(X)$, then there exists $\mu_6 \in \mathbb{R}$ such that, $\forall \mu > \mu_7 = \max\{\mu_5, \mu_6\}$, $f + \mu\psi$ is component-wise strictly concave.

Proof Put $\Phi : X \times X \rightarrow \mathbb{R}^l$, $\Phi(x; y) = \psi(y) - \psi(x)$. According to Remark 5, under Assumptions (H_5), the function $F(x; y) = f(y) - f(x)$ satisfies (H_1) of Theorem 33 and (H_3) of Theorem 34. Moreover, Assumption (H_2) of Theorem 33 and (H_4) of Theorem 34 is fulfilled by the present Φ given by (91), as shown in Sect. 5.3. As concerns the second part of the thesis, it is enough to note that (93) and (95) are equivalent to \mathcal{P} and $\mathcal{P}(\mu)$, respectively. Hence, Theorem 36 can be applied. This completes the proof. \square

In the special—but important—case where R is a polyhedron, Corollary 7 shows that the class of vector minimization problems with component-wise strictly concave objective function (95) has all vector minimum points necessarily at the vertices of the feasible region. This is not true in general. Indeed, while the next theorem shows that component-wise quasi-concavity guarantees the existence of a vector minimum point at a vertex of a polytope, the following Examples 6 and 7 show that component-wise strict concavity need not imply that *all* vector minimum points must be among the vertices of a polytope.

Theorem 37 *Let $P \subset \mathbb{R}^n$ be a nonempty polytope and let $g := (g_1, \dots, g_l) : \mathbb{R}^n \rightarrow \mathbb{R}^l$ be such that either g_i is quasi-concave for all i (component-wise quasi-concavity) or there exists an index i_0 for which g_{i_0} is strictly quasi-concave. Then, at least one vector minimum point of the problem*

$$\min_C g(x) \quad \text{s.t. } x \in P \tag{96}$$

is attained at a vertex of P .

Proof Without loss of generality assume that $i_0 = 1$. For $i = 1, \dots, l$, consider the problem

$$a_i := \min g_i(x) \quad \text{s.t. } x \in S_{i-1},$$

where

$$S_0 = P, \quad S_i := \operatorname{argmin}_{x \in S_{i-1}} g_i(x), \quad i = 1, \dots, l.$$

Note that

$$S_i \subseteq S_{i-1}, \quad i = 1, \dots, l.$$

If g_i is quasi-concave for all i , then the sets S_1, \dots, S_l are unions of faces of P . On the other hand, if g_1 is strictly concave, then S_1 , and thus also every S_2, \dots, S_l , is a subset of the vertices of P . It will be now shown that each element of S_l is a VMP of (96) so that the thesis will follow. Consider any $x^0 \in S_l$. Ab absurdo, suppose that x^0 be not solution of (96). Then, $\exists y_{x^0} \in P$, such that

$$g(y_{x^0}) \leq_c g(x^0),$$

so that $\exists i_{x^0} \in \{i = 1, \dots, l\}$ such that

$$g_{i_{x^0}}(y_{x^0}) < g_{i_{x^0}}(x^0) = a_{i_{x^0}}, \quad (97)$$

$$g_{i_{x^0}}(y_{x^0}) \leq g_i(x^0), \quad \forall i = 1, \dots, l, \quad i \neq i_{x^0}. \quad (98)$$

Then y_{x^0} must belong to S_l . Otherwise, $\forall i = 0, \dots, l-1$,

$$y_{x^0} \in S_i \setminus S_{i+1} \implies g_{i+1}(y_{x^0}) > g_{i+1}(x^0) = a_{i+1},$$

which contradicts (97) and (98). Since

$$g(x) = (a_1, \dots, a_l), \quad \forall x \in S_l,$$

it follows that $g(y_{x^0}) = (a_1, \dots, a_l)$, which contradicts (97). This completes the proof. \square

Remark 8 If, for any $k \in \{1, \dots, l\}$, S_k is a singleton, then obviously its (unique) element is a VMP of (96), and the subsequent S_i coincide with S_k . This observation suggests a method for finding a solution of (96). However, this method does not necessarily find all VMPs; for instance, even if g is component-wise strictly concave, the method cannot find the VMPs (if any) which fall in $\text{int } P$ whatever the ordering of the component of g may be. The following examples show some strictly concave cases where there are non-vertex solutions even under the further assumption that the (global) maximum points of all g_i fall into the interior of P .

Example 6 In (96), put $n = 1$, $P = [0, 1]$, $\mathcal{C} = \mathbb{R}_+ \setminus \{0\}$, $g_1(x) = 1 - x^2$, and $g_2(x) = x(2 - x)$; it is easy to check that every element of P is a VMP.

Example 7 In (96), put $n = 1$, $P = [-3, 3]$, $\mathcal{C} = \mathbb{R}_+ \setminus \{0\}$, $g_1(x) = (x + 3)(7 - x)$, and $g_2(x) = (3 - x)(x + 7)$. It is easy to check that the VMP are now ± 3 and all the elements of $]-1, 1[$.

Now, consider the vector variational inequality

$$\text{find } y \in R \cap Z \text{ s.t. } \langle G(y), x - y \rangle_l \not\leq_C 0, \forall x \in R \cap Z, \quad (99)$$

where $Z = \mathbb{B}^n$ and $C = \mathbb{R}_+^l \setminus \{0\}$. As noted in [Remark 6](#), y solves [\(Eq. 99\)](#) if and only if it solves the problem \mathcal{P} given by the following: find $y \in R \cap Z$ such that

$$\langle G(y), y - x \rangle_l \in C, x \in R \cap Z$$

is impossible.

Similarly, y solves the vector variational inequality:

$$\text{find } y \in R \cap X_Q \text{ s.t. } \langle G(y), x - y \rangle_l - \mu \Phi(x; y) \not\leq_C 0, \forall x \in R \cap X_Q, \quad (100)$$

where Φ is the function in [\(91\)](#) and $\mu \in \mathbb{R}_+$, if and only if y solves the problem $\mathcal{P}(\mu)$ given by the following: find $y \in R \cap X_Q$ such that

$$\langle G(y), y - x \rangle_l + \mu \Phi(x; y) \in C, x \in R \cap X_Q$$

is impossible. So, next result is a direct application of [Theorems 33](#) and [34](#).

Corollary 8 *Let $G : \mathbb{R}^n \rightarrow \mathbb{R}^{l \times n}$ be bounded on X_Q . Then, there exists a real $\mu_8 \in \mathbb{R}$, such that, $\forall \mu > \mu_8$, [\(99\)](#) and [\(100\)](#) have the same set of solutions.*

Proof The function F defined by $F(x; y) = \langle G(y), y - x \rangle$ fulfills (H_1) of [Theorem 33](#) according to [Remark 6](#). Moreover, Assumption (H_3) of [Theorem 34](#) holds, since

$$\begin{aligned} \| F(x_1; y) - F(x_2; y) \| &= \| \langle G(y), y - x_1 \rangle - \langle G(y), y - x_2 \rangle \| \\ &\leq \| G \| \| x_1 - x_2 \|, \forall x_1, x_2, y \in X_Q. \end{aligned}$$

The present Φ fulfills (H_2) of [Theorem 33](#) and (H_4) of [Theorem 34](#) as shown in [Sect. 5.3](#). Hence, [Theorems 33](#) and [34](#) guarantee the existence of a real $\mu_8 \in \mathbb{R}$ such that \mathcal{P} and $\mathcal{P}(\mu)$, and then [\(99\)](#) and [\(100\)](#) have the same set of solutions. \square

In the special—but important—case where R is a polyhedron, [Corollary 8](#) provides a class of vector variational inequalities with bounded operator, i.e., [\(100\)](#), having—because of the equivalence with [\(99\)](#)—a solution necessarily at a vertex of the domain. This is not true in general, as simple examples show.

6 Conclusion

The developments of the previous sections suggest some interesting topics that should be further investigated. A first question concerns the identification of a class of constrained extremum problems, or Complementarity Systems, or generalized

systems, or Variational Inequalities for which the exact penalty parameter can be improved. Some results on this topic have been presented in Sect. 2.3.

Some of the assumptions of Theorems 2 or 3 might be weakened; in the general case, \mathbb{R}^n might be replaced by a metric space. For instance, isoperimetric problems or optimal control problems, where the feasible region has only a discrete or even finite number of curves, might be equivalently transformed into a classic differentiable problems which admits Euler equation as necessary condition.

In Sect. 2.2, it has been observed that integer programs can be reduced to (16). However, such a reduction implies, in general, an enormous increase in the number of variables. Hence, it is interesting to extend the analysis to the case where $\{0, 1\}^n$ is replaced by \mathbb{Z}^n . In this case, functions like $\sum_{j=1}^n \sin(\pi x_j)$ or $\sum_{j=1}^n \prod_{s=0}^{L_j} (x_j - s)^2$, with L_j upper bound on x_j , might be used as penalty functions. Furthermore, for problem (16)—or, more generally, when Z is finite—it is interesting to investigate other types of penalty functions, e.g., in the field of gauge functions. The idea of resolvent for a Boolean problem [42] might be transferred to a concave minimization problem through the equivalence established in Sects. 2.2 and 3.4.

Theorem 4 states a connection between 0–1 programming problems and complementarity problems, which are a special type (when the domain is a cone) of variational inequalities. Hence, one has the possibility of connecting two fields very far from each other. For instance, fixed-point methods or gap function methods, which have been designed for variational inequalities, may be adapted to 0–1 problems. On the other hand, cutting plane methods and the related group theory, as well as other methods conceived for integer programs, may be transferred to variational inequalities.

It is well known that the concept of saddle of the Lagrangian function associated to a problem like (18) can be used to achieve sufficient optimality conditions (beside necessary ones). Through the equivalence such a concept can be introduced for 0–1 programs.

The equivalence between nonlinear and 0–1 programs can be used also in the context of duality. For instance, it can be used to close the duality gap when Lagrangian duality is applied to facial constraint [55]. Since the optimality of a constrained extremum problem can be put in terms of the impossibility of a suitable system of inequalities, it might be useful to extend the connections between continuous and discrete problems to a system of inequalities, recovering constrained extremum problems as special cases. This could also embrace vector extremum problems.

General classes of functions that attain their minimum at the vertices of a polyhedron have been described in Sect. 3. It is interesting to investigate the possibility of extending the methods employed for concave minimization problems [11, 46, 62] to this more general case.

Consider a special case of (85), where $R = \mathbb{R}^n$, $Z = \cup_{k=1}^r Z_k$, with Z_k convex and compact, $f : \mathbb{R}^n \rightarrow \mathbb{R}^l$ component-wise convex, and $\mathcal{C} = \mathbb{R}_+^l \setminus \{0\}$, namely, the problem

$$\min_{\mathcal{C}} f(x), \quad \text{s.t. } x \in \cup_{k=1}^r Z_k; \quad (101)$$

y is a solution of (101) if and only if the system (in the unknown x)

$$f(y) - f(x) \in \mathcal{C}, \quad x \in \cup_{k=1}^r Z_k \quad (102)$$

is impossible. Consider compact sets $X_k \supseteq Z_k$ and functions $h_k : \cup_{k=1}^r X_k \rightarrow \mathbb{R}$, $k = 1, \dots, r$, such that there is an $\alpha \in \mathbb{R}$ for which each h_k fulfills $(H_2)'$ of Sect. 5.2 with $l = 1$, $\mathcal{C}^+ = \mathbb{R}_+$. It is easily seen that

$$H(x) := \prod_{k=1}^r h_k(x)^{\alpha/r} \quad (103)$$

fulfills $(H_2)'$. In fact, it is trivial to verify $(H_2)'(i)$, (ii) , and $(3i)$. In the following formulas, k as index will denote that one is referring to Z_k and X_k instead of Z and X . H fulfills also $(4i)$:

$$\begin{aligned} H(x) &= \prod_{k=1}^r h_k(x)^{\alpha/r} \geq \prod_{k=1}^r [\epsilon_k(z)^{\alpha/r} \|x - p_k(x)\|]^{\alpha/r} \\ &= \prod_{k=1}^r \epsilon_k(z)^{\alpha/r} \prod_{k=1}^r \|x - p_k(x)\|^{\alpha/r} \geq \prod_{k=1}^r \epsilon_k(z)^{\alpha/r} \|x - p(x)\|^\alpha \\ &= \tilde{\epsilon}(z) \|x - p(x)\|^\alpha, \quad \tilde{\epsilon}(z) = \prod_{k=1}^r \epsilon_k(z)^{\alpha/r}, \end{aligned}$$

where the first inequality comes from $(H_2)'$ at $\varphi = h_k$ and the second inequality is due to the fact that $\|x - p(x)\| = \min\{\|x - p_k(x)\|, k = 1, \dots, r\}$. The function $\Phi : X \times X \rightarrow \mathbb{R}^l$ defined by

$$\Phi(x; y) = \begin{pmatrix} H(y) - H(x) \\ \vdots \\ H(y) - H(x) \end{pmatrix} \quad (104)$$

can be chosen as ‘‘penalty term.’’ The decomposition (103) may help in setting up H and in conceiving solution methods. For instance, if Z_k is a polytope defined by

$$Z_k = \{x \in \mathbb{R}^n; A^k x \geq b^k\}, \quad k = 1, \dots, r,$$

where $A^k \in \mathbb{R}^{m_k \times n}$, $b^k \in \mathbb{R}^{m_k}$, then one can set

$$h_k(x) = \max \left\{ 0, \exp \left(-\alpha_i^k \sum_{j=1}^n a_{ij}^k x_j - b_i^k \right) - 1, i = 1, \dots, m_k \right\},$$

where $A^k = (a_{ij}^k, i = 1, \dots, m_k, j = 1, \dots, n)$, $b^k = (b_1^k, \dots, b_{m_k}^k)^T$, α_i^k being positive parameters. A particular but interesting case is that where Z is not convex, while the sets Z_i , X_i , and $\cup_{i=1}^r X_i$ are all convex.

[Corollary 7](#) suggests a method for solving (93) that is based on the theory introduced in [46, 77] and that will be shortly outlined. To this end, consider the special, but common, case where R is a polytope. Because of [Corollary 7](#), the combinatorial vector problem (93) can be replaced by the continuous vector problem (95). If μ is large enough (i.e., $\mu > \mu_7$), then, because of [Theorem 37](#) (see [Remark 8](#)), a VMP of (95) is a vertex of $P \cap X_Q$. Hence, a method could be the following. The first step must consist in finding a local VMP of (95). Then, consider the family of strictly concave (scalar) problems:

$$\min g_i(x; \mu), \quad x \in P \cap X_Q; i = 1, \dots, l, \quad (105)$$

where $g_i(x; \mu) := f_i(x) + \mu \varphi(x)$. If i is such that x^0 is a local¹ (scalar) minimum point of (105), then Tuy's Theory [46, 77] provides a “cutting halfspace,” say H_i , such that

$$x^0 \notin H_i; \quad \left\{ \begin{array}{l} x \in P \cap X_Q \\ g_i(x; \mu) < g_i(x^0; \mu) \end{array} \right\} \implies x \in (P \cap H_i) \cap X_Q. \quad (106)$$

This condition means that, if there exists an x at which g_i takes a value less than $g_i(x^0; \mu)$, then x must belong to H_i . For all other indices i Tuy's “cutting halfspace” collapses to a supporting halfspace of $P \cap X_Q$; this will be denoted again by H_i . The former (latter) set of indexes will be denoted by I^+ (respectively I^-). If $I^+ \neq \emptyset$, then from (106) one can easily deduce that

$$\left\{ \begin{array}{l} x \in P \cap X_Q \\ g(x; \mu) <_c g(x^0; \mu) \end{array} \right\} \implies x \in P \cap \left(\cap_{i \in I^+} H_i \right) \cap X_Q. \quad (107)$$

This condition means that, if there exists an x at which g takes a value less (in vector sense, with respect to C) than $g(x^0; \mu)$, then x must belong to $\cap_{i \in I^+} H_i$; hence, such an intersection plays a role for vector problems as Tuy's cut does for scalar ones. The case $I^+ = \emptyset$ is a degenerate one for all Tuy's cuts and requires a special analysis: the present vertex can be replaced by any of the adjacent vertices, since they are alternative local VMP. From (107) one derives the condition:

¹In the sense of not necessarily global.

$$I^+ \neq \emptyset, \quad P_1 \cap X_Q = \emptyset, \quad (108)$$

where

$$P_1 := P \cap \left(\cap_{i \in I^+} H_i \right),$$

is a sufficient condition for x^0 to be a VMP of (93) at $R = P$. If (108) is not satisfied, then one can replace P with P_1 in (105), and repeat the above argument. Noting that the set

$$P \cap \left(\cap_{i \in I^+} (\mathbb{R}^n \setminus H_i) \right) \cap X_Q$$

does not contain any alternative VMP of (95), while they might belong to the set

$$P \cap (\mathbb{R}^n \setminus H_r) \cap \left(\cap_{i \in I^+ \setminus \{r\}} H_i \right) \cap X_Q, \quad r \in I^+.$$

An interesting application of the above decomposition should be to the case where (101) is replaced by a vector variational inequality.

According to Remark 8, an alternative method for finding a VMP of (93) may consists in solving l scalar problems, having a strictly concave objective function and a union of vertices of P as feasible region.

the sensors observe the physical space? Many coverage problems have been addressed by the research literature due to a variety of sensors and applications. They vary on the subject to be covered (area, discrete points), sensor deployment mechanism (random, deterministic), sensor mobility (stationary, mobile), event structure (simple, composite), and network properties (connectivity, energyefficiency). This chapter surveys various coverage formulations, their assumptions, and an overview of the solutions proposed.

1 Introduction

Wireless sensor networks provide rapid, untethered access to information and computing, eliminating the barriers of distance, time, and location for many applications in national security, surveillance, health care, environmental monitoring, and many more. A wireless sensor network (WSN) is a deployment of a large number of small, inexpensive, self-powered devices that can sense, compute, and communicate with other devices for the purpose of gathering local information used to make global decisions about a physical environment. Research on sensor networks was originally motivated by military applications, such as acoustic surveillance and target detection. However, WSNs have many other applications such as [14]:

- Infrastructure security: instrument critical buildings and facilities such as power plants with networks of acoustic, video, and other sensors in order to provide early detection of any potential threat.
- Environmental and habitat monitoring: environmental sensors can be used to study vegetation response to climatic changes and diseases, while acoustic and imaging sensors can be used to identify, track, and measure the population of birds and other species.
- Traffic monitoring: sensors are deployed in intersections for traffic monitoring and control and to control traffic lights. Another concept is deploying sensors along the highways and attaching them to each vehicle. Such a network can be used to avoid traffic jams and plan alternative routes.

WSNs are application specific; thus, sensors nodes are equipped with sensors accordingly. Some applications (e.g., building monitoring) require a smaller number of sensors that can be placed individually. Others (e.g., surveillance of a battlefield) require a large number of sensors (e.g., thousands or even millions) that will be deployed ad hoc. Using a larger number of sensors increases network robustness and fault tolerance. The IrisNet (Internet-scale Resource-Intensive Sensor Network Services) project [19] at Intel Research is envisioning a worldwide sensor web of millions of widely distributed, heterogeneous sensors.

Sensor nodes are tiny devices equipped with one or more sensors, one or more transceivers, processing and storage resources, and, possibly, actuators. Sensor nodes have limited resources: they have finite battery resources, low CPU speed, little memory, and small transmission range. For example, the Crossbow MICAz mote [16] operates on the 2.4 GHz ISM band, uses two AA batteries, and has an ATmega 128 L processor at 8 MHz, 4 Kbytes RAM, and a transmission range up to 30 m (indoor)/100 m (outdoor).

An important topic researched in literature is the sensor coverage problem. This problem addresses an important question: *how well do the sensors observe the physical space?* As pointed out in [28], the coverage concept is a measure of the quality of service (QoS) of the sensing function and is subject to a wide range of interpretations due to a large variety of sensors and applications. The goal is to have each location in the physical space of interest within the sensing range of at least one sensor.

This chapter presents various coverage problem formulations. [Section 2](#) presents the main types of coverage and their design choices. [Sections 3](#) and [4](#) discuss relevant contributions addressing area coverage and point coverage. These works are characterized based on the design choices introduced in [Sect. 2](#). The chapter is concluded in [Sect. 5](#).

2 Sensor Coverage Problems and Design Choices

2.1 Coverage Types

Two main types of coverage are (i) area coverage and (ii) point coverage. They depend on the objective to be covered.

In the *area coverage*, the main objective of the sensor network is to cover (monitor) a given area of interest. An area is covered by a WSN if every point in the area is located within communication range of an active sensor which is part of the network. [Figure 1a](#) shows an example of a square area which is covered by a WSN.

In the *point coverage*, the main objective of the sensor network is to cover a set of points. These points may represent targets that have to be monitored continuously by the sensors in the network. Yet in some other scenarios, these points can approximate an area or a region. [Figure 1b](#) shows an example of point coverage.

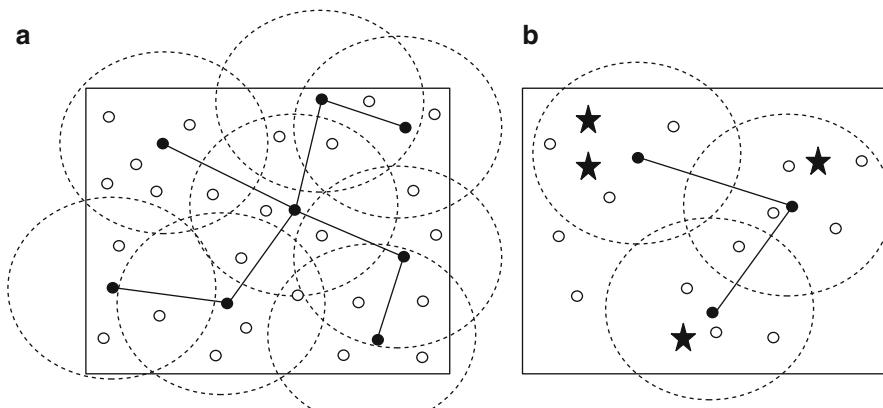

Fig. 1 Coverage types. (a) Area coverage. (b) Point coverage

2.2 Design Choices

Various coverage problems have been formulated based on different design choices, such as:

- *Sensor deployment method*: deterministic versus random. A deterministic sensor placement may be feasible in friendly and accessible environments and when the network size is relatively small. Random sensor distribution is generally considered in remote or inhospitable areas, for military applications, and for applications involving a large population of sensors.
- *Sensor type*: homogeneous versus heterogeneous. Some applications assume that all sensor nodes in the network have the same characteristics (e.g., sensing range, communication range, types of sensors on the sensor board), while other applications assume that the sensors are heterogeneous.
- *Sensor mobility*: static versus mobile. Majority of studies assume that the sensors are stationary, while some works consider mobile sensors. In mobile sensor networks, sensors can self-propel via springs [11], wheels [18], or they can be attached to transporters, such as robots [18] and vehicles [23].
- *Network type*: simple or heterogeneous. Some problems consider a simple (or standard) architecture consisting of sensor nodes that report data to a sink, see [Fig. 2a](#). Other works consider a heterogeneous architecture. One architecture which has been recently explored contains two types of wireless devices, as presented in [Fig. 2b](#). Lower layer is formed by sensor nodes with size and weight restrictions, low cost (projected to be less than \$1), limited battery power, short transmission range, low data rate (up to several hundred Kbps), and low duty cycle. Main tasks performed by a sensor node are sensing, data processing, and data transmission/relaying. The dominant power consumer is the radio transceiver. Upper layer consists of resource-rich supernodes overlaid over the sensor network, as illustrated in [Fig. 2b](#). Supernodes can have two radio transceivers, one for communication with sensor nodes and the other for communication with other supernodes. Supernodes have more power reserves and better processing and storage capabilities than sensor nodes. Wireless communication links between supernodes have considerably longer range and higher data rates, allowing supernode network to bridge remote regions of the interest area. One or more supernodes are sinks, that is, they relay data between the heterogeneous WSN and users. Supernodes are more expensive, and, therefore, fewer are used than sensor nodes. One of the main tasks performed by a supernode is to transmit/relay data from sensor nodes to/from the sinks. Other tasks can include sensor data aggregation, complex computations, and decision making. One example of such an architecture consists of Crossbow MPR400 motes [16] communicating on 916 MHz and Crossbow Stargate Xscale platform [16] used as supernodes. A Stargate can be connected to a mote MPR400 and can use a IEEE 802.11 wireless card on 2.4 GHz. Using two transceivers, a Stargate is part of the WSN and can also communicate with the other Stargate devices on 2.4 GHz.

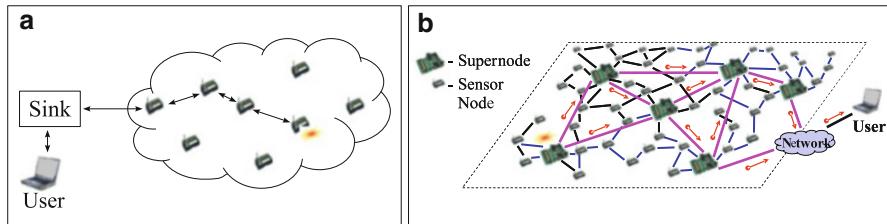

Fig. 2 Network types. (a) Simple WSN. (b) Heterogeneous WSN

- *Sink mobility*: static or mobile. Some works assume that the sinks are stationary, while others assume they are mobile. Recent advances in the field of robotics [3, 22] make it possible to integrate robots as sinks (or gateways) in WSNs [32]. Adding mobile devices to WSNs infrastructure has attracted increased attention recently. Much of the work has been conducted on data gathering applications, where the mobile sinks move randomly [30, 34], using predetermined paths [10, 25, 32], or autonomously [2]. A random moving sink is not aware of the sensor residual energy and thus might threaten the energy balance among the sensors. The predetermined path models lack flexibility and scalability with network size. The moving strategies where the sinks take the moving decisions autonomously can better adapt to various network conditions.
- *Event type*: simple or composite. Some works assume only one sensing measure (e.g., acoustic sensor), while others address composite events. For example, a fire event is better detected if temperature, humidity, and smoke sensor measurements are combined. This will form a composite event. In such a situation, there are coverage requirements for each of the atomic events forming the composite event.
- *Fault tolerance*: simple or k-coverage. Some works require that each point of interest be simply covered, that is, to be monitored by at least one sensor. Other works require that each point of interest be k-covered, that is, it will be monitored by at least k sensors at each time. k-coverage improves fault tolerance, as some of the sensors may die over time due to physical damage or by depleting their energy resources.
- *Coverage breach*: some applications allow coverage breach. If a target (or monitor region) is not covered by an active sensor, then it is called breached. The objective is to minimize the coverage breach (e.g., minimize the maximum accumulated breach time of any target and minimize the number of breached targets).
- *Additional requirements*: energy efficiency, connectivity, maximum network lifetime, etc. There are usually additional requirements needed for a healthy functioning of the WSN. Sensor nodes are resource constraints, and they can function a limited amount of time before depleting their energy resource. When sensors are remotely deployed, it is infeasible and sometimes impossible to replace their battery. Thus, developing mechanisms which are energy-efficient is one of the main requirements in WSN design. A sensor node's radio can be in one of the following four states: transmit, receive, idle, or sleep. The idle

state is when the transceiver is neither transmitting nor receiving, and the sleep mode is when the radio is turned off. As presented in [29], an analysis of the power usage for Rockwell WINS seismic sensor indicates power consumption for the transmit state between 0.38 and 0.7 W, for the receive state 0.36 W, for the idle state 0.34 W, and for the sleep state 0.03 W. The receive and idle modes may require as much energy as transmitting, while the sleep mode requires the less energy. Another observation is the communication/computation power usage ratio, which can be higher than 1,000 (e.g., for Rockwell WINS [29] is from 1,500 to 2,700); therefore, local data processing, data fusion, and data compression are highly desirable. Judiciously selecting the state of each sensor node's radio is accomplished through a *scheduling* mechanism. Power saving techniques can generally be classified in the following categories:

1. Schedule the wireless nodes to alternate between active and sleep mode
2. Power control by adjusting the transmission range of wireless nodes
3. Energy-efficient routing, data gathering
4. Reduce the amount of data transmitted and avoid useless activity

Energy-efficiency mechanisms have also direct impact on WSN lifetime. Yet another important requirement is WSN connectivity. Active sensors must form a connected topology to allow sensor data to be relayed to the user. Sometimes, k -connectivity is enforced, where each sensor node has k distinct paths to a sink. This improves reliability: in case some paths or sensors become unavailable, data can be relayed on alternate paths. There are also cases when sensors do not have to be connected. In this case, all sensors are within communication range with the sink (or base station), or a mobile sink can be used to collect sensor data.

3 Area Coverage

In the area coverage problem, the main objective of the sensor network is to cover (monitor) an area (also referred sometimes as region). [Figure 1a](#) shows an example of a random deployment of sensors to cover a given rectangular-shaped area, where circles represent the sensing range. Each point of the area is monitored by at least one sensor. The connected black nodes form the set of active sensors, the result of a scheduling mechanism. Several energy-efficient area coverage problem formulations, their models and assumptions, and solutions proposed are surveyed next.

3.1 Energy-Efficient Coverage

The works in [6, 31] consider a large population of sensors, deployed randomly for area monitoring. The goal is to achieve an energy-efficient design that maintains area coverage. As the number of sensors deployed is greater than the optimum required to perform the monitoring task, the solution proposed is to divide the sensor nodes into disjoint sets, such that every set can individually perform the

area monitoring tasks. These sets are activated successively, and while the current sensor set is active, all other nodes are in a low-energy sleep mode. The goal of this approach is to determine a maximum number of disjoint sets, as this has a direct impact on conserving sensor energy resources as well as on prolonging the network lifetime. The solutions proposed are centralized.

Slijepcevic and Potkonjak [31] model the area as a collection of fields, where every field has the property that any enclosed point is covered by the same set of sensors. The most-constrained least-constraining algorithm [31] computes the disjoint covers successively, selecting sensors that cover the critical element (field covered by a minimal number of sensors), giving priority to sensors that cover a high number of uncovered fields, cover sparsely covered fields, and do not cover fields redundantly.

Cardei et al. [6] model the disjoint sets as disjoint dominating sets in an undirected graph, where sensors form the vertex set and an edge joins any two vertices that are within each other's sensing range. The maximum disjoint dominating sets computation is NP-complete, and any polynomial-time approximation algorithm has a lower bound of 1.5. A graph-coloring mechanism is proposed for computing the disjoint dominating sets. First, disjoint sets are formed by coloring all nodes, using the sequential coloring algorithm. Then, each non-dominating set is considered in an increasing color number and transformed into a dominating set by recoloring a smallest number of higher-color vertices. When this process ends and no more dominating sets can be formed, the remaining nodes are added to the sets where they have the greatest contribution in covering parts of the uncovered given area. Simulations have shown that the number of sets computed is between 1.5 and 2 times greater than by using the algorithm in [31], with lapses in area coverage less than 5 %, on average.

Another energy-efficient node-scheduling-based coverage mechanism is proposed by Tian and Georganas in [33]. The protocol proposed is distributed and localized. Power savings are obtained both by scheduling the sensor nodes activity as well as by considering an adjustable sensing range. The off-duty *eligibility rule* determines whether a node's sensing area is included in its neighbors' sensing area. Solutions for determining whether a node's coverage can be sponsored by its neighbors (sponsored coverage calculation) are provided for several cases: when nodes have the same sensing range and know their location, when nodes have the same sensing range and can obtain neighboring node's directional information, or in particular scenarios when nodes have different sensing ranges. The node-scheduling scheme is divided into rounds, where each round has a self-scheduling phase followed by a sensing phase. In the self-scheduling phase, the nodes investigate the off-duty eligibility rule. Eligible nodes turn off their communication and sensing units, while all other nodes will perform sensing tasks in the sensing phase. In order to obtain neighboring information, each node broadcasts a position advertisement message at the beginning of each round. This message contains the node ID and node location. If the off-duty eligibility rule is tested simultaneously by neighboring nodes, a node and its sponsor may decide to turn off simultaneously, triggering the occurrence of *blind points*. To avoid this, a back-off scheme is used, where every

node starts the evaluation rule after a random time and then broadcasts a status advertisement message to announce if it is available for turning off. Before turning off, a node waits another T_w time to listen for neighboring nodes update. This work does not specify synchronization mechanisms in detail. It is implemented as an extension of the data gathering LEACH protocol [20], and simulation results show an increase of 1.7 on average in system lifetime.

A probing-based, node-scheduling solution for the energy-efficient coverage problem is proposed in [43] by Ye et al. Here, all sensors are characterized by the same sensing range, and coverage is measured as the ratio between the area under monitoring and total size of the network field. The off-duty eligibility rule is based on a probing mechanism. Basically, a sensor broadcasts a probing message PRB within a probing range r . Any working node that hears this message responds with a PRB_RPY . If at least one reply is received, the node enters the sleep mode. Probing range is selected based on the desired working node density (number of sensors per unit area) or based on the desired coverage redundancy, whereas the wake-up time is based on the tolerable sensing intermittence. This protocol is distributed, localized, and has low complexity but still does not preserve the original coverage area.

3.2 Energy-Efficient Connected Coverage

An important issue in WSNs is connectivity. A network is connected if any active node can communicate with any other active node, possibly using intermediate nodes as relays. Once the sensors are deployed, they organize into a network that must be connected so that the information collected by sensor nodes can be relayed back to data sinks or controllers. An important, frequently addressed objective is to determine a minimal number of working sensors required to maintain the initial coverage area as well as connectivity. Selecting a minimal set of working nodes reduces power consumption and prolongs network lifetime. Several connected coverage mechanisms are presented next.

An important, but intuitive result was proved by Zhang and Hou [44], which states that if the communication range R_c is at least twice the sensing range R_s , a complete coverage of a convex area implies connectivity of the working nodes. If the communication range set up is too large, radio communication may be subject to excessive interference. Therefore, if the communication range can be adjusted, a good approach to assure connectivity is to set transmission range as twice the sensing range. Two nodes are neighbors if they have overlapping sensing areas. By intuition, when $R_c \geq 2R_s$, two neighbors are within their communication ranges, as shown in Fig. 3.

Based on this result, Zhang and Hou [44] further discussed the case $R_c \geq R_s$. An important observation is that an area is completely covered if there are at least two disks that intersect and all crossings are covered. Here, a disk refers to a node's sensing area, and a crossing is an intersection point of the circle boundaries of two disks. In the ideal case, in which node density is sufficiently high, the full

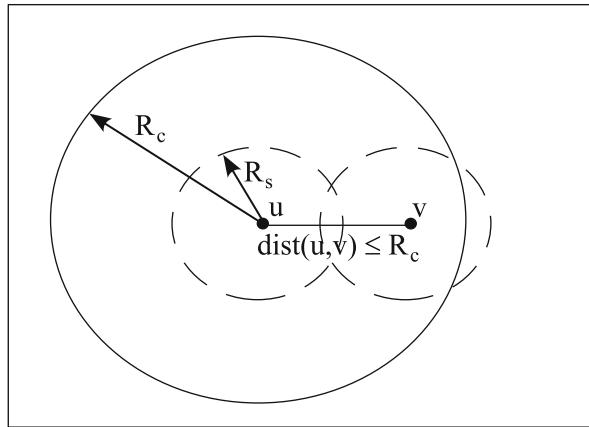

Fig. 3 Two sensors, u and v , with overlapping sensing areas can directly communicate with each other if $R_c \geq 2R_s$

coverage can be obtained by optimally placing the subset of working nodes at the vertices of regular hexagonal plane tiling. Based on these results, authors proposed a distributed, localized algorithm, called Optimal Geographical Density Control (OGDC). At any time, a node can be in one of the states: UNDECIDED, ON, and OFF. The algorithm runs in rounds, and at the beginning of each round, a set of one or more starting nodes are selected as working nodes. After a back-off time, a starting node broadcasts a power-on message and changes its state to ON. The power-on message contains (1) the position of the sender and (2) the direction along which a working node should be located. The direction indicated by the power-on message of a starting node is randomly distributed. Having starting nodes randomly selected at the beginning of each round ensures uniform power consumption across the network. Also, the back-off mechanism avoids packet collisions. At the beginning of each round, all nodes are UNDECIDED and will change either to ON or OFF state until the beginning of the next round. This decision is based on the power-on messages received. Every node keeps a list with neighbor information. When a node receives a power-on message, it checks whether its neighbors cover its sensing area, and if so, it will change to OFF state. A node decides to change into the ON state if it is the closest node to the optimal location of an ideal working node selected to cover the crossing points of the coverage areas of two working neighbors. NS-2-based simulation shows good results in terms of percentage of coverage, number of working nodes, and system lifetime.

Some applications may require different degrees of coverage while still maintaining working node connectivity. A network has a coverage degree k (k -coverage) if every location is within the sensing range of at least k sensors. Networks with a higher coverage degree can obtain higher sensing accuracy and be more robust to sensor failure. Wang et al. [36] generalized the result in [44] by showing that, when the communication range R_c is at least twice the sensing range R_s ,

a k-covered network will result in a k-connected network. A k-connected network has the property that removing any $k - 1$ nodes will still maintain the network connectivity. The following discussion addresses the case when $R_c \geq 2R_s$. To define the k-coverage eligibility mechanism, the problem of determining the coverage degree of a region is reduced to a simpler problem of determining the coverage degrees of all the intersection points. Given a coverage region A , a point p is called an *intersection point* if (1) p is an intersection point of the sensing cycles of any two nodes u and v , for example, $p \in u \cup v$, and (2) for any node v , $p \in v \cap A$ and $|pv| = R_s$, where R_s is the sensing range. The authors proved that a convex region is k-covered if it contains intersection points, and all these intersection points are k-covered. Based on this, a sensor is ineligible to turn active if all the intersection points inside its sensing circle are at least k-covered.

Wang et al. proposed the coverage configuration protocol (CCP) [36] that can dynamically configure the network to provide different coverage degrees requested by applications. To facilitate the computation of intersection points, every node maintains a table with neighbor information (location, status: active/inactive) and periodically broadcasts a HELLO beacon with its current location and status. A node can be in one of the three states: SLEEP, LISTEN, and ACTIVE. All nodes start in the SLEEP state for a random time. When a node wakes up, it enters LISTEN state, and based on the outcome of the eligibility rule over a time interval, it will enter either SLEEP or ACTIVE state. Once a node is in the ACTIVE state, it will reevaluate the coverage eligibility every time it receives a HELLO message and decide whether to go into the SLEEP state or remain in the ACTIVE state.

For the case when $R_c < 2R_s$, CCP does not guarantee network connectivity. The solution adopted in [36] is to integrate CCP with SPAN [12] to provide both sensing coverage and network connectivity. The combined eligibility rule is as follows: (1) an inactive node goes into the active state if it satisfies the eligibility rules of SPAN and CCP and (2) an active node withdraws if it satisfies neither the eligibility rule of SPAN nor CCP. With this combined mechanism, k-coverage can be obtained using CCP and 1-connectivity using SPAN. The algorithm was implemented and tested using NS-2 and showed good performance results in terms of coverage, active nodes, and system lifetime.

Carle and Simplot [9] propose another mechanism for energy-efficient connected area coverage for the case when all sensor nodes have the same sensing range and the communication range equals the sensing range. The goal of the algorithm is to select an area-dominating set of nodes of minimum cardinality, such that the selected set covers the given area. The main idea is to use one of the existing protocols for building a connected dominating set (e.g., Dai and Wu's algorithm in [17]) but instead of providing the node coverage to assure the area coverage. Once a node has decided its status (active or sleeping) for the next round, it transmits a message to its neighbors. The message sent is referred to as positive or negative advertising, depending on whether the node has decided to be active or in the sleep mode, respectively. Each node sets its priority depending on the remaining battery life and employs a back-off mechanism, such that the nodes with larger energy resources decide their status first. The protocol run by a node u is as follows: (1) node u

determines whether its monitoring area is already covered by its neighbors, based on the positive or negative advertising messages. If the scheme by Tian and Georganas [33] is used for determining whether the neighbor set covers u 's monitoring area, then each node needs to know its neighbors' locations; (2) at the end of the back-off interval, node u computes a subgraph of its one-hop active neighbors; (3) if the subgraph is connected and fully covers u 's area, then node u will be in the sleep mode; otherwise, it will be in the active mode during the next round. Since this algorithm follows the steps in [17], the resulting area-dominating set is connected.

3.3 Area Coverage Using Multiple Mobile Sinks

The work [26] considers a WSN consisting of sensor nodes deployed randomly in large number and several mobile sinks used to collect data from the sensors. Sinks have two transceivers, one to communicate with the sensors and another to communicate with the other sinks. Sensors send their data to the sinks using multi-hop communication. In WSNs, sensors closer to a sink tend to consume more energy than those farther away from the sinks. This is mainly because, besides transmitting their own packets, they forward packets on behalf of other sensors that are located farther away. As a result, the sensors closer to the sink will drain their energy resources first, resulting in holes in the WSN. This uneven energy consumption will reduce network lifetime.

One method to alleviate this problem is using mobile sinks which move to a new location when the energy of the sensors near the sink becomes low. Article [26] presents an algorithm where sinks move autonomously such that (1) the sinks remain interconnected all the time forming a virtual sink backbone and (2) network lifetime is maximized. This sink movement mechanism is then combined with the area coverage application. Sensors are scheduled to alternate between active and sleep states such that the active nodes satisfy the area coverage requirement. The problem requirements can be summarized as follows: (1) the set of active sensors provides area coverage, (2) the sinks remain interconnected all the time, and (3) network lifetime is maximized.

The algorithm [26] runs in rounds. The steps at the beginning of the first round are:

1. Sensors run a scheduling mechanism to decide which sensors stay active and which sensors go to sleep such that the active sensors ensure the area coverage.
2. Sensors form cluster-based data collection trees, where mobile sinks are the clusterheads.
3. Start data collection phase.

At the beginning of each other round (excluding the first round), each sink S_i executes the following steps:

1. Sink S_i decides if it has to move. If not, then nothing has to be done until the beginning of the next round; go to step 5. Otherwise, the steps below are executed.

2. Sink S_i announces the sensors in its cluster area to change the set of active sensors (e.g., alternate the set of active sensors with some sleep sensors with more residual energy), such that the set of active sensors ensure area coverage and connectivity.
3. After deciding the set of active sensors in S_i 's cluster area, form a data collection tree for the sink S_i .
4. Sink S_i decides if it has to move based on the energy in the new tree. If it does not need to move, then nothing has to be done until the beginning of the next round; go to the step 5. Otherwise, S_i invokes the mechanism for deciding the new sink location (see [26]).
5. Start data collection phase.

Sensors compute a scheduling mechanism to decide which of them stay active to satisfy the area coverage and sensor connectivity requirements. Two such mechanisms are discussed. The first approximates the area coverage by point coverage, thus approximating the requirement of area coverage with the requirement that every sensor node needs to be covered by the set of active sensor nodes (see Sect. 4.3). The covering nodes are formed by finding a connected dominating set using Rule k [17]. The second method divides the area into grids, such that any sensor active in a grid can cover that grid area and can communicate with any of the neighboring grids. Then one sensor (e.g., the node with highest residual energy) will be active in each grid.

Starting with the second and subsequent rounds, sinks might move in order to prolong network lifetime. A sink S_i decides to move if p% of its 1-hop sensors have $E \leq E_{th}$. If the sink has to move, then before it actually moves, the set of active nodes in its cluster is recomputed based on the residual energy in the sensor nodes. After the new active nodes are decided, they form a data collection tree. The sink S_i rechecks the moving criteria, and if p% of its 1-hop sensors have $E \leq E_{th}$, then it moves; this means that the neighboring sensors have low-energy resources.

3.4 Area Coverage for Composite Event Detection

A WSN can detect single (or atomic) events or composite events [27]. Considering the sensors manufactured by Crossbow Technology, Inc. [16] as an example, a sensor equipped with MTS400 multi-sensor board can sense temperature, humidity, barometric pressure, and ambient light. Thus, it can detect multiple atomic events.

For a single sensing component, for example, the temperature, if the temperature rises above some predefined threshold, then an *atomic event* is detected. A *composite event* is the combination of several atomic events. For example, a fire-detection application uses sensors to measure various parameters of the environment. A composite event fire might be defined as the combination of the atomic events $\text{temperature} > th_1$, $\text{light} > th_2$, and $\text{smoke} > th_3$, where “th” denotes a threshold for the corresponding attribute. That is, $\text{fire} = (\text{temperature} > th_1) \wedge (\text{light} > th_2) \wedge (\text{smoke} > th_3)$. It is more accurate to report the fire when all these atomic events occur, instead of the case when only one attribute is above the threshold.

The definitions for k-watching an atomic event and a composite event are as follows:

- *k-Watched Atomic Event*: An atomic event is k-watched by a set of sensors if at any time this event occurs at any point within the interested area, at least k sensors in the network can detect this occurrence.
- *k-Watched Composite Event*: A composite event is k-watched by a set of sensors if every atomic event part of the composite event is k-watched by the set of sensors.

The problem studied in [27] is defined as follows: given a set of N sensors with different sensing capabilities, a monitored area A, a composite event which is a combination of M atomic events involving sensing components x_1, x_2, \dots, x_M , and the energy constraint of each sensor E_{init} design a sensor scheduling mechanism such that (1) the composite event is k-watched in the area A, (2) the set of active sensor nodes is connected, and (3) network lifetime is maximized.

The mechanism proposes using sensor scheduling to achieve energy efficiency. Network activity is organized in rounds. Each round has two phases: initialization phase and event detection phase. In the initialization phase, sensor nodes decide if they will be active or if they go to sleep during the next round. The active sensor set must provide a connected topology and must ensure k-watching property across the deployment area. Each node u has a priority $p(u) = (E(u), ID(u))$, where $E(u)$ is the node u's residual energy and $ID(u)$ is the node u's ID. A node with higher residual energy has a higher priority. Note that a node priority change over time: if the node is active, then its residual energy decreases, so it has a lower priority in the next round.

The h-hop neighborhood of a node u is defined as $N_h(u) = \{v | \text{distance}(u, v) \leq h \text{ hops}\}$. The set of nodes within the h-hop neighborhood of u that have higher priority is defined as $N'_h(u) = \{v \in N_h(u) | p(v) > p(u)\}$. A node u decides its status (active/sleep) for the next round by using the following rule:

The default status of a sensor node is active. A sensor u is in sleep mode if the following two conditions hold:

1. (k-Watching property) the set of nodes $N'_h(u)$ provides the k-watching of each of u's sensing components.
2. (Connectivity property) any two of u's neighbors in $N_1(u)$, w and v, are connected by a path with all intermediate nodes in $N'_h(u)$.

The intuition behind this rule is that a sensor u can go to sleep if the nodes with higher priority in its h-hop neighborhood can provide the k-watching property and the connectivity property on behalf of u. Note that a node with higher priority can also go to sleep if the rule holds true in its h-hop neighborhood. To avoid inconsistencies, a mechanism that assigns global priorities to the nodes is used. If a node u has only one neighbor, then the connectivity requirement is fulfilled, and u goes to sleep if the k-watching property holds.

Work [35] proposes a centralized approach that builds the detection sets (or data collection trees) using the breadth-first search algorithm [15] starting from a gateway, which can be any sensor node with richer energy resources. One drawback of the proposed approach is the global knowledge required by the algorithm constructing the detection sets. The sets are computed by the gateway node, and

the decision if an event (simple or composite) occurs is also made by the gateway node. Simulation results show that the centralized tree-based approach has a longer network lifetime (more detection sets), but the trade-off consists in using a single point of failure and large overhead for a large network size.

3.5 Adaptive Sensor Scheduling for Area Coverage

Article [41] considers a publish-subscribe scenario similar to [21]. The sink sends a query as interest toward sensors in the monitored area. When sensors receive a query, if they can satisfy the interests and meet the query, then they activate to perform the sensing task. The intermediate sensors help route sensed data toward the sink, and the results are finally reported to the sink. For example, assume that the sink is interested in whether a fire will happen in the next 2h; then it sends the interest query:

```
type = temperature ∧ smoke
interval = 1 min
rect = [(50, 70), (90, 90)]
timestamp = 01 : 30 : 00
expiresAt = 03 : 30 : 00
```

The sensors that can sense the temperature and/or smoke and are within the rectangle with the lower left end (50, 70) and the upper right end (90, 90) are activated and report data every 1 min from time 01: 30: 00 to 03: 30: 00. In general, the *type* field in the interest query is the combination of one or more sensing components, that is, $x_1 \wedge x_2 \wedge \dots \wedge x_l$.

More than one query can be sent to the monitored area. For example, another query can be issued as follows:

```
type = temperature
interval = 2 min
rect = [(30, 60), (70, 80)]
timestamp = 03 : 00 : 00
expiresAt = 04 : 00 : 00
```

The areas of interest for the two queries intersect; thus, some sensors might report data for both queries. The active sensors have to satisfy both the coverage and the global connectivity requirements.

The objective in [41] is to design a sensor scheduling algorithm that allows sensors not actively participating in sensing or data relaying to go to sleep in order to conserve energy and to prolong the network lifetime. The sensor scheduling mechanism adaptively decides the set of active sensor nodes such that both the coverage and the connectivity requirements are met:

- *Coverage requirement*: as queries propagate in the monitored area, related sensors in the area of interest are activated for the sensing tasks. This is an adaptive mechanism: as new query requests arrive, new sensors are activated as

needed; as queries expire, sensors in the area of interest go to sleep if they are not sensing any other request.

- *Connectivity requirement:* the set of active sensors must be connected all the time. This is needed for the communication between sensors and the sink in operations such as data reporting, query propagation, and forwarding of control messages.

The problem studied in [41] is as follows: Given a WSN with sensors equipped with one or more sensing components (attributes) from the set $\{x_1, x_2, \dots, x_M\}$, design an adaptive sensor scheduling mechanism such that the set of active sensors change over time such that to satisfy the *coverage* and *connectivity* requirements, and the WSN lifetime is maximized.

The adaptive sensor scheduling in WSNs (ASW) localized mechanism proposed in [41] forms an adaptive connected dominating set (CDS) that change over time as new requests arrive or expire. When a new request regarding sensing a particular rectangular area is received/expires, sensors adaptively update the active nodes in the required area to satisfy both coverage requirement and global connectivity.

Initially, a CDS backbone is selected so that the requests can be propagated to the monitored area along the backbone. The CDS is updated periodically after each time interval T . Before rerunning the CDS, sensors update their priority based on the remaining energy. Then for a time T , priority and the CDS stays unchanged. All the nodes participate in the new CDS selection and update their fields accordingly depending on whether they will be part of the CDS or not. The nodes serving queries will continue to be active and to perform their sensing tasks. Nodes which are not in the CDS or serving queries go to sleep.

Every sensor u decides whether it will be a CDS node or not during the next period T as follows. Initially, a node u sets $CDS(u) = \text{TRUE}$. Then sensor u sets $CDS(u) = \text{FALSE}$ if the following condition holds: for any two of u 's neighbors in $N_1(u)$, w and v , w and v are connected by a path with all intermediate nodes in $N'_h(u)$. See Sect. 3.4 for a definition of $N_h(u)$ and $N'_h(u)$.

Consider that the following query is sent by the BS: *Query(type, interval, area R, Tstart, Tend)*. The field *type* contains the attributes of interest that have to be reported, for example, $type = x_1 \wedge x_3$. The CDS nodes awake the 1-hop sleeping nodes in area R and forward the query information. An awaken node checks if it has at least one of the sensing components from the query type field, then it remains active for the duration of the query and will report data according to the reporting interval in the query. When a query time request ends, the reporting sensors check their role field. If a sensor is part of the CDS or is serving another query, then it remains active. Otherwise, it returns to sleep.

One case that can occur regards overlapping queries. A sensor may serve multiple queries if their reporting areas intersect. The frequency of reporting is done according to the requesting queries, and this field updates as queries expire or new queries arrive.

Compared with directed diffusion [21], ASW is more energy efficient, it generates less overhead; however, it may have a longer delivery path. This is because in the directed diffusion, all sensors are active and they may form shorter data delivery paths, while in ASW, only part of the sensors are active.

4 Point Coverage

In the point coverage problem, the objective is to cover a set of points. [Figure 1b](#) shows an example of a set of sensors randomly deployed to cover a set of points (star nodes). The connected black nodes form the set of active sensors, the result of a scheduling mechanism. Some important cases discussed in this section are energyefficiency, sensors with adjustable sensing ranges, multiple point coverage, connectivity, heterogeneous WSNs, and coverage breach.

4.1 Energy-Efficient Coverage

Article [5] addresses the point coverage problem in which a limited number of points (targets) with known locations need to be monitored. A large number of sensors are dispersed randomly in close proximity of the targets and send the monitored information to a central processing node. The requirement is that every target is monitored at all times by at least one sensor, assuming that every sensor is able to monitor all targets within its sensing range.

One method for extending sensor network lifetime through energy efficiency is to divide the set of sensors into disjoint sets such that every set completely covers all targets. These disjoint sets are activated successively, such that at any moment in time, only one set is active. Using this approach, all targets are monitored by every sensor set. The goal of this approach is to determine a maximum number of disjoint sets, such that the time interval between two activations for any given sensor is longer. By decreasing the fraction of time, a sensor is active, the overall time until power runs out for all sensors is increased, and the application lifetime is extended proportionally by a factor equal to the number of disjoint sets.

A solution for this application is proposed in [5], where disjoint sets are modeled as disjoint set covers, such that every cover completely monitors all the target points. Article [5] shows that the disjoint set coverage problem is NP-complete and any polynomial-time approximation algorithm has a lower bound of 2. The disjoint set cover problem is reduced to a maximum flow problem, which is modeled as a mixed integer programming. Simulations show better results in terms of the number of disjoint set covers computed compared with most-constrained least-constraining algorithm [31], where every target is modeled as a field.

In [7], the scheduling mechanism also forms sets of sensor nodes that monitor the targets successively. In contrast with the previous approach, a sensor can be part of multiple sets (e.g., the sets are not necessarily disjoint) and the sets can be operational for different time intervals. The objective of the maximum set covers (MSC) problem is to organize the sensors in sets and to determine the time interval of each set such that the sum of all time intervals is maximized (e.g., maximum network lifetime), subject to the constraints that each sensor cover monitors all targets and the time a sensor is active is less than the sensor lifetime. The paper assumes all sensors can be active for the same amount of time (e.g., they have the same starting energy). Article [7] shows that the MSC problem is NP-hard by reduction from the 3-SAT problem.

Two heuristic solutions are proposed. The first one formulates the MSC problem using integer programming (IP) and then uses the relaxation technique to design a linear programming (LP)-based heuristic. The total complexity is $O(p^3n^3)$, where p is an upperbound on the number of covers and n is the number of sensor nodes. The second heuristic builds the covers successively. When building a new cover, sensors with greatest contribution (e.g., covers more uncovered targets and has more residual energy) are added first. Sensors are added to a cover until all the targets are covered. The complexity is $O(dm^2n)$, where d is the number of sensors that cover the most sparsely covered target, m is the number of targets, and n is the number of sensors. Simulation results show that the IP approach returns a longer network lifetime but has a larger complexity than the greedy mechanism.

4.2 Point Coverage in Sensor Networks with Adjustable Sensing Ranges

Article [8] addresses the case when sensor nodes can adjust their sensing range. In the adjustable range set covers (AR-SC) problem, a set of points (or targets) and a set of sensors with adjustable sensing ranges are given. The objective is to find a family of set covers such that (1) the number of covers is maximized, (2) each set monitors all targets, and (3) a sensor consumes at most E energy. The problem assumes a discrete set of sensing ranges for the sensors.

The first approach uses IP to determine the set covers $c_1, c_2 \dots c_K$ and the sensors in each cover x_{ikp} . Given:

- N sensor nodes s_1, \dots, s_N .
- M targets t_1, t_2, \dots, t_M .
- P sensing ranges r_1, r_2, \dots, r_P and the corresponding energy consumption e_1, e_2, \dots, e_P .
- Initial sensor energy E .
- The coefficients showing the relationship between sensor, radius, and target: $a_{ipj} = 1$ if sensor s_i with radius r_p covers the target t_j .

Maximize $c_1 + \dots + c_K$

subject to

$$\begin{aligned} \sum_{k=1}^K (\sum_{p=1}^P x_{ikp} e_p) &\leq E && \text{for all } i = 1 \dots N \\ \sum_{p=1}^P x_{ikp} &\leq c_k && \text{for all } i = 1..N, k = 1 \dots K \\ \sum_{i=1}^N (\sum_{p=1}^P x_{ikp} * a_{ipj}) &\geq c_k && \text{for all } k = 1 \dots K, j = 1 \dots M \\ x_{ikp} &\in \{0, 1\} \text{ and } c_k \in \{0, 1\} \end{aligned} \quad (1)$$

The variables used are:

- c_k , boolean variable, for $k=1..K$; $c_k = 1$ if this subset is a set cover; otherwise, $c_k = 0$.
- x_{ikp} , boolean variable, for $i = 1..N$, $k = 1..K$, $p = 1..P$; $x_{ikp} = 1$ if sensor i with range r_p is in cover k ; otherwise, $x_{ikp} = 0$.

The first constraint guarantees that the energy consumed by each sensor i is less than or equal to E , which is the starting energy of each sensor. The second constraint ensures that if sensor i is part of the cover k , then exactly one of its P sensing ranges is set. The third constraint guarantees that each target t_j is covered by each set c_k .

Since the complexity of the IP is large for large number of sensors, the IP is relaxed to a LP and then rounded to get a solution to the original problem AR-SC. In the relaxed LP, the variables x_{ikp} and c_k are relaxed to $0 \leq x_{ikp} \leq 1$ and $0 \leq c_k \leq 1$. To form a set cover c_k (taken in decreasing order), sensors are added in decreasing order of x_{ikp} as long as they have enough energy resources and new uncovered targets are monitored.

The second solution is a centralized greedy algorithm, which repeatedly constructs set covers and sets sensors' sensing ranges as long as each target is covered by at least one sensor with enough energy resources. In forming a set cover, sensors are selected based on their contribution. ΔB_{ip} is the incremental contribution of the sensor i when its sensing range is increased to r_p . $\Delta B_{ip} = \Delta T_{ip}/\Delta e_p$, where $\Delta T_{ip} = |T_{ip}| - |T_{iq}|$ and $\Delta e_p = e_p - e_q$. The range r_q is the current sensing range of the sensor i , thus $r_p > r_q$. Initially, all the sensors have assigned a sensing range $r_0 = 0$, and the corresponding energy is $e_0 = 0$. Sensors with higher contribution are added first (e.g., by increasing their sensing range) until all the targets are covered. Intuitively, a smaller sensing range is preferable as long as the target coverage objective is met, since energy resources are conserved, allowing the sensor to be operational longer. Once the set cover is formed (e.g., all targets are covered by the selected set of sensors), the sensors with a sensing range greater than zero form the set of active sensors, while all other sensors with sensing range $r_0 = 0$ will be in sleep mode.

The third method proposed in [8] is a distributed and localized method. In a *distributed and localized* method, the decision process at each node makes use of only information in a neighborhood within a constant number of hops. A distributed and localized algorithm is desirable in WSN since it adapts better to dynamic and large topologies. The algorithm runs in rounds. Each round begins with an initialization phase, where sensors decide whether they will be in an active or sleep mode during the current round.

Each sensor maintains a waiting time, after which it decides its status (sleep or active) and its sensing range, and then it broadcasts the list of targets it covers to its one-hop neighbors. The waiting time of each sensor s_i depends on s_i 's contribution, and it is set up initially to $W_i = \left(1 - \frac{B_{ip}}{B_{\max}}\right) \times W$ where B_{\max} is the largest possible contribution, defined as $B_{\max} = M/e_1$, where M is the number of targets. B_{ip} is the contribution of sensor i with range r_p , defined as $B_{ip} = |T_{ip}|/e_p$, where T_{ip} is the set of uncovered targets within the sensing range r_p of sensor s_i .

When its waiting time expires, a sensor broadcasts its status (active or sleep) as well as the list of targets it covers. The neighbors receiving the message update their contribution and waiting time accordingly. If a sensor has all the targets in its range already covered, then it sets its range to $r_0 = 0$. In the initialization phase, nodes which are active during the current round are determined. If, after the initialization time, one of the sensors cannot cover a target in their range, then it announces a

failure message to the base station (BS). Network lifetime is computed as the time elapsed until the BS detects the first failure.

Simulation results show that the centralized greedy algorithm performs the best, followed by the LP-based mechanism, and then the distributed greedy one. There is also high improvement in network lifetime when sensors can adjust their sensing ranges. Compared to the base case when sensors have only one sensing range, the most noticeable improvements are for up to four different sensing range values. Between 4 and 6, the network lifetime improvement was not significant.

4.3 Node Coverage as Approximation

This section has two parts. [Section 4.3.1](#) discusses the case when each point has to be monitored by at least one sensor, and [Sect. 4.3.2](#) discusses the case when each point has to be covered by at least k sensors.

4.3.1 Simple Point Coverage

When a large and dense sensor network is randomly deployed for area monitoring, the area coverage can be approximated by the coverage of the sensor locations. That is, based on the assumption of a large and dense population of sensors, covering each sensor location approximates the coverage of each point in the given area. One method to assure coverage and connectivity is to design the set of active sensors as a connected dominating set (CDS). A distributed and localized protocol for constructing the CDS is proposed by Wu and Li, using the *marking process* in [38]. A node is a coverage node if there are two neighbors that are not connected (i.e., not within the transmission range of each other). Coverage nodes (also called gateway nodes) form a CDS. A pruning process can be used to reduce the size of coverage node set while keeping the CDS property. A generalized pruning rule called *pruning rule k* is proposed in [17]. Basically, a coverage node can be withdrawn if its neighbor set can be collectively covered by those of k coverage nodes. In addition, these k coverage nodes have higher priority and are connected. Pruning rule k ensures a constant approximation ratio. The CDS derived from the marking process with Rule k can be locally maintained, when sensors switch on/off.

Wu et al. [40] also discuss the energy-efficient dominating set coverage approach. In general, nodes in the connected dominating set consume more energy in order to handle various bypass traffic than nodes outside the set. To prolong the life span of each node and, hence, the network by balancing the energy consumption in the network, nodes should be alternated in being chosen to form a connected dominating set. A set of power-aware pruning rules is proposed, where coverage nodes are selected based on their energy levels. Simulation results in [40] show that the modified power-aware marking process outperforms several existing approaches in terms of life span of the network.

The node coverage problem can be related to the broadcasting problem, where a small set of forwarding nodes is selected [37]. Forwarding set selection in broadcasting is similar to the point coverage problem, where both try to find a small coverage set. Note that directed diffusion [21] also uses this platform to

collect information through broadcasting. As the interest is propagated through the network, sensor nodes set up reverse gradients to the sink in a decentralized way. The difference is that in the directed diffusion, all sensors forward the data. One difference between node coverage and area coverage is that neighbor set information is sufficient for node coverage, while in area coverage, geometric/directional information is needed.

4.3.2 Multiple Point Coverage

Article [42] considers that the sensor network is sufficiently dense so that covering the sensors can approximate area coverage. Thus, area coverage is reduced to the point coverage. The desired level of coverage is defined as a multiple coverage for the purpose of reliability in case of failure or for other applications related to security (e.g., localized intrusion detection) or localization (e.g. triangulation-based positioning).

The k-coverage set (k-CS) problem is defined as follows: given a constant $k > 0$ and an undirected graph $G = (V, E)$, find a subset of nodes $C \subseteq V$ such that (1) each node in V is dominated (covered) by at least k different nodes in C and (2) the number of nodes in C is minimized. The k-connected coverage set (k-CCS) problem is defined similarly, with the additional requirement (3) the nodes in C are connected.

First, a centralized IP-based approach with performance ratio ρ is proposed for the k-CS problem. Given:

- n nodes s_1, \dots, s_n
- a_{ij} , the coefficients showing the coverage relationship between nodes. These coefficients are defined as follows:

$$a_{ij} = \begin{cases} 1 & \text{if node } s_i \text{ is covered by node } s_j \\ 0 & \text{otherwise} \end{cases}$$

Variables: x_j , boolean variable, for $j = 1 \dots n$:

$$x_j = \begin{cases} 1 & \text{if node } s_j \text{ is selected in the subset } C \\ 0 & \text{otherwise} \end{cases}$$

Integer programming:

$$\text{Minimize } x_1 + x_2 + \dots + x_n$$

$$\text{subject to } \sum_{j=1}^n a_{ij} x_j \geq k \quad \text{for all } i = 1, \dots, n \quad (2)$$

$$x_j \in \{0, 1\} \quad \text{for } i = 1, \dots, n$$

The constraint $\sum_{j=1}^n a_{ij} x_j \geq k$, for all $i = 1, \dots, n$, guarantees that each node in V is covered by at least k nodes in C . Relaxation and rounding technique are used and provide an algorithm with approximation ratio ρ , where $\rho = \Delta + 1$ and Δ the maximum node degree in G . The IP is relaxed to an LP by requiring that $0 \leq x_j \leq 1$

for $j = 1, \dots, n$. As part of the rounding technique, a sensor s_j is added to the set C if its corresponding variable $x_j \geq 1/\rho$.

The second approach [42] is called the cluster-based k-CCS/k-CS algorithm:

1. Using a clustering algorithm to select clusterheads, set C_1 , and the selected clusterheads are marked and removed from the network.
2. Repeat step 1 for k times; mark and remove C_i , $i = 2, \dots, k$.
3. Use a gateway selection approach to select gateways to connect clusterheads in the first set C_1 ; denote the gateway set by D . (This step is removed for without connectivity.)
4. For each node in $C_1 \cup C_2 \cup \dots \cup C_k \cup D$ (clusterhead or gateway), if the number of its marked neighbors t is smaller than k , then it designates $k - t$ unmarked neighbors to be marked.

The clustering algorithm divides the network into several clusters; each cluster has a clusterhead and several neighbors of this clusterhead as members. Any two clusterheads are not neighbors, and the clusterhead set is a maximum independent set of the network in addition to a dominating set. Such a clustering algorithm is provided in [39]. The gateway selection can be tree-based, whereby gateways are selected globally to make the connected domination set (CDS) a tree, or mesh-based, whereby each clusterhead is connected to all of its neighboring clusterheads, and thus the CDS is a mesh structure. For coverage without connectivity, the third step, gateway selection, can be removed.

The third approach [42] is a completely localized solution, where each node determines its status (marked or unmarked) based on its 2-hop neighborhood information:

1. Each sensor node u is given a unique priority $L(u)$, and each node u is represented by tuple $(L(u), ID(u))$, where $ID(u)$ is the ID of u .
2. Each node broadcasts its neighbor set $N(u)$, where $N(u) = \{v | v \text{ is a neighbor of } u\}$.
3. At node u , build a subset: $C(u) = \{v | v \in N(u), L(v) > L(u)\}$. Node u is unmarked if
 - a. Subset $C(u)$ is connected by nodes with higher priorities than u (This constraint is removed for a solution without connectivity)
 - b. For any node $w \in N(u)$, there are k distinct nodes in $C(u)$, say v_1, v_2, \dots, v_k , such that $w \in N(v_i)$

After the algorithm terminates, all the marked nodes form the k-CCS/k-CS. Simulation results show that (i) cluster-based algorithm has better performance in terms of the size of the set C of nodes selected to be active, and (ii) cluster and localized algorithms have better scalability than the IP approach, especially when the network is relatively dense.

4.4 Connected Point Coverage

One of the important issues regards sensor connectivity which forms a network that allows the gathering of the sensed data to the sink. Article [24] addresses the adjustable sensing range connected sensor cover (ASR-CSC) problem: given a set of

targets (or monitoring points) and a set of sensors with adjustable sensing ranges in a WSN, schedule sensors' sensing ranges such that the WSN lifetime is maximized, under the conditions that both target coverage and network connectivity are satisfied, and each sensor energy consumption is upperbounded by the initial energy E .

Two localized algorithms are proposed [24] depending on the order in which connectivity and coverage are ensured. The first algorithm first ensures connectivity, then the target coverage. In the second algorithm, the order is reversed: coverage first, then connectivity.

The first algorithm starts by building a *virtual backbone* consisting of sensor nodes that will be active and participate in data forwarding. It has the property that any sensor node which is not in the backbone is one hop away from a node in the backbone. Thus, if it has to be active for the coverage task, then it can send its sensing data through the backbone. The algorithm executes in rounds, and each round has the following steps: (1) construct a virtual backbone for the WSN; (2) for each sensor in the virtual backbone, set its transmission range d_c and calculate its transmission energy consumption; (3) all sensors including inactive sensors (dominatees) together with active sensors in the virtual backbone (dominators) iteratively adjust their sensing ranges based on contribution until a full coverage is found; and (4) each sensor i active for sensing and connectivity consumes $e p(i) + g_e$ from its residual energy, while sensors active only for connectivity consume g_e .

The virtual backbone is constructed by forming a connected dominating set and pruning redundant sensors by applying the Rule k in [17]. If a sensor node meets the rule's requirement, then it is not part of the backbone in the next round; otherwise, it is part of the backbone for the next round. The coverage mechanism is the same as the one in [8], which means sensors use a waiting time based on the sensor contribution, and when this expires, they decide the coverage responsibilities.

The second algorithm starts by deciding the sensing sensors first. These sensors are connected using Rule k, where sensing nodes have the highest priority; thus, it is ensured they will be part of the backbone. The simulation study shows that the two algorithms have comparable network lifetime and that using sensors with adjustable sensing ranges has a good impact on network lifetime.

Another connected point-coverage approach is presented in [4]. Here the objective is that the sensing nodes are connected to a base station (BS) which collects sensed data, see Fig. 4. This is different from requiring that two sensor nodes be connected to each other, as discussed in the article [24].

The connected set cover (CSC) problem [4] is defined as follows: given a set of sensors s_1, s_2, \dots, s_N , a base station s_0 , and a set of targets r_1, r_2, \dots, r_M , find a family of set covers c_1, c_2, \dots, c_K such that (1) K is maximized, (2) sensors in each set c_k ($k = 1, \dots, K$) are BS-connected, (3) each sensor set monitors all targets, and (4) each sensor appearing in the sets c_1, c_2, \dots, c_K consumes at most E energy.

The first method proposed in [4] is a centralized approach using IP. The target coverage and the energy constraints have been introduced in the previous discussions. The connectivity requirement has been modeled using flows. Each edge has capacity M . Sensing nodes are the nodes in charge with monitoring the targets and they must be able to transmit data to the sink. In Fig. 4, s_1, s_3, s_5 , and s_6 are the

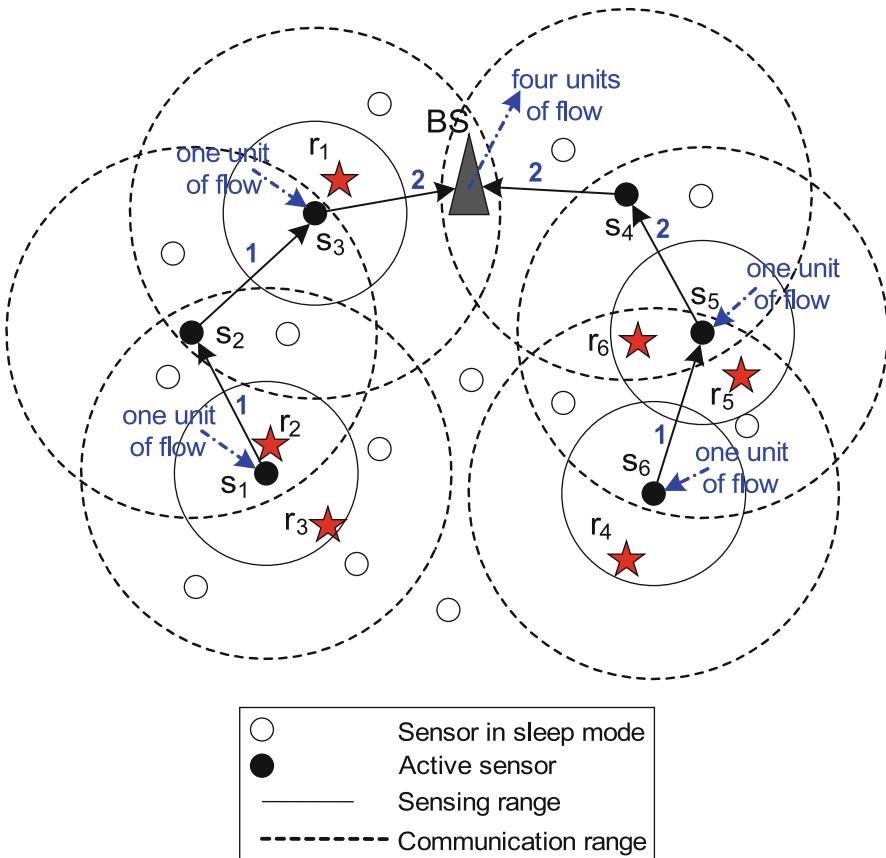

Fig. 4 Connected point coverage

sensing nodes. Some of the sensing nodes (e.g., s_1) may not be able to communicate directly with the BS, so some relay nodes must be used to ensure BS connectivity. In the IP, one unit of flow is inserted at each sensing node (which are the flow sources), and the flow is collected at the BS (which is the flow sink). In Fig. 4, one unit of flow is inserted at each of the four sensing nodes, and four units of flow are collected at the BS. Flow conservation property is also ensured for all nodes in the network.

Secondly, a centralized greedy algorithm [4] is proposed which is executed at the BS. Once the sensors are deployed, they send their coordinates to the BS. The BS computes the connected set covers and broadcasts back the sensors' schedule. The algorithm builds each set consecutively, as long as remaining sensor energy resources allow building a new set. The mechanism to build a set is as follows. At each step, a critical target is selected to be covered. This can be, for example, the target most sparsely covered, both in terms of number of sensors as well as with regard to the residual energy of those sensors. The sensors considered as candidates must have sufficient residual energy. Once the critical target has been

selected, the heuristic selects the sensor with the greatest contribution that covers the critical target. Various sensor contribution functions can be defined. For example, a sensor can be defined to have a greater contribution if it covers a larger number of uncovered targets and if it has more residual energy available. Once a sensor s has been selected, it is added to the current set cover and all additionally targets within range of s are marked as covered.

Once the sensing sensors have been determined, the BS connectivity is ensured by running the breadth-first search algorithm [15] starting from the BS. The resulting breadth-first tree is pruned: only the paths from the sensing nodes to the BS are kept. The sensors on these paths become relay nodes for the current round.

The third mechanism [4] is a localized approach, which runs in rounds. Each round starts with an initialization phase where sensors decide whether they will be in active mode (sensing or relaying) or sleep mode during the current round. First, the sensing nodes are selected. Each node with uncovered targets has a waiting time which is inverse proportional with the residual energy and the number of uncovered targets. When the timer expires, the node declares itself as a sensing node for the current round and broadcasts this decision and the set of covered targets to its 2-hop neighborhood.

In the second part, the relay nodes are selected. Each sensing node builds a virtual tree where the set of vertices is comprised of the BS and the set of targets. The tree is a minimum spanning tree built using Prim's algorithm [15], where the BS is the root. Each target t has a supervisor sensor, which is the first sensing sensor which covers it. Each supervisor selects relay nodes to allow it to connect with the supervisor of t 's parent in the virtual tree. Simulation results show that the IP algorithm finds the largest number of covers, but it has a long run time and therefore is not feasible for large scenarios. In general, the distributed algorithm performs better than the greedy approach because it employs a virtual tree-based mechanism for finding relay nodes, and this promotes the reuse of already active supervisor nodes, while the greedy one uses a breadth-first tree that results in shorter sensor-BS paths, involving more relay nodes.

4.5 Point Coverage in Heterogeneous Wireless Sensor Networks

Article [1] considers a heterogeneous WSNs that contains two types of wireless devices: resource-constrained wireless sensor nodes deployed randomly in large number and several resource-rich, predeployed supernodes, see Fig. 2b. Sensor nodes transmit and relay measurements. Once data packets encounter a supernode, they are forwarded using fast supernode to supernode communication toward the user application. Additionally, supernodes could process sensor data before forwarding.

The heterogeneous connected set covers problem is defined as follows: given a set of points (or targets) t_1, t_2, \dots, t_T , a set of supernodes g_1, g_2, \dots, g_M , and a set of randomly deployed sensors s_1, s_2, \dots, s_N , find a family of sensor set covers

c_1, c_2, \dots, c_p , such that (1) P is maximized, (2) sensors in each set cover c_p ($p = 1, \dots, P$) are connected to supernodes, (3) each sensor set monitors all targets, and (4) each sensor appearing in the sets c_1, c_2, \dots, c_p consumes at most E energy.

Network activity is organized in rounds. Each round has two phases: initialization and data collection. During the initialization phase, a set of active sensors (e.g., the set cover c_i) is established such that conditions (2), (3), and (4) are satisfied. During the data collection phase, sensors in the set cover c_i are active, while all other sensors are in the sleep mode for the rest of the round, and they will wake up for the next initialization phase.

Building a set cover c_i has two steps: (1) choosing the sensing nodes and (2) choosing the relay nodes. To select the sensing nodes, each node defines a waiting time which is smaller for sensors that have a higher residual energy and cover a larger number of uncovered targets. When a timer expires and a sensor node decides to be a sensing node, then it broadcasts this decision to its 2-hop neighborhood. Nodes that receive this message update the waiting time accordingly.

Three mechanisms are proposed to select the relay nodes: two of them use a cluster-based approach, and the third one uses a greedy mechanism. For the clustering mechanisms, supernodes serve as clusterheads. Each supernode serves as clusterhead, and it broadcasts a *CLUSTER-INIT* message containing the supernode id and the number of hops which is initially zero. Each sensor node maintains information about the closest supernode and forwards only messages from which it learns about a closer supernode. Once the clusters have been constructed, there are two algorithms for relay nodes selection: the shortest-path mechanism and the Rule k mechanism.

In the shortest-path mechanism, each sensing node broadcasts a special control message *RELAY-REQ* to the supernode of the cluster where it belongs to. The message is sent along the parent path which was set up during cluster formation. All nodes that participate in relaying the *RELAY-REQ* message become relay nodes.

In the Rule k mechanism, each cluster selects first a backbone using the Rule k algorithm [37]. Then, similar with the previous mechanism, a *RELAY-REQ* message is sent by the supernode, but this time, the message is forwarded only by the backbone nodes. Sensing nodes send back *RELAY-REQ* messages that help set up the relay nodes.

In the greedy approach, one or more connected components are formed such that the sensing nodes in each component are connected through relay nodes to a supernode. The goal is to activate a minimum number of relay nodes in order to satisfy the supernode connectivity requirement. Components are built in a greedy fashion, similar to Kruskal's algorithm [15], by successively merging two components connected by a minimum number of relay nodes. Components merge successively until each component contains one supernode. More details are presented in [1].

Simulation results show that the greedy algorithm performs better than the cluster Rule k which performs better than cluster shortest-path. Still the complexity of the greedy is higher since it operates over the whole network. Greedy gets the best

results since it minimizes the number of relay nodes added on the whole network, while the two other algorithms minimize the number of relay nodes added per cluster.

4.6 Minimum Coverage Breach Under Bandwidth Constraints

An efficient method used for data reporting is to divide sensor nodes in sets; then only one set is active in each round, while all other sensors are in sleep mode to conserve their energy resources. Consider the case when the BS is within direct communication of all sensors. If each active sensor sends the sensed data to the BS, this requires that there must be sufficient bandwidths for this activity. The bandwidth could be the total number of time slots if a time division scheme is used on a single shared channel or the total number of channels if multiple channels are available.

The issue occurs when there are W channels available and a subset has more than W sensors. Then some sensors cannot have channel access for data transmission. To properly allocate time slots or channels to sensors, the scheduling techniques must select sensors in each set such that they satisfy the coverage requirement while being fully restricted by the bandwidth constraints. If a target (or monitor region) is not covered by any active sensor, it is called *breached*. The objective is to minimize the total breach of all targets.

The minimum breach problem has been introduced in [13]: given a set A of fixed points, and a set S of sensor nodes, organize sensor nodes into disjoint subsets $C_i = \{s_{i_1}, s_{i_2}, \dots\}$, $i = 1, \dots, K$, where each subset $|C_i| \leq W$ and the overall breach is minimized. Article [13] shows that the decision version of the minimum breach problem is NP-complete. Then two solutions are proposed using IP and LP approaches. Simulation results show that to improve the coverage performance in WSNs, the bandwidth also needs to be increased; in bandwidth constrained networks, increasing the number of sensors alone does not always improve the coverage results.

5 Conclusion

This chapter categorizes and describes recent area and point coverage problems proposed in literature, their formulations, assumptions, and proposed solution. Sensor coverage is an important element of QoS in applications with WSNs. Coverage is, in general, associated with energyefficiency and network connectivity, two important properties of a WSNs. To accommodate a large WSN with limited resources and a dynamic topology, coverage control algorithms and protocols perform best if they are distributed and localized. Various interesting formulations for sensor coverage have been proposed in literature. Scheduling sensor nodes to alternate between sleep and active mode is an important method to conserve energy resources. Such mechanisms that efficiently organize or schedule the sensor activity after deployment are very efficient and have a direct impact on prolonging the

network lifetime. Sensor coverage with various design choices, such as breach coverage, composite event coverage, heterogeneous WSNs, and so on, poses interesting research problems. The literature on coverage problems is more vast than the papers surveyed here, and the readers are invited to explore them in the research literature.

Abstract

A data-correcting (DC) algorithm is a branch-and-bound-type algorithm, in which the data of a given problem is “heuristically corrected” at the various stages in such a way that the new instance will be polynomially solvable and its optimal solution is within a prespecified deviation (called prescribed accuracy) from the optimal solution to the original problem. The DC approach is applied to determining exact and approximate global optima of NP-hard problems. DC algorithms are designed for various classes of NP-hard problems including the quadratic cost partition (QCP), simple plant location (SPL), and traveling salesman problems based on the algorithmically defined polynomially solvable special cases. Results of computational experiments on the publicly available benchmark instances as well as on random instances are presented. The striking computational result is the ability of DC algorithms to find exact solutions for many relatively difficult instances within fractions of a second. For example, an exact global optimum of the QCP problem with 80 vertices and 100 % density was found within 0.22 s on a PC with 133-Mhz processor, and for the SPL problem with 200 sites and 200 clients, within 0.2 s on a PC with 733-Mhz processor.

1 Introduction

Let us consider the following combinatorial minimization problem (CMP) (E, C, D, f_C) which is the problem of finding

$$S^* \in \arg \min\{f_C(S) \mid S \in D\},$$

where $C : E \rightarrow \Re$ is the given *instance* of the problem with a *ground set* E satisfying $|E| = m$ ($m \geq 1$), $D \subseteq 2^E$ is the *set of feasible solutions*, and $f_C : 2^E \rightarrow \Re$ is the *objective function* of the problem. By $D^* = \arg \min\{f_C(S) \mid S \in D\}$, the set of optimal solutions is denoted. It is assumed that $D^* \neq \emptyset$ and that $S \neq \emptyset$ for some $S \in D$.

Classic examples of routing and location problems include, among others, the following:

- (A) The asymmetric traveling salesman problem (ATSP) [29]: it is given $n \geq 3$ cities and distances $C = ||c(i, j)||$ between i -th and j -th cities, find a Hamiltonian cycle of minimum length, which enters and leaves each city exactly once. Here in the CMP (E, C, D, f_C) , $E = A$ is the set of arcs in a directed weighted simple graph $G = (V, A, C)$ with the set of vertices $V = \{1, 2, \dots, n\}$, and $A \subset V \times V$ is the set of arcs $(i, j) \in A$ with nonnegative weights (distances) $c(i, j)$ connecting vertices i and j ; D is the set of all Hamiltonian cycles, and the objective function of ATSP f_C is given by $f_C(S) = \sum_{(i,j) \in S} c(i, j)$ for $S \in D$.

- (B) The assignment problem (AP): it is given a directed graph $G = (V, A, C)$ as above and a nonnegative cost function C on $E = A$, find a vertex permutation $\pi_a^* : V \rightarrow V$ such that $\sum_{i=1}^n c(i, \pi_a(i))$ is minimized on the set of all possible permutations of V . An optimal solution to the AP is denoted by π_a^* and its optimal value $f_C(\pi_a^*)$. Note that a set $S \subset A$ is a feasible solution of the AP if it is of the form $S = \{(1, \pi(1)), (2, \pi(2)), \dots, (n, \pi(n))\}$ for some permutation π of V . Clearly, a Hamiltonian cycle corresponds to the cyclic permutation π_c of V and vice versa.
- (C) The simple plant location problem (SPLP): it is given a weighted bipartite graph $G = (V, A, C, F)$ with the set of vertices $V = I \cup J$, such that $I = \{1, \dots, m\}$ is the set of sites in which plants can be located and $J = \{1, \dots, n\}$ is the set of clients, each having a unit demand. Thus, $A \subseteq I \times J$ is the set of arcs, $F = (f_i)$ are fixed costs for setting up plants at sites $i \in I$, and $C = ||c(i, j)||$ is a matrix of transportation costs from $i \in I$ to $j \in J$ as input. The SPLP computes a set $S^* : \emptyset \subset S^* \subseteq I$, at which plants can be located so that the total costs of satisfying all client demands are minimal. The costs involved in meeting the client demands include the fixed costs of setting up plants and the transportation costs of supplying clients from the plants that are set up. An instance of the problem is described by an m -vector $F = (f_i)$ and an $m \times n$ matrix $C = ||c(i, j)||$. It is assumed that F and C are nonnegative, that is, $F \in \Re_+^m$ and $C \in \Re_+^{mn}$. The $m \times (n + 1)$ augmented matrix $[F|C]$ will be used as a shorthand for describing an instance of the SPLP. The total cost $f_{[F|C]}(S)$ associated with a solution S consists of two components, the fixed costs $\sum_{i \in S} f_i$ and the transportation costs $\sum_{j \in J} \min\{c(i, j) : i \in S\}$, that is,

$$f_{[F|C]}(S) = \sum_{i \in S} f_i + \sum_{j \in J} \min\{c(i, j) : i \in S\},$$

and the SPLP is the problem of finding

$$S^* \in \arg \min\{f_{[F|C]}(S) : \emptyset \subset S \subseteq I\}. \quad (1)$$

- (D) The p-median problem (PMP): the PMP is defined on a weighted bipartite graph $G = (V, A, C)$ and related to the SPLP as follows. Given a set I of m potential facilities, a set J of n clients (or customers), a distance function $c : I \times J \rightarrow \Re_+$, and a constant $p \leq m$, determine which p facilities to open so as to minimize the sum of the distances from each client to its closest open facility. The PMP and SPLP differ in the following details. First, the SPLP involves a fixed cost for locating a facility at a given location, while the PMP does not. Second, unlike the PMP, SPLP does not have a constraint p on the maximum number of facilities. Typical SPLP formulations separate the set of candidate sites from the set of clients. In the PMP, these sets are identical, that is, $I = J$. The objective function f_C is given by $f_C(S) = \sum_{j \in J} \min\{c(i, j) : i \in S\}$, and the PMP is the problem of finding

$$S^* \in \arg \min \{f_C(S) : \emptyset \subset S \subseteq I, |S| = p\}. \quad (2)$$

The adopted approach is to develop what is termed the data-correcting algorithm (DCA), which forms a class of algorithms, introduced in Goldengorin [33, 37] for the solution of NP-hard problems. Crucial in these algorithms is the fact that the data of a given problem instance (E, C, D, f_C) is corrected to obtain a new problem instance (E, H, D, f_H) belonging to a polynomially solvable class of instances \mathcal{P} . A polynomially solvable class of instances that is used in DCA might be determined either algorithmically or analytically [29].

For example, let us consider the DC algorithm applied to the traveling salesman problem (TSP) with the following algorithmically defined polynomially solvable class. A nonnegative square $n \times n$ -matrix $H = ||h(i, j)||$ is called a *Hungarian matrix* (see [44]) if the Hungarian algorithm (see, e.g., [64]) with input algorithm (see, e.g., [64]) and with input H results in an optimal Hamiltonian cycle: notation $H \in \mathcal{P} = \mathcal{H}$. If a nonnegative square $n \times n$ -matrix $C = ||c(i, j)||$ is not Hungarian, then by correcting some entries of C , a Hungarian matrix H that is as close as possible to C will be tried to be found for some *proximity measure*

$$\rho(C, H) = \min\{\mu(C, H), \nu(C, H)\} \quad (3)$$

of C and H , with $\mu(C, H) = \sum_{i=1}^n \max\{|c(i, j) - h(i, j)| : j = 1, \dots, n\}$ and $\nu(C, H) = \sum_{j=1}^n \max\{|c(i, j) - h(i, j)| : i = 1, \dots, n\}$.

The proximity measure $\rho(C, H)$ is used in the framework of the DCA for finding, by means of a heuristic procedure, an instance H that is as close as possible to C . Usually, this heuristic can be easily constructed by a simple modification of a polynomial algorithm by which a polynomially solvable class is defined. In case of the Hungarian algorithm, the so-called Hungarian matrix is obtained by patching the subcycles [51].

In the following theorem, which is first published in Goldengorin [37], it is formulated that the proximity measure is an upper bound for the difference of the lengths of shortest Hamiltonian cycles of C and H , denoted by $f_C(\pi_C^*)$ and $f_H(\pi_H^*)$, respectively, with the corresponding optimal permutations π_C^* and π_H^* .

Theorem 1 *Let $C, H \in R^{n \times n}$. Then the following holds: $|f_C(\pi_C^*) - f_H(\pi_H^*)| \leq \rho(C, H)$.*

Proof This proof is split into two cases:

Case 1. $f_C(\pi_C^*) \geq f_H(\pi_H^*)$ and Case 2. $f_C(\pi_C^*) < f_H(\pi_H^*)$.

Theorem 1 will be proved because the proof of Case 2 might be done in similar lines as follows: $0 \leq f_C(\pi_C^*) - f_H(\pi_H^*) = |f_C(\pi_C^*) - f_H(\pi_H^*)| \leq f_C(\pi_C^*) - f_H(\pi_H^*) = \sum_{(i,j) \in \pi_H^*} c(i, j) - \sum_{(i,j) \in \pi_H^*} h(i, j) = \sum_{(i,j) \in \pi_H^*} [c(i, j) - h(i, j)] \leq \sum_{(i,j) \in \pi_H^*} |c(i, j) - h(i, j)| = A$. Note that $A \leq \sum_{i=1}^n \max\{|c(i, j) - h(i, j)| : j = 1, \dots, n\} = \rho(C, H)$.

$j = 1, \dots, n\} = \mu(C, H)$ and $A \leq \sum_{j=1}^n \max\{|c(i, j) - h(i, j)| : i = 1, \dots, n\} = v(C, H)$, and hence, $A \leq \min\{\mu(C, H), v(C, H)\} = \rho(C, H)$. \square

If $\rho(C, H)$ is smaller than a prescribed accuracy ε_0 , then the ATSP solution with respect to H is also an ε_0 solution with respect to C . Otherwise, the DCA decreases the current value of $\rho(C, H)$ by means of a binary branching procedure which cancels the largest contribution $0 < |c(i, j) - h(i, j)|$ to $\rho(C, H)$ by an inclusion of the arc (i, j) in all Hamiltonian cycles with $h(i, j) = c(i, j)$ and an exclusion of the arc (i, j) from all Hamiltonian cycles with $h(i, j) = \infty$. In other words, the DCA gives an answer to the most challenging question for any branch-and-bound algorithm: by means of which element (arc in case of the ATSP) one should branch such that to arrive to a feasible solution with the prescribed accuracy within the minimum number of branchings. Moreover, [Theorem 1](#) provides virtual lower lb and upper ub bounds to the unknown optimal value $f_C(\pi_C^*)$ as follows.

Corollary 1 *Let $C, H \in R^{n \times n}$. Then the following holds: $lb = f_H(\pi_H^*) - \rho(C, H) \leq f_C(\pi_C^*) \leq f_H(\pi_H^*) + \rho(C, H) = ub$.*

Another example can be described as follows. Let Φ be a function defined on a set D , and let Ψ belong to a polynomially solvable class of functions which is a subclass of a given class of functions Φ defined also on D , and let $\rho(\Phi, \Psi) = \max\{|\Phi(S) - \Psi(S)| : S \in D\}$ be the proximity measure. If the optimal values of $\Phi(S)$ and $\Psi(S)$ are denoted on D by $\Phi^*(D)$ and $\Psi^*(D)$, respectively, then an analogue of the above-mentioned inequality is read as follows.

Theorem 2 *Let Φ and Ψ be functions on the set D with optimal values $\Phi^*(D)$ and $\Psi^*(D)$. Then the following holds: $|\Phi^*(D) - \Psi^*(D)| \leq \rho(\Phi, \Psi)$.*

Again, if $\rho(\Phi, \Psi)$ is smaller than a prescribed accuracy ε_0 , then the problem of finding $\Phi^*(D)$ with the given prescribed accuracy ε_0 is solved by $\Psi^*(D)$. More information about DC algorithms (general scheme, comparison with branch-and-bound-type algorithms, steps of construction, methods, etc.) can be found in Goldengorin [33, 37].

This chapter describes a step in the direction of incorporating polynomially solvable special cases into approximation algorithms. *Data-correcting algorithms* are reviewed – approximation algorithms that make use of polynomially solvable special cases to arrive at high-quality solutions. The basic insight that leads to these algorithms is the fact that it is often easy to compute a bound on the difference between the costs of optimal solutions to two instances of a problem, even though it may be hard to compute optimal solutions for the two instances. These algorithms were first reported in the Russian literature (see [32–36]) and later on in the Western literature (see, e.g., [27, 28, 38, 40–42, 44, 46]).

The approximation in data-correcting algorithms is determined in terms of an *accuracy parameter*, which is an upper bound on the difference between the

objective value of an optimal solution to the instance and that of a solution returned by the data-correcting algorithm. Note that this is *not* expressed as a fraction of the optimal objective value for this instance as in common ε -optimal algorithms but as actual deviations from the cost of optimal solutions.

Although it is suggested to use the data-correcting algorithms to solve NP-hard routing and location problems, they form a general problem-solving tool and can be used for functions defined on a continuous domain with a finite range as well (see [27, 28, 38]).

The next four sections contain a description of actual implementation of data-correcting algorithms to four problems: the asymmetric traveling salesman problem, simple plant location problem, p-median problem, and maximization of a general submodular function. It means that the problem examples cover the most widely used models in routing and location problems, namely, problems defined either on a subset of permutations (see, e.g., [30]) or on a subset of all sets of the finite (ground) set (see, e.g., [22]). This chapter is an essentially revised chapter of Ghosh et al. [27] which is concentrated on data-correcting algorithms to solve routing [30] and location problems.

2 The Asymmetric Traveling Salesman Problem

In an asymmetric traveling salesman problem (ATSP) instance there are given a weighted digraph $G = (V, A, C)$ and a $|V| \times |V|$ distance matrix $C = ||c(i, j)||$, and the objective is to output a least cost Hamiltonian cycle in this graph. This is one of the most studied problems in combinatorial optimization (see Lawler et al. [58] and Gutin and Punnen [47] for a detailed introduction).

2.1 The Data-Correcting Algorithm

[Theorem 1](#) presents the idea of data-correcting algorithm (DCA) for solving the ATSP instances.

Before presenting a pseudocode for the DCA, let us illustrate the data-correcting step for the ATSP with an example. Consider the six-city ATSP instance with the distance matrix $C = ||c(i, j)||$ shown below.

C	1	2	3	4	5	6
1	-	10	16	19	25	22
2	19	-	10	13	13	10
3	10	28	-	22	16	13
4	19	25	13	-	10	19
5	16	22	19	13	-	11
6	13	22	15	13	10	-

If subtours in solutions to the ATSP are allowed, the assignment problem relaxation is obtained. Solving the assignment problem on C , using the Hungarian method, the following reduced distance matrix $C^H = [c^H(i, j)]$ is got.

C^H	1	2	3	4	5	6
1	-	0	6	7	16	12
2	9	-	0	1	4	0
3	0	18	-	10	7	3
4	8	14	2	-	0	8
5	5	11	8	0	-	0
6	2	11	4	0	0	-

This leads to a solution with two cycles (1231) and (4564) (corresponding to π_H^*). Using patching techniques (see, e.g., [58]), a feasible ATSP solution (1245631) is obtained. Notice that (1245631) would be an optimal solution to the assignment problem if $c^H(2, 4)$ and $c^H(6, 3)$ had been set to zero in C^H , and that would have been the situation if $c(2, 4)$ and $c(6, 3)$ were initially reduced by 4 and 1, respectively, that is, if the distance matrix in the original ATSP instance was a Hungarian matrix H defined below.

H	1	2	3	4	5	6
1	-	10	16	19	25	22
2	19	-	10	9	13	10
3	10	28	-	22	16	13
4	19	25	13	-	10	19
5	16	22	19	13	-	11
6	13	22	14	13	10	-

Therefore, H is the distance matrix of the correction of the instance with distance matrix C . The proximity measure $\rho(C, H) = \sum_{i=1}^6 \sum_{j=1}^6 |c(i, j) - h(i, j)| = |c(2, 4) - h(2, 4)| + |c(6, 3) - h(6, 3)| = 4 + 1 = 5$.

A proximity measure (3) is an upper bound to the difference between the costs of two solutions for a problem instance, so the stronger the bound, the better would be the performance of any enumeration algorithm dependent on such bounds.

The pseudocode for a recursive version of the DCA for the ATSP is given below.

Note that a good lower bound can be incorporated into DCA-ATSP to make it more efficient.

Algorithm DCA-ATSP(G, ε)

Output: A tour π_C^* such that the difference between the cost of π_C^* and the cost of an optimal tour π_C^* is not more than ε

Code:

```

1. begin
2.    $\pi_C :=$  an arbitrary tour in  $G$ ;
3.    $lb :=$  a lower bound on the cost of an optimal tour;
4.   if  $f_C(\pi_C) = lb$  return  $\pi_C$ ;
5.    $\pi_a^* :=$  an optimal solution to the assignment problem on  $G$ ;
6.   construct a solution  $\pi_p$  from  $\pi_a^*$  through patching;
7.   using  $\pi_a^*$ , compute the proximity measure  $\rho$ ;
8.   if  $\rho \leq \alpha$ 
9.     return  $\pi_C$ ;
10.    else begin
11.      branch according to a pre-decided branching rule;
12.      for each subproblem  $i$  generated
13.         $\pi_C(i) :=$  the solution output by DCA-ATSP on subproblem  $i$ ;
14.      return the best solution from among all  $\pi_C(i)$ 's;
15.    end;
16. end.

```

(* Branch *)

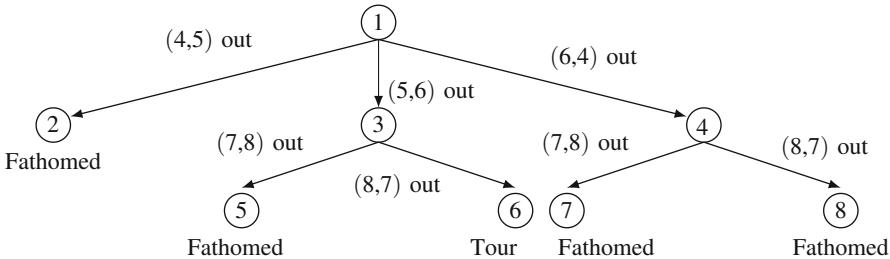

Next, the DCA-ATSP algorithm above will be illustrated on an instance of the ATSP. Consider the eight-city ATSP instance with the distance matrix $D = [d(ij)]$ shown below (this example was taken from Balas and Toth [5], p. 381).

D	1	2	3	4	5	6	7	8
1	-	2	11	10	8	7	6	5
2	6	-	1	8	8	4	6	7
3	5	12	-	11	8	12	3	11
4	11	9	10	-	1	9	8	10
5	11	11	9	4	-	2	10	9
6	12	8	5	2	11	-	11	9
7	10	11	12	10	9	12	-	3
8	7	10	10	10	6	3	1	-

The following are used:

- The proximity measure ρ , see (3), for data correction
- The assignment algorithm to compute lower bounds for subproblems
- A patching algorithm to create feasible solutions and compute proximity measures
- The patched solution derived from the assignment solution as a feasible solution

The branching rule used in this example is as follows. At each subproblem, the assignment problem solution is constructed and then patched. Also, the original matrix is corrected to a new matrix that would output the patched solution if the assignment problem is solved on it. Next, the arc corresponding to the entry in the new matrix that had to be corrected by the maximum amount is identified. The tail

Subproblem at node	Upper bound	Lower bound	Assignment solution	Patched tour	Cost of patching	Revised bound
1	∞	17	(1231)(4564)(787)	(123786451)	9	26
2	26	29		Fathomed by bounds	–	26
3	26	25	(12631)(454)(787)	(126453781)	6	26
4	26	25	(12631)(454)(787)	(126453781)	6	26
5	26	31		Fathomed by bounds	–	26
6	26	26	(123786451)	Patching not required	26	26
7	26	31		Fathomed by bounds	–	26
8	26	27		Fathomed by bounds	–	26

Fig. 1 Branch-and-bound tree for the instance in the example

of this arc is identified, and it should be branched on all the arcs in the subtour containing that vertex. For example, in this problem, the assignment solution is (1231)(4564)(787), which is patched to (123786451), and the cost of patching is 9. If the problem data is corrected, it will be seen that the entry $d(5, 1)$ (corresponding to arc (5, 1)) contributes the maximum amount (7) to the patching. Hence, it should be branched on each arc in the cycle (4564), and three subproblems should be constructed, the first with the additional constraint that arc (4, 5) be excluded from the solution, the second with the additional constraint that arc (5, 6) be excluded from the solution, and the third with the additional constraint that arc (4, 5) be excluded from the solution.

The polynomially solvable special case under consideration is the set of all ATSP instances for which the assignment procedure gives rise to a cyclic permutation.

Using the branching rule described above, depth-first branch and bound generates the enumeration tree of Fig. 1. The nodes are labeled according to the order in which the problems at the corresponding nodes were evaluated.

Since the cost of patching equals the value of ρ , the performance of data correcting on this example can now be evaluated. If the allowable accuracy parameter α is set to 0, then the enumeration tree constructed by DC will be the one shown in Fig. 1, and it will evaluate eight subproblems. However, if the value of α is set to 1, then enumeration stops after node 4, since the lower bound obtained is 25 which is one less than the solution at hand.

The previous example shows that the data-correcting algorithm can be a very attractive alternative to branch-and-bound algorithms. In the next subsection,

experiences of the performance of the data-correcting algorithm on ATSP instances from the TSPLIB [73] are presented [68].

2.2 Computational Experience with ATSP Instances

TSPLIB has 27 ATSP instances, out of which for the experiments 12 have been chosen. These 12 can be solved to optimality within 5 h using an ordinary branch-and-bound algorithm. Eight of these belong to the “*ftv*” class of instances, while four belong to the “*rbg*” class. DCA-ATSP in C was implemented on an Intel Pentium-based computer running at 666 MHz with 128-MB RAM.

The results of the experiments are presented graphically in Figs. 2 through 5. In computing accuracies (Figs. 2 and 4), the accuracy and deviation of the solution output by the data-correcting algorithm from the optimal (called “achieved accuracy” in the figures) have been plotted as a fraction of the cost of an optimal solution to the instance. It was observed that for each of the 12 instances studied, the achieved accuracy is consistently less than 80 % of the prespecified accuracy.

There was a wide variation in the CPU time required to solve the different instances. For example, *ftv70* required 17,206 s to solve it to optimality, while *rbg323* required just 5 s. Thus, in order to maintain uniformity while demonstrating the variation in execution times with respect to changes in α values, the execution

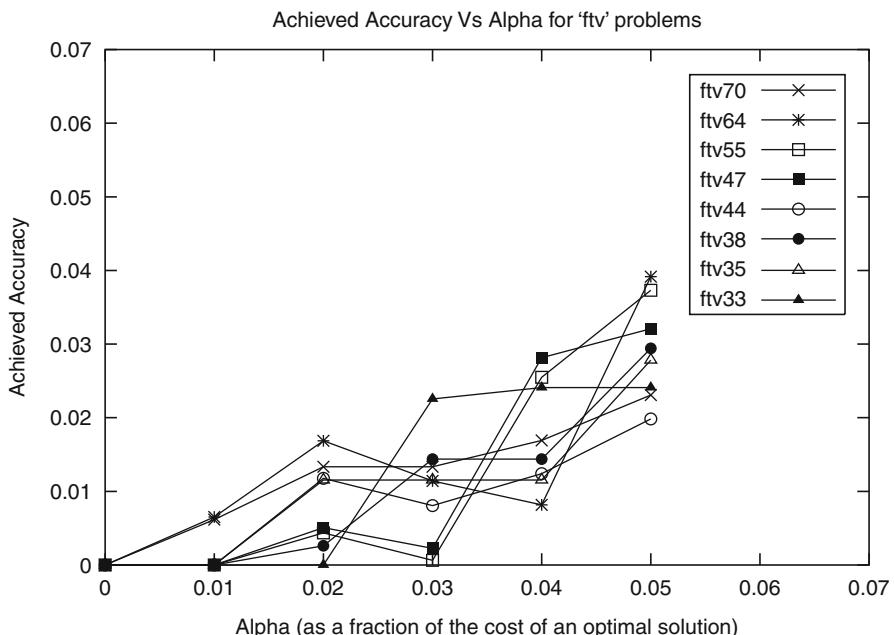

Fig. 2 Accuracy achieved versus α for *ftv* instances

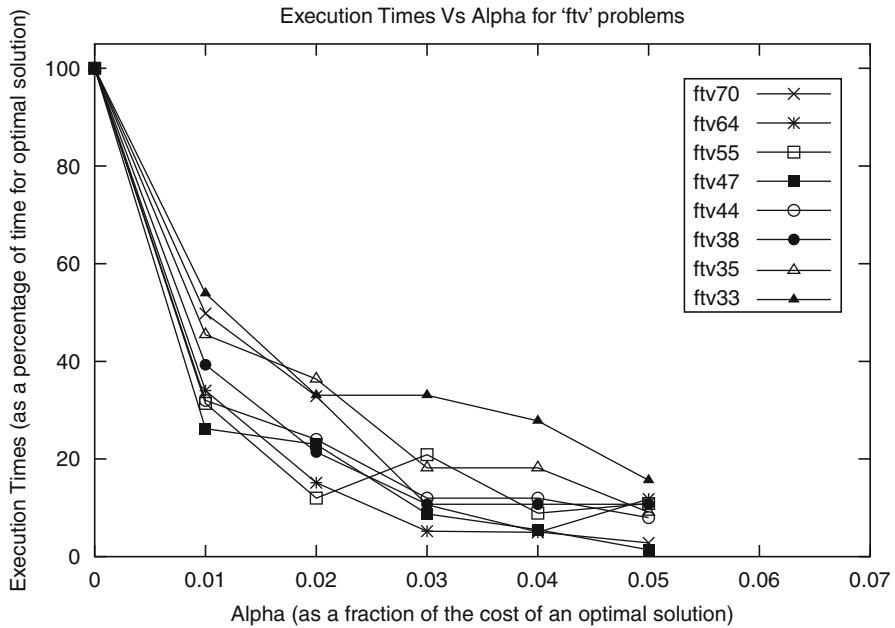

Fig. 3 Variation of execution times versus α for *ftv* instances

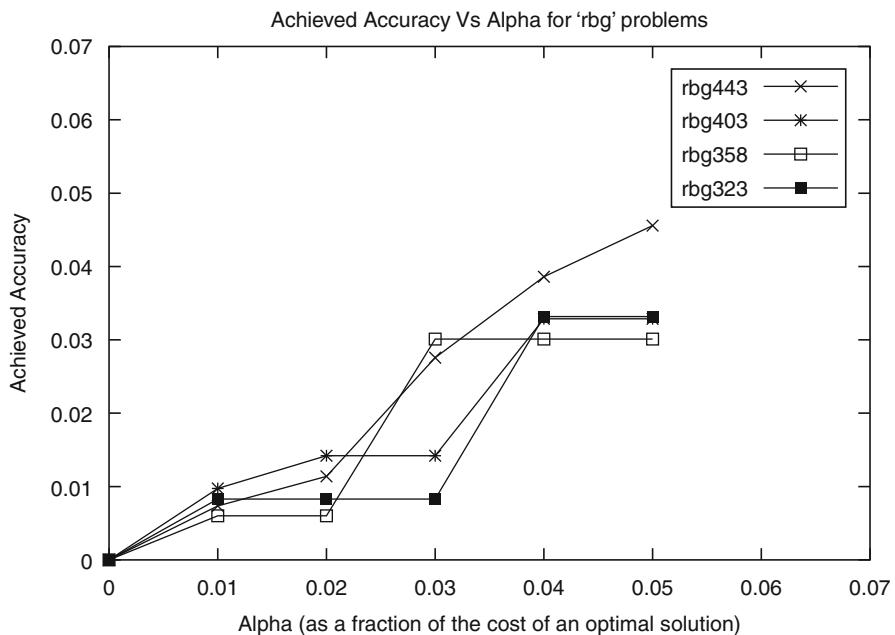

Fig. 4 Accuracy achieved versus α for *rbg* instances

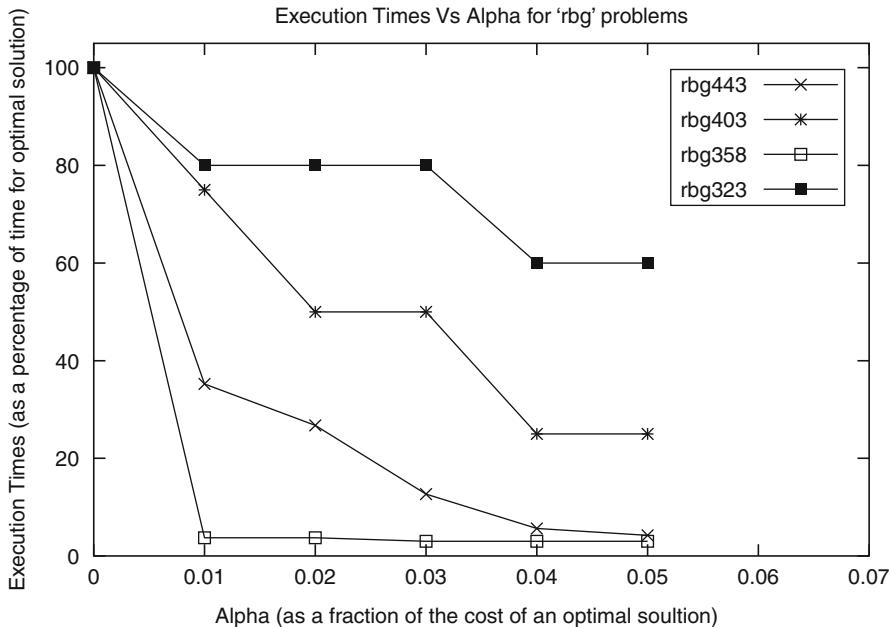

Fig. 5 Variation of execution times versus α for rbg instances

times for each instance for each α value were represented as a percentage of the execution time required to solve that instance to optimality. Notice that for all the f_{tv} instances when α was 5 % of the cost of the optimal solution, the execution time was reduced to 20 % of that required to solve the respective instance to optimality. The reduction in execution times for rbg instance was equally steep, with the exception of $rbg323$ which was in any case an easy instance to solve.

In summary, it is quite clear that data correcting is an effective methodology for solving ATSP instances. There are usually steep reductions in execution times even when the allowed accuracy is very small. This makes the method very useful for solving real-world problems where a near-optimal solution is often acceptable provided the execution times are not too long.

3 The Simple Plant Location Problem

The simple plant location problem (SPLP) takes a set $I = \{1, 2, \dots, m\}$ of sites in which plants can be located; a set $J = \{1, 2, \dots, n\}$ of clients, each having a unit demand; a vector $F = (f_i)$ of fixed costs for setting up plants at sites $i \in I$; and a matrix $C = [c_{ij}]$ of transportation costs from $i \in I$ to $j \in J$ as input. It computes a set $S^*, \emptyset \subset S^* \subseteq I$, at which plants can be located so that the total cost of satisfying all client demands is minimal. The costs involved in meeting the

client demands include the fixed costs of setting up plants and the transportation cost of supplying clients from the plants that are set up. A detailed introduction to this problem has appeared in Cornuejols et al. [21], which also classifies the problem as NP-hard.

In applying data correcting to the SPLP, a pseudo-Boolean formulation of the problem is taken. It is shown how data correcting can be used to preprocess SPLP instances efficiently and then to solve the problem.

3.1 A Pseudo-Boolean Formulation of the SPLP

The pseudo-Boolean approach to solving the SPLP [11, 50] is a penalty-based approach that relies on the fact that any instance of the SPLP has an optimal solution in which each client is supplied by exactly one plant. This implies that in an optimal solution, each client will be served fully by the plant located closest to it. Therefore, it is sufficient to determine the sites where plants are to be located and then use a minimum cost assignment of clients to plants.

An instance of the SPLP can be described by an m -vector $F = (f_i)$ and an $m \times n$ matrix $C = [c_{ij}]$: $m, n \geq 1$. The $m \times (n + 1)$ *augmented matrix* $[F|C]$ will be used as a shorthand for describing an instance of the SPLP. The total cost $f_{[F|C]}(S)$ associated with a subset S of I consists of two components, namely, the fixed costs $\sum_{i \in S} f_i$ and the transportation costs $\sum_{j \in J} \min\{c_{ij} | i \in S\}$; that is,

$$f_{[F|C]}(S) = \sum_{i \in S} f_i + \sum_{j \in J} \min\{c_{ij} | i \in S\},$$

and the SPLP is the problem of finding

$$S^* \in \arg \min\{f_{[F|C]}(S) | \emptyset \subset S \subseteq I\}. \quad (4)$$

In the remainder of this subsection, there will be described the pseudo-Boolean formulation of the SPLP due to Beresnev [11] and Hammer [50].

An $m \times n$ *ordering matrix* $\Pi = [\pi_{ij}]$ is a matrix each of whose columns $\Pi_j = (\pi_{1j}, \dots, \pi_{mj})^T$ defines a permutation of $1, \dots, m$. Given a transportation matrix C , the set of all ordering matrices Π such that $c[\pi_{1j}, j] \leq c[\pi_{2j}, j] \leq \dots \leq c[\pi_{mj}, j]$ for $j = 1, \dots, n$ is denoted by $\text{perm}(C)$.

Defining for each $i = 1, \dots, m$

$$y_i = \begin{cases} 0 & \text{if } i \in S \\ 1 & \text{otherwise,} \end{cases} \quad (5)$$

any solution P can be indicated by a vector $y = (y_1, y_2, \dots, y_m)$. The fixed cost component of the total cost can be written as

$$F_F(y) = \sum_{i=1}^m f_i(1 - y_i). \quad (6)$$

Corresponding to an ordering matrix $\Pi \in perm(C)$, an $m \times n$ difference matrix $\Delta = ||\Delta c(i, j)||$ can be constructed for each $j \in J$ as

$$\Delta c[0, j] = c[\pi_{1j}, j] \quad \text{and}$$

$$\Delta c[l, j] = c[\pi_{(l+1)j}, j] - c[\pi_{lj}, j], \quad l = 1, \dots, m-1. \quad (7)$$

Note that $\Delta c[l, j] \geq 0$, even if the transportation cost matrix C contains negative entries. The transportation costs of supplying any client $j \in J$ from any open plant can be expressed in terms of the $\Delta c[\cdot, j]$ values. It is clear that it is necessary to spend at least $\Delta c[0, j]$ in order to satisfy j 's demand, since this is the cheapest cost of satisfying j . If no plant is located at the site closest to j , that is, $y_{\pi_{1j}} = 1$, the demand is tried to be satisfied from the next closest site. In that case, an additional $\Delta c[1, j]$ is spent. Continuing in this manner, the transportation cost of supplying $j \in J$ is

$$\begin{aligned} \min\{c_{ij} | i \in S\} &= \Delta c[0, j] + \Delta c[1, j] \cdot y_{\pi_{1j}} + \Delta c[2, j] \cdot y_{\pi_{1j}} \cdot y_{\pi_{2j}} \\ &\quad + \cdots + \Delta c[m-1, j] \cdot y_{\pi_{1j}} \cdots y_{\pi_{(m-1)j}} \\ &= \Delta c[0, j] + \sum_{k=1}^{m-1} \Delta c[k, j] \cdot \prod_{r=1}^k y_{\pi_{rj}}, \end{aligned}$$

so that the transportation cost component of the cost of a solution y corresponding to an ordering matrix $\Pi \in perm(C)$ is

$$T_{C,\Pi}(y) = \sum_{j=1}^n \left\{ \Delta c[0, j] + \sum_{k=1}^{m-1} \Delta c[k, j] \cdot \prod_{r=1}^k y_{\pi_{rj}} \right\}. \quad (8)$$

Combining (6) and (8), the total cost of a solution y to the instance $[F|C]$ corresponding to an ordering matrix $\Pi \in perm(C)$ is given by the pseudo-Boolean polynomial

$$\begin{aligned} f_{[F|C],\Pi}(y) &= F_F(y) + T_{C,\Pi}(y) \\ &= \sum_{i=1}^m f_i(1 - y_i) \\ &\quad + \sum_{j=1}^n \left\{ \Delta c[0, j] + \sum_{k=1}^{m-1} \Delta c[k, j] \cdot \prod_{r=1}^k y_{\pi_{rj}} \right\}. \end{aligned} \quad (9)$$

It can be shown (see [1]) that the total cost function $f_{[F|C],\Pi}(\cdot)$ is identical for all $\Pi \in \text{perm}(C)$. This pseudo-Boolean polynomial is called the *Hammer-Beresnev function* $H_{[F|C]}(y)$ corresponding to the SPLP instance $[F|C]$ and $\Pi \in \text{perm}(C)$. In other words

$$H_{[F|C]}(y) = f_{[F|C],\Pi}(y) \text{ where } \Pi \in \text{perm}(C). \quad (10)$$

The SPLP (4) can be formulated in terms of Hammer-Beresnev functions as

$$y^* \in \arg \min \{H_{[F|C]}(y) | y \in \{0, 1\}^m, y \neq \bar{1}\}. \quad (11)$$

As an example, consider the SPLP instance:

$$[F|C] = \left[\begin{array}{c|ccccc} 9 & 7 & 12 & 22 & 13 \\ 4 & 8 & 9 & 18 & 17 \\ 3 & 16 & 17 & 10 & 27 \\ 6 & 9 & 13 & 10 & 11 \end{array} \right]. \quad (12)$$

Two possible ordering matrices corresponding to C are

$$\Pi_1 = \left[\begin{array}{cccc} 1 & 2 & 3 & 4 \\ 2 & 1 & 4 & 1 \\ 4 & 4 & 2 & 2 \\ 3 & 3 & 1 & 3 \end{array} \right] \text{ and } \Pi_2 = \left[\begin{array}{cccc} 1 & 2 & 4 & 4 \\ 2 & 1 & 3 & 1 \\ 4 & 4 & 2 & 2 \\ 3 & 3 & 1 & 3 \end{array} \right], \quad (13)$$

and the difference matrix is

$$\Delta = \left[\begin{array}{cccc} 7 & 3 & 10 & 11 \\ 1 & 3 & 0 & 2 \\ 1 & 1 & 8 & 4 \\ 7 & 4 & 4 & 10 \end{array} \right]. \quad (14)$$

The Hammer-Beresnev function is $H_{[F|C]}(y) = \{9(1 - y_1) + 4(1 - y_2) + 3(1 - y_3) + 6(1 - y_4)\} + \{7 + 1y_1 + 1y_1y_2 + 7y_1y_2y_4\} + \{9 + 3y_2 + 1y_1y_2 + 4y_1y_2y_4\} + \{10 + 0y_3 + 8y_3y_4 + 4y_2y_3y_4\} + \{11 + 2y_4 + 4y_1y_4 + 10y_1y_2y_4\} = 59 - 8y_1 - y_2 - 3y_3 - 4y_4 + 2y_1y_2 + 4y_1y_4 + 8y_3y_4 + 21y_1y_2y_4 + 4y_2y_3y_4$.

3.2 Preprocessing SPLP Instances

The first preprocessing rules for the SPLP involving both fixed costs and transportation costs appeared in Khumawala [54]. In terms of Hammer-Beresnev

functions, these rules are stated in the following theorem. It is assumed (without loss of generality) that I cannot be partitioned into sets I_1 and I_2 , and J into sets J_1 and J_2 , such that the transportation costs from sites in I_1 to clients in J_2 and from sites in I_2 to clients in J_1 are not finite. It is assumed too that the site indices are arranged in nonincreasing order of $f_i + \sum_{j \in J} c_{ij}$ values.

Theorem 3 *Let $H_{[F|C]}(y)$ be the Hammer-Beresnev function corresponding to the SPLP instance $[F|C]$ in which similar monomials have been aggregated. For each site index k , let a_k be the coefficient of the linear monomial corresponding to y_k and let t_k be the sum of the coefficients of all nonlinear monomials containing y_k . Then the following assertion holds:*

- RO:** *If $a_k \geq 0$, then there is an optimal solution y^* in which $y_k^* = 0$, else*
RC: *If $a_k + t_k \leq 0$, then there is an optimal solution y^* in which $y_k^* = 1$, provided that $y_i^* \neq 1$ for some $i \neq k$.*

Notice that RO and RC primarily try to either open or close sites. If it succeeds, it also changes the Hammer-Beresnev function for the instance, reducing the number of nonlinear monomials therein. In the remaining portion of this subsection, there will be described a completely new reduction procedure (RP), whose primary aim is to reduce the coefficients of terms in the Hammer-Beresnev function and, if it can be reduced to zero, to eliminate the term from the Hammer-Beresnev function. This procedure is based on fathoming rules of branch-and-bound algorithms and data-correcting principles.

Let us assume that there is an upper bound (UB) on the cost of an optimal solution for the given SPLP instance. This can be obtained by running a heuristic on the problem data. Now consider a nonlinear monomial $s \cdot \prod_{r=1}^k y_{\pi_{rj}}$ in the Hammer-Beresnev function. This term will contribute to the cost of a solution, only if plants are *not* located in any of the sites $\pi_{1j}, \dots, \pi_{kj}$. Let LB be a lower bound on the cost of solutions in which facilities are not located in sites $\pi_{1j}, \dots, \pi_{kj}$. If $LB \leq UB$, then any judgment about this term cannot be made. On the other hand, if $LB > UB$, then it is known that there cannot be an optimal solution with $y_{\pi_{1j}} = \dots = y_{\pi_{kj}} = 1$. In this case, if the coefficient s is reduced by $LB - UB - \varepsilon$ ($\varepsilon > 0$, small), then the new Hammer-Beresnev function and the original one have identical sets of optimal solutions. If after the reduction s is nonpositive, then the term can be removed from the Hammer-Beresnev function. Such changes in the Hammer-Beresnev function alter the values of t_k and can possibly allow us to use Khumawala's rules to close certain sites. Once some sites are closed, some of the linear monomials in the Hammer-Beresnev function change into constant terms, and some of the quadratic terms change into linear ones. These changes cause changes in both the a_k and the t_k values and can make further application of Khumawala's rules possible, thus preprocessing some other sites and making further changes in the Hammer-Beresnev function. A pseudocode of the reduction procedure (RP) is provided below.

Procedure RP($H_{[F|C]}(y)$)

Output: A preprocessed instance of the SPLP, i.e. an equivalent instance of reduced size, and decisions to either locate or not locate plants in some of the sites.

Code:

```

1. begin
2.   repeat
3.     compute an upper bound  $UB$  for the instance;
4.     for each nonlinear monomial  $s \cdot \prod_{r=1}^k y_{\pi_{rj}}$  in  $H_{[F|C]}(y)$  do
5.       begin
6.         compute lower bound  $LB$  on the cost of solutions in
7.         which plants are not located in sites  $\pi_{1j}, \dots, \pi_{kj}$ ;
8.         if  $LB > UB$  then
9.           reduce the coefficient of the term by
10.           $\max\{s, LB - UB - \varepsilon\}$ ;
11.         apply Khumawala's rules until no further preprocessing is possible;
12.         recompute the Hammer-Beresnev function  $H_{[F|C]}(y)$ ;
13.       until no further preprocessing of sites was achieved in the current iteration;
14. end;
```

Let us consider the application of all preprocessing rules to the example with the Hammer-Beresnev function $H_{[F|C]}(y) = 59 - 8y_1 - y_2 - 3y_3 - 4y_4 + 2y_1y_2 + 4y_1y_4 + 8y_3y_4 + 21y_1y_2y_4 + 4y_2y_3y_4$. The values of a_k , t_k , and $a_k + t_k$ are as follows:

$k :$	1	2	3	4
$a_k :$	-8	-1	-3	-4
$t_k :$	27	27	12	37
$a_k + t_k :$	19	26	9	33

It is clear that neither RO nor RC is applicable here, since the coefficient of the term $21y_1y_2y_4$ is too large. Therefore, this coefficient is tried to be reduced by applying the RP.

An upper bound of $UB = 51$ to the original problem can be obtained by setting $y_1 = y_4 = 1$ and $y_2 = y_3 = 0$. A lower bound to the problem under the restriction $y_1 = y_2 = y_4 = 1$ is 73, since $H_{[F|C]}(1, 1, 0, 1) = 73$. Using RP therefore, the coefficient of $21y_1y_2y_4$ can be reduced by $73 - 51 - \varepsilon = 20$, so that the new Hammer-Beresnev function with the same set of optimal solutions as the original function becomes $H'(y) = 59 - 8y_1 - y_2 - 3y_3 - 4y_4 + 2y_1y_2 + 4y_1y_4 + 8y_3y_4 + 1y_1y_2y_4 + 4y_2y_3y_4$. The updated values of a_k , t_k , and $a_k + t_k$ are presented below.

$k :$	1	2	3	4
$a_k :$	-8	-1	-3	-4
$t_k :$	7	7	12	17
$a_k + t_k :$	-1	6	9	13

RC can immediately be applied in this situation to set $y_3 = 1$. Updating $H'(y)$, RO and set $y_2 = y_4 = 0$ can be applied. This makes it possible to apply RC again to set $y_3 = 1$, thus giving an optimal solution (i.e., $(1, 0, 1, 0)$) to the instance, with a cost of 48.

3.3 The Data-Correcting Algorithm

The basic idea behind the data-correcting algorithm is to modify the Hammer-Beresnev function in a way such that the RO and RC rules can be applied to the modified instance. While modifying the instance, care is taken so that an optimal solution to the modified instance is not too suboptimal for the original instance. The following suitably modified version of [Theorem 1](#) for this problem is used:

Lemma 1 *Consider two Hammer-Beresnev functions $H_1(y)$ and $H_2(y)$. Let y_1^* and y_2^* be the optimal solutions to $H_1(y)$ and $H_2(y)$ respectively. Then,*

$$|H_1(y_1^*) - H_1(y_2^*)| \leq \sum_{i=0}^{m-1} \sum_{j=1}^n |\Delta c^1[i, j] - \Delta c^2[i, j]|.$$

Consider an SPLP instance with accuracy parameter α in which RO and RC cannot be applied. Clearly, in the Hammer-Beresnev function for this instance, $a_k < 0$ and $a_k + t_k > 0$ for all k . Let $k_0 = \arg \min\{|a_k|, a_k + t_k\}$. Also, let $|a_{k_0}| \leq a_{k_0} + t_{k_0}$. In this case, if the Hammer-Beresnev function of the instance is changed (corrected) by increasing the coefficient of y_{k_0} to zero, then RO can be applied to the corrected instance, and preprocessing can continue. However, this is allowed only if $\min\{|a_{k_0}|, a_{k_0} + t_{k_0}\} \leq \alpha$. In such a situation, if $|a_{k_0}| > a_{k_0} + t_{k_0}$, then the instance can be corrected by decreasing the coefficient of y_{k_0} by $a_{k_0} + t_{k_0}$; then, RC can be applied to the corrected instance, and preprocessing can continue. Notice that while correcting the instance, suboptimality to the extent of $|a_{k_0}|$ in the first case and $a_{k_0} + t_{k_0}$ in the second case is allowed for. Thus, the accuracy parameter for the corrected instance is reduced appropriately.

It may happen, however, that $\min\{|a_{k_0}|, a_{k_0} + t_{k_0}\} > \alpha$. In that case, correction is not possible at this stage, and the problem has to be broken down into subproblems. This is done by a branching operation. Goldengorin et al. [46] suggest that the algorithm branches on an index from $\arg \max\{t_k\}$.

The logic behind this rule is the following. A plant would have been located in this site in an optimal solution if the coefficient of linear monomial involving y_k in the Hammer-Beresnev function would have been increased by $-a_k$. It could have been predicted that a plant would not be located there if the same coefficient would have been decreased by $t_k + a_k$. Therefore, the average of $-a_k$ and $a_k + t_k$ could be used as a measure of the chance that the researcher will *not* be able to predict the fate of site k in any subproblem of the current subproblem [44]. If it is necessary to reduce the size of the branch-and-bound tree by assigning values to such variables, then it is possible to think of a branching function that branches on the index k_0 with the largest average value, that is, the largest value of $-a_k + (a_k + t_k)$, that is, the largest value of t_k .

On the basis of the discussion above, the pseudocode for a data-correcting algorithm for SPLP is given below. It works by maintaining three sets, Ω containing the sites where facilities are to be located, Λ containing the sites where facilities are not to be located, and Ψ containing the rest of the sites. RO and RC rules are assumed to be able to manipulate these three sets.

Algorithm DCA-SPLP($H_{[F|C]}(y)$, α)

Output: A solution y^α to the SPLP such that $H_{[F|C]}(y^\alpha) \leq H_{[F|C]}(y^*) + \alpha$.

Code:

```

1. begin
2.     apply RP to initialize  $\Omega$ ,  $\Lambda$  and  $\Psi$ ;
3.      $y^\alpha := \text{Int-DCA-SPLP}(\Omega, \Lambda, \Psi, H_{[F|C]}(\cdot), \alpha);$ 
4.     return  $y^\alpha$ ;
5. end.

```

Function Int-DCA-SPLP(Ω , Λ , Ψ , $H_{[F|C]}(\cdot)$, α)

```

1. begin
2.     while RO or RC is applicable
3.         update  $\Omega$ ,  $\Lambda$ ,  $\Psi$ , and  $H_{[F|C]}(\cdot)$  by applying RO and RC;
4.          $k^* \in \arg\{k \in \Psi \mid \min\{|a_k|, a_k + t_k\} =$ 
...            $\min\{\min\{|a_s|, a_s + t_s\} \mid s \in \Psi\}\};$ 
5.         if  $|a_{k^*}| \leq a_{k^*} + t_{k^*}$  then begin
6.             if  $|a_{k^*}| \leq \alpha$  then                                     (* Correct *)
7.                 return Int-DCA-SPLP( $\Omega + k^*$ ,  $\Lambda$ ,  $\Psi - k^*$ ,  $H_{[F|C]}(\cdot)$ ,  $\alpha - |a_{k^*}|$ );
8.             else begin                                              (* Branch *)
9.                  $k^b := \arg \max\{t_k \mid k \in \Psi\};$ 
10.                 $y^1 := \text{Int-DCA-SPLP}(\Omega + k^b, \Lambda, \Psi - k^b, H_{[F|C]}(\cdot), \alpha);$ 
11.                 $y^2 := \text{Int-DCA-SPLP}(\Omega, \Lambda + k^b, \Psi - k^b, H_{[F|C]}(\cdot), \alpha);$ 
12.                return  $\arg \max\{H_{[F|C]}(y^1), H_{[F|C]}(y^2)\};$ 
13.            end;
14.        else begin
15.            if  $a_{k^*} + t_{k^*} \leq \alpha$  then                               (* Correct *)
16.                return Int-DCA-SPLP( $\Omega, \Lambda + k^*, \Psi - k^*$ ,  $H_{[F|C]}(\cdot)$ ,  $\alpha - a_{k^*} - t_{k^*}$ );
17.            else begin                                              (* Branch *)
18.                 $k^b := \arg \max\{t_k \mid k \in \Psi\};$ 
19.                 $y^1 := \text{Int-DCA-SPLP}(\Omega + k^b, \Lambda, \Psi - k^b, H_{[F|C]}(\cdot), \alpha);$ 
20.                 $y^2 := \text{Int-DCA-SPLP}(\Omega, \Lambda + k^b, \Psi - k^b, H_{[F|C]}(\cdot), \alpha);$ 
21.                return  $\arg \max\{H_{[F|C]}(y^1), H_{[F|C]}(y^2)\};$ 
22.            end;
23.        end;
24.    end;

```

3.4 Computational Experience with SPLP Instances

The computational experience with the DCA-SPLP on several benchmark instances of the SPLP is reported in the remainder of this section. The performance of the algorithm is compared with that of the algorithms described in the papers that suggested these instances. One of two bounds was used in the

implementations of RP and DCA-SPLP: a combinatorial Khachaturov-Minoux bound [52, 61] and a much stronger Erlenkotter bound based on an LP dual-ascent algorithm [24]. There was implemented the DCA-SPLP in PASCAL, which was compiled using Prospero Pascal and which was run on a 733-MHz Pentium III machine. The computation times reported are in seconds on the machine used.

3.4.1 Testing the Effectiveness of the Reduction Procedure RP

Given an instance of the SPLP, the reduction procedure RP reduces it to a smaller core instance by making decisions to locate or not locate plants in several sites. The effectiveness of the RP can thus be measured either by computing the number of free locations in the core instance or by computing the number of nonzero nonlinear monomials present in the Hammer-Beresnev function of the core instance. Tables 1 and 2 show how the various methods of reduction perform on the benchmark SPLP instances in the OR-Library [7]. In the tables, procedure (a) refers to the use of the “delta” and “omega” rules from Khumawala [54], procedure (b) to the RP with the Khachaturov-Minoux combinatorial bound to obtain a lower bound, and procedure (c) to the RP with the Erlenkotter bound to obtain a lower bound.

The existing preprocessing rules due to Khumawala [54] and Goldengorin et al. [1] (i.e., procedure (a), which was used in the SPLP example in Goldengorin et al. [44]) cannot solve any of the OR-Library instances to optimality. However, the variants of the new reduction procedure (i.e., procedures (b) and (c)) solve a large number of these instances to optimality. Procedure (c), based on the Erlenkotter bound, is marginally better than procedure (b) in terms of the number of free locations (Table 1), but substantially better in terms of the number of nonzero nonlinear terms in the Hammer-Beresnev function (Table 2).

Tables 1 and 2 also demonstrate the superiority of the new preprocessing rule over the “delta” and “omega” rules. Consider, for example, the problem cap132. The

Table 1 Number of free locations after preprocessing SPLP instances in the OR-Library

Problem	m	n	Procedure		
			a	b	c
cap71	16	50	4	0	0
cap72	16	50	6	0	0
cap73	16	50	6	3	3
cap74	16	50	2	0	0
cap101	25	50	9	0	0
cap102	25	50	13	3	0
cap103	25	50	14	0	0
cap104	25	50	12	0	0
cap131	50	50	34	32	8
cap132	50	50	27	25	5
cap133	50	50	25	19	10
cap134	50	50	19	0	0

Table 2 Number of nonzero nonlinear monomials in the Beresnev function after preprocessing SPLP instances in the OR-Library

Problem	Nonzero terms before preprocessing	Procedure		
		a	b	c
cap71	699	6	0	0
cap72	699	12	0	0
cap73	699	13	2	2
cap74	699	1	0	0
cap101	1,147	24	0	0
cap102	1,147	33	2	0
cap103	1,147	38	0	0
cap104	1,147	29	0	0
cap131	2,389	163	135	8
cap132	2,389	112	92	3
cap133	2,389	101	60	11
cap134	2,389	62	0	0

“delta” and “omega” rules reduce the problem size from $m = 50$ and 2,389 nonzero nonlinear variables to $m = 27$ and 112 non-zero nonlinear variables. However, the new preprocessing rule reduces the same problem to one having $m = 5$ and 3 nonzero nonlinear variables!

3.4.2 Bilde- and Krarup-Type Instances

These are the earliest benchmark problems that are considered here. The exact instance data is not available, but the process of generating the problem instances is described in Bilde and Krarup [13]. There are 22 different classes of instances, and in this subsection, the nomenclature used in Bilde and Krarup [13] is applied. In the performed experiments, 10 instances for each of the types of problems were generated, and the mean values of the received solutions were used to evaluate the performance of the discussed algorithm with the one used in Bilde and Krarup [13]. In the implementation, the Khachaturov-Minoux combinatorial bound was used in the reduction procedure RP as well as in the DCA-SPLP.

The reduction procedure was not useful for these instances, but the DCA-SPLP could solve all the instances in reasonable time. The results of the experiments are presented in Table 3. The performance of the algorithm implemented in Bilde and Krarup [13] was measured in terms of the number of branching operations performed by the algorithm and its execution time in CPU seconds on an IBM 7094 machine. The number of branching operations is estimated by the suggested algorithm as the logarithm (to the base 2) of the number of subproblems it generated. From the table, it can be seen that the DCA-SPLP reduces the number of subproblems generated by the algorithm in Bilde and Krarup [13] by a factor of 1,000. This is especially interesting because Bilde and Krarup use a bound (discovered in 1967, see [12]) identical to the Erlenkotter bound in their algorithm (see [55]), and in the proposed algorithm, the Khachaturov-Minoux combinatorial bound is used. The CPU time required by the DCA-SPLP to solve these problems was too low to warrant the use of any $\alpha > 0$.

Table 3 Results from Bilde- and Krarup-type instances

*Could not be solved in 250 s

3.4.3 Galvão and Raggi-Type Instances

Galvão and Raggi [25] developed a general 0–1 formulation of the SPLP and presented a three-stage method to solve it. The benchmark instances suggested in this work are unique, in that the fixed costs are assumed to come from a normal distribution rather than the more commonly used uniform distribution. The reader is referred to Galvão and Raggi [25] for a detailed description of the problem data.

As with the data in Bilde and Krarup [13], the exact data for the instances are not known. So, 10 instances for each problem size were generated, and the mean values of the solutions were used for comparison purposes. In the DCA-SPLP implementation, the Khachaturov-Minoux combinatorial bound was used in the reduction procedure RP and in the DCA-SPLP. The comparative results are given in Table 4. Since the computers used are different, it is not possible to comment on the relative performance of the solution procedures. However, since the average number of subproblems generated by the DCA-SPLP is always less than 10 for each of these instances, it can be concluded that these problems are easy for the discussed algorithm. In fact, they are too easy for the DCA-SPLP to warrant $\alpha > 0$.

Notice that the average number of opened plants in the optimal solutions to the instances generated is quite close to the number of opened plants in the optimal solutions reported in Galvão and Raggi [25]. Also, notice that the reduction procedure was quite effective – it solved 35 of the 80 instances generated.

3.4.4 Instances from the OR-Library

The OR-Library [7] has a set of instances of the SPLP. These instances were solved in Beasley [6] using an algorithm based on the Lagrangian heuristic for the SPLP. Here too, the Khachaturov-Minoux combinatorial bound was used in the reduction procedure RP as well as in the DCA-SPLP. The problems was solved to optimality using the DCA. The results of the computations are provided in [Table 5](#). The

execution times suggest that the DCA-SPLP is faster than the Lagrangian heuristic described in Beasley [6]. The reduction procedure was also quite effective for these instances, solving 4 of the 16 instances to optimality and reducing the number of free sites appreciably in the other instances. Once again, the use of $\alpha > 0$ cannot be justified, considering the execution times of the DCA.

3.4.5 Körkel-Type Instances with 65 Sites

Körkel [55] described several relatively large Euclidean SPLP instances ($m = n = 100$ and $m = n = 400$) and used a branch-and-bound algorithm to solve these problems. The bound used in that work is an improvement on a bound based on the dual of the linear programming relaxation of the SPLP due to Erlenkotter [24] and is extremely effective. In this subsection, instances that have the same cost structure as the ones in Körkel [55] but for which $m = n = 65$ were used. Instances of this size were not dealt with in Körkel [55]. The Khachaturov-Minoux combinatorial bound was implemented both for the reduction procedure RP and the DCA-SPLP.

In Körkel [55], 120 instances of each problem size are described. These can be divided into 28 sets (the first 18 sets contain 5 instances each, and the rest contain 3 instances each). All the 120 generated instances were solved, and it was found out that the instances in sets 1, 2, 3, 4, 10, 11, and 12 are more difficult to solve than others. Therefore, these instances were used in the experiments in this section. The transportation cost matrix for a Körkel instance of size $n \times n$ is generated by distributing n points in random within a rectangular area of size $700 \times 1,300$ and calculating the Euclidean distances between them. The fixed costs are computed as in [Table 6](#).

The value of the results that is presented for each set is the average of the values obtained for all the instances in that set. Interestingly, the preprocessing rules were found to be totally ineffective for all of these problems. Since the fixed costs are identical for all the sites, the sites are distributed randomly over a region, and the variable cost matrix is symmetric; no site presents a distinct advantage over any other. This prevents our reduction procedure to open or close any site. [Table 7](#) shows the variation in the costs of the solution output by the DCA-SPLP with changes in α , and [Table 8](#) shows the corresponding decrease in execution times.

The effect of varying the acceptable accuracy α on the cost of the solution output by the DCA-SPLP is also presented graphically in [Fig. 6](#). The *achieved accuracy* β is defined as

*As a percentage of the optimal cost

$$\beta = \frac{\text{cost of the DCA-SPLP output} - \text{cost of an optimal solution}}{\text{cost of optimal solution}},$$

and the *relative time* τ as

$$\tau = \frac{\text{execution time for the DCA-SPLP for acceptable accuracy } \alpha}{\text{execution time for the DCA-SPLP to compute an optimal solution}}.$$

Note that the achieved accuracy β varies almost linearly with α , with a slope close to 0.5. Also, note that the relative time τ of the DCA-SPLP reduces with increasing α . The reduction is slightly better than linear, with an average slope of -8 .

3.4.6 Körkel-Type Instances with 100 Sites

The benchmark instances in Körkel [55] with $m = n = 100$ were solved to optimality, and it was observed that the instances in sets 10, 11, and 12 required relatively longer execution times. So, further computations were restricted to instances in those sets. The fixed and transportation costs for these problems are computed in the procedure described in Sect. 3.4.5. Tables 9 and 10 show the results obtained by running the DCA-SPLP on these problem instances. In the

DCA-SPLP implementation for solving these instances, the Erlenkotter bound in both the reduction procedure RP and the DCA-SPLP was used.

Figure 7 illustrates the effect of varying the acceptable accuracy α on the cost of the solution output by the DCA-SPLP for the instances mentioned above. The nature of the graphs is similar to those in Fig. 6. However, in several of the instances, it was observed that β is reduced when α is increased, and in some other instances, τ was increased when α was increased.

4 The p -Median Problem

The objective of the p -median problem (PMP) is to locate p facilities (medians) such that the sum of the distances from each demand point to its nearest facility is minimized. A justification for this research is that there is evidence that the PMP can provide better cluster recovery than alternative clustering procedures (the complete and average linkage, minimum variance, K-means, and p -cliques, see [16]). The PMP is formulated as a minimization problem of a pseudo-Boolean polynomial (pBp) and presents three types of data correcting for the given PMP instance, represented by an $m \times n$ input matrix and the fixed number $p : 1 \leq p \leq m$. The first type of data correcting is the truncation of the corresponding pBp and the columns of an input matrix, which leads to the preprocessing rule fixing at least one site closed. The second type of data correcting is based on the construction of pBp monomials and aggregation of similar monomials in pBp which leads to formation of some terms with zero coefficients and sometimes to preprocessing (reducing) the number of columns (clients) in the input matrix. The third data correction is similar to the data correcting applied in the SPLP and leads to the reduction of monomials at each of which an optimal solution to the PMP cannot be attained. All three types of data correcting are incorporated into the linearized pBp and corresponding mixed

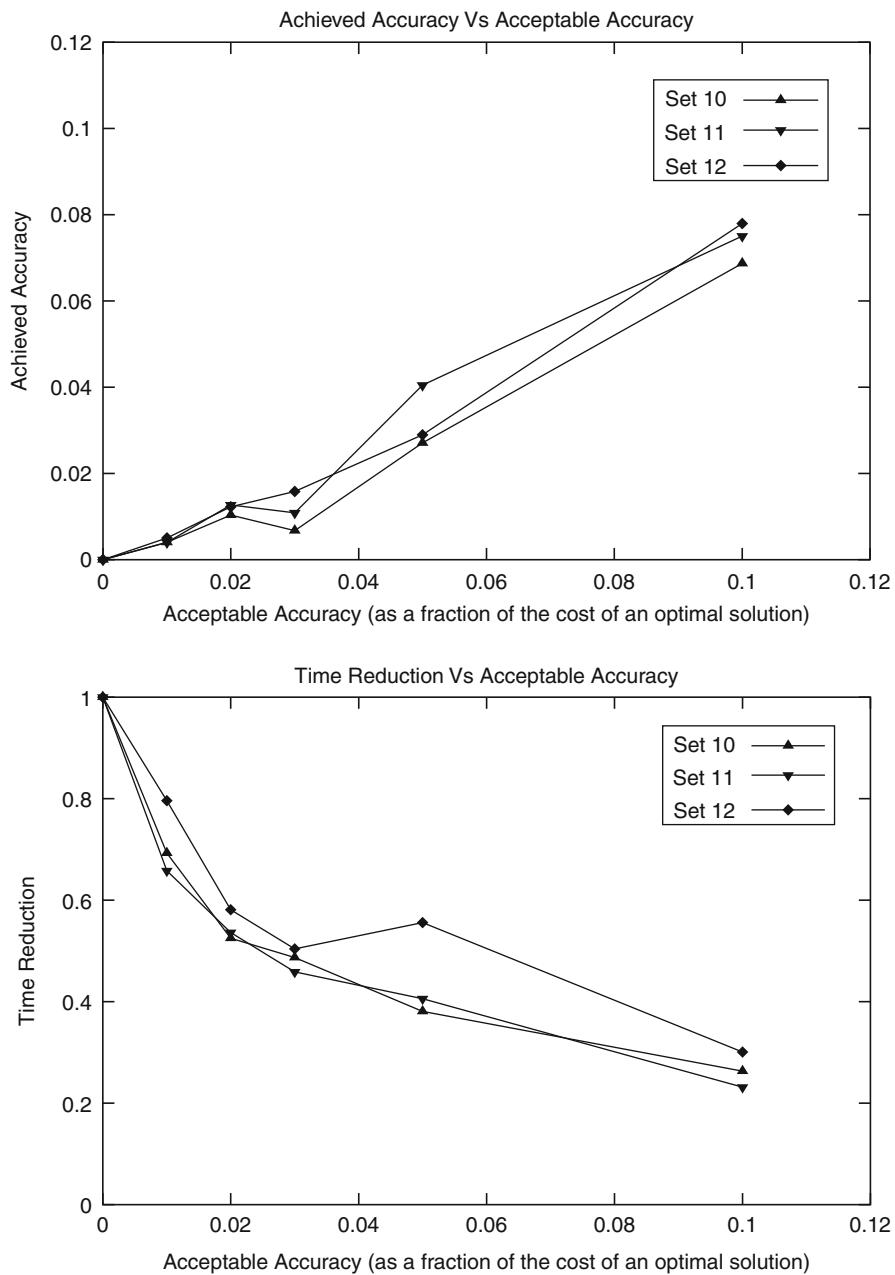

Fig. 7 Performance of the DCA-SPLP for Körkel-type instances with 100 sites

integer linear programming (MILP) PMP model. The computational experiment has showed that the new model is able to solve to optimality some of PMP benchmark instances which were intractable by general-purpose ILP software and even by the state-of-the-art algorithms (see [4, 9, 16, 67, 72]). Also, CPU times with the proposed model outperform CPU times for the best available PMP models (see [18, 19, 23, 70]).

4.1 Introduction

The p-median problem (PMP) is a well-known NP-hard problem which was originally defined by Hakimi [48, 49] and involves the location of p facilities on a network in such a manner that the total weighted distance of serving all demands is minimized. It has been widely studied in literature and applied in cluster analysis, quantitative psychology, marketing, telecommunications industry [16], sales force territory design [63], political districting [8] and references within, optimal diversity management [15], cell formation in group technology [75], vehicle routing [56], and topological design of computer communication networks [66].

The basic PMP model that has remained almost unchanged during the recent 30 years is the so-called ReVelle and Swain [69] integer linear programming formulation [19]. Note that in this formulation there are n^2 Boolean decision variables and, hence, this is a Boolean linear programming formulation. The PMP has since been the subject of considerable research involving the development of some different types of adjusted model formats (Rosing et al. [71], Cornuejols et al. [20], Church [18] and recently by Church [19], AlBdaiwi et al. [1], and Elloumi [23]) as well as the development of advanced solution approaches [67] and references within and some recent publications by Senne et al. [72], Beltran et al. [9], Avella et al. [4], Brusco and Köhn [16]. For a comprehensive list of references to the PMP, the reader is addressed to Reese [67] and Mladenovich et al. [62] and a bibliographical overview by ReVelle et al. [70].

A Boolean linear programming formulation of the PMP can be defined on a weighted bipartite graph $G = (V, A, C)$ with $V = I \cup J$, $A \subseteq I \times J$, and non-negative weights $C = \{c_{ij} : c_{ij} \geq 0, (i, j) \in A\}$ as follows. For the given sets $I = \{1, 2, \dots, m\}$ of sites at which plants (cluster centers) can be located, $J = \{1, 2, \dots, n\}$ of clients (cluster points) with unit demand at each client site, and a matrix $C = [c_{ij}]$ of non-negative costs (distances or some other dissimilarity measure) of supplying each $j \in J$ from each $i \in I$, the number p of plants to be opened, the PMP is

$$\text{minimize} \quad \sum_{i=1}^m \sum_{j=1}^n c_{ij} x_{ij} \quad (15)$$

$$\text{subject to} \quad \sum_{i=1}^m x_{ij} = 1, \quad j = 1, \dots, n. \quad (16)$$

$$x_{ij} \leq \bar{y}_i, \quad i = 1, \dots, m; \quad j = 1, \dots, n. \quad (17)$$

$$\sum_{i=1}^m \bar{y}_i = p, \quad (18)$$

$$\bar{y}_i \in \{0, 1\}, \quad i = 1, \dots, m. \quad (19)$$

$$x_{ij} \in \{0, 1\}, \quad i = 1, \dots, m; \quad j = 1, \dots, n. \quad (20)$$

For any feasible solution (x_{ij}, \bar{y}_i) , $\bar{y}_i = 1$ if plant i is open, and $\bar{y}_i = 0$, otherwise; $x_{ij} = 1$ if client j is assigned to plant i , and $x_{ij} = 0$, otherwise. Constraints (16) assign each client to exactly one plant, constraints (17) forbid the assignment of a client to a closed plant, and constraint (18) fixes the number of opened plants to p .

A PMP instance is described by an $m \times n$ matrix $C = [c_{ij}]$ and the number $1 \leq p \leq |I|$. It is assumed that the entries of C are nonnegative and finite, that is, $C \in \mathbb{R}_+^{mn}$. If $I = J$, we have the classic ReVelle and Swain's PMP model [69] with n^2 Boolean decision variables.

In this section, the study of the classic p -median model represented as a Boolean linear programming model is started by posing the following questions: (i) What are the optimal numbers of decision variables partitioned into Boolean and non-Boolean variables? (ii) What is the optimal number of constraints? (iii) do the above-mentioned numbers of decision variables and constraints depend on the PMP input data, more specifically on the number p of medians?

Further progress with improvements of ReVelle and Swain's PMP model are done by Rosing et al. [71], Cornuejols et al. [20], Church [18, 19], and recently by AlBdaiwi et al. [1] and Elloumi [23]. All of them have incorporated in different ways the following properties of PMP:

- (i) Based on an ordering of the distances with respect to a given demand point, they have either reduced the number of clients or excluded from (15) to (20) a repetition of decision variables x_{pj} and x_{qj} corresponding to the equal costs $c_{pj} = c_{qj}$ for some $j \in J$.
- (ii) The $mn + m$ Boolean decision variables are replaced by m Boolean decision variables and mn nonnegative decision variables, that is, (20) is replaced by

$$x_{ij} \geq 0, \quad i = 1, \dots, m; \quad j = 1, \dots, n. \quad (21)$$

To the best of the author's knowledge based on available publications, there is no PMP model that adjusts the numbers of nonnegative decision variables and corresponding linear constraints depending on the number p of medians.

This section proposes a new model formulation for the PMP that contains all previously suggested improvements which have been incorporated in a concise and simplified notation including the proposed adjustment of decision variables and corresponding linear constraints depending on the number p of medians. This new p -median formulation is called *a mixed Boolean pseudo-Boolean model for the PMP*. It is shown that the suggested model can result in a substantially smaller

mixed Boolean linear programming formulation for a given application of the PMP and can be used either to find a global optimum by means of general-purpose ILP solvers or to develop new exact and approximate algorithms based on the well-known methods in mixed integer programming (see, e.g., [74]).

As sometimes happened, some of the above-mentioned improvements were separately done for the PMP without taking into account the ongoing progress with model formulations for another common model within minsum location-allocation problems, namely, the simple plant location problem (SPLP), often referred to as the uncapacitated facility location problem (UFLP) (see [21]) or the warehouse location problem (see, e.g., [70]). Such problems are well known in cluster analysis (see, e.g., [16] and references within). Both problems form underlying models in several combinatorial problems, like set covering, set partitioning, information retrieval, simplification of logical Boolean expressions, airline crew scheduling, vehicle dispatching (see [17]), and assortment (see, e.g., [37, 65]), and are subproblems of various location analysis problems (see [70]).

An instance of the SPLP has an optimal solution in which each client is satisfied by exactly one plant. A similar observation is valid for the PMP. In Hammer [50], this fact is used to derive a pseudo-Boolean representation of the SPLP. The pseudo-Boolean polynomial (PBP) developed in that work has terms that contain both a literal and its complement. Subsequently, in Beresnev [11], a different pseudo-Boolean form has been developed in which each term contains only literals or only their complements. This form was found easier to manipulate, and hence Beresnev's formulation of the SPLP was adjusted to the PMP in AlBdaiwi et al. [1].

The purpose of this section is twofold. First, a new model for the p -median problem is designed, and it is shown that the number of nonnegative decision variables and corresponding constraints depends on the number of p -medians and will be adjusted in the suggested model. Moreover, these numbers are minimal in the class of mixed integer linear programs for the PMP. Second, it is shown that the new model allows solving by means of a general-purpose solver on PC some PMP benchmark instances previously intractable neither by general-purpose solver nor by the state-of-the-art exact algorithms.

In Sect. 4.2, there is a brief overview of mathematical models for the p -median problems based on combinatorial, pseudo-Boolean, and classic Boolean programming models. Based on the overview of the p -median models and reported computational results, a new model is motivated and formulated in Sect. 4.3. Section 4.4 presents data-correcting reductions, and Sect. 4.5 reports the computational study. Section 4.6 concludes this section with a summary and future research directions.

4.2 Brief Overview of PMP Formulations

Recall that it is given sets $I = \{1, 2, \dots, m\}$ of sites in which plants can be located, $J = \{1, 2, \dots, n\}$ of clients, a nonnegative matrix $C = [c_{ij}]$ of costs of supplying each $j \in J$ from each $i \in I$, the number p of plants to be opened, and unit demand

at each client site. The p -Median Problem (PMP) is one of finding a set $S \subseteq I$ with $|S| = p$, such that the total cost

$$f_C(S) = \sum_{j \in J} \min\{c_{i,j} | i \in S\} \quad (22)$$

is minimized. An instance of the problem is described by an $m \times n$ matrix $C = [c_{ij}]$ and the number $1 \leq p \leq |I|$. The *combinatorial formulation of PMP* is to find

$$S^* \in \arg \min\{f_C(S) : \emptyset \subset S \subseteq I, |S| = p\}. \quad (23)$$

The PMP (23) can be reformulated in terms of Hammer-Beresnev polynomials as the *pseudo-Boolean formulation of PMP*.

$$y^* \in \arg \min\{\mathcal{B}_C(y) : y \in \{0, 1\}^m, \sum_{i=1}^m y_i = m - p\}. \quad (24)$$

Here is $\mathcal{B}_C(y) = T_{C,\Pi}(y)$ (see (8)).

Example 1 Consider a PMP instance with $m = 4, n = 5, p = 2$, and

$$C = \begin{bmatrix} 1 & 6 & 5 & 3 & 4 \\ 2 & 1 & 2 & 3 & 5 \\ 1 & 2 & 3 & 3 & 3 \\ 4 & 3 & 1 & 8 & 2 \end{bmatrix} \quad (25)$$

borrowed from [23]. A possible ordering matrix for this problem is given by

$$\Pi = \begin{bmatrix} 1 & 2 & 4 & 1 & 4 \\ 3 & 3 & 2 & 2 & 3 \\ 2 & 4 & 3 & 3 & 1 \\ 4 & 1 & 1 & 4 & 2 \end{bmatrix}, \quad (26)$$

and the difference matrix is

$$\Delta = \begin{bmatrix} 1 & 1 & 1 & 3 & 2 \\ 0 & 1 & 1 & 0 & 1 \\ 1 & 1 & 1 & 0 & 1 \\ 2 & 3 & 2 & 5 & 1 \end{bmatrix}. \quad (27)$$

The Hammer-Beresnev polynomial representing the total cost function for this instance in the form (8) is

$$\begin{aligned}\mathcal{B}_C(y) = & [1 + 0y_1 + 1y_1y_3 + 2y_1y_2y_3] + \\ & [1 + 1y_2 + 1y_2y_3 + 3y_2y_3y_4] + \\ & [1 + 1y_4 + 1y_2y_4 + 2y_2y_3y_4] + \\ & [3 + 0y_1 + 0y_1y_2 + 5y_1y_2y_3] + \\ & [2 + 1y_4 + 1y_3y_4 + 1y_1y_3y_4].\end{aligned}\quad (28)$$

After reduction of similar monomials in the obtained polynomial, the following pseudo-Boolean representation of the instance is obtained:

$$\begin{aligned}\mathcal{B}_C(y) = & 8 + 1y_2 + 2y_4 + 1y_1y_3 + 1y_2y_3 + 1y_2y_4 + 1y_3y_4 + \\ & 7y_1y_2y_3 + 1y_1y_3y_4 + 5y_2y_3y_4 \rightarrow \min \\ s.t. \quad & y_1 + y_2 + y_3 + y_4 = m - p = 2 \\ & y \in \{0, 1\}^m.\end{aligned}\quad (29)$$

Let us show that the pseudo-Boolean formulation (24) is a generalization of the so-called *alternative formulation (AF)* (see [20]) and *new formulation (NF)* (see [23]). The reader should be careful with two different Boolean decision variables \bar{y}_i and y_i , such that $\bar{y}_i = 1 - y_i$ for all $i \in I$.

For any client j , let K_j be the number of different distances $C_{1j} < C_{2j} < \dots < C_{K_j j}$, within sorted distances $c_{\pi_1 j} \leq c_{\pi_2 j} \leq \dots \leq c_{\pi_m j}$, from j to any facility; hence, $K_j \leq m$, and $j = 1, \dots, n$. For each client j , let us define a hierarchy of neighborhoods as follows. For $k = 1, \dots, K_j$, denote by V_{kj} the k -th neighborhood of client j , that is, the set of facility sites located within distance C_{kj} from j or, formally, $V_{kj} = \{i : c_{ij} \leq C_{kj}\}$. AF uses the same \bar{y} variables as classical formulation (CF) (15)–(20) and introduces new variables z_{kj} . For any client j and $k = 1, \dots, K_j$, $z_{kj} = 1$ if and only if all the sites in V_{kj} are closed and 0, otherwise. Note that similar to the pseudo-Boolean formulation of PMP, the AF uses an inversion of standard assignments of the Boolean variables z_{kj} , namely, an opened plant is 0 and a closed one is 1.

The AF of PMP is

$$\text{minimize} \quad \sum_{j=1}^n \left(C_{1j} + \sum_{k=1}^{K_j-1} (C_{k+1j} - C_{kj}) z_{kj} \right) \quad (30)$$

$$\text{subject to} \quad z_{kj} + \sum_{i : c_{ij} \leq C_{kj}} \bar{y}_i \geq 1, \quad j = 1, \dots, n; \quad k = 1, \dots, K_j; \quad (31)$$

$$\sum_{i=1}^m \bar{y}_i = p; \quad (32)$$

$$z_{K_j j} = 0, \quad j = 1, \dots, n; \quad (33)$$

$$z_{kj} \geq 0, \quad j = 1, \dots, n; \quad k = 1, \dots, K_j; \quad (34)$$

$$\bar{y}_i \in \{0, 1\}, \quad i = 1, \dots, m. \quad (35)$$

Constraints (31) say that for any client j and for any of its neighborhoods V_{kj} , either at least one facility is open in V_{kj} or $z_{kj} = 1$. Constraints (33) ensure that for every client j , at least one plant is open in $V_{K_j,j}$ that is precisely the set of all plants. Finally, the objective function (30) sums up the allocation distances of all clients up to the first open plant.

CF and AF have the same number of Boolean variables y_i , but the number of nonnegative variables x_{ij} in CF is mn , and that of z_{kj} in AF is $K = \sum_{j=1}^m K_j$. Similarly, the number of constraints in CF and AF is $m + 1 + mn$ and $m + K + 1$, respectively. Hence, AF has approximately $mn - K$ less variables and constraints. If all distances are pairwise different, that is, for each j , $K_j = m$, then both formulations have the same size. For the example instance considered above (25), the AF formulation is as follows:

$$\begin{aligned}
& [1 + 1z_{11} + 2z_{21}] + [1 + 1z_{12} + 1z_{22} + 3z_{32}] + \\
& [1 + 1z_{13} + 1z_{23} + 2z_{33}] + [3 + 5z_{14}] + \\
& [2 + 1z_{15} + 1z_{25} + 1z_{35}] \rightarrow \min \\
& s.t. \\
& \bar{y}_1 + \bar{y}_2 + \bar{y}_3 + \bar{y}_4 = 2 \\
& z_{11} + \bar{y}_1 + \bar{y}_3 \geq 1 \\
& z_{21} + \bar{y}_1 + \bar{y}_2 + \bar{y}_3 \geq 1 \\
& z_{12} + \bar{y}_2 \geq 1 \\
& z_{22} + \bar{y}_2 + \bar{y}_3 \geq 1 \\
& z_{32} + \bar{y}_2 + \bar{y}_3 + \bar{y}_4 \geq 1 \\
& z_{13} + \bar{y}_4 \geq 1 \\
& z_{23} + \bar{y}_2 + \bar{y}_4 \\
& z_{33} + \bar{y}_2 + \bar{y}_3 + \bar{y}_4 \geq 1 \\
& z_{14} + \bar{y}_1 + \bar{y}_2 + \bar{y}_3 \geq 1 \\
& z_{15} + \bar{y}_4 \geq 1 \\
& z_{25} + \bar{y}_3 + \bar{y}_4 \geq 1 \\
& z_{35} + \bar{y}_1 + \bar{y}_3 + \bar{y}_4 \geq 1 \\
& z_{k,j} \geq 0, \quad j = 1, \dots, n; k = 1, \dots, K_j \\
& \bar{y}_i \in \{0, 1\}, \quad i = 1, \dots, m.
\end{aligned}$$

As indicated in Elloumi [23], AF is not always better than CF in terms of the running time needed by a general-purpose ILP solver, for example, CPLEX 8.1. With the purpose to reduce the above-mentioned CPU times for AF, Elloumi [23] has replaced constraints (31) by the following constraints:

$$z_{1j} + \sum_{i : c_{ij} = C_{1j}} \bar{y}_i \geq 1, \quad j = 1, \dots, n. \quad (36)$$

$$z_{kj} + \sum_{i : c_{ij} = C_{kj}} \bar{y}_i \geq z_{k-1j}, \quad j = 1, \dots, n; \quad k = 2, \dots, K_j. \quad (37)$$

The obtained PMP formulation (30), (36), (37), (32), (33), (34), and (35) is called a *new formulation* (NF) of PMP (see [23]). Similarly, to the neighborhoods V_{kj} , Church [19] has incorporated into CF the set of h_j closest sites to demand j by using a penalty variable f_j if demand j must be assigned to a plant further than its h_j closest plant. Church [19] calls such a model BEAMR (both exact and approximate model representation) and has demonstrated that BEAMR is useful to solve PMPs exactly without fully specifying all of the assignment variables and constraints needed in the CF. Moreover, any feasible solution to BEAMR is a valid lower bound to the PMP, and when some f_j values are positive, the solution can be used to test how close to optimality the solution obtained is. Church's [19] BEAMR as well as COBRA [18] (condensed Balinski constraints with the reduction of assignment variables using equivalent variable substitution) are very closed variations of the AF and NF applied to create a set of PMP models with the purpose to use general-purpose ILP software. For the cost matrix (25), Church's model is

$$\begin{aligned} & (1+3)x_{11} + 2x_{21} + 1x_{31} + 1x_{22} + 2x_{32} + (3+1)x_{42} + \\ & 2x_{23} + 3x_{33} + 3x_{24} + 3x_{34} + 4x_{13} + 3x_{35} + 2x_{45} \rightarrow \min \\ & s.t. \\ & \bar{y}_1 + \bar{y}_2 + \bar{y}_3 + \bar{y}_4 = 2 \\ & x_{11} + x_{21} + x_{31} = 1 \\ & x_{22} + x_{32} + x_{42} = 1 \\ & x_{23} + x_{33} + x_{43} = 1 \\ & x_{11} + x_{24} + x_{34} = 1 \\ & x_{13} + x_{35} + x_{45} = 1 \\ & x_{11} + x_{11} + x_{13} \leq (4-2+1)\bar{y}_1 \\ & x_{21} + x_{22} + x_{23} + x_{24} \leq 3\bar{y}_2 \\ & x_{31} + x_{32} + x_{33} + x_{34} + x_{35} \leq 3\bar{y}_3 \\ & x_{41} + x_{42} + x_{45} \leq 3\bar{y}_4 \end{aligned}$$

$$x_{11} \leq \bar{y}_1$$

$$x_{12} \leq \bar{y}_1$$

$$x_{13} \leq \bar{y}_1$$

$$x_{21} \leq \bar{y}_2$$

$$x_{22} \leq \bar{y}_2$$

$$x_{23} \leq \bar{y}_2$$

$$x_{24} \leq \bar{y}_2$$

$$x_{25} \leq \bar{y}_2$$

$$x_{31} \leq \bar{y}_3$$

$$x_{32} \leq \bar{y}_3$$

$$x_{33} \leq \bar{y}_3$$

$$x_{34} \leq \bar{y}_3$$

$$x_{35} \leq \bar{y}_3$$

$$x_{41} \leq \bar{y}_4$$

$$x_{42} \leq \bar{y}_4$$

$$x_{45} \leq \bar{y}_4$$

$$x_{i,j}, y_i \in \{0, 1\} \quad i = 1, \dots, m; \quad j = 1, \dots, n.$$

Elloumi [23] proves that the above-mentioned three mixed Boolean programs CF, AF, and NF formulate the same PMP and have the same lower bound by linear relaxation. Anyway, Elloumi [23] shows by means of computational experiments that the NF leads to better CPU times compared to CF or AF formulations because the NF sometimes has smaller number of constraints. Further speedup of NF linear programming relaxation (abbreviated by NFExr, see Elloumi [23]) is done by introduction of three reduction rules R1–R3 which eliminate z_{kj} variables corresponding either to different columns with the same ordering of distances or within a column with equal distances corresponding to different plants. The example PMP instance (25) borrowed from Elloumi [23] illustrates the corresponding numbers of variables and constraints for the above-reviewed formulations of PMP: CF, NF, NFExr, and finally the mixed Boolean pseudo-Boolean model (MBpBM). For CF, 4 Boolean variables y_i , 20 nonnegative variables x_{ij} , and 26 constraints including 4 Boolean constraints; for NF, 4 Boolean variables y_i , 18 nonnegative variables x_{ij} (in Elloumi [23], 17 nonnegative variables x_{ij} are indicated), and 28 constraints (in Elloumi [23], 23 constraints are indicated) including 4 Boolean constraints; for NFExr, 4 Boolean variables y_i , 7 nonnegative variables x_{ij} , and 21 constraints (in Elloumi [23], 11 constraints are indicated) including 4 Boolean constraints.

In the following fragment, it is shown that the proposed MBpBM applied to the PMP instance (25) has 4 Boolean variables y_i , 4 nonnegative variables z_i , and 13 constraints including 4 Boolean constraints. Recall that the original Hammer-Beresnev polynomial $\mathcal{B}_C(y)$ has 20 monomials including the monomials with zero coefficients, and after reducing similar monomials, there are 10 monomials. The number of monomials in the Hammer-Beresnev representation of a PMP instance can be further reduced by exploiting the fact that for any feasible solution y to the PMP instance, $\sum_{i=1}^m y_i = m - p$. This implies that any monomial in the Hammer-Beresnev polynomial for a PMP instance which can be expressed as a constant multiplied with more than $m - p$ literals necessarily evaluates to zero. This is formalized in [Theorem 4](#) (see [2]).

Theorem 4 *For any PMP instance C with $p \leq m$, the following assertions hold:*

1. *The degree of truncated Hammer-Beresnev polynomial $\mathcal{B}_{C,p}(y)$ is at most $m - p$.*
2. *The truncated Hammer-Beresnev polynomial is equal to the Hammer-Beresnev polynomial for any feasible solution y to the PMP instance, that is, $\mathcal{B}_C(y) = \mathcal{B}_{C,p}(y)$.*

Proof Suppose some monomial of degree d ($m - p < d < m$) evaluates to 1 in a feasible solution. By definition of $\mathcal{B}_C(y)$, such a monomial contains exactly d different variables y_i and evaluates to 1 only if all these d variables are ones. However, this contradicts the restriction on the number of opened facilities (see (24)) that ensures that in any feasible solution, exactly $m - p$ variables are set to 1. Thus, any monomial of degree greater than $m - p$ is zero for any feasible solution and $\mathcal{B}_C(y) = \mathcal{B}_{C,p}(y)$. \square

Taking into account that $p = 2$, the reduced and truncated Hammer-Beresnev polynomial $\mathcal{B}_{C,p=2}(y) = 8 + 1y_2 + 2y_4 + 1y_1y_3 + 1y_2y_3 + 1y_2y_4 + 1y_3y_4$ and has just 7 monomials with the corresponding ($p = 2$)-truncated matrix (see [2]) $C_{(p=2)}$ of the given matrix (25) as follows:

$$C_{(p=2)} = \begin{bmatrix} 1 & 3 & 3 & 3 & 4 \\ 2 & 1 & 2 & 3 & 4 \\ 1 & 2 & 3 & 3 & 3 \\ 2 & 3 & 1 & 3 & 2 \end{bmatrix}.$$

After introduction of nonnegative variables z_i , $i = 5, \dots, 8$, the objective function (see, e.g., [74]) was linearized such that $\mathcal{B}_{C,p=2}(y) = 8 + y_2 + 2y_4 + y_1y_3 + y_2y_3 + y_2y_4 + y_3y_4 = 8 + y_2 + 2y_4 + z_5 + z_6 + z_7 + z_8$ and the MBpBM is

$$\text{Minimize } 8 + y_2 + 2y_4 + z_5 + z_6 + z_7 + z_8 \quad (38)$$

$$\text{subject to } z_5 + 1 \geq y_1 + y_3, \quad (39)$$

$$z_6 + 1 \geq y_2 + y_3, \quad (40)$$

$$z_7 + 1 \geq y_2 + y_4, \quad (41)$$

$$z_8 + 1 \geq y_3 + y_4, \quad (42)$$

$$\sum_{i=1}^4 y_i = m - p = 2, \quad (43)$$

$$z_i \geq 0, \quad i = 5, \dots, 8; \quad (44)$$

$$y_i \in \{0, 1\}, \quad i = 1, \dots, 4. \quad (45)$$

This MBpBM (38)–(45) has the same decision variables y_i as the pseudo-Boolean formulation (24), but its objective function is a linear function on y_i and new variables z_i , coefficients of which are reflecting some penalties depending on the values of y_i . For example, $z_5 = y_1 y_3$ and this relationship can be reflected by the following linear constraint $y_1 + y_3 - 1 \leq z_5$ which is equivalent to $z_5 + 1 \geq y_1 + y_3$. In other words, each nonlinear monomial in the original pseudo-Boolean polynomial induces a linear inequality which must be added to the set of constraints. In the restrictions of MBpBM, the new variables z_i must be just nonnegative because Boolean variables y_i imply that all z_i are Boolean. Informally, the linear constraints (39)–(42) indicate whether or not a specific penalty to the linear part of objective function (38) should be added depending on the subset of opened and closed sites. For the sake of completeness, the best Elloumi's model (NFexr) (46) is included for the same example (38)–(45) as follows.

$$\begin{aligned} \text{Minimize } & 8 + (1 - \bar{y}_2) + 2(1 - \bar{y}_4) + z_{11} + 7z_{21} + z_{22} + 5z_{32} \\ & + z_{23} + z_{25} + z_{35} \end{aligned} \quad (46)$$

$$\text{subject to } z_{11} + \bar{y}_1 + \bar{y}_3 \geq 1,$$

$$z_{21} + \bar{y}_2 \geq z_{11},$$

$$\bar{y}_4 \geq z_{21},$$

$$z_{22} + \bar{y}_3 \geq 1 - \bar{y}_2,$$

$$z_{32} + \bar{y}_4 \geq z_{22},$$

$$\bar{y}_1 \geq z_{32},$$

$$z_{23} + \bar{y}_2 \geq 1 - \bar{y}_4,$$

$$z_{25} + \bar{y}_3 \geq 1 - \bar{y}_4,$$

$$z_{35} + \bar{y}_1 \geq z_{25},$$

$$\bar{y}_2 \geq z_{35},$$

$$\sum_{i=1}^4 \bar{y}_i = p = 2,$$

$$\begin{aligned} z_{ij} &\geq 0, \quad i = 1, \dots, 4; \quad j = 1, \dots, 5; \\ \bar{y}_i &\in \{0, 1\}, \quad i = 1, \dots, 4. \end{aligned}$$

Remember that compared to Elloumi's paper [23] in the suggested PMP, a transpose of matrix C was used, and hence the order of indices indicated in the variables z_{ji} is changed to z_{ij} . As easy to conclude, the objective function (38) in MBpBM has only 7 nonzero coefficients compared to 10 nonzero coefficients in (46). Hence, the main distinction between the MBpBM and Elloumi's NFexr model is the truncation in the new model of all terms with degree at least $(m - p + 1) = 4 - 2 + 1 = 3$ in pBp and corresponding linear constraints. Actually, the reduced but non-truncated pBp is

$$8 + y_2 + 2y_4 + y_1y_3 + 1y_2y_3 + 1y_2y_4 + 1y_3y_4 + 7y_1y_2y_3 + 1y_1y_3y_4 + 5y_2y_3y_4$$

and has also 10 terms with the same set of nonzero coefficients, namely,

$$8 + y_2 + 2y_4 + z_{11} + z_{22} + z_{23} + z_{25} + 7z_{21} + z_{35} + 5z_{32}.$$

The number of linear constraints in (38)–(45) is 9 including 4 non-negativity constraints (44) compared to 18 linear constraints including 7 non-negativity constraints for Elloumi's NFexr model.

4.3 The Mixed Boolean Pseudo-Boolean Model (MBpBM)

As a consequence of [Theorem 4](#), the objective function of a PMP instance with $p \leq m$ and a cost matrix C can be described using the following *truncated Hammer-Beresnev polynomial*:

$$\mathcal{B}_{C,p}(y) = \sum_{j=1}^n \left\{ \Delta c[0, j] + \sum_{k=1}^{m-p} \Delta c[k, j] \cdot \prod_{r=1}^k y_{\pi_{rj}} \right\}. \quad (47)$$

A corollary to [Theorem 4](#) is a reformulation of the definition of PMPs in terms of truncated Hammer-Beresnev polynomials.

Corollary 2 A PMP instance with m possible facilities, n clients, and a cost matrix C can be represented as

$$\mathbf{y}^* \in \arg \min \left\{ \mathcal{B}_{C,p}(y) : y \in \{0, 1\}^m, \sum_{i=1}^m y_i = m - p \right\}. \quad (48)$$

Let us denote the truncated and reduced Hammer-Beresnev polynomial [14] $\mathcal{B}_{C,p}(y)$ by

$$\mathcal{A}_{C,p}(y) = \sum_{r=0}^k \alpha_r \prod_{i \in T_r} y_i, \quad (49)$$

with the set T_r of Boolean variables y_i included in term r and new variables $z_r = y_r$, for $r = 1, \dots, m$, and $z_r = \prod_{i \in T_r} y_i$ for $r = m+1, \dots, k$. Since $\alpha_r \geq 0$ and PMP is a minimization problem (48), it is possible to replace each nonlinear equality $\prod_{i \in T_r} y_i = z_r$ by an equivalent nonlinear inequality $\prod_{i \in T_r} y_i \leq z_r$ which is equivalent to the following linear inequalities $\sum_{i \in T_r} y_i - |T_r| + 1 \leq z_r$ and $z_r \geq 0$. In any optimal PMP solution, the variable $z_r = 0$ if and only if at least one variable $y_i = 0$, and $z_r = 1$ if and only if all $y_i = 1$, that is, $z_r \in \{0, 1\}$. Now, the pseudo-Boolean formulation of PMP with a nonlinear objective function (49) can be presented as the following mixed Boolean linear programming model:

$$\text{Minimize} \quad \left\{ \alpha_0 + \sum_{r=1}^m \alpha_r y_r + \sum_{r=m+1}^k \alpha_r z_r \right\} \quad (50)$$

$$\text{subject to} \quad \sum_{i=1}^m y_i = m - p; \quad (51)$$

$$\sum_{i \in T_r} y_i - |T_r| + 1 \leq z_r, \quad r = m+1, \dots, k; \quad (52)$$

$$z_i \geq 0, \quad i = m+1, \dots, k. \quad (53)$$

$$y_i \in \{0, 1\}, \quad i = 1, \dots, m. \quad (54)$$

The objective function (50) is split into three parts: the first part α_0 is the sum of all smallest entries δ_{1k} per column (client) k under assumption that all sites are opened, the second part reflects the penalties incurred by the next δ_{2k} to the smallest entries, and the third part represents all other penalties corresponding to δ_{rk} for $1 < r \leq m-p$. All other constraints are explained similarly to the example (38)–(45).

4.3.1 Further Data Correcting

Even though MBpBM is a very compact model, it can be further reduced by involving upper and lower bounds on the cost of optimal solutions similarly to the SPLP (see Preprocessing SPLP instances, in Sect. 3.2). Suppose we know from some “oracle” an (global) upper bound f^{UB} on the cost of optimal solutions. Let us now consider some term r and the set of indices of its variables T_r . If now a vector y^r is made by setting its i -th entry to 1 if $i \in T_r$ and to 0, otherwise, then the value of the pseudo-Boolean polynomial on y^r is a trivial lower bound for the subspace of solutions having locations from T_r closed. More formally,

$$f_r^{LB} = \mathcal{B}_{C,p}(y^r) \quad (55)$$

The essence of the reduction that is considered here can be expressed by the following lemma.

Lemma 2 *If for some term $r = r(y)$ of a truncated Hammer-Beresnev polynomial holds $f_r^{LB} > f^{UB}$, then for every optimal solution y^* holds $r(y^*) = 0$.*

Proof Taking into account that there is a truncated polynomial, any term r has a degree of at most $m - p$ and $|T_r| \leq m - p$. This means that to keep r equal to 1, at least p sites are to be opened, implying that the costs of any feasible solution with sites from T_r closed is at least $\mathcal{B}_{C,p}(y')$ (by closing additional sites, the objective value can only be increased). By condition of the lemma, there exists a cheaper feasible solution; thus, any feasible solution y with $y_i = 1$ for any $i \in T_r$ is not optimal. \square

The following counterexample shows that the inequality in Lemma 2 should be strict.

Example 2 Consider an instance defined by the following cost matrix C :

$$C = \begin{bmatrix} 0 & 6 & 6 \\ 1 & 0 & 8 \\ 2 & 9 & 9 \\ 5 & 4 & 0 \end{bmatrix}.$$

A possible permutation and difference matrices are

$$\Pi = \begin{bmatrix} 1 & 2 & 4 \\ 2 & 4 & 1 \\ 3 & 1 & 2 \\ 4 & 3 & 3 \end{bmatrix} \Delta = \begin{bmatrix} 0 & 0 & 0 \\ 1 & 4 & 6 \\ 1 & 2 & 2 \\ 3 & 3 & 1 \end{bmatrix}.$$

In case $p = 2$, the Hammer-Beresnev polynomial is

$$\mathcal{B}_{C,p=2}(y) = 1y_1 + 4y_2 + 6y_4 + 1y_1y_2 + 3y_1y_4 + 2y_2y_4.$$

Considering the first term $r = y_1$, there are $T_1 = \{1\}$, $y^1 = (1, 0, 0, 0)^T$, and $f_1^{LB} = (B)_C((y)^1) = 1$. Suppose the upper bound is the same $f^{UB} = 1$. If the inequality in Lemma 2 was non-strict, then this would imply that for any optimal solution $y_1 = 0$. However, it can be checked that for the unique optimal solution to the instance $y^* = (1, 0, 1, 0)^T$, this does not hold.

Now the above condition of the Lemma 2 for every term of the pseudo-Boolean polynomial can be checked, starting from terms with the lowest degree. Such order of checking terms is beneficial because if some term is found to be zero in any

optimal solution (let us call such terms *null terms*), then all terms of higher degree that contain it are also zero. There are two possibilities of dealing with null terms within the MBpBM model.

The first and the most straightforward approach is to set the variable that corresponds to a null term to zero throughout the formulation. This eliminates one term from the objective function but preserves the number of constraints. We call the model reduced according to this approach based on bounds MBpBMb. The following example shows how this reduction works. Having the cost matrix C (25), $p = 2$, and an MBpBM model (38)–(45), the global upper bound f^{UB} can be computed, for example, by greedy heuristics that work as follows. Starting with all facilities opened, at each iteration, the facility that minimizes the cost of obtained solution is closed until exactly p facilities remain opened. For the considered case, $f^{UB} = 9$. Now for every term r , f_r^{LB} is computed. The first term is y_2 , and the corresponding lower bound for all solutions having second facility closed is $f_2^{LB} = \mathcal{B}_{C,p=2}(0, 1, 0, 0) = 9$. Thus, this term does not pass the test. The next term is y_4 and $f_4^{LB} = \mathcal{B}_{C,p=2}(0, 0, 0, 1) = 10 > f^{UB}$, implying that for every optimal solution, $y_4 = 0$ and (38)–(45) can be reduced to

$$\begin{aligned} \text{minimize} \quad & 8 + y_2 + z_5 + z_6 + 0z_7 + 0z_8 \\ \text{subject to} \quad & z_5 + 1 \geq y_1 + y_3, \\ & z_6 + 1 \geq y_2 + y_3, \\ & 0 + 1 \geq y_2 + 0, \\ & 0 + 1 \geq y_3 + 0, \\ & y_1 + y_2 + y_3 = 2, \\ & y_4 = 0 \\ & z_i \geq 0, \quad i = 5, \dots, 8; \\ & y_i \in \{0, 1\}, \quad i = 1, \dots, 4. \end{aligned}$$

Here is used the fact that $z_7 = y_2y_4$ and $z_8 = y_3y_4$ both contain the variable that is set to 0 and thus can also be eliminated. It should be noted that third and fourth constraints are redundant and can be dropped. The next term is y_1y_3 , and the lower bound is $f_{1,3}^{LB} = \mathcal{B}_{C,p=2}(1, 0, 1, 0) = 9$. The last term is y_2y_3 , and the lower bound is $f_{2,3}^{LB} = \mathcal{B}_{C,p=2}(0, 1, 1, 0) = 10 > f^{UB}$ implying that for every optimal solution, the corresponding variable is $z_6 = 0$. This leads to the following MBpBMb model:

$$\begin{aligned} \text{Minimize} \quad & 8 + y_2 + z_5 \\ \text{subject to} \quad & z_5 + 1 \geq y_1 + y_3, \\ & 1 \geq y_2 + y_3, \\ & y_1 + y_2 + y_3 = 2, \end{aligned}$$

$$\begin{aligned} y_4 &= 0, \\ z_5 &\geq 0; \\ y_i &\in \{0, 1\}, \quad i = 1, \dots, 4. \end{aligned}$$

Another approach to dealing with null terms allows not only to reduce the size of the objective function but also the number of constraints. Its essence is expressed by the following lemmas.

Lemma 3 *Increasing a coefficient at a null term does not affect the cost of optimal solutions.*

Proof Straightforward from the definition of null terms. If some term is found to be equal to 0 in any optimal solution, then increasing the coefficient of the corresponding monomial will not result in new optimal solutions. \square

Lemma 4 *If for some term r_1 in the Hammer-Beresnev polynomial there exists an embedded term r_0 with infinitely large coefficient, then r_1 can be given a zero coefficient without affecting the cost of optimal solutions.*

Proof If there exists an optimal solution of finite cost, then closing locations from $T_{r_1} \setminus T_{r_0}$ does not change the cost of a solution. Thus, the coefficient at r_1 does not influence the objective value and can be set to an arbitrary number, for example, 0. \square

Thus, if a null term is found, it can be given an infinite (large enough) coefficient, and all terms for which it is embedded can be eliminated from the Hammer-Beresnev polynomial without a need for additional constraints. The model with this reduction is called MBpBMB1. Even though it allows smaller reduction of the objective function, it can benefit from the reduced number of constraints. For the considered above instance with cost matrix C (25) and $p = 2$, the MBpBMB1 model is as follows:

$$\begin{aligned} \text{Minimize } \quad & 8 + y_2 + 1000y_4 + z_5 + 1000z_6 \\ \text{subject to } \quad & z_5 + 1 \geq y_1 + y_3, \\ & z_6 + 1 \geq y_2 + y_3, \\ & y_1 + y_2 + y_3 + y_4 = 2, \\ & y_4 = 0, \\ & z_i \geq 0, \quad i = 5, \dots, 8; \\ & y_i \in \{0, 1\}, \quad i = 1, \dots, 4. \end{aligned}$$

Here, infinite coefficients were set to 1,000 for the sake of clarity, while in practice the value of $f^{UB} + 1 = 10$ suffices for this purpose. It is also clear that if a linear null term is found, then the corresponding y variable is fixed to 0, and it is eliminated from the objective function (instead of raising its coefficient to infinity). Moreover, if for some null term there are no terms into which it is embedded, then it is beneficial to eliminate it and add a corresponding constraint. If these exceptions are introduced into MBpBMb1, then for the considered example both formulations (MBpBMb and MBpBMb1) become equal, although the mechanisms by which some constraints were dropped are different. While in MBpBMb third and fourth constraints became redundant as most of the variables in them were set to 0, in MBpBMb1 these constraints did not exist at all because the corresponding terms were eliminated from the pseudo-Boolean polynomial.

Finally, it should be mentioned that instead of $f_r^{LB} = \mathcal{B}_{C,p}(y^r)$, a somewhat stronger lower bound can be used:

$$f_r^{LB} = f_C(\bar{T}_r) + \min_{k_i \in \bar{T}_r} \sum_{i=1}^{m-p-|\bar{T}_r|} [f_C(\bar{T}_r \setminus \{k_i\}) - f_C(\bar{T}_r)] \quad (56)$$

where $f_C(\cdot)$ – cost function of the PMP, that is, $f_C(\bar{T}_r) = \mathcal{B}_{C,p}(y^r)$ and \bar{T}_r denotes the complement of T_r , that is, $\bar{T}_r = \{1, \dots, m\} \setminus T_r$. In the computational experiments reported in the following section, lower bounds given by (56) were used.

4.4 Reduction Tests for the p -Median Problem

Looking back on the formulations described in the available literature and on the principles behind the formulation, it can be noticed that all improvements over the classical formulation by ReVelle and Swain [69] are done by application of various reduction tests to the instances of the problem. These tests can be classified into the following two broad groups:

- Pure
- Optimizational

The first group includes all kinds of tests exploiting structural redundancies in the input data. For example, presence of equal entries within a column of the cost matrix was first used by Cornuejols [20] in his alternative formulation (AF) (30) and is present in most of the recent models, including Elloumi's NF [23] and the MBpBM (50)–(54). Another pure reduction is an exclusion of the largest p entries from the formulation of each column of the cost matrix. This reduction was used by Avella et al. ([3], reduction test *FIX1*) and Church [18], and the proposed model is implemented via truncation of the Hammer-Beresnev polynomial. It is worth mentioning that this reduction has a universal nature in a sense that it always allows to exclude from consideration exactly p entries from each column of the cost matrix, irrespective of the particular instance data. The next structural peculiarity

that can be exploited for strengthening the formulation is related to the similarity of neighborhoods of the clients, that is, the order in which potential locations are listed if being sorted by increasing distance from a client. If two clients have equal neighborhoods, then they may be considered as one aggregated client. In the new model, this rule is reflected by combining similar monomials in the pseudo-Boolean polynomial, while in Elloumi's NF (reduction rules R2 and R3 in [23]) and Church's COBRA [18], this is done by "substitution of equivalent variables" (as it is called in [18]). Finally, for the sake of completeness, it is important to mention Elloumi's reduction rule R1 that is related to the obtained ILP formulation rather than to initial data. The essence of this rule is that some z variables can be expressed in terms of y variables in a linear way. In fact, this rule is implicitly present in the proposed model as no new variables were introduced for linear monomials of the Hammer-Beresnev polynomial. The effect of these pure reductions can be illustrated by [Table 11](#) where reduction tests were applied to several selected benchmark instances that are widely used for testing PMP-related algorithms. The first three columns contain the title of the instance, number of potential locations m , and the number of medians p , correspondingly. Next, two columns indicate the number of entries in the cost matrix $|C|$ and the number of nonzero coefficients in the pseudo-Boolean polynomial $|B|$. The last column displays the achieved reduction that was computed as $reduction = (|C| - |B|)/|C| \times 100\%$.

The second group of reduction tests includes optimizational approaches that suggest (pre-)solving the problem. These are reductions based on comparison of estimated upper and (restricted or particular) lower bounds of the optimal solution. Such a reduction was used by Avella et al. ([3], reduction test *FIX2*) and is implemented in the given formulations MBpBMB and MBpBMB1 leading to even more compact models and, as will be showed in the next section, lower computing times.

The above can be summarized as follows: MBpBM in a natural way incorporates all the available in literature pure reductions and can be subjected to optimizational problem size reduction techniques.

4.5 Computational Results

In order to show the applicability of the compact MBpBM formulation, a number of computational experiments were held. The benchmark instances employed have been taken from two of the most widely used libraries: J. Beasley's OR-library (see <http://people.brunel.ac.uk/~mastjjb/jeb/orlib/pmedinfo.html>) and randomly generated RW instances by Resende and Werneck (see, e.g., [23]). The common class of benchmark instances included in almost all publications devoted to the PMP itself is just the OR-Library instances. Since the main purpose of the experiments is to show that the new model for PMP is one of the best currently known models (see [19, 23]) which could be used to solve PMP instances to optimality based on general-purpose software, Xpress-MP and 15 largest instances (see [Tables 12](#) and [14](#)) have been used from OR-Library [7]. This problem library contains

Table 11 Effect of reduction tests for selected benchmark instances

40 different PMP instances, each representing a graph of n vertices and each being a client and a potential facility, and a specific value of p . Graphs are complete and range in size from 100 (with 10,000 arcs) to 900 (with 810,000 arcs) nodes. The distance c_{ij} between two nodes is the length of a shortest path linking them.

The experiments have been conducted on a personal computer with Intel 2.33-GHz processor 1.95-GB RAM and Xpress-MP as an ILP solver.

Tables 12 and 13 summarize the computational results obtained for the largest 15 OR instances and random RW instances, correspondingly. The first three columns contain the name of instance, the number of m nodes, and the number p of medians. The next three columns are related to the running times (in seconds) of the considered above variations of the new model: the initial MBpBM formulation and its modifications incorporating reductions based on bounds. The last column reflects computing times for Elloumi's NF model that were implemented and tested within the same environment as the proposed models so as to ensure consistent comparison of performance.

The computational experiments with OR and RW instances can be summarized as follows. The basic MBpBM formulation outperforms Elloumi's new formulation in most of the tested cases, especially for larger numbers of medians p . At the same time, the reduction based on bounds (see column MBpBMB) has comparatively poor performance in general. This can be explained by an increased number of nonzero coefficients in a constraint matrix. However, there exist instances (e.g., pmmed36 and pmmed38) for which MBpBMB performs better than other variations of the formulation based on a pseudo-Boolean polynomial and for which instance pmmed36 has three times smaller computing times compared to NF. Finally, the revised

reduction based on bounds MBpBMb1 outperformed other considered models in almost all cases except pmed32, pmed36, and pmed38 (for pmed36, it is better than NF but is worse than MBpBM).

Trying to understand which of the considered, in Sect. 4.2, models is the best one, Elloumi [23] has compared the number of variables, constraints, and non-zero entries in the constraint matrix. For pmed33 instance, Elloumi's (our) model contains 31,852 (20,329) variables, 31,852 + 1 (20,329 + 1) constraints, and 553,004 (407,981) nonzero entries of constraint matrix. For the same instance pmed33, Church's BEAMR contains 9,940 variables and 9,241 constraints. The numbers of nonzero entries in constraint matrices are not indicated.

4.6 Summary and Future Research Directions

In this section, a new approach to formulate models for the p -median problem (PMP) is presented. First, the PMP is formulated using a pseudo-Boolean polynomial (pBp) as the objective function and with just one constraint related to the number of medians in a feasible solution. Then, the objective function is compacted by reducing similar monomials. After this, the nonlinear monomials in the objective function are linearized with additional variables and linear constraints. The resulting model belongs to the well-studied class of mixed Boolean linear programming models which is called mixed Boolean pseudo-Boolean model (MBpBM). The MBpBM allows to solve PMPs with much less execution times than are required by the best known models in the literature. It also allows us to solve much larger problems by general-purpose ILP software than is currently possible using previous model formulations. The MBpBM has been able to obtain an optimal solution to the fl1400 instance with $p = 400$, which remained unsolved in Avella et al. [4] by their state-of-the-art-algorithm for PMP as well as by Beltran et al.'s [9] advanced semi-Lagrangian approach based on proximal analytic center cutting plane method.

The main distinction between MBpBM and all well-known mixed integer PMP formulations is that the number of decision variables in MBpBM is automatically adjusted according to the number p of medians, that is, the number of decision variables as well as the number of constraints decrease linearly with increasing values of p . This feature of MBpBM implies that PMP instances with relatively large numbers of medians are easier to solve using standard MILP software applied with the MBpBM. Thus, the new model and the approach to create it not only extend the capability of general-purpose software to solve larger sized p -median problems but also make it possible to solve smaller problems more efficiently when using general-purpose software.

The MBpBM approach should also lead to reduced model sizes for other location models like the simple plant location problem and the capacitated simple plant location problem (SPLP), which is a generalization of PMP with fixed charges, as well as to improved data-correcting approach to the SPLP (see [46]). There are several interesting extensions to the work done in this chapter. One clear extension is in the development of heuristics based on either Hammer-Beresnev's functions (polynomials) or their linearized MILP.

A second important direction in this type of research is to exploit the most important ingredient of data correcting for Hammer-Beresnev functions (polynomials), namely, their truncations, by adding an artificial constraint on the cardinality of unknown optimal solution $p = |S^*|$ to the SPLP, for example, to an analogue of MBpBM, and hence to reduce the number of monomials in the corresponding Hammer-Beresnev polynomial. The correct number p of artificial medians might be found by solving a sequence of SPLPs based on the binary search as follows: $p = m/2, m/4, \dots$

Computational results reported in Table 14 show that the MBpBM is useful for p -median approach to large cell formation instances in group technology [43]. A third direction of research, and the one that is planned for the immediate future, is to find the optimal number of cells (see [42]).

5 Maximization of General Submodular Functions

Let $N = \{1, 2, \dots, n\}$ and 2^N denote the set of all subsets of N . A function $z : 2^N \rightarrow \mathbb{R}$ is called *submodular* if for each $I, J \in 2^N$, $z(I) + z(J) \geq z(I \cup J) + z(I \cap J)$. The solution process of many classical combinatorial optimization problems, like the generalized transportation problem, quadratic cost partition (QCP) problem with nonnegative edge weights and set covering, can be formulated as the maximization of a submodular function (MSF), that is, the problem:

$$\max\{z(T) | T \subseteq N\}.$$

Although the general problem of the maximization of a submodular function is known to be NP-hard (see [60]), there has been a sustained research effort aimed at developing practical procedures for solving medium and large-scale problems in this class (see [39]). In the remainder of this section, two data-correcting algorithms for solving the problem are suggested. Note that [Theorem 1](#) assumes the following form for this problem.

Lemma 5 Consider two submodular functions $z_1(\bar{x}) = \sum_{i=1}^n \sum_{j=i}^n c_{ij}^1$ $\prod_{k=i}^j x_k$ and $z_2(\bar{x}) = \sum_{i=1}^n \sum_{j=i}^n c_{ij}^2 \prod_{k=i}^j x_k$. Let \bar{x}_1^* and \bar{x}_2^* be the maximum

points of $z_1(\bar{x})$ and $z_2(\bar{x})$ respectively. Then,

$$z_1(\bar{x}_1^*) - z_1(\bar{x}_2^*) \leq \sum_{i=1}^n \sum_{j=1}^n |c_{ij}^1 - c_{ij}^2|.$$

The algorithm described in Sect. 5.1 has been published in Goldengorin et al. [44], while that described in Sect. 5.2 has been published in Goldengorin and Ghosh [40]. For each of the two algorithms, a class of polynomially solvable instances for the submodular function maximization problems is described. Then, the data-correcting algorithms that use this class of polynomially solvable instances to solve a general submodular function maximization problem are described. The classes of polynomially solvable instances are algorithmically defined, that is, they are classes of instances that are solved to optimality using a prespecified polynomial algorithm.

5.1 A Simple Data-Correcting Algorithm

The class of polynomially solvable instances described here is defined using a polynomial time algorithm called the preliminary preservation (PP) algorithm. Normally, these algorithms terminate with a subgraph of the Hasse diagram of the original instance which is guaranteed to contain the maximum. However, for instances where PP returns a subgraph with a single node, that node is the maximum, and the instance is said to have been solved in polynomial time. Instances such as these make up the class of polynomially solvable instances that is considered here.

Let z be a real-valued function defined on the power set 2^N of $N = \{1, 2, \dots, n\}$; $n \geq 1$. For each $S, T \in 2^N$ with $S \subseteq T$ is defined

$$[S, T] = \{I \in 2^N \mid S \subseteq I \subseteq T\}.$$

Note that $[\emptyset, N] = 2^N$. Any interval $[S, T]$ is a subinterval of $[\emptyset, N]$ if $\emptyset \subseteq S \subseteq T \subseteq N$. This is denoted using the notation $[S, T] \subseteq [\emptyset, N]$. In this section, an interval is always a subinterval of $[\emptyset, N]$. It is assumed that z attains a finite maximum value on $[\emptyset, N]$ which is denoted by $z^*[\emptyset, N]$, and $z^*[S, T] = \max\{z(I) \mid I \in [S, T]\}$ for any $[S, T] \subseteq [\emptyset, N]$. $d_k^+(I) = z(I + k) - z(I)$ and $d_k^-(I) = z(I - k) - z(I)$ are also defined.

The following theorem and corollaries from Goldengorin et al. [44] act as a basis for the preliminary preservation (PP) algorithm described therein.

Theorem 5 Let z be a submodular function on $[S, T] \subseteq [\emptyset, N]$ and let $k \in T \setminus S$. Then the following assertions hold:

1. $z^*[S + k, T] - z^*[S, T - k] \leq z(S + k) - z(S) = d_k^+(S)$.
2. $z^*[S, T - k] - z^*[S + k, T] \leq z(T - k) - z(T) = d_k^-(T)$.

Corollary 3 ((Preservation rules of order zero)) *Let z be a submodular function on $[S, T] \subseteq [\emptyset, N]$, and let $k \in T \setminus S$. Then the following assertions hold:*

1. *First preservation rule: If $d_k^+(S) \leq 0$, then $z^*[S, T] = z^*[S, T - k] \geq z^*[S + k, T]$.*
2. *Second preservation rule: If $d_k^-(T) \leq 0$, then $z^*[S, T] = z^*[S + k, T] \geq z^*[S, T - k]$.*

The PP algorithm accepts an interval $[S, T]$, $S \subseteq T$ and tries to apply Corollary 3 repeatedly. It returns an interval $[X, Y]$, $S \subseteq X \subseteq Y \subseteq T$, such that $z^*[S, T] = z^*[X, Y]$. The pseudocode for this algorithm is given below.

Algorithm PP($[S, T]$)

Output: A subinterval of $[S, T]$ containing the maximum of z over $[S, T]$.

Code:

```

1. begin
2.     if  $T = S$  return  $[S, S]$ ;
3.     while  $T \neq S$  do begin
4.          $d_{max}^+ := \max\{d_k^+ | k \in T \setminus S\}$ ;
5.          $d_{max}^- := \max\{d_k^- | k \in T \setminus S\}$ ;
6.         if  $d_{max}^+ \leq 0$  then begin
7.              $k_{max}^+ := \arg \min\{k \in T \setminus S | d_k^+ = d_{max}^+\}$ ;
8.              $T := T - k_{max}^+$ ;
9.         end
10.        else if  $d_{max}^- \leq 0$  then begin
11.             $k_{max}^- := \arg \min\{k \in T \setminus S | d_k^- = d_{max}^-\}$ ;
12.             $S := S + k_{max}^-$ ;
13.        end
14.    end;
15. end;
16. end.

```

The PP algorithm is called repeatedly by the DCA-MSF to generate a solution to the MSF instance within the prescribed accuracy level α . The pseudocode for DCA-MSF is given below. As in the case of ATSP, a good problem-specific upper bound will improve the performance of the algorithm.

Algorithm DCA-MSF($[S, T], \alpha$)

Output: $x^\alpha \in [S, T]$ such that $z(x^\alpha) \geq z^*[S, T] - \alpha$.

Code:

```

1. begin
2.      $[S, T] := \text{PP}([S, T])$ ;
3.     if  $T = S$  return  $S$ ;
4.      $d_{max}^+ := \max\{d_k^+ | k \in T \setminus S\}$ ;
5.      $d_{max}^- := \max\{d_k^- | k \in T \setminus S\}$ ;
6.     if  $d_{max}^+ \leq d_{max}^-$  then begin

```

```

7.           if  $d_{max}^+ \leq \alpha$  then begin
8.                $k_{max}^+ := \arg \min\{k \in T \setminus S | d_k^+ = d_{max}^+\};$ 
9.               return DCA-MSF([S, T - k_{max}^+], \alpha - d_{max}^+) (* Correction *)
10.          end;
11.         else begin                                     (* Branch *)
12.              $x_1 := \text{DCA-MSF}([S + k_{max}^+, T], \alpha);$ 
13.              $x_2 := \text{DCA-MSF}([S, T - k_{max}^+], \alpha);$ 
14.             if  $z(x_1) \geq z(x_2)$  return  $x_1$ 
15.             else return  $x_2;$ 
16.         end;
17.     end
18.     else begin
19.         if  $d_{max}^- \leq \alpha$  then begin
20.              $k_{max}^- := \arg \min\{k \in T \setminus S | d_k^- = d_{max}^-\};$ 
21.             return DCA-MSF([S + k_{max}^-, T], \alpha - d_{max}^-) (* Correction*)
22.         end;
23.         else begin                                     (* Branch *)
24.              $x_1 := \text{DCA-MSF}([S + k_{max}^-, T], \alpha);$ 
25.              $x_2 := \text{DCA-MSF}([S, T - k_{max}^-], \alpha);$ 
26.             if  $z(x_1) \geq z(x_2)$  return  $x_1$ 
27.             else return  $x_2;$ 
28.         end;
29.     end;
30. end.

```

A version of this DCA is implemented in a toolbox for use in MATLAB or Octave (see [57]) with a correct note that “The Data Correcting Algorithm for maximizing general (not necessarily nondecreasing) submodular functions.”

5.2 A Data-Correcting Algorithm Based on Multi-level Search

The preservation rules mentioned in Corollary 3 look at a level which is exactly one level deeper in the Hasse diagram than the levels of S and T . However, instead of looking one level deep, it is possible to look r levels deep in order to determine whether an element can be included or excluded. Let

$$\begin{aligned} M_r^+[S, T] &= \{I \in [S, T] | |I \setminus S| \leq r\}, \\ M_r^-[S, T] &= \{I \in [S, T] | |T \setminus I| \leq r\}. \end{aligned}$$

The set $M_r^+[S, T]$ is a collection of all sets representing solutions containing more elements than S and which are no more than r levels deeper than S in the Hasse diagram. Similarly, the set $M_r^-[S, T]$ is a collection of all sets representing solutions containing less elements than T and which are no more than r levels deeper than T in the Hasse diagram. Let us further define the collections of sets.

$$N_r^+[S, T] = M_r^+[S, T] \setminus M_{r-1}^+[S, T],$$

$$N_r^-[S, T] = M_r^-[S, T] \setminus M_{r-1}^-[S, T].$$

The sets $N_r^+[S, T]$ and $N_r^-[S, T]$ are the collection of sets which are located exactly r levels above S and below T in the Hasse diagram, respectively.

Further, let $v_r^+[S, T] = \max\{z(I) | I \in M_r^+[S, T]\}$, $v_r^-[S, T] = \max\{z(I) | I \in M_r^-[S, T]\}$, $w_{rk}^+[S, T] = \max\{d_k^+(I) | I \in N_r^+[S+k, T]\}$ and $w_{rk}^-[S, T] = \max\{d_k^-(I) | I \in N_r^-[S, T-k]\}$.

Theorem 6 Let z be a submodular function on $[S, T] \subseteq [\emptyset, N]$ with $k \in T \setminus S$, and let r be a positive integer. Then the following assertions hold:

1. If $|N_r^+[S+k, T]| > 0$, then $z^*[S+k, T] - \max\{z^*[S, T-k], v_r^+[S, T]\} \leq \max\{w_{rk}^+[S, T], 0\}$.
2. If $|N_r^-[S, T-k]| > 0$, then $z^*[S, T-k] - \max\{z^*[S+k, T], v_r^-[S, T]\} \leq \max\{w_{rk}^-[S, T], 0\}$.

Proof Only part 1 is proved since the proof of part 2 is similar. The partition of interval $[S, T]$ may be represented as follows:

$$[S, T] = M_r^+[S, T] \cup \bigcup_{I \in N_r^+[S, T]} [I, T].$$

Using this representation on the interval $[S+k, T]$, we have $z^*[S+k, T] = \max\{v_r^+[S+k, T], \max\{z^*[I+k, T] | I \in N_r^+[S, T]\}\}$. Let $I(k) \in \arg \max\{z^*[I+k, T] | I \in N_r^+[S, T]\}$.

There are two cases to consider: $z^*[I(k)+k, T] \geq v_r^+[S+k, T]$ and $z^*[I(k)+k, T] < v_r^+[S+k, T]$.

In the first case, $z^*[S+k, T] = z^*[I(k)+k, T]$. For $I(k) \in N_r^+[S, T]$, [Theorem 5\(1\)](#) can be applied on the interval $[I(k), T]$ to obtain $z^*[I(k)+k, T] - z^*[I(k), T-k] \leq d_k^+(I(k))$, so that in this case, $z^*[S+k, T] - z^*[I(k), T-k] \leq d_k^+(I(k))$. Note that for $[I(k), T-k] \subseteq [S, T-k]$, we have $z^*[S, T-k] \geq z^*[I(k), T-k]$, which implies that $z^*[S+k, T] - z^*[S, T-k] \leq d_k^+(I(k))$. Adding two maximum operations, we get

$$z^*[S+k, T] - \max\{z^*[S, T-k], v_r^+[S+k, T]\} \leq \max\{d_k^+(I(k)), 0\}.$$

Since $w_{rk}^+[S, T]$ is the maximum of $d_k^+(I)$ for $I \in N_r^+[S+k, T]$, the required result is obtained.

In the second case, $z^*[S+k, T] = v_r^+[S+k, T]$ which implies that $z^*[S+k, T] - v_r^+[S+k, T] = 0$ or $z^*[S+k, T] - \max\{z^*[S, T-k], v_r^+[S+k, T]\} \leq 0$. Adding a maximum operation with $w_{rk}^+[S, T]$ completes the proof. ■

Corollary 4 (Preservation rules of order r) Let z be a submodular function on $[S, T] \subseteq [\emptyset, N]$ and let $k \in T \setminus S$. Then the following assertions hold:

1. *First Preservation Rule of Order r:* If $w_{rk}^+[S, T] \leq 0$, then $z^*[S, T] = \max\{z^*[S, T - k], v_r^+[S + k, T]\} \geq z^*[S + k, T]$.
2. *Second Preservation Rule of Order r:* If $w_{rk}^-[S, T] \leq 0$, then $z^*[S, T] = \max\{z^*[S + k, T], v_r^-[S, T - k]\} \geq z^*[S, T - k]$.

Notice that when [Corollary 3](#) is applied to an interval, a reduced interval is got; however, when [Corollary 4](#) is applied, a value v_r is got in addition to a reduced interval.

It can be proved by induction that the portion of the Hasse diagram eliminated by preservation rules of order $r - 1$ while searching for a maximum of the submodular function will certainly be eliminated by preservation rules of order r . In this sense, preservation rules of order r are not weaker than preservation rules of order $r - 1$ (for a detailed proof for the result that preservation rules of order 1 are not weaker than preservation rules of order 0, refer to Goldengorin [\[38\]](#)).

In order to apply [Corollary 4](#), functions that compute the value of $w_{rk}^+[S, T]$, $w_{rk}^-[S, T]$, $v_r^+[S + k, T]$, and $v_r^-[S, T - k]$ are needed. To that end, two recursive functions are defined, *PPArplus* to compute $w_{rk}^+[S, T]$ and $v_r^+[S + k, T]$ and *PPArminus* to compute $w_{rk}^-[S, T]$ and $v_r^-[S, T - k]$. The pseudocode for *PPArplus* is shown below. Its output is a three-tuple, containing, in order, $w_{rk}^+[S, T]$ and $v_r^+[S + k, T]$, and a solution in $M_r^+[S + k, T]$ whose objective function value is $v_r^+[S + k, T]$. The pseudocode for *PPArminus* can be constructed in a similar manner.

```

function PParplus([S, T], r, k)
1. begin
2.      $w := -\infty$ ;
3.      $v := -\infty$ ;
4.      $vset := \emptyset$ ;
5.      $(w, v, vset) := \text{IntPPArPlus}([S + k, T], r, w, v, vset)$ ;
6.     return  $(w, v, vset)$ ;
7. end;

function IntPPArplus([X, Y], r, w, v, vset)
1. begin
2.     for each  $t \in Y \setminus X$  do begin
3.         if  $z(X + t) > v$  then begin
4.              $v := z(X + t)$ ;
5.              $vset := (X + t)$ ;
6.         end;
7.         if  $d_t^+(X + t) > w$  then  $w := d_t^+(X + t)$ ;
8.         if  $d_t^+(X + t) > 0$  and  $r > 1$  then
9.              $(w, v, vset) := \text{IntPPArPlus}([X + t, Y], r - 1, w, v, vset)$ ;
10.    end;
11.    return  $(w, v, vset)$ ;
12. end;
```

Note that *PPArplus* and *PPArminus* are both $\mathcal{O}(n \binom{n}{r})$, that is, polynomial for a fixed value of r . However, in general, they are not polynomial in r .

PPArplus and *PPArminus* are used to describe the preliminary preservation algorithm of order r (*PPAr*(r)). Given a submodular function z on $[X, Y] \subseteq [\emptyset, N]$, *PPAr* outputs a subinterval $[S, T]$ of $[X, Y]$ and a set B such that $z^*[X, Y] = \max\{z^*[S, T], z(B)\}$ and $\min\{w_{rk}^+[S, T], w_{rk}^-[S, T]\} > 0$ for all $k \in T \setminus S$. At iteration i of the algorithm, when the search has been restricted to $[S_i, T_i]$, the algorithm starts by applying the PP algorithm (from Goldengorin et al. [44]) to this interval and reduces it to $[S'_i, T'_i]$. If $|T'_i \setminus S'_i| > 0$, an element $k \in T'_i \setminus S'_i$ is chosen, and the algorithm tries to apply [Corollary 4\(1\)](#) to decide whether it belongs to the set that maximizes $z(\cdot)$ over $[S_i, T_i]$ or not. If it does, then the search is restricted to the interval $[S'_i + k, T'_i]$. Otherwise, the search tries to apply [Corollary 4\(2\)](#) to decide whether the interval can be reduced to $[S'_i, T'_i - k]$.

Algorithm PPAr($[S, T], r$)

Output: $x^\alpha \in [S, T]$ such that $z(x^\alpha) \geq z^*[S, T] - \alpha$.

Code:

```

1. begin
2.    $X := S, Y := T; B := \arg \max\{z(S), z(T)\};$ 
3.   while  $Y \neq X$  do begin
4.      $[S_i, T_i] := \text{PP}([X, Y]);$ 
5.      $d^+ := \max\{d_k^+(S) | k \in T \setminus S\};$ 
6.      $d^- := \max\{d_k^-(T) | k \in T \setminus S\};$ 
7.     if  $d^+ > d^-$  then begin
8.        $k := \arg \max\{d_t^+(S) | t \in T \setminus S\};$ 
9.        $(w, v, vset) := \text{PPArplus}([S_i, T_i], r, k);$ 
10.      if  $v > z(B)$  then  $B := vset;$ 
11.      if  $w \leq 0$  then  $Y := T_i - k;$ 
12.      else return  $([S_i, T_i], B);$ 
13.    else begin
14.       $k := \arg \max\{d_t^-(S) | t \in T \setminus S\};$ 
15.       $(w, v, vset) := \text{PPArminus}([S_i, T_i], r, k);$ 
16.      if  $v > z(B)$  then  $B := vset;$ 
17.      if  $w \leq 0$  then  $X := S_i + k;$ 
18.      else return  $([S_i, T_i], \{w_{ri}^+[S_i, T_i]\}, \{w_{ri}^-[S_i, T_i]\}, B);$ 
19.    end;
20.  end;
21. end.
```

It is clear that if $r = |T \setminus S|$, then *PPAr* will always find an optimal solution to the given problem. However, *PPAr* is not a polynomial in r , and so *PPAr* with a large r is not practically useful.

PPAr can be embedded in a branch-and-bound framework to describe DCA-MSFr, a data-correcting algorithm based on *PPAr*. It is similar to the DCA-MSF proposed in Goldengorin et al. [44]. For DCA-MSFr, a submodular function z to be maximized over an interval $[S, T]$ and an accuracy parameter α are given, and it is needed to find a solution such that the difference between the objective function values of the solution output by DCA-MSFr and the optimal solution will not exceed α .

Notice that for a submodular function z , PPar with a fixed r may terminate with $T \neq S$ and $\min\{w_{ri}^+[S, T], w_{ri}^-[S, T] \mid i \in T \setminus S\} = \omega > 0$. The basic idea behind DCA-MSFr is that if this situation occurs, then the data of the current problem is corrected in such a way that ω is nonpositive for the corrected function and PPar can continue. Moreover, each correction of z needs to be carried out in such a way that the corrected function remains submodular. The attempted correction is carried out implicitly, in a manner similar to the one in Goldengorin et al. [44] but using Corollary 4 instead of Corollary 3. Thus, for example, if $w_{rj}^+[S, T] = \omega \leq \alpha$, then PPar is allowed to continue, but the accuracy parameter is reduced to $\alpha - \omega$.

If such a correction is not possible, that is, if ω exceeds the accuracy parameter, then it is branched on a variable $k \in \arg \max\{d_i^+(S), d_i^-(T) | i \in T \setminus S\}$ to partition the interval $[S, T]$ into two intervals $[S + k, T]$ and $[S, T - k]$. This branching rule was proposed in Goldengorin [33]. An upper bound for the value of z for each of the two intervals is then computed to see if either of the two can be pruned. The use of an upper bound due to Khachaturov [53] is described as follows. Let $d^+(S, T) = \{d_i^+(S) | d_i^+(S) > 0, i \in T \setminus S\}$ and $d^-(S, T) = \{d_i^-(T) | d_i^-(T) > 0, i \in T \setminus S\}$. Further, let $d^+[i]$ (respectively $d^-[i]$) denote the i -th largest element of $d^+(S, T)$ (respectively $d^-(S, T)$). Then ub described below is an upper bound to $z^*[S, T]$.

$$ub[S, T] = \max \left\{ \min_{i=1, \dots, |T \setminus S|} \left\{ z(S) + \sum_{j=1}^i d^+[j], z(T) + \sum_{j=1}^i d^-[j] \right\} \right\}.$$

The following pseudocode describes DCA-MSFr formally.

Algorithm DCA-MSFr($[S, T]$, α , r)

- ```

1. begin
2. $best_set := \arg \max\{z(S), z(T)\};$
3. $best := z(best_set);$
4. $(best_set, best) := \text{IntDCA-MSFr}([S, T], \alpha, r, best_set, best);$
5. return $best_set;$
6. end.

```

**function** IntDCA-MSFr( $[S, T]$ ,  $\alpha, r, best\_set, best$ )

- ```

1. begin
2.    $([S, T], \{w_{rk}^+\}, \{w_{rk}^-\}, B) := \text{PPAr}([S, T], r);$ 
3.   if  $z(B) > best$  then begin
4.      $best\_set := B;$ 
5.      $best := z(B);$ 
6.   end;
7.   if  $S = T$  return ( $best\_set, best$ );
8.    $\omega^+ := \max\{w_{rk}^+[S, T] | k \in T \setminus S\};$ 
9.   choose  $j^+$  from  $\min\{k | w_{rk}^+[S, T] = \omega^+, k \in T \setminus S\};$ 
10.   $\omega^- := \max\{w_{rk}^-[S, T] | k \in T \setminus S\};$ 
11.  choose  $j^-$  from  $j^- := \min\{k | w_{rk}^-[S, T] = \omega^-, k \in T \setminus S\};$ 
12.  if  $\omega^+ \leq \alpha$  then (* Correction *)
13.    IntDCA-MSFr( $[S + j^+, T], \alpha - \omega^+, r, best\_set, best$ );

```

```

14.      else if  $\omega^- \leq \alpha$  then                                (* Correction *)
15.          IntDCA-MSFr([S, T - j^-],  $\alpha - \omega^-$ , r, best_set, best);
16.      else begin                                         (* Branch [S, T] → [S + k, T], [S, T - k] *)
17.          choose k from arg max{ $d_i^+(S), d_i^-(T)$  |  $i \in T \setminus S$ };
18.          if ub[S + k, T] > best then begin                  (* Bound *)
19.              ( $bs_1, b_1$ ) := IntDCA-MSFr([S + k, T],  $\alpha, r, best\_set, best$ );
20.              if  $b_1 > best$  then begin
21.                  best_set :=  $bs_1$ ;
22.                  best :=  $b_1$ ;
23.              end;
24.          end;
25.          if ub[S, T - k] > best then begin                  (* Bound *)
26.              ( $bs_2, b_2$ ) := IntDCA-MSFr([S, T - k],  $\alpha, r, best\_set, best$ );
27.              if  $b_2 > best$  then begin
28.                  best_set :=  $bs_2$ ;
29.                  best :=  $b_2$ ;
30.              end;
31.          end;
32.      end;
33.  end;

```

5.3 Computational Experience with Quadratic Cost Partition Instances

In this section, the computational experience with DCA-MSFr is reported. The quadratic cost partition problem is chosen as a test bed. The quadratic cost partition (QCP) problem can be described as follows (see, e.g., [59]). Given nonnegative real numbers q_{ij} and real numbers p_i with $i, j \in N = \{1, 2, \dots, n\}$, the QCP is the problem of finding a subset $S \subseteq N$ such that the function $z(S) = \sum_{j \in S} p_j - \frac{1}{2} \sum_{i,j \in S} q_{ij}$ will be maximized. The density d of a QCP instance is the ratio of the number of finite q_{ij} values to $n(n - 1)/2$ and is expressed as a percentage. It is proved in Theorem 2.2 of Lee et al. [59] that $z(\cdot)$ is submodular.

In Goldengorin et al. [44], computational experiments with QCP have been restricted to instances of size not more than 80 because instances of that size have been considered in Lee et al. [59]. For these instances, it was shown that the average calculation times grow exponentially when the number of vertices increases and reduces exponentially with increasing density.

Herein, the performance of DCA-MSFr on QCP instances of varying size and densities is reported. The maximum time allowed for an instance is 10 CPU minutes on a personal computer running on a 300-MHz Pentium processor with 64-MB memory. The algorithms have been implemented in Delphi 3.

The instances on which the described algorithms are tested are statistically similar to the instances in Lee et al. [59]. Instances of size n and density $d\%$ are generated as follows. A graph with n nodes and $\frac{d}{100} \times \frac{n(n-1)}{2}$ random edges is generated. The edges are assigned costs from a $\mathcal{U}[1, 100]$ distribution. n edges connect each node to itself, and these edges are assigned costs from a $\mathcal{U}[0, 100]$ distribution. The distance matrix of this graph forms a QCP instance.

Fig. 8 Average number of subproblems generated against r for QCP instances with $n = 100$ and varying d values

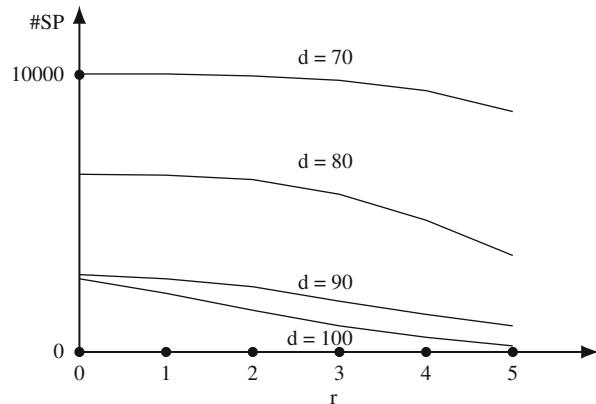

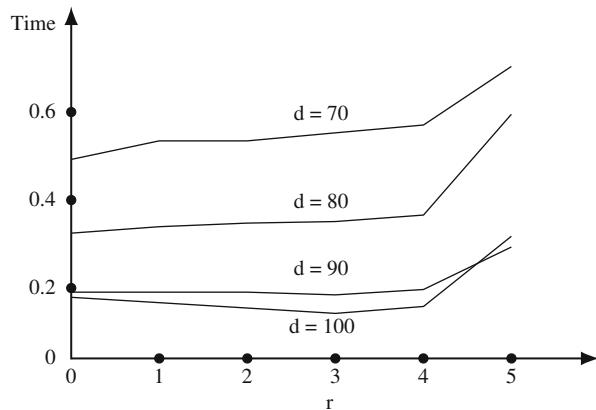

Fig. 9 Average execution time (in seconds) against r for QCP instances with $n = 100$ and varying d values

First, the effect of varying the value of r on the performance of DCA-MSFr(r) is reported. It is intuitive that DCA-MSFr(r) will require more execution times when the value of r increases. The computation experience with 10 QCP instances of size 100 and different densities is shown in Figs. 8–10. Figure 8 shows the number of subproblems generated when r is increased from a value of 0 (i.e., DCA-MSF) to 5. As is intuitive, the number of subproblems is reduced with increasing r for all density values. Figure 9 shows the execution times of DCA-MSFr(r) with varying d and r values. Recall that when the value of r increases, the time required at each subproblem increases, since PPAR requires more computations for larger r values. The decrease in the number of subproblems approximately balances the increase in the time at each subproblem for r values in the range 0 through 4. When $r = 5$, the computation times for DCA-MSFr(r) increase significantly for all density values. From Fig. 9, it seems that for dense graphs, r values of 3 or 4 are most favorable. This effect also holds for larger instances – Fig. 10 shows the execution times for instances with $n = 200$ and $d = 100$.

Fig. 10 Average execution time (in seconds) against r for QCP instances with $n = 200$ and $d = 100$

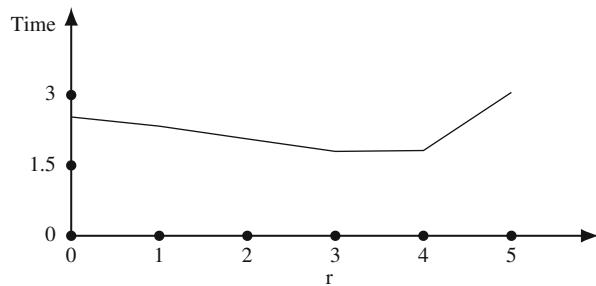

Table 15 Average execution times on QCP instances when $\alpha = 0\%$

Density(%)	Algorithm	Problem size (n)				
		100	200	300	400	500
100	DCA-MSFr(3)	0.098	2.63	18.316	85.827	229.408
	DCA-MSF	0.831	64.372	340.681	1,894.811	*
90	DCA-MSFr(3)	0.138	3.824	37.931	173.063	624.925
	DCA-MSF	1.027	78.614	794.037	3,505.892	*
80	DCA-MSFr(3)	0.28	9.506	98.69	679.914	*
	DCA-MSF	1.784	217.898	2,681.973	*	*
70	DCA-MSFr(3)	0.393	17.643	413.585	*	*
	DCA-MSF	2.498	631.492	*	*	*
60	DCA-MSFr(3)	0.731	86.33	*	*	*
	DCA-MSF	3.509	1,414.103	*	*	*
50	DCA-MSFr(3)	1.752	345.723	*	*	*
	DCA-MSF	9.382	*	*	*	*
40	DCA-MSFr(3)	3.457	*	*	*	*
	DCA-MSF	17.245	*	*	*	*
30	DCA-MSFr(3)	11.032	*	*	*	*
	DCA-MSF	48.013	*	*	*	*
20	DCA-MSFr(3)	47.162	*	*	*	*
	DCA-MSF	195.82	*	*	*	*
10	DCA-MSFr(3)	70.081	*	*	*	*
	DCA-MSF	446.293	*	*	*	*

Next, the results of the experiments to solve large-sized QCP instances with DCA-MSFr(r) are reported. Using the results obtained from the previous part of the study, DCA-MSFr(3) was chosen to be used as the algorithm of choice. For consideration, instances of the QCP with size n ranging from 100 to 500 and densities varying between 10 and 100 % have been chosen. These instances were tried to be solved exactly ($\alpha_0 = 0\%$), and with a prescribed accuracy $\alpha_0 = 5\%$ within 10 min. Tables 15 and 16 contain the average execution times in seconds for exact and approximate solutions with DCA-MSFr(3) and DCA-MSF. The entries marked “*” could not be solved within 10 min. From the table, it is possible to note that the execution times increase exponentially with increasing problem size

Table 16 Average execution times on QCP instances when $\alpha = 5\%$

Density(%)	Algorithm	Problem size (n)				
		100	200	300	400	500
100	DCA-MSFr(3)	0.094	2.444	17.179	85.096	222.883
	DCA-MSF	0.752	38.351	229.396	1,162.396	*
90	DCA-MSFr(3)	0.118	3.607	34.972	166.996	608.755
	DCA-MSF	0.916	49.926	583.754	1,996.544	*
80	DCA-MSFr(3)	0.228	8.186	89.685	580.789	*
	DCA-MSF	1.108	162.455	1,875.603	3,604.715	*
70	DCA-MSFr(3)	0.304	15.693	364.48	*	*
	DCA-MSF	1.593	376.629	3,165.384	*	*
60	DCA-MSFr(3)	0.517	72.931	*	*	*
	DCA-MSF	2.874	895.426	*	*	*
50	DCA-MSFr(3)	1.298	267.445	*	*	*
	DCA-MSF	5.931	1,937.673	*	*	*
40	DCA-MSFr(3)	2.179	*	*	*	*
	DCA-MSF	10.327	*	*	*	*
30	DCA-MSFr(3)	5.88	*	*	*	*
	DCA-MSF	22.209	*	*	*	*
20	DCA-MSFr(3)	17.477	*	*	*	*
	DCA-MSF	74.841	*	*	*	*
10	DCA-MSFr(3)	12.196	*	*	*	*
	DCA-MSF	95.122	*	*	*	*

and decreasing problem densities. Therefore, QCP instances with 500 vertices and densities between 90 and 100 % are the largest instances which can be solved by the DCA-MSFr(3) within 10 min on a standard personal computer. It is also seen that on average DCA-MSFr(3) takes roughly 11 % of the time taken by DCA-MSF for the exact solutions and roughly 13 % of the time taken by DCA-MSF for the approximate solutions. The reduction in time is more pronounced for problems with higher size and higher densities.

6 Conclusion

This chapter is concluded by the following fragment cited from Benati [10] “In (Goldengorin et al., [44]) a new branch and bound scheme to solve the submodular function maximization is proposed. It outperforms previous algorithms, such as branch and cut methods, in the max-cut problem solution. The algorithm is called data correcting method (DC-method), because it tries to obtain a polynomially solvable instance of the general problem by modifying the original data, and then the upper bound of the objective function of the original problem is calculated by the corrected instance. This method was developed by Russian scientists in the 70s. In this paper, the DC method is applied to the UCFLP with probabilistic customers.”

The first paper with successful application of data-correcting approach to solve a real-world assortment problem is published in Goldengorin [31].

Abstract

The notion of total dual integrality and its variants are powerful tools to derive combinatorial min–max relation efficiently, yielding many fundamental results in combinatorial optimization. Following the pioneering work of Edmonds and Gales (A min–max relation for submodular functions on graphs, in *Annals of Discrete Mathematics*, vol. 1, North-Holland, Amsterdam, 1977, pp. 185–204), considerable research efforts have been devoted to the study of the dual integrality from theoretical and algorithmic points of view. This chapter reviews significant progresses that have been made since the publication of Schrijver’s celebrated monograph (*Combinatorial Optimization - Polyhedra and Efficiency*, Springer, Berlin, 2003), which contained a comprehensive and in-depth treatment of the state-of-the-art in dual integrality theory and its application, among many others.

1 Introduction

Many important combinatorial optimization problems, such as stable matching, facility location, and pattern recognition can be naturally formulated as integer linear programs, most of which are known to be NP-hard. One approach to getting around these problems is to consider corresponding linear programming (LP) relaxations and explore integrality properties satisfied by their constraints.

Definition 1 A rational system $A\mathbf{x} \geq \mathbf{b}$, $\mathbf{x} \geq \mathbf{0}$ of linear inequalities is *integral* or equivalently the polyhedron $P = \{\mathbf{x} : A\mathbf{x} \geq \mathbf{b}, \mathbf{x} \geq \mathbf{0}\}$ is *integral* if all extreme points of P are integral.

It is well known that polyhedron P is integral if and only if the minimum in the LP-duality equation

$$\min\{\mathbf{w}^T \mathbf{x} : A\mathbf{x} \geq \mathbf{b}, \mathbf{x} \geq \mathbf{0}\} = \max\{\mathbf{y}^T \mathbf{b} : \mathbf{y}^T A \leq \mathbf{w}^T, \mathbf{y} \geq \mathbf{0}\} \quad (1)$$

has an integral optimal solution, for every integral vector \mathbf{w} for which the optimum is finite. If, instead, the maximum in the equation enjoys this property, then the system $A\mathbf{x} \geq \mathbf{b}$, $\mathbf{x} \geq \mathbf{0}$ is associated with total dual integrality.

Definition 2 A rational system $Ax \geq b, x \geq \mathbf{0}$ of linear inequalities is *totally dual integral (TDI)* if the maximum in (1) has an integral solution y , for every integral vector w for which the maximum is finite. The system $Ax \geq b, x \geq \mathbf{0}$ is called *box-totally dual integral (box-TDI)* if $Ax \geq b, x \geq \mathbf{0}, u \geq x \geq l$ is TDI for all rational vectors u and l , where coordinates of u are allowed to be $+\infty$.

The model of TDI systems and box-TDI systems plays a crucial role in combinatorial optimization and serves as a general framework for establishing various min–max theorems because total dual integrality implies primal integrality (shown by Edmonds and Giles [41]) and box-total dual integrality implies total dual integrality (shown by Schrijver [101]).

Theorem 1 Let π denote the linear system $Ax \geq b, x \geq \mathbf{0}$. (i) If π is TDI and b is integral, then π is integral. (ii) If π is box-TDI, then π is TDI.

Under what conditions do these dual integrality and/or their variants hold? This question is of both great theoretical interest and practical value; it is also the major concern of polyhedral combinatorics (see, e.g., [102]). Many celebrated results and conjectures in combinatorial optimization can be rephrased by saying that certain systems are TDI or box-TDI. Since its introduction by Edmonds and Giles [41], extensive research on total dual integrality and its variants, referred to collectively in this chapter as *dual integrality*, has brought about a variety of exciting results, as well as challenges, on theory and applications. Many of the deepest results in this area come in “excluded minor” flavor, while their proofs often employ “decomposition” characterizations to decompose the combinatorial structures to building blocks and make use of “sum” operations to recover the whole pictures.

In 2003, Schrijver published a three-volume monograph [103] giving a comprehensive review of the state-of-the-art of those topics on dual integrality in combinatorial optimization. Since then ten years have passed, during which significant progresses have been made on both the theoretical side and the algorithmic side. The main purpose of this chapter is to give a brief overview of the recent progress on the dual integrality theory and its applications that were not included in [103], putting emphasis on the study of hypergraphs in the context of packing and covering.

Chapter Outline. Section 2 provides preliminaries for dual integrality, as well as graphs and matroids. Section 3 discusses complexity issues for recognizing (box)-TDI systems and packing feedback vertex sets. Section 4 presents a unified approach to establishing box-Mengerian hypergraphs and reviews box-TDI systems (not) falling within this general framework. Section 5 exhibits in separate subsections TDI systems established by publications over the last decade. Section 6 deals with dual half-integrality, which is a natural relaxation of dual integrality, and has interesting real-world applications. Section 7 concludes this chapter by commenting on some missing topics and pointing out several future research directions.

2 Preliminaries

The reader is assumed to be familiar with basic polyhedral theory; see Sect. 5 of [103] for an introduction to this subject. This chapter discusses mainly the (box-)total dual integrality for linear systems of form $Ax \geq b, x \geq 0$, in view that typical combinatorial optimization problems either minimize over this kind of systems or maximize over their duals (cf. the LP-duality equation (1)). Generalizing Definition 2, TDI and box-TDI systems are defined as follows.

Definition 3 A rational system $Ax \geq b$ is said to be *TDI* if for every integral vector w , the dual of minimizing $w^T x$ over $Ax \geq b$: $\max\{y^T b : y^T A = w^T, y \geq 0\}$ has an integral optimal solution y , provided the optimum is finite. A rational $Ax \geq b$ is *box-TDI* if $Ax \geq b, u \geq x \geq l$ is TDI for all rational vector u and l , where coordinates of u and l are allowed to be $+\infty$ or $-\infty$.

The present section is divided into five subsections. Section 2.1 presents two classical sufficient conditions, one of which is also necessary, for linear systems to be box-TDI. Section 2.2 generalizes the classical concepts of TDI and box-TDI systems to their fractional $\frac{1}{d}$ -counterparts. Implication relations among dual integral properties are also discussed. Section 2.3 rephrases dual integrality in the context of hypergraphs and clutters, defining the notion of (box-)Mengerian hypergraph which is naturally and closely related to min-max relation in combinatorial optimization. Section 2.4 discusses operations on linear systems that preserve (box-)total dual integrality. Section 2.5 gives preliminaries on graph theory and matroid theory.

2.1 Two Classical Theorems

Schrijver [100] analyzed proof techniques of a number of classical min–max theorems, such as the max-flow min-cut theorem, the Lucchesi–Younger theorem [82], and the Fulkerson’s optimal arborescence theorem [58], and observed that these proofs essentially proceed by showing that, first, the active constraints in the optimum of the LP relaxation of the problem in consideration can be chosen to be “nice,” say “cross-free” or “laminar”; second, these nice constraint sets are totally unimodular. Based on this observation, Schrijver proved the following general theorem (see Theorem 5.35 in [103]), which implies that the above-mentioned min–max theorems can all be further strengthened with box-TDI properties:

Theorem 2 *Let $Ax \geq b$ be a linear system. Suppose that for any rational vector c , the program $\min\{c^T x : Ax \geq b\}$ has (if finite) an optimal dual solution y such that the rows of A corresponding to positive components of y form a totally unimodular submatrix of A . Then $Ax \geq b$ is box-TDI.*

Let \mathbb{R} , \mathbb{Q} , and \mathbb{Z} denote the sets of real numbers, rational numbers, and integers, respectively; let \mathbb{R}_+ , \mathbb{Q}_+ , and \mathbb{Z}_+ denote the sets of nonnegative numbers in the

corresponding sets. For any two sets Ω and K , where Ω is always a set of numbers and K is always finite, symbol Ω^K denotes the set of vectors $\mathbf{x} = (x(k) : k \in K)$ whose coordinates are members of Ω . Given $\mathbf{x} \in \Omega^K$, the vectors $(\lfloor x_k \rfloor : k \in K)$ and $(\lceil x_k \rceil : k \in K)$ are written as $\lfloor \mathbf{x} \rfloor$ and $\lceil \mathbf{x} \rceil$, respectively. The next is a characterization of box-TDI systems due to Cook [25] (cf. Corollary 22.9a of [101]).

Theorem 3 *A rational system $A\mathbf{x} \geq \mathbf{b}$ defined on \mathbb{R}^n is box-TDI if and only if it is TDI and for every $\mathbf{w} \in \mathbb{Q}^n$ there exists $\tilde{\mathbf{w}} \in \mathbb{Z}^n$ such that $\lfloor \mathbf{w} \rfloor \leq \tilde{\mathbf{w}} \leq \lceil \mathbf{w} \rceil$ and such that each optimal solution of $\min\{\mathbf{w}^\top \mathbf{x} : A\mathbf{x} \geq \mathbf{b}\}$ is also an optimal solution of $\min\{\tilde{\mathbf{w}}^\top \mathbf{x} : A\mathbf{x} \geq \mathbf{b}\}$.*

Almost all known box-TDI systems can be verified via totally unimodular matrices (cf. [Theorem 2](#)) or the ESP property to be discussed in [Sect. 4](#) (cf. [Theorem 14](#)), but the box-TDI system associated with 2-edge-connected spanning subgraphs [19] is an exception (cf. [Theorems 45](#) and [46](#)), where the proof relied heavily on the above Cook's Theorem ([Theorem 3](#)).

2.2 Dual $1/d$ -Integrality

In this chapter, symbol “ d ” is reserved for representing a positive integer; adjectives “ $\frac{1}{d}$ -” and “half-” are used interchangeably. A real vector \mathbf{x} is $\frac{1}{d}$ -integral if all coordinates of $d\mathbf{x}$ are integers. This subsection discusses briefly moderate relaxations on primal and dual integrality (cf. [Definitions 1](#) and [2](#)), which give “primal” (box-) $\frac{1}{d}$ -integrality (see [Definitions 4](#) and [6](#)), and (box-)total dual $\frac{1}{d}$ -integrality (see [Definition 5](#)).

Definition 4 A rational system $A\mathbf{x} \geq \mathbf{b}, \mathbf{x} \geq \mathbf{0}$ of linear inequalities is $\frac{1}{d}$ -integral or equivalently the polyhedron $P = \{\mathbf{x} : A\mathbf{x} \geq \mathbf{b}, \mathbf{x} \geq \mathbf{0}\}$ is $\frac{1}{d}$ -integral if all extreme points of P are $\frac{1}{d}$ -integral.

Definition 5 A linear system $A\mathbf{x} \geq \mathbf{b}, \mathbf{x} \geq \mathbf{0}$ is called totally dual $\frac{1}{d}$ -integral ($\frac{1}{d}$ -TDI) if the maximum in the LP-duality equation (1) has a $\frac{1}{d}$ -integral optimal solution, for every integral vector \mathbf{w} for which the optimum is finite. Furthermore, the system is called box-totally dual $\frac{1}{d}$ -integral (box- $\frac{1}{d}$ -TDI) if $A\mathbf{x} \geq \mathbf{b}, \mathbf{x} \geq \mathbf{0}, \mathbf{u} \geq \mathbf{x} \geq \mathbf{l}$ is $\frac{1}{d}$ -TDI for all rational vectors \mathbf{u} and \mathbf{l} , where coordinates of \mathbf{u} are allowed to be $+\infty$.

Similar to the Edmonds–Giles theorem [41] (see [Theorem 1\(i\)](#)), from total dual $\frac{1}{d}$ -integrality, one can derive $\frac{1}{d}$ -integrality, provided the system has an integral right-hand-side vector.

Theorem 4 *If $A\mathbf{x} \geq \mathbf{b}, \mathbf{x} \geq \mathbf{0}$ is a $\frac{1}{d}$ -TDI system and \mathbf{b} is integral, then $A\mathbf{x} \geq \mathbf{b}, \mathbf{x} \geq \mathbf{0}$ is $\frac{1}{d}$ -integral.*

Proof It suffices to show that $\min\{w^T x : Ax \geq b, x \geq 0\}$ has a $\frac{1}{d}$ -integral optimal solution for any integral w such that the optimal value of $\min\{w^T x : Ax \geq b, x \geq 0\}$ is finite (cf. Sect. 5.15 of [103] or Sect. 1.1 of [28]). Note from the definition of the $\frac{1}{d}$ -TDI system that $\max\{y^T(\frac{1}{d}b) : y^T(\frac{1}{d}A) \leq w^T, y \geq 0\}$ has an integral optimal solution; this solution is obviously an optimal solution to $\max\{y^T b : y^T(\frac{1}{d}A) \leq w^T, y \geq 0\}$. It follows from [Definition 5](#) that $\frac{1}{d}Ax \geq b$, $x \geq 0$ is TDI and further from [Theorem 1\(i\)](#) that $\min\{w^T x : \frac{1}{d}Ax \geq b, x \geq 0\}$ has an integral optimal solution x^* . It is easy to see that $\frac{1}{d}x^*$ is a $\frac{1}{d}$ -integral optimal solution to $\min\{w^T x : Ax \geq b, x \geq 0\}$. \square

For brevity, given linear system $Ax \geq b$, $x \geq 0$, $u \geq x \geq l$ and vector w , let $\text{Min}(A, b, l, u, w)$ and $\text{Max}(A, b, l, u, w)$ denote the minimization problem and maximization problem, respectively, in the LP-duality equation

$$\begin{aligned} \min\{w^T x : Ax \geq b, x \geq 0, u \geq x \geq l\} &= \max\{\alpha^T \mathbf{1} + \beta^T l - \gamma^T u \\ &\quad : \alpha^T A + \beta^T - \gamma^T \leq w^T, \alpha, \beta, \gamma \geq 0\} \end{aligned}$$

Lemma 1 *If linear system $\frac{1}{d}Ax \geq b$, $x \geq 0$ is box-TDI, then the linear system $Ax \geq b$, $x \geq 0$ is box- $\frac{1}{d}$ -TDI.*

Proof For any integral w and rational u, l , the box-TDI-ness says that $\text{Max}(\frac{1}{d}A, b, dl, du, w)$ has an integral optimal solution (y^*, α^*, β^*) , which is obviously an integral optimal solution to $\text{Max}(\frac{1}{d}A, \frac{1}{d}b, l, u, w)$. It follows that $(\frac{1}{d}y^*, \alpha^*, \beta^*)$ is a $\frac{1}{d}$ -integral optimal solution to $\text{Max}(A, b, l, u, w)$ as desired. \square

Lemma 2 *If linear system $Ax \geq b$, $x \geq 0$ is box- $\frac{1}{d}$ -TDI, then $\frac{1}{d}Ax \geq b$, $u \geq x \geq l$ is integral for all rational u and l .*

Proof For any integral w and rational u, l , the box- $\frac{1}{d}$ -TDI-ness of $Ax \geq b$, $x \geq 0$ and [Theorem 4](#) imply that $\text{Min}(A, b, \frac{1}{d}l, \frac{1}{d}u, dw)$ has a $\frac{1}{d}$ -integral optimal solution x^* . It follows that dx^* is an integral solution to $\text{Min}(\frac{1}{d}A, b, l, u, w)$ as desired. \square

Gerards and Laurent [62] proposed the concept of box- $\frac{1}{d}$ -integrality of a linear system (and its associated polyhedron), which is evidently stronger than integrality, and can be derived from box-total dual integrality as shown by Chen et al. [20].

Definition 6 A linear system $Ax \geq b$, $x \geq 0$ or equivalently polyhedron $\{x : Ax \geq b, x \geq 0\}$ is called *box- $\frac{1}{d}$ -integral* if $Ax \geq b$, $x \geq 0$, $u \geq x \geq l$ is $\frac{1}{d}$ -integral for all $\frac{1}{d}$ -integral vectors u and l .

Lemma 3 *If $Ax \geq b$, $x \geq 0$ is a box-TDI system and b is integral, then $Ax \geq b$, $x \geq 0$ is box- $\frac{1}{d}$ -integral, for every integer $d > 0$.*

2.3 Hypergraphs

In this chapter, a *collection* is a synonym of a multiset in which elements may occur more than once. So if $\Lambda = \{\lambda_1, \lambda_2, \dots, \lambda_m\}$ is a collection, then possibly $\lambda_i = \lambda_j$ for some distinct i, j . In contrast, in a *set* and in a *subset* (of a collection), all its elements are distinct. The *size* $|\Lambda|$ of Λ is defined to be m . The union of two collections Λ_1 and Λ_2 , written as $\Lambda_1 \cup \Lambda_2$, is the collection where the multiplicity of every element is the sum of its multiplicities in Λ_1 and Λ_2 . A *family of sets* is a collection of subsets of some given ground set.

A rich variety of combinatorial optimization problems falls within the general framework of *packing* and *covering* in hypergraphs for which total dual integrality is rephrased as the so-called Mengerian property [36, 62, 103].

Definition 7 A *hypergraph* is a pair $\mathcal{H} = (V, \mathcal{E})$, where V is a finite set and \mathcal{E} is a collection of subsets of V . Elements of V and \mathcal{E} are called the *nodes* and *hyperedges* of \mathcal{H} , respectively. A *clutter* is a hypergraph in which no hyperedge is contained in another one. A hypergraph is often referred to as the hypergraph of its hyperedges.

Definition 8 Let $\mathcal{H} = (V, \mathcal{E})$ be a hypergraph and let w be a nonnegative integral *weight* function (vector) defined on V . A collection \mathcal{F} of hyperedges in \mathcal{E} is called a w -*packing* of \mathcal{H} (or hyperedges of \mathcal{H}) if each $v \in V$ belongs to at most $w(v)$ members of \mathcal{F} . A node subset U of V is called a *node cover* of \mathcal{H} if U intersects all hyperedges in \mathcal{E} . Let $\nu(\mathcal{H}, w)$ denote the maximum size of a w -packing of \mathcal{H} , and let $\tau(\mathcal{H}, w)$ denote the minimum total weight of a node cover of \mathcal{H} . The integers $\nu(\mathcal{H}, w)$ and $\tau(\mathcal{H}, w)$ are referred to as *w-packing number* and *w-covering number* of \mathcal{H} , respectively.

Let A be the V - \mathcal{E} incidence matrix of hypergraph \mathcal{H} . Then a w -packing and a node cover of \mathcal{H} correspond to an integral solution of the maximization and that of the minimization in (1), respectively. So, the weak duality theorem of linear programming implies that

$$\nu(\mathcal{H}, w) \leq \tau(\mathcal{H}, w). \quad (2)$$

This inequality, however, needs not hold equality in general. As a matter of fact, the ratio of $\nu(\mathcal{H}, w)$ over $\tau(\mathcal{H}, w)$ can be arbitrarily close to 0 even when $w = \mathbf{1}$, the all one vector, as shown by Erdős and Pósa [43].

A hypergraph \mathcal{H} is called *Mengerian* if the min–max relation $\nu(\mathcal{H}, w) = \tau(\mathcal{H}, w)$ is satisfied by any nonnegative integral function w defined on V . (3)

It follows from [Theorem 1\(i\)](#) that \mathcal{H} is Mengerian if and only if $Ax \geq \mathbf{1}$, $x \geq \mathbf{0}$ is a TDI system. From the strong combinatorial feature of hypergraphs, one can see

that the total dual integrality is a common framework to prove a bunch of min–max relations in combinatorial optimization.

Definition 9 Let $\mathcal{H} = (V, \mathcal{E})$ be a hypergraph, and let A be the \mathcal{E} - V incidence matrix of \mathcal{H} .

- (i) \mathcal{H} is *ideal* if the system $Ax \geq \mathbf{1}, x \geq \mathbf{0}$ is integral.
- (ii) \mathcal{H} is *Mengerian* if the system $Ax \geq \mathbf{1}, x \geq \mathbf{0}$ is TDI
- (iii) \mathcal{H} is *box-Mengerian* if the system $Ax \geq \mathbf{1}, x \geq \mathbf{0}$ is box-TDI.

Mengerian hypergraphs [62, 103, 107] are also known as hypergraphs of the *max-flow min-cut property* [107]. They derive the “Mengerian” name from the following interpretation [20]. Given a graph $G = (V, E)$ together with two distinct vertices s and t in V , let \mathcal{H} be the hypergraph with node set E and hyperedge set consisting of the edge sets of all st -paths in G . Then the statement “ \mathcal{H} is Mengerian” is exactly the edge version of Menger’s Theorem (see Corollary 9.1b of [103]). The notion of idealness is also known as the *width-length property* (A. Lehman, 1981, On the width-length inequality and degenerate projective planes, unpublished manuscript), the *weak max-flow min-cut property* [107], or the \mathcal{Q}_+ -*MFMC property* [99]. The following corollary of [Theorem 1](#) says that box-Mengerian property implies Mengerian property, and Mengerian property implies idealness.

Corollary 1 (i) Every box-Mengerian hypergraph is Mengerian.
(ii) Every Mengerian hypergraph is ideal.

The following simple clutters (cf. [Definition 7](#)) will act as excluded minors (cf. [Definition 12](#)) in characterizing Mengerian and box-Mengerian hypergraphs; see for instance [Corollaries 4](#) and [5](#).

Example 1 None of the following clutters is box-Mengerian:

- (i) Clutter $C_3 = (\{1, 2, 3\}, \{\{1, 2\}, \{2, 3\}, \{1, 3\}\})$ is not ideal.
- (ii) Clutter $Q_6 = (\{1, 2, 3, 4, 5, 6\}, \{\{1, 3, 5\}, \{1, 2, 6\}, \{2, 3, 4\}, \{4, 5, 6\}\})$ = (the edge set of K_4 , {edge sets of triangles in K_4 }) is ideal but not Mengerian (see, e.g., [107]), where K_4 denotes the complete graph on four vertices.
- (iii) Clutter $Q_7 = (\{1, 2, 3, 4, 5, 6, 7\}, \{\{1, 4, 7\}, \{2, 5, 7\}, \{3, 6, 7\}, \{1, 2, 6, 7\}, \{1, 3, 5, 7\}, \{2, 3, 4, 7\}, \{4, 5, 6, 7\}\})$ is Mengerian but not box-Mengerian (see Lemma 2.1 of [20]).

Every hypergraph $\mathcal{H} = (V, \mathcal{E})$ is associated with a clutter $\mathcal{H}^{\min} = (V, \{F \in \mathcal{E} : \nexists F' \in \mathcal{E} \text{ with } F' \subset F\})$. The following easy observation legitimizes switching between “hypergraphs” and “clutters” whichever is more convenient for stating total dual integrality:

Observation 1 \mathcal{H} is Mengerian (resp. box-Mengerian) if and only if so is \mathcal{H}^{\min} .

Definition 10 The blocker $b(\mathcal{H})$ of a hypergraph \mathcal{H} is the hypergraph which has node set the same as \mathcal{H} and hyperedge set consist of all inclusionwise minimal node covers of \mathcal{H} (cf. Definition 8). A clutter and its blocker form a *blocking pair* in the sense that the blocker of the blocker of a clutter is the clutter itself.

More generally, one can easily show that $b(b(\mathcal{H})) = \mathcal{H}^{\min}$ holds for all hypergraphs \mathcal{H} [40]. The blocking pair Q_6 (see Example 1(ii)) and its blocker $b(Q_6)$ often occur in counterexamples of min–max relations on packing and covering (see, e.g., [107] and Sect. 4.4 of this chapter).

Example 2 Clutter $b(Q_6) = (E(K_4), \mathcal{E})$ has its node set the edge set of K_4 and its hyperedge set \mathcal{E} consist of the triangles and perfect matchings of K_4 . It has been well known that $b(Q_6)$ is Mengerian (see, e.g., [103, 107]).

It is clear from Definition 10 that the blocker of any hypergraph is a clutter. Let \mathcal{H} be a hypergraph with hyperedge-node incidence matrix A . Observe that the polytope

$$B(\mathcal{H}) = \{x : Ax \geq \mathbf{1}, \mathbf{1} \geq x \geq \mathbf{0}\} \quad (4)$$

contains all incidence vectors of node covers of \mathcal{H} . For this reason, the polytope $B(\mathcal{H})$ is often referred to as the *fractional node cover polytope* of \mathcal{H} and as the *node cover polytope* of \mathcal{H} if $B(\mathcal{H})$ is integral. It follows from Corollary 1 that if $\mathcal{H} = (V, \mathcal{E})$ is Mengerian, then $B(\mathcal{H})$ is the polytope of the node cover of \mathcal{H} , and, given any weight on V , a node cover of \mathcal{H} with minimum weight can be found in polynomial time provided the problem of finding a minimum weighted hyperedge in \mathcal{E} is polynomial-time solvable (cf. [65]). Corresponding to Definition 5, (box-)Mengerian hypergraphs have the following fractional $\frac{1}{d}$ - generalizations:

Definition 11 Let $\mathcal{H} = (V, \mathcal{E})$ be a hypergraph and let A be the \mathcal{E} - V incidence matrix. Then \mathcal{H} is called $\frac{1}{d}$ -Mengerian (resp. box- $\frac{1}{d}$ -Mengerian) if $Ax \geq \mathbf{1}$, $x \geq \mathbf{0}$ is a $\frac{1}{d}$ -TDI (resp. box- $\frac{1}{d}$ -TDI) system.

2.4 Transformations Preserving Dual Integrality

Operations on linear systems which preserve (box-)total dual integrality serve as tools for making inductive proof or directly discovering new (box-)TDI systems. This subsection presents some operations introduced recently that are useful in combinatorial applications. The interested reader is referred to Sect. 22.5 of [101] and Sect. 5.17 of [103] to see how the (box-)total dual integrality behaves under more transformations: scalar multiplications, “slack” variable addition and removal, variable repetition, and Fourier–Motzkin elimination, to name a few.

Theorem 5 Let A be an nonnegative integer matrix. If $Ax \geq \mathbf{1}$, $x \geq \mathbf{0}$ is a TDI system, then so is $Ax \geq \mathbf{1}$, $\mathbf{1} \geq x \geq \mathbf{0}$.

The above result by Schrijver (Theorem 5.23 of [103]) implies that the fractional polytope of the node cover (see [Definition 10](#)) of a Mengerian hypergraph (see [Definition 9](#)) is integral.

Corollary 2 Let \mathcal{H} be a Mengerian hypergraph with hyperedge-node incidence matrix A . Then the polytope of the node cover of \mathcal{H} is $\{x : Ax \geq \mathbf{1}, \mathbf{1} \geq x \geq \mathbf{0}\}$.

The following two lemmas [19] follow immediately from the definition of box-TDI systems ([Definition 2](#)). In particular the second lemma exhibits some dominance consistent with intuition.

Lemma 4 Let matrix A' be obtained from matrix A by adding a zero-column. If system $Ax \geq b$, $x \geq \mathbf{0}$ is box-TDI, then so is the system $A'x' \geq b$, $x' \geq \mathbf{0}$.

Lemma 5 Suppose a_1 and a_2 are rational vectors with $a_1 \leq a_2$, and b_1 and b_2 are rational numbers with $b_1 \geq b_2$. Then the system $Ax \geq b$, $a_1^T x \geq b_1$, $a_2^T x \geq b_2$, $x \geq \mathbf{0}$ is box-TDI if and only if the system $Ax \geq b$, $a_1^T x \geq b_1$, $x \geq \mathbf{0}$ is box-TDI.

Column Contraction and Deletion. Suppose the rows and columns of matrix A are indexed by disjoint sets R and S , respectively. For any $s \in S$, let A/s be the matrix obtained from A by deleting the column indexed by s ; let $A\backslash s$ be the matrix obtained from A by deleting column s and all rows r for which the (r, s) -th entry $A_{r,s}$ of A is not zero. As the notations indicate, A/s and $A\backslash s$ are viewed as the “contraction” and “deletion,” respectively, of column (coordinate) s from the system. The following two theorems show that the property of being a box-TDI system is preserved under the “contraction” and “deletion” of columns. The first fact was observed in [101], on page 323.

Theorem 6 If $Ax \geq b$, $x \geq \mathbf{0}$ is a box-TDI system and $A' = A/s$, then $A'x' \geq b$, $x' \geq \mathbf{0}$ is also box-TDI.

Similarly, the operation on A to produce $A\backslash s$ also preserves box-total dual integrality, as recently shown by Chen et al. [19]. In this chapter, for any vector $x \in \Omega^K$ and any $J \subseteq K$, the $|J|$ -dimensional vector $x|_J = (x(j) : j \in J)$ stands for the projection of x to Ω^J . In addition, $x(J)$ denotes the value $\sum_{j \in J} x(j)$.

Theorem 7 If $Ax \geq b$, $x \geq \mathbf{0}$ is a box-TDI system, $A' = A\backslash s$, and A is nonnegative, then $A'x' \geq b'$, $x' \geq \mathbf{0}$ is also box-TDI, where $b' = b|_{R'}$ with $R' = \{r : A_{r,s} = 0\}$.

Taking Minors. As the names indicate, column contraction and deletion on linear systems discussed above generalize contraction and deletion on hypergraphs defined below.

Definition 12 Let $\mathcal{H} = (V, \mathcal{E})$ be a hypergraph. For any two disjoint subsets X and Y of V (possibly X or Y is empty), let $V' = V - (X \cup Y)$ and let \mathcal{E}' be the set of all *minimal* members in $\{F - Y : F \cap X = \emptyset \text{ and } F \in \mathcal{E}\}$, where the adjective *minimal* is meant with respect to set-inclusion rather than size. Then $\mathcal{H}' = (V', \mathcal{E}')$ is called the *minor* of \mathcal{H} obtained by deleting X and contracting Y and written as $\mathcal{H}' = H \setminus X / Y$.

For brevity, the empty set \emptyset will be omitted from the notations by putting $\mathcal{H} \setminus X / \emptyset = \mathcal{H} \setminus X$ and $\mathcal{H} \setminus \emptyset / Y = \mathcal{H} / Y$. As shown by Seymour [107], Mengerian property is closed under taking minors, so is the idealness. The same is true for box-Mengerian property, which can be seen from Lemma 5 and Theorems 6 and 7.

Theorem 8 All minors of a box-Mengerian (resp. Mengerian, ideal) are box-Mengerian (resp. Mengerian, ideal).

Series Extension. Let A be a matrix and let A' be obtained from A by adding a new column equal to an existing one. Then A' is called a *series extension* of A . The next lemma follows easily from the definition of TDI systems (Definition 2).

Lemma 6 If the system $Ax \geq b$, $x \geq \mathbf{0}$ is TDI and A' is a series extension of A , then the system $A'x' \geq b$, $x' \geq \mathbf{0}$ is also TDI.

Chen et al. [19] proved the following analogous result for box-TDI systems.

Theorem 9 If the system $Ax \geq b$, $x \geq \mathbf{0}$ is box-TDI and A' is a series extension of A , then the system $A'x' \geq b$, $x' \geq \mathbf{0}$ is also box-TDI.

This theorem resembles a result of Edmonds and Giles [42] on repeating variables (cf. Theorem 22.10 of Schrijver [101]), but does not follow from Edmonds and Giles' result which could imply as follows: “if the system $Ax \geq b$, $x \geq \mathbf{0}$ is box-TDI and A' is a series extension of A , then the system $A'x' \geq b$, $Bx' \geq \mathbf{0}$ is also box-TDI, where matrix B is obtained from an identity matrix by adding a unit vector.” Interestingly, the proof of Theorem 9 in [19] and that of Edmonds and Giles' result in [101] used Cook's characterization of box-TDI systems (see Theorem 3).

Parallel Extension. Unlike series extension, the operation of parallel extension requires the original matrix A and its outcome A' the *parallel extension* of A to take the following form:

$$A = \begin{bmatrix} A_1 & \frac{1}{2}\mathbf{1} \\ A_2 & \mathbf{0} \end{bmatrix} \text{ and } A' = \begin{bmatrix} \mathbf{0} & \frac{1}{2} & \frac{1}{2} \\ A_1 & \frac{1}{2}\mathbf{1} & \mathbf{0} \\ A_1 & \mathbf{0} & \frac{1}{2}\mathbf{1} \\ A_2 & \mathbf{0} & \mathbf{0} \end{bmatrix}. \quad (5)$$

By applying Cook's sufficient and necessary condition ([Theorem 3](#)) for box-TDI systems to both systems $A\mathbf{x} \geq \mathbf{1}$, $\mathbf{x} \geq \mathbf{0}$ and $A'\mathbf{x}' \geq \mathbf{1}$, $\mathbf{x}' \geq \mathbf{0}$ with various objective functions, Chen et al. [19] proved that the box-total dual integrality of $A\mathbf{x} \geq \mathbf{1}$, $\mathbf{x} \geq \mathbf{0}$ is maintained under the parallel extension.

Theorem 10 *Let matrix A and its parallel extension be as expressed in (5). If $A\mathbf{x} \geq \mathbf{1}$, $\mathbf{x} \geq \mathbf{0}$ is box-TDI, then so is $A'\mathbf{x}' \geq \mathbf{1}$, $\mathbf{x}' \geq \mathbf{0}$.*

2.5 Graphs and Matroids

Polyhedral combinatorics benefit greatly from results and techniques from graph theory and matroid theory as they provide structures on more realistic settings. This subsection gives basic concepts and notations on graphs and matroids, in particular those related to the topics of the present chapter.

For terminology on graphs, this chapter follows [6, 33]. A *graph* $G = (V, E)$ consists of a *vertex set* $V = V(G)$ of *vertices* and an *edge set* $E = E(G)$ of *edges*. An edge with end vertices (ends) u and v is written as uv . When G is a directed graph, elements in $E(G)$ are often called *arcs*. Given graph G , writing $G' \subseteq G$ means that G' is a subgraph of G . In this chapter, graphs are finite; a cycle in a directed graph is always understood as a directed one. This chapter often does not distinguish a one-element set $\{v\}$ (sometimes called a singleton) from its only element v .

- (i) A *triangle* in a graph is a cycle of length 3 in terms of number of vertices on the cycle.

Let F be a set of edges (arcs) of a graph G , the graph derived from G by deleting F and identifying each pair of ends of the edges (arcs) in F is said to be obtained by *contracting* S , and is denoted by G/F .

- (ii) A *minor* of a graph G is a graph obtained from a subgraph of G by contracting edges (arcs).

For any graph $G = (V, E)$ and $S \subseteq V \cup E$, notation $G \setminus S$ denotes the graph obtained from G by deleting S as well as edges (arcs) incident with any vertex in S . An undirected graph is *complete* if any two of vertices are adjacent.

- (iii) The simple complete graph on n vertices is denoted by K_n .

An undirected graph G is *bipartite* if $V(G)$ can be partitioned into nonempty disjoint subsets X and Y so that both X and Y are stable sets (also known as independent sets) of G ; such a partition (X, Y) is called a *bipartition* of G .

If, in addition, each vertex of X is adjacent to each vertex of Y , then G is called a *complete bipartite graph*.

- (iv) The simple complete bipartite graph with bipartition (X, Y) is denoted by $K_{m,n}$, where $|X| = m$ and $|Y| = n$.

It is well known that an undirected graph is bipartite if and only if it contains no cycle of odd length.

To *subdivide* an edge uv in an undirected graph is to replace uv by a path utv , where t is not a vertex in the original graph.

- (v) A *subdivision* of an undirected graph is any graph derivable from it by recursively subdividing edges.

Definition 13 Let $G = (V, E)$ be an undirected graph. A vertex subset $U \subseteq V$ is called a *vertex cover* of G if $G \setminus U$ contains no edge. An edge subset $F \subseteq E$ is called an *edge cover* of G if every vertex of G is incident with at least one edge in F .

Definition 14 Let $G = (V, E)$ be an undirected graph. For any $\emptyset \neq S \subset V$, let $\delta(S)$ denote the set of edges in E with one end in S and the other in $V - S$. In particular, if $v \in V$, then $\delta(v)$ denotes the set of edges in G incident with v . A set of edges in G is called a *cut* if it is $\delta(S)$ for some nonempty proper subset S of V .

Let $G = (V, E)$ be a directed graph. For any $S \subseteq V$, let $\delta^{\text{in}}(S)$ denote the set of arcs in E that *enter* S , that is, arcs with their heads in S and tails in $V - S$; and let $\delta^{\text{out}}(S)$ denote the set of arcs in E that *leave* S , that is, arcs with their tails in S and heads in $V - S$.

Definition 15 A set of arcs in a directed graph $G = (V, E)$ is called a (*directed*) *cut* if it is $\delta^{\text{in}}(S)$ for some nonempty proper subset S of V .

For terminology on matroids, this chapter follows [88]. Basically, a matroid M is a pair (E, \mathcal{C}) , where E is a finite set and \mathcal{C} is a set of subsets of E that satisfies certain axioms (see Sect. 1.1 of [88]). Members of E and \mathcal{C} are called *elements* and *circuits* of M , respectively. In this chapter, matroid $M = (E, \mathcal{C})$ is often considered as a hypergraph with node set E and hyperedge set \mathcal{C} . So:

- (vi) Minors of matroid $M = (E, \mathcal{C})$ are defined as in [Definition 12](#).

Of special interest is the fact that minors of matroids are matroids.

- (vii) The *uniform matroid* $U_{n,r} = (E, \mathcal{C})$ has $|E| = n$ elements, and its circuit set \mathcal{C} consists of all subsets of E of size $r + 1$.
- (viii) The *Fano matroid* $F_7 = (E, \mathcal{C})$, whose elements and circuits correspond to points and lines of the Fano plane, has element set $E = \{1, 2, 3, 4, 5, 6, 7\}$, and circuit set \mathcal{C} consist of $\{1, 2, 3\}$, $\{1, 4, 7\}$, $\{1, 5, 6\}$, $\{2, 4, 6\}$, $\{2, 5, 7\}$, $\{3, 4, 5\}$, $\{3, 6, 7\}$ (the lines of the Fano plane) and their complements.
- (ix) The *series extension* F_7^+ of the Fano matroid F_7 is the matroid obtained from F_7 by adding a new element 8 in series with, say, the element 7. Hence, F_7^+ is the matroid defined on $\{1, 2, 3, 4, 5, 6, 7, 8\}$ whose circuit set is $\{C : C \text{ is}$

a circuit of F_7 with $7 \notin C\} \cup \{C \cup \{8\} : C \text{ is a circuit of } F_7 \text{ with } 7 \in C\}$. The elements 7, 8 are called *series elements* of F_7^+ . Up to isomorphism, the series extension of F_7 is unique.

Every matroid $M = (E, \mathcal{C})$ is determined by a set $\mathcal{I}(M) \subseteq 2^E$ such that circuits of M are precisely the minimal elements of $2^E - \mathcal{I}(M)$. With each matroid $M = (E, \mathcal{C})$, a *dual* matroid M^* , on the same set E of elements, can be associated in such a way that $\mathcal{I}(M^*) = \{I \subseteq E : E - I \text{ contains a maximal element of } \mathcal{I}(M)\}$.

- (x) The *dual Fano matroid* F_7^* is the dual of F_7 ; its circuits are $\{4, 5, 6, 7\}$, $\{2, 3, 5, 6\}$, $\{2, 3, 4, 7\}$, $\{1, 3, 5, 7\}$, $\{1, 3, 4, 6\}$, $\{1, 2, 6, 7\}$, and $\{1, 2, 4, 5\}$ (the complements of the lines of the Fano plane).

Definition 16 Every undirected graph $G = (V, E)$ defines a matroid $M(G) = (E, \mathcal{C})$, where \mathcal{C} consists of edge sets of all cycles of G . Every matroid of this kind is called a *graphic matroid*. The dual of a graphic matroid $M(G)$ is the matroid $M^*(G) = (E, \mathcal{D})$, where \mathcal{D} consists of all nonempty minimal cuts of G . The dual of a graphic matroid is called a *cographic matroid*.

3 Complexity

For the background of computational complexity, the reader is referred to the classic book [60] by Garey and Johnson. Two subsections below mainly report negative results on the complexity of recognizing TDI systems and that of packing feedback vertex sets in tournaments, respectively.

3.1 Recognition of TDI Systems

A number of well-known results and difficult conjectures in combinatorial optimization can be rephrased by saying that certain polyhedra are integral or certain linear systems are TDI, for instance, the celebrated strong perfect graph theorem [23]. So the following recognition problems, all proposed in Schrijver [101], are of both great theoretical interest and practical value:

Problem 1 Given a rational linear system, does it determine an integral polyhedron?

Problem 2 Given a rational linear system, is it TDI (cf. Definition 3)?

Problem 3 Given a rational linear system, is it box-TDI (cf. Definition 3)?

Schrijver [101] showed that Problem 1 is in co-NP, and so are Problems 2 and 3 if the matrix involved in the linear system is integral. In general, however, the question whether Problems 2 and 3 are in NP or co-NP is still unanswered. It is worthwhile pointing out that, first, Problems 2 and 3 can all be solved in polynomial time if the

rank of the matrix involved in the linear system is a fixed constant, as shown by Cook et al. [26]; second, classical results of Chvátal [24], Fulkerson [57], and Lovász [81] imply that for any 0–1 matrix A , the system $Ax \leq \mathbf{1}, x \geq \mathbf{0}$ defines an integral polyhedron if and only if it is TDI (cf. [Definition 3](#)) if and only if A is the clique-vertex incidence matrix of a perfect graph. Since clique-vertex incidence matrices of graphs can be recognized in polynomial time, according to a result of Gilmore on conformal hypergraphs (see page 396 of Berge [4]), the recent breakthrough on perfect graphs [22, 23] implies that such a TDI system can be recognized in polynomial time.

In connection with [Problem 2](#), Edmonds and Giles [42] conjectured that it is co-NP-complete to decide whether a given rational linear system is TDI. This conjecture was recently confirmed by Ding et al. [35] who established the following result.

Theorem 11 *Let A be a 0–1 matrix with precisely two 1s in each column. Then the problems of deciding whether the linear system $Ax \geq \mathbf{1}, x \geq \mathbf{0}$ (i) defines an integral polyhedron, (ii) is TDI, and (iii) is box-TDI are all co-NP-complete.*

Ding et al. [35] showed that the problems addressed in (i)–(iii) are essentially equivalent to the problem of recognizing the so-called quasi-bipartite graphs.

Definition 17 A graph G is called *quasi-bipartite* if for any odd cycle C in G , the deletion of all vertices on C from G results in at least one isolated vertex.

They [35] verified that it is co-NP-complete to recognize quasi-bipartite graphs, thus proving [Theorem 11](#). It can be deduced from the theorem that [Problems 1–3](#) are all NP-hard. Since the matrix in [Theorem 11](#) has only 0,1 elements, the NP-hardness is strengthened by the following corollary.

Corollary 3 *It is NP-hard to recognize (box-) Mengerian hypergraphs.*

A polyhedron is called a 0–1 *Polyhedron* if all its extreme points are 0–1 vectors [12]. Due to the graphical construction of their proofs, the results of Ding et al. [35] imply that distinguishing whether a polyhedron, given by its facets, is either a 0–1 polyhedron or fractional is an NP-hard problem.

Recently, the co-NP-completeness of deciding whether $Ax \geq \mathbf{1}, x \geq \mathbf{0}$ is TDI has been extended to the conic system by Pap [89] as follows.

Theorem 12 *Let A be a 0–1 matrix with at most three 1s in each row. Then the problem of deciding whether the linear system $Ax \geq \mathbf{0}$ is TDI is co-NP-complete.*

For characterizing properties of a general TDI system (see [Definition 3](#)), the reader is referred to the recent paper on testing total dual integrality by O’Shea and Sebö [87], who showed that a system of linear inequalities is TDI if and only if

its coefficient vectors form a Hilbert basis, and there exists a test-set for the system's dual integer programs where all test vectors have positive entries equal to 1.

3.2 Maximum Feedback Vertex Set Packing in Tournaments

Given a directed graph $G = (V, E)$ with a nonnegative integral weight function w on V , a *feedback vertex set* (FVS) is a subset of V that meets all directed cycle in G . The *FVS packing problem* on G is to find a w -FVS packing in G of maximum size (cf. Definition 8). In connection with this problem, Frank [50] suggested the following question: Given a directed graph G , can one decide in polynomial time whether the vertices of G can be colored by red or blue so that every cycle contains at least one red vertex and at least one blue vertex? Or is this an NP-complete problem? The following theorem [21] states that Frank's problem is NP-complete even when G is restricted to a tournament (an orientation of a complete graph):

Theorem 13 *It is NP-complete to decide whether the vertex set of a given tournament can be partitioned into two feedback vertex sets.*

Chen et al. [21] proved the NP-completeness by reduction from the NOT-ALL-EQUAL 3-SATISFIABILITY problem [96]. Particularly, Theorem 13 says that the FVS packing problem on tournament is NP-hard even for the unweighted version with $w = \mathbf{1}$.

4 A Unified Approach to Box-Mengerian Hypergraphs

In this section, five subsections combine to make an exposition of a unified approach to studying box-Mengerian hypergraphs. Section 4.1 presents a sufficient condition for box-Mengerian hypergraphs: the so-called ESP property (see Definition 18). Sections 4.2–4.4 exhibit several classes of box-Mengerian hypergraphs discovered by using ESP property. Section 4.5 relates some well-known min–max relation in the literature with the ESP property. Section 4.6 discusses the blockers (cf. Definition 10) of ESP hypergraphs in the context of the ESP property.

4.1 ESP Property

Due to NP-hardness of recognizing box-Mengerian hypergraphs (see Corollary 3), a basic theme in combinatorial optimization is to identify such objects associated with various problems. By Cook's characterization of box-TDI systems [25], a hypergraph $\mathcal{H} = (V, \mathcal{E})$ is box-Mengerian if and only if $Ax \geq \mathbf{1}$, $x \geq \mathbf{0}$ is a TDI system and for any rational vector $c = (c_1, c_2, \dots, c_n)^T$, where $n = |V|$, there exists an integral vector $\tilde{c} = (\tilde{c}_1, \tilde{c}_2, \dots, \tilde{c}_n)^T$ such that $\lfloor c_i \rfloor \leq \tilde{c}_i \leq \lceil c_i \rceil$, for all $1 \leq i \leq n$, and such that every optimal solution of $\min \{c^T x : Ax \geq \mathbf{1}, x \geq \mathbf{0}\}$

is also an optimal solution of $\min \{\tilde{c}^T x : Ax \geq \mathbf{1}, x \geq \mathbf{0}\}$. Nevertheless, this necessary and sufficient condition is not so ‘‘user-friendly’’ and can hardly be verified in practice. Recalling Schrijver’s sufficient condition for box-TDI systems [103] ([Theorem 2](#)), when matrix A over there is restricted to the hyperedge-node incidence matrix of a hypergraph and vector b over there is set to $\mathbf{1}$, the theorem yields a sufficient condition for box-Mengerian hypergraphs. For various classes of box-Mengerian hypergraphs resulted from this theorem, see [100, 103]. Owing to the demanding total unimodularity requirement, it is desirable to have some other powerful approaches for establishing box-Mengerian hypergraphs. Chen et al. [17] derived an analogue of [Theorem 2](#) to fulfill such a need.

Definition 18 Let $\mathcal{H} = (V, \mathcal{E})$ be a hypergraph and let Λ be a collection of its hyperedges. Let $d_\Lambda(v)$ denote the number of hyperedges in Λ that contain v . An *equitable subpartition* of Λ consists of two collections Λ_1 and Λ_2 of hyperedges in \mathcal{E} (which are not necessarily in Λ) such that:

- (i) $|\Lambda_1| + |\Lambda_2| \geq |\Lambda|$.
- (ii) $d_{\Lambda_1 \cup \Lambda_2}(v) \leq d_\Lambda(v)$ for all $v \in V$.
- (iii) $\max\{d_{\Lambda_1}(v), d_{\Lambda_2}(v)\} \leq \lceil d_\Lambda(v)/2 \rceil$ for all $v \in V$.

The hypergraph \mathcal{H} is called *equitably subpartitionable*, abbreviated ESP, if every collection of its hyperedges admits an equitable subpartition.

The above (i), (ii), and (iii) are referred to as *ESP property*, which was first introduced by Ding and Zang [36] in their characterization of all graphs with the min–max relation on packing and covering cycles, where they proved that every ESP hypergraph is Mengerian. Chen et al. [17] showed that ESP property turns out to be even sufficient for box-Mengerian hypergraphs.

Theorem 14 Every ESP hypergraph is box-Mengerian.

Let $Ax \geq \mathbf{1}, x \geq \mathbf{0}, u \geq x \geq l$ be a linear system. With a slight abuse of notation, let $\text{Max}(A, l, u, w)$ stand for both the linear program $\max\{\alpha^T \mathbf{1} + \beta^T l - \gamma^T u : \alpha^T A + \beta^T - \gamma^T \leq w^T, \alpha, \beta, \gamma \geq \mathbf{0}\}$ and its optimal value. When integrality is imposed on its solutions, let $\text{Max}(A, l, u, w; \mathbb{Z})$ stand for the corresponding integer program and optimal value. When half-integrality is imposed, let $\text{Max}(A, l, u, w; \mathbb{Z}/2)$ stand for the corresponding program and optimal value, where $\mathbb{Z}/2 = \{k/2 : k \in \mathbb{Z}\}$. Suppose A is the \mathcal{E} - V incidence matrix of a hypergraph $\mathcal{H} = (V, \mathcal{E})$, and suppose $(\alpha^*, \beta^*, \gamma^*)$ is an optimal solution to $\text{Max}(A, l, u, w; \mathbb{Z})$.

Definition 19 Let Λ be the hyperedge collection of \mathcal{H} such that each $U \in \mathcal{E}$ appears exactly $\alpha^*(U)$ times in Λ . The hyperedge collection Λ is said to be the one *corresponding* to α^* .

[Theorem 14](#) is straightforward from the following stronger statement [17].

Theorem 15 Let $\mathcal{H} = (V, \mathcal{E})$ be a hypergraph and let A be the \mathcal{E} - V incidence matrix. Suppose that for any $\mathbf{l}, \mathbf{u} \in \mathbb{Q}_+^V$ and $\mathbf{w} \in \mathbb{Z}^V$ with finite $\text{Max}(A, \mathbf{l}, \mathbf{u}, \mathbf{w})$, there exists an optimal solution $(\boldsymbol{\alpha}^*, \boldsymbol{\beta}^*, \boldsymbol{\gamma}^*)$ to $\text{Max}(A, \mathbf{l}, \mathbf{u}, 2\mathbf{w}; \mathbb{Z})$ such that the hyperedge collection corresponding to $\boldsymbol{\alpha}^*$ admits an equitable subpartition. Then \mathcal{H} is box-Mengerian.

The proof of this theorem relies on the following fundamental result on total dual integrality, as shown by Schrijver and Seymour [104].

Lemma 7 The system $A\mathbf{x} \geq \mathbf{1}, \mathbf{x} \geq \mathbf{0}, \mathbf{u} \geq \mathbf{x} \geq \mathbf{l}$ is TDI if and only if

$$\text{Max}(A, \mathbf{l}, \mathbf{u}, 2\mathbf{w}; \mathbb{Z}) \leq 2 \text{Max}(A, \mathbf{l}, \mathbf{u}, \mathbf{w}; \mathbb{Z}) \quad (6)$$

for any integral vector \mathbf{w} for which $\text{Max}(A, \mathbf{l}, \mathbf{u}, \mathbf{w})$ is finite.

By the hypothesis of [Theorem 15](#), there exists an optimal solution $(\boldsymbol{\alpha}^*, \boldsymbol{\beta}^*, \boldsymbol{\gamma}^*)$ to $\text{Max}(A, \mathbf{l}, \mathbf{u}, 2\mathbf{w}; \mathbb{Z})$ such that the hyperedge collection Λ corresponding to $\boldsymbol{\alpha}^*$ admits an equitable subpartition (Λ_1, Λ_2) . Suppose that for $i = 1, 2$, the hyperedge collection Λ_i corresponds to $\boldsymbol{\alpha}_i \in \mathbb{Z}_+^{\mathcal{E}}$. Based on the ESP property, $\boldsymbol{\beta}_i, \boldsymbol{\gamma}_i \in \mathbb{Z}_+^V, i = 1, 2$ can be defined such that both $(\boldsymbol{\alpha}_1, \boldsymbol{\beta}_1, \boldsymbol{\gamma}_1)$ and $(\boldsymbol{\alpha}_2, \boldsymbol{\beta}_2, \boldsymbol{\gamma}_2)$ are feasible solutions to $\text{Max}(A, \mathbf{l}, \mathbf{u}, \mathbf{w}; \mathbb{Z})$, and $\sum_{i=1}^2 (\boldsymbol{\alpha}_i^T \mathbf{1} + \boldsymbol{\beta}_i^T \mathbf{l} - \boldsymbol{\gamma}_i^T \mathbf{u}) \geq (\boldsymbol{\alpha}^*)^T \mathbf{1} + (\boldsymbol{\beta}^*)^T \mathbf{l} - (\boldsymbol{\gamma}^*)^T \mathbf{u}$. It follows that the inequality $\boldsymbol{\alpha}_i^T \mathbf{1} + \boldsymbol{\beta}_i^T \mathbf{l} - \boldsymbol{\gamma}_i^T \mathbf{u} \geq [(\boldsymbol{\alpha}^*)^T \mathbf{1} + (\boldsymbol{\beta}^*)^T \mathbf{l} - (\boldsymbol{\gamma}^*)^T \mathbf{u}] / 2$ holds for $i = 1$ or 2 , establishing (6) and thus [Theorem 15](#).

Let \mathcal{H} be a hypergraph. The combination of [Theorem 14](#) and [Corollary 1](#) provides the following string of implications, which will be used explicitly or implicitly in the remaining discussions:

$$\mathcal{H} \text{ is ESP} \Rightarrow \mathcal{H} \text{ is box-Mengerian} \Rightarrow \mathcal{H} \text{ is Mengerian} \Rightarrow \mathcal{H} \text{ is ideal.} \quad (7)$$

[Sections 4.2–4.4](#) below exhibit some applications of [Theorem 14](#), where several classes of box-Mengerian hypergraphs (on paths, cycles, matroid ports) have been established. In comparison with [Theorem 2](#) from which none of these box-TDI-ness can be derived directly, the approach involving ESP property is of transparent combinatorial nature and hence is fairly easy to work with.

4.2 Path Hypergraphs

Let T be a tree with edge set V , and let \mathcal{E} be edge sets of some paths in T , such that each edge of T is contained in at least one of these paths. The hypergraph $\mathcal{H} = (V, \mathcal{E})$ is called the *edge path tree* (EPT) hypergraph supported by T , where T is known as a *supporting tree* of \mathcal{H} (note that a supporting tree may not be unique). A subset of hyperedges $\{P_1, P_2, \dots, P_k\}$ in \mathcal{H} is called a *pie*

if T contains a vertex u and k edges e_1, e_2, \dots, e_k all incident with u , such that $P_i \cap \{e_1, e_2, \dots, e_k\} = \{e_i, e_{i+1}\}$ for $i = 1, 2, \dots, k$, where $e_{k+1} = e_1$; the pie is called *odd* if k is odd. For any two disjoint subsets X and Y of V (possibly X or Y is empty), let $\mathcal{H}' = \mathcal{H} \setminus X / Y$ be the minor of \mathcal{H} obtained by deleting X and contracting Y (cf. [Definition 12](#)). Clearly, \mathcal{H}' is supported by T' , the tree obtained from T by contracting edges in $X \cup Y$. The hypergraph \mathcal{H} is said to be *odd-pie-free* if it contains no odd pies and is said to be *odd-M-pie-free* if none of its minors is an odd pie. As observed by Apollonio [1], an odd-M-pie-free hypergraph may contain an odd pie.

Theorem 16 *Let $\mathcal{H} = (V, \mathcal{E})$ be an EPT clutter. Then the following statements are equivalent: (i) \mathcal{H} is odd-M-pie-free; (ii) \mathcal{H} is ideal; (iii) \mathcal{H} is Mengerian; (iv) \mathcal{H} is box-Mengerian; and (v) \mathcal{H} is ESP.*

The equivalence of the first three statements was established by Apollonio [1]. Recently, it was shown that for the same combinatorial structures, the stronger statements (iv) and (v) hold. The proof [17] relies heavily on the following two results due to Apollonio [1]:

- The incidence matrix of every odd-pie-free EPT hypergraph is totally unimodular.
- If an odd-M-pie-free EPT clutter \mathcal{H} contains an odd pie \mathcal{P} , then there exist four hyperedges P_1, P_2, P_3, P_4 in \mathcal{H} , with $\{P_3, P_4\} \subseteq \mathcal{P}$, such that $P_1 \cap P_2 = \emptyset$, $P_3 \cap P_4 \neq \emptyset$, and $P_1 \cup P_2 \subseteq (P_3 - P_4) \cup (P_4 - P_3)$.

The first result, together with the Ghouila-Houri theorem (see Theorem 19.3 of [101]), implies that every odd-pie-free EPT hypergraph is ESP, while the second result provides a recursive method to transform any hyperedge collection Λ of an odd-M-pie-free EPT clutter to a hyperedge collection Λ' of an odd-pie-free EPT hypergraph such that every equitable subpartition of Λ' is an equitable subpartition of Λ . It follows that every odd-M-pie-free EPT clutter is ESP and thus box-Mengerian by [Theorem 14](#).

4.3 Cycle Hypergraphs

Let $G = (V, E)$ be a graph (undirected or directed) and let $w \in \mathbb{Z}_+^V$ be a weight function on V . Let $\mathcal{H} = (V, \mathcal{E})$ be *cycle hypergraph* of G , where \mathcal{E} consists of the vertex sets of all cycles in G .

Definition 20 A *feedback vertex set* (FVS) of G , or equivalently a node cover of cycle hypergraph \mathcal{H} (see [Definition 8](#)), is a vertex subset that intersects each cycle in G . A w -*cycle packing* of G , or equivalently a w -packing of \mathcal{H} (see [Definition 8](#)), is a collection \mathcal{C} of cycles (with repetition allowed) such that each vertex v is contained in at most $w(v)$ members of \mathcal{C} . The *feedback vertex set problem* is to find an FVS with minimum total weight, denoted as $\tau(G, w) = \tau(\mathcal{H}, w)$.

The *cycle packing problem* is to find a w -cycle packing with maximum size, denoted as $v(G, w) = v(\mathcal{H}, w)$.

Graph G is said to be *cycle Mengerian* if its cycle hypergraph is Mengerian. The problems of computing $\tau(G, w)$ and $v(G, w)$ arise in a variety of applications, and both problems are known to be NP-hard [60]. However, according to a powerful result of Grötschel et al. [65], in case of cycle Mengerian graph G , the problem of computing $\tau(G, w)$ and $v(G, w)$ is equivalent to finding a shortest cycle in a graph, which is solvable in polynomial time. Therefore, cycle Mengerian graphs form a class for which both $\tau(G, w)$ and $v(G, w)$ can be computed in polynomial time.

4.3.1 Cycle Mengerian Undirected Graphs

Ding and Zang [36] obtained a characterization of all cycle Mengerian undirected graphs. This characterization involves forbidden subgraphs depicted in Fig. 1. An *odd ring* is a graph obtained from an odd cycle by replacing each edge $e = xy$ with either a triangle containing e or two triangles xab, ycd together with two additional edges ac and bd . A *wheel* is obtained from a cycle by adding a new vertex and making it adjacent to all vertices of the cycle. As usual, $K_{2,3}$ denotes the complete bipartite graph whose bipartition consists of independent sets of sizes 2 and 3, respectively (cf. Sect. 2.5(iv)).

Theorem 17 *Let $G = (V, E)$ be a simple undirected graph and let $\mathcal{H} = (V, \mathcal{E})$ be its cycle hypergraph. Then the following statements are equivalent: (i) G contains no induced subgraph isomorphic to a subdivision of an odd ring, or a wheel, or $K_{2,3}$; (ii) \mathcal{H} is ideal; (iii) \mathcal{H} is Mengerian; (iv) \mathcal{H} is box-Mengerian; and (v) \mathcal{H} is ESP.*

The equivalence of statements (i)–(iii) and (v) was established by Ding and Zang [36]; the strengthening from the total dual integrality to the box-total dual integrality follows instantly from Theorem 14 [17]. The most difficult part of proving Theorem 17 is showing the implication from (i) to (v). Ding and Zang [36] accomplished this task by deriving a structural theorem, which asserts that if a graph has no forbidden structures, then it can be expressed as “sums” of some prime graphs. They showed that every prime graph possesses an ESP cycle hypergraph and that, when piecing together (according to the “sum” operations) graphs whose cycle hypergraphs are ESP, the resulting graph also has an ESP cycle hypergraph.

One may consider the edge version of the above cycle packing problem, where associated the simple undirected graph G is the hypergraph $\mathcal{H}' = (E, \mathcal{E}')$ whose hyperedge set \mathcal{E}' consists of the edge sets of all cycles in G . The characterization of the edge version, however, is quite easy as remarked by Ding and Zang [36].

Remark 1 Every block of graph G is either K_2 or a cycle, if and only if \mathcal{H}' is ideal, if and only if \mathcal{H}' is Mengerian, if and only if \mathcal{H}' is box-Mengerian, and if and only if \mathcal{H}' is ESP.

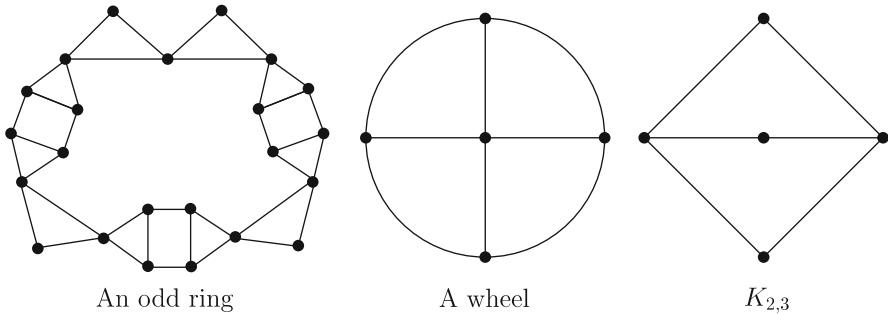

Fig. 1 Forbidden subgraphs for cycle Mengerian graphs

It is straightforward to check that \mathcal{H}' is ESP if G is as described. On the other hand, when G is not such a graph, it must have a subgraph H that is a subdivision of K_4 with one edge missing (cf. Sect. 2.5(v)). With the weight setting $w|_{E(H)} = \mathbf{1}$ and $w|_{E-E(H)} = \mathbf{0}$ [36], it is easy to see that $\min\{w^T \mathbf{x} : A\mathbf{x} \geq \mathbf{1}, \mathbf{x} \geq \mathbf{0}\}$ has an optimal value 1.5, which says that \mathcal{H}' is not ideal (cf. Definition 9). Now all equivalences follow from (7).

4.3.2 Cycle Mengerian Directed Graphs

As far as integral packing properties are concerned, directed cycles are not so manageable as their undirected counterparts. Due to the long list of forbidden structures, to find a good characterization of all cycle Mengerian directed graphs seems to be extremely difficult. While this characterization problem remains open in general, it was resolved completely on tournaments (orientations of undirected complete graphs) and bipartite tournaments (orientations of undirected complete bipartite graphs) by Cai et al. [13, 14].

Theorem 18 *Let $G = (V, E)$ be a tournament and let $\mathcal{H} = (V, \mathcal{E})$ be its cycle hypergraph. Then the following statements are equivalent: (i) G contains neither F_1 nor F_2 as a subgraph (see Fig. 2); (ii) \mathcal{H} is ideal; (iii) \mathcal{H} is Mengerian; (iv) \mathcal{H} is box-Mengerian; and (v) \mathcal{H} is ESP.*

Note that a vertex subset of a tournament is an FVS if and only if it intersects all triangles (see Sect. 2.5(i)) and that the cycle packing problem (see Definition 20) on tournaments actually reduces to the triangle packing problem.

The equivalence of statements (i) and (iii) of Theorem 18 was derived in [13], where Cai et al. gave a structural description of tournaments $G = (V, E)$ with no F_1 nor F_2 . The authors started with a vertex u with the maximum out-degree in G and partitioned the vertices of G according to their distances (in terms of number of arcs) from u , that is, $V = \bigcup_{i=1}^k V_i$ where a vertex $v \in V_i$ if and only if the distance from u to v is $i - 1$. The subtournament induced by V_i was shown to be acyclic if G contains

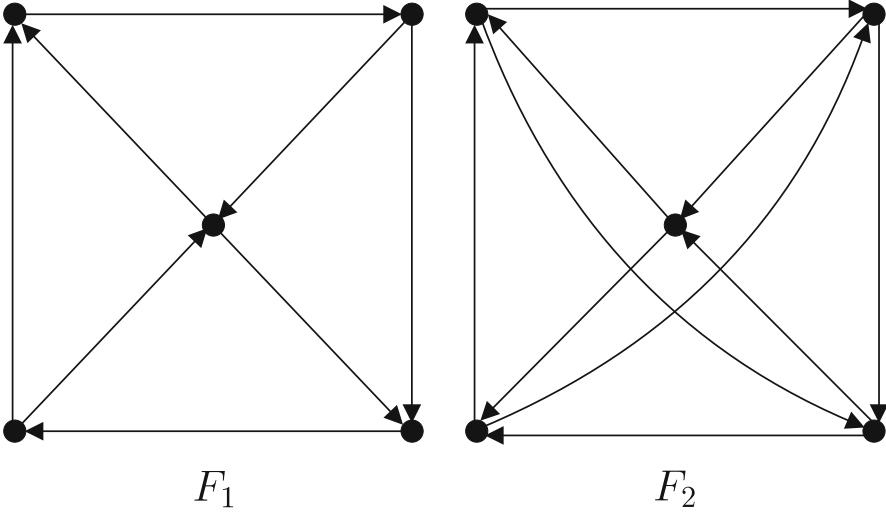

Fig. 2 Forbidden subtournaments F_1 and F_2 , where the two arcs not shown in F_1 may take any directions

no F_1 nor F_2 . This property leads to a natural order for vertices in V_i . Moreover, for every triangle in the tournament, its three vertices are in three consecutive subsets of the partition, that is, V_i, V_{i+1}, V_{i+2} for some i . Therefore, from the ordering of vertices, a lexicographical ordering \prec on all triangles in G free of F_1 and F_2 can be obtained in strongly polynomial time [13, 17]. To prove (i) \Rightarrow (iii), Cai et al. [13] showed the “smallest” triangle under \prec must be contained in a maximum w -cycle packing in G (see Definition 20), and this triangle contains a vertex such that decreasing its weight by 1 would reduce the cycle covering number $\tau(G, w)$ of G by 1 (cf. Definitions 20 and (2.3)). This fact leads to an inductive argument to verify statement (iii) and provides an efficient combinatorial algorithm for finding a maximum w -cycle packing in G as well as a minimum w -cycle covering in G . In addition, applying the local ratio technique (see, e.g., [3]) to F_1 and F_2 , Cai et al. [13] devised a 2.5-approximation algorithm for the feedback vertex set problem in any tournament, which is known to be NP-hard by reduction from the vertex cover problem [110] (see Definition 40).

Chen et al. [17] exhibited box-TDI and ESP properties associated with the same combinatorial structures. Roughly speaking, given tournament G with no F_1 nor F_2 , and a collection $\Lambda = \{V(T_1), V(T_2), \dots, V(T_m)\}$ of vertex sets of triangles T_1, T_2, \dots, T_m in G , where triangle T_i is “smaller than or equal to” T_{i+1} under \prec for $i = 1, 2, \dots, m - 1$, it can be shown that $\Lambda_1 = \{V(T_i) : i \text{ is odd and } 1 \leq i \leq m\}$ and $\Lambda_2 = \{V(T_i) : i \text{ is even and } 1 \leq i \leq m\}$ form an equitable subpartition (Λ_1, Λ_2) of Λ , thus giving the implication (i) \Rightarrow (v) in Theorem 18.

To verify the relatively easy implication from (ii) to (i) in Theorem 18, Chen et al. [17] considered tournament $G = (V, E)$ containing F_1 or F_2 . Let A be the

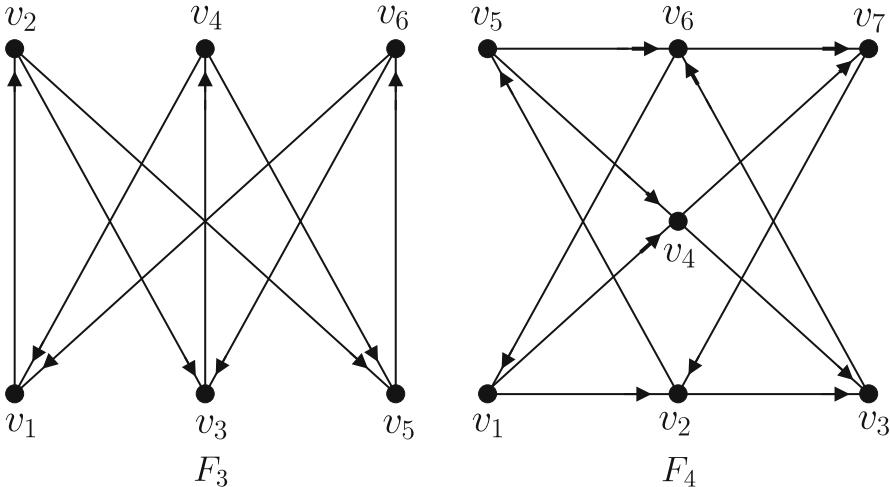

Fig. 3 Forbidden bipartite subtournaments F_3 and F_4

\mathcal{E} - V incidence matrix of $\mathcal{H} = (V, \mathcal{E})$. The authors defined integral weight $w \in \mathbb{Z}_+^V$ such that the optimal value of the linear program $\min\{w^T x : Ax \geq \mathbf{1}, x \geq \mathbf{0}\}$ is within interval $[3/2, 5/3]$ and thus cannot be an integer, saying that \mathcal{H} is not ideal (cf. [Definition 9](#)).

Theorem 19 Let $G = (V, E)$ be a tournament and let $\mathcal{H} = (V, \mathcal{E})$ be its cycle hypergraph. Then the following statements are equivalent: (i) G contains neither F_3 nor F_4 as a subgraph (see [Fig. 3](#)); (ii) \mathcal{H} is ideal; (iii) \mathcal{H} is Mengerian; (iv) \mathcal{H} is box-Mengerian; and (v) \mathcal{H} is ESP.

The situation in bipartite tournaments is similar in spirit to that in tournaments. Strengthening the equivalence (i) \Leftrightarrow (iii) established by Cai et al. [14], one can show that the exclusion of F_3 and F_4 actually characterizes ESP cycle hypergraphs for bipartite tournaments.

A directed cycle of length 4 is called a 4-cycle. The 4-cycles in bipartite tournaments are counterparts of triangles in tournaments, as bipartite graphs contain no cycle of odd length. Let $G = (V, E)$ be a bipartite tournament with no bipartite subtournament isomorphic to F_3 or F_4 . Then V can be partitioned into V_1, V_2, \dots, V_k such that for every 4-cycle in G , its four vertices are in $V_i, V_{i+1}, V_{i+2}, V_{i+3}$ for some i , and a lexicographical ordering \prec can be defined on 4-cycles in G such that the lexicographically smallest 4-cycle is contained in some maximum w -cycle packing of G (see [14]). From the structural description, Cai et al. [14] obtained not only a min–max theorem—the w -cycle packing number $v(G, w)$ equals the w -cycle covering number $\tau(G, w)$ for any bipartite tournament G with no F_3 nor F_4 —but also strongly polynomial time algorithms for the cycle packing

problem and the feedback vertex set problem (cf. [Definition 20](#)). Cai et al. [14] also showed the NP-completeness of the feedback vertex set problem on general bipartite tournaments. A 4-approximation algorithm for this problem can be obtained by the primal-dual method of Goemans and Williamson [63]. Based on the min–max theorem, Cai et al. [14] improved the ratio from 4 to 3.5. This exhibits another example of applying the duality structures of linear programs to approximation algorithms.

The proof of sufficiency of (i) for \mathcal{H} to be ESP is almost identical to that of [Theorem 18](#). In view of (7), it remains to show the necessity of (i) for $\mathcal{H} = (V, \mathcal{E})$ to be ideal. To this end, suppose that G contains F_i as a subgraph for $i = 3$ or 4. Let vertices $v_1, v_2, \dots \in V(F_i)$ be as specified in [Fig. 3](#), let A be the \mathcal{E} - V incidence matrix of \mathcal{H} , and let integral weight $w \in \mathbb{Z}_+^V$ be defined by

$$w|_{V(F_i)} = \mathbf{1} \text{ and } w|_{V - V(F_i)} = \mathbf{0}.$$

It is easy to see that $x \in \mathbb{Q}_+^V$ with $x|_{\{v_2, v_4, v_6\}} = \frac{1}{2}\mathbf{1}$, $x|_{V(F_i) - \{v_2, v_4, v_6\}} = \mathbf{0}$ and $x|_{V - V(F_i)} = \mathbf{1}$ is a feasible solution to $\min\{w^T x : Ax \geq \mathbf{1}, x \geq \mathbf{0}\}$ of value $w^T x = 3/2$, giving

$$\min\{w^T x : Ax \geq \mathbf{1}, x \geq \mathbf{0}\} \leq 3/2. \quad (8)$$

In case of $F_3 \subseteq G$, let C_1 , C_2 , and C_3 be the three 4-cycles in F_3 with vertex sets $\{v_1, v_2, v_3, v_4\}$, $\{v_3, v_4, v_5, v_6\}$, and $\{v_5, v_6, v_1, v_2\}$, respectively. Then $\{C_1, C_2, C_3\}$ is a $2w$ -cycle packing in G of size 3, which, together with the primal and dual relation between packing and covering (cf. (1)), implies

$$\min\{w^T x : Ax \geq \mathbf{1}, x \geq \mathbf{0}\} \geq 3/2. \quad (9)$$

In case of $F_4 \subseteq G$, let C_1 , C_2 , C_3 , and C_4 be the 4-cycles in F_4 with vertex sets $\{v_1, v_2, v_5, v_6\}$, $\{v_2, v_3, v_6, v_7\}$, $\{v_1, v_4, v_3, v_6\}$, and $\{v_2, v_5, v_4, v_7\}$, respectively. Then $\{C_1, C_2, C_3, C_4\}$ is a $3w$ -cycle packing in G of size 4, implying

$$\min\{w^T x : Ax \geq \mathbf{1}, x \geq \mathbf{0}\} \geq 4/3. \quad (10)$$

It follows from (8) to (10) that $\min\{w^T x : Ax \geq \mathbf{1}, x \geq \mathbf{0}\} \in [4/3, 3/2]$ is not an integer and \mathcal{H} is not ideal (cf. [Definition 9](#)).

4.4 Matroid Port Hypergraphs

The reader is referred to [88] for an in-depth account of matroid theory and undefined terms. Let M be a matroid on $E \cup \{\ell\}$, where $\ell \notin E$ is a distinguished element of M . A matroid obtained from M by deleting and contracting elements in E is called a *minor* of M using ℓ (cf. [Sect. 2.5\(vi\)](#)).

Definition 21 The ℓ -port of matroid M on $E \cup \{\ell\}$ is the hypergraph $\mathcal{P}_{M,\ell} = (E, \mathcal{E})$ with node set E and hyperedge set $\mathcal{E} = \{P : P \subseteq E \text{ with } P \cup \{\ell\} \text{ a circuit of } M\}$.

As usual, let $U_{2,4}$ be the uniform matroid on four elements of rank two, let F_7 be the Fano matroid, let F_7^* be the dual of F_7 , and let F_7^+ be the unique series extension of F_7 (see Sect. 2.5(vii)–(ix)). In 1977, Seymour [107] characterized all pairs (M, ℓ) for which $\mathcal{P}_{M,\ell}$ is Mengerian.

Theorem 20 Let M be a matroid and let ℓ be an element of M . Then $\mathcal{P}_{M,\ell}$ is Mengerian if and only if M has neither $U_{2,4}$ -minor using ℓ nor F_7^* -minor using ℓ .

This far-reaching theorem, which yields a number of important min–max relations in combinatorial optimization, has attracted tremendous research efforts in matroid optimization; see, for instance, Ding and Zang [37], Gerards and Laurent [62], Guenin [68], Seymour [108], Truemper [111], Tseng and Truemper [112]. Let $\mathcal{P}_{M,\ell} = (E, \mathcal{E})$ be the ℓ -port of matroid M on $E \cup \{\ell\}$, and let A be the \mathcal{E} - E incidence matrix of $\mathcal{P}_{M,\ell}$. A natural extension of the fractional node cover polytope $B(\mathcal{P}_{M,\ell})$ of $\mathcal{P}_{M,\ell}$ (see (4)) is given by dropping the upper constraint as follows:

$$\tilde{B}(\mathcal{P}_{M,\ell}) = \{x : Ax \geq 1, x \geq 0\}.$$

In 1995, Gerards and Laurent [62] obtained a structural characterization of all pairs (M, ℓ) for which $\tilde{B}(\mathcal{P}_{M,\ell})$ is box- $\frac{1}{d}$ -integral (see Definition 6) for all positive integers d ; this theorem can be found in several interesting applications [62, 78]. In 2008, Chen et al. [20] managed to characterize all pairs (M, ℓ) for which $\mathcal{P}_{M,\ell}$ is box-Mengerian; this characterization also yields a number of interesting results in combinatorial optimization. Recently, Chen et al. [17] strengthened this box-TDI property with ESP property (cf. Theorem 14) and presented a much shorter proof than the one given in [20]. The latter proof [17] curtails many technical parts of the original proof [20] and hence is much easier to follow, which exhibits the power of ESP property approach for packing and covering in hypergraphs.

Theorem 21 Let M be a matroid on $E \cup \{\ell\}$ with $\ell \notin E$. Then the following statements are equivalent: (i) M has no $U_{2,4}$ -minor using ℓ , no F_7^* -minor using ℓ , and no F_7^+ -minor using ℓ as a series element; (ii) $\tilde{B}(\mathcal{P}_{M,\ell})$ is box- $\frac{1}{d}$ -integral for all positive integers d ; (iii) $\mathcal{P}_{M,\ell}$ is box-Mengerian; and (iv) $\mathcal{P}_{M,\ell}$ is ESP.

The equivalence of (i) and (ii) was established by Gerards and Laurent [62], and that of (i) and (iii) was verified by Chen et al. [20], who particularly showed that box-total dual integrality of a linear system implies its box- $\frac{1}{d}$ -integrality for all positive integers d (see also Lemma 3). Therefore, (i) \Rightarrow (ii) turns out a corollary of (i) \Rightarrow (iii). The proof of (i) \Rightarrow (iii) [17] is in the same spirit as the proof of (i) \Rightarrow (v) in Theorem 17. For convenience, let \mathfrak{I} be the set of all pairs (M, ℓ) , where M is a matroid on at least two elements, including ℓ , such that M has no

$U_{2,4}$ -minor using ℓ , no F_7^* -minor using ℓ , and no F_7^+ -minor using ℓ as a series element. By the structural result of Gerards and Laurent [62], which says that, for every (M, ℓ) in \mathfrak{I} , either M is regular or M/ℓ is not 3-connected, matroids in \mathfrak{I} can be decomposed into regular matroids. Chen et al. [17] first proved that $\mathcal{P}_{M,\ell}$ is ESP if M is regular and then showed the preservation of ESP property when smaller matroids in \mathfrak{I} associated with ESP properties are composed to form a larger matroid in \mathfrak{I} .

By symmetry, all ports of $U_{2,4}$ (cf. Sect. 2.5(vii)) are isomorphic and so are all ports of F_7^* (cf. Sect. 2.5(x)). These two kinds of ports are precisely clutters C_3 and Q_6 , respectively, defined in Example 1. Similarly, if ℓ_1 and ℓ_2 are the two elements of F_7^+ (cf. Sect. 2.5(ix)) that are in series, then the ℓ_1 -port and ℓ_2 -port of F_7^+ are isomorphic, which are clutter Q_7 in Example 1(iii). The next two corollaries of Theorem 21 [20] are stated in terms of clutters.

Corollary 4 *A matroid port is ESP, if and only if it is box-Mengerian, if and only if none of C_3 , Q_6 , and Q_7 is its minor.*

Ports with no C_3 -minors are known as *binary* clutters, which are precisely ports of binary matroids [106]. Corollary 4 clearly implies the following, which is basically equivalent to Theorem 21.

Corollary 5 *A binary clutter is ESP, if and only if it is box-Mengerian, if and only if neither Q_6 nor Q_7 is its minor.*

By the above two corollaries, it is easy to see that *all bipartite graphs are ESP*, which strengthens the well-known statement that bipartite graphs are Mengerian (see, e.g., [103] page 1399). Moreover, all applications in Sect. 7 of [20] have automatic “strengthening” from “box-TDI” to “ESP.”

Definition 22 A *signed graph* is a pair (G, Σ) of an undirected graph G and a subset $\Sigma \subseteq E(G)$. A cycle C of G is *odd* if $|E(C) \cap \Sigma|$ is odd.

It is well known [62, 107] that the clutter of edge sets of odd cycles in a signed graph (G, Σ) (cf. Definition 7) is a binary clutter, written as $\mathcal{H}_{G,\Sigma}$. Note that Q_6 equals $\mathcal{H}_{K_4,E(K_4)}$ yet Q_7 does not equal any $\mathcal{H}_{G,\Sigma}$. More on signed graphs and odd cycles can be found in [28, 103]; in particular, the reader is referred to Corollary 7.1 of [20] for minor operations on signed graphs. When restricted to signed graphs, Corollary 5 combined with Theorem 20 gives the following.

Remark 2 The clutter of odd cycles in a signed graph (G, Σ) is ESP, if and only if it is box-Mengerian, if and only if it is Mengerian, if and only if (G, Σ) has no $(K_4, E(K_4))$ -minor.

Definition 23 A *graft* (G, T) is an undirected graph G together with a subset $T \subseteq V(G)$ with even $|T|$. A subset of $E(G)$ is a *T-join* if it induces a forest whose

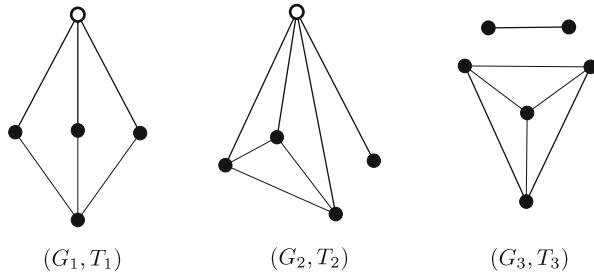

Fig. 4 Excluded grafts for ESP hypergraphs of T -joins

odd-degree vertices coincide with those in T . A subset C of $E(G)$ is called a T -cut if there exists subset $S \subseteq V$ with odd $|S \cap T|$ such that $C = \delta(S)$. cf. [Definition 14](#).

The set of all T -joins (resp. T -cuts) forms a binary clutter [20, 28, 103, 109]. More specifically, one can define a binary matroid M such that the ℓ -port of M is the T -join clutter of G , and the ℓ -port of M^* , the dual of M , is the T -cut clutter of G (see, e.g., [20]). A *minor* of a graft is obtained by performing a sequence of edge deletions and edge contractions (cf. [Sect. 2.5\(ii\)](#)), where in contracting edge uv into a vertex, the vertex is put in new T if exactly one of u and v is in old T . In the context of T -joins and T -cuts, [Corollary 5](#) and [Theorem 20](#) are rephrased as the following characterizations.

Remark 3 The clutter of T -cuts in graft (G, T) is ESP, if and only if it is box-Mengerian, if and only if it is Mengerian, if and only if (G, T) has no $(K_4, V(K_4))$ -minor.

Remark 4 The clutter of T -joins in graft (G, T) is ESP, if and only if it is box-Mengerian, if and only if (G, T) has no (G_i, T_i) -minor, $i = 1, 2, 3$, depicted in [Fig. 4](#), where solid vertices are those in T_i , $i = 1, 2, 3$. The clutter of T -joins in (G, T) is Mengerian if and only if (G, T) has no (G_1, T_1) -minor.

Let $G = (V, E)$ be an undirected graph, and let $\{s_1, t_1\}$ and $\{s_2, t_2\}$ be two pairs of vertices in V with $s_1 \neq t_1$ and $s_2 \neq t_2$.

Definition 24 A *two-commodity path* is an s_1t_1 -path or an s_2t_2 -path. A *two-commodity cut* is a minimal set of edges separating both s_1 from t_1 , and s_2 from t_2 .

As pointed out in [107], two-commodity paths (resp. two-commodity cuts) form a binary clutter; in fact, if M is the matroid on $E \cup \{\ell\}$ such that its ℓ -port is the two-commodity path clutter of G , then the ℓ -port of M^* , the dual of M , is the two-commodity cut clutter of G , and vice versa. [Corollary 5](#) and [Theorem 20](#) provide the following remarks on two-commodity paths and two-commodity cuts, where the

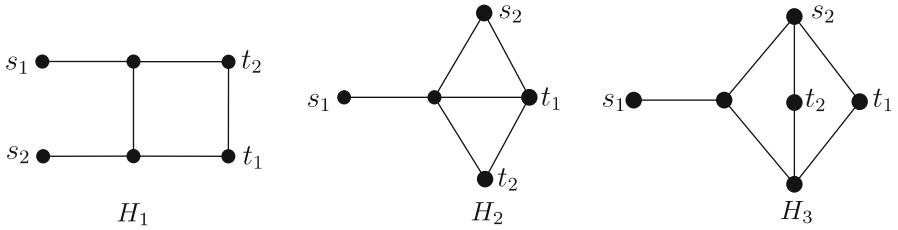

Fig. 5 Excluded graph minors for ESP hypergraphs of two-commodity paths/cuts

exclusion of graphs H_1 , H_2 , H_3 in Fig. 5 is up to permuting indices of s_1, s_2, t_1, t_2 and exchanging s_i with t_i , $i = 1, 2$.

Remark 5 The clutter of two-commodity paths in G is ESP, if and only if it is box-Mengerian, if and only if it is Mengerian, if and only if no subgraph of G can be contracted to H_1 .

Remark 6 The clutter of two-commodity cuts in G is ESP, if and only if it is box-Mengerian, if and only if no subgraph of G can be contracted to H_2 or H_3 . The clutter of two-commodity cuts in G is Mengerian if and only if no subgraph of G can be contracted to H_2 .

4.5 ESP Hypergraphs vs. Min–Max Theorems

A number of known min–max relations enjoy the ESP property (cf. Definition 18), due to their cross-free structures.

Definition 25 A collection Λ of subsets of a ground set U is *cross-free* if, for all $U_1, U_2 \in \Lambda$, one has $U_1 \subseteq U_2$ or $U_2 \subseteq U_1$ or $U_1 \cap U_2 = \emptyset$ or $U_1 \cup U_2 = U$.

Lemma 8 Let Λ be a collection of directed cuts in $D = (V, E)$ (see Definition 15) such that $\{S \subseteq V : C = \delta^{\text{in}}(S) \text{ and } C \in \Lambda\}$ is cross-free. Then Λ admits an equitable subpartition.

Proof Let A be the Λ - E incidence matrix. It can be seen from Corollary 13.21a of [103] that A is totally unimodular. Using (iv) of Corollary 19.3 in [101], collection Λ can be partitioned into two collections Λ_1 and Λ_2 such that the sum of rows of M indexed by Λ_1 minus the sum of rows of M index Λ_2 is a $\{0, \pm 1\}$ -vector. It is easy to see that (Λ_1, Λ_2) is an equitable subpartition of Λ as desired. \square

Definition 26 In a directed graph $D = (V, E)$, a *dicut* is a cut $\delta^{\text{in}}(U)$ with $U \subset V$ (cf. Definition 15) such that no arcs leaves U . Given $r \in V$, an r -*cut* is a cut $\delta^{\text{in}}(U)$ with $U \subseteq V - \{r\}$. Let V be partitioned into two sets R and S . An R - S *bicut* is a cut $\delta^{\text{in}}(U)$ in D with U a subset or a superset of S . Let $D_0 = (V, E_0)$ be a directed

graph such that for each arc rs of D , there exist vertices $r', s' \in V$, and directed rr' -path, $s'r'$ -path, and $s's$ -path in D_0 . A D_0 -cut is a cut $\delta^{\text{in}}(U)$ in D such that no arc in E_0 entering U .

Notice that for $r \in V$, an $\{r\}-(V - \{r\})$ bicut is simply an r -cut. The next corollary summarizes the cross-free essences in Lucchesi–Younger theorem [82], Fulkerson’s optimum arborescence theorem [58], Schrijver’s bibranching theorem, and Shrijver’s strong connector theorem [98].

Corollary 6 *The following hypergraphs are ESP, and so box-Mengerian: (i) the hypergraph of dicuts, (ii) the hypergraph of r -cuts, (iii) the hypergraph of R - S bicuts, and (iv) the hypergraph of D_0 -cuts.*

Proof Let Λ be a collection of hyperedges of the hypergraph in consideration. It was shown that there exists collection Ω of hyperedges of the hypergraph such that $|\Omega| \geq |\Lambda|$, $d_\Omega(v) \leq d_\Lambda(v)$ for all nodes v of the hypergraph, and the collection $\{U \subseteq V : C = \delta^{\text{in}}(U) \text{ and } C \in \Omega\}$ is cross-free (see, e.g., Theorems 55.2, 54.8 and 57.3 in [103]). It can be deduced from Lemma 8 that Ω admits an equitable subpartition, so does Λ . \square

4.6 Blockers of ESP Hypergraphs

This subsection investigates the blockers (see Definition 10) of ESP hypergraphs in the context of ESP property. Similar to Observation Observation 1, it is easy to see that a hypergraph \mathcal{H} is ESP if and only if so is \mathcal{H}^{\min} .

4.6.1 ESP Blockers

A blocking pair (see Definition 10) is said to be *ESP* if both clutters of the pair are ESP.

Corollary 7 *Each of the following form an ESP blocking pair:*

- (i) *The clutter of T -cuts and the clutter of T -joins in grafts with no $(K_4, V(K_4))$ -minor nor (G_i, T_i) -minor, $i = 1, 2, 3$ (see Definition 23 and Fig. 4)*
- (ii) *The clutter of st -paths and the clutter of st -cuts in an undirected graph*
- (iii) *The clutter of edges and the clutter of vertex cover (see Definition 13) in a bipartite graph*

Proof Statement (i) follows from Remarks 3 and 4. When $T = \{s, t\}$, Statement (i) specializes to Statement (ii). Both clutters in (iii) are known to be binary (cf. Chap. 80 of [103]). It is easy to check that neither clutter can have Q_6 or Q_7 as a minor. Hence (iii) follows from Corollary 5. \square

4.6.2 Non-ESP Blockers

Recall from Example 2 that $b(Q_6)$ is Mengerian [103]. It is actually box-Mengerian, as implied by Theorem 15 and the following ESP property.

Remark 7 $b(Q_6)$ is ESP, and so box-Mengerian.

An instant example for “non-ESP blockers of ESP hypergraphs” is the clutter Q_6 (see [Example 1\(ii\)](#)), which is the blocker of the ESP hypergraph $b(Q_6)$ (see [Remark 7](#)). Since Q_6 is non-Mengerian [103, 107], it is non-ESP by [Theorem 15](#). Another example comes from dijoins.

Definition 27 A *dijoin* of a directed graph D is a set of arcs in D that intersects every dicut of D (see [Definition 26](#)).

The clutter of dijoins in a directed graph D is the blocker of the hypergraph of dicuts in D . The former may be non-Mengerian (so non-ESP) as Shrijver’s example [97] shows (cf. [Corollary 8\(iv\)](#)), while the latter is always ESP as [Corollary 6\(i\)](#) asserts.

At this point, it might be more interesting to see if there exist Mengerian blockers of ESP hypergraphs that are not ESP. The examples to be presented for the non-ESP blockers of the ESP-hypergraphs have the common feature described in the next lemma.

Lemma 9 Let $\mathcal{H} = (V, \mathcal{E})$ be a hypergraph with node set $V = \{v_i : i = 1, 2, \dots, |V|\}$. Suppose that \mathcal{E} contains three hyperedges $S_1 = \{v_1, v_4, v_5\}$, $S_2 = \{v_2, v_5, v_6\}$, and $S_3 = \{v_3, v_6, v_4\}$. Then \mathcal{H} is not ESP. If $b(\mathcal{H})$ has four hyperedges whose intersections with $\{v_1, v_2, v_3, v_4, v_5, v_6\}$ are $\{v_1, v_2, v_3\}$, $\{v_1, v_6\}$, $\{v_2, v_4\}$, and $\{v_3, v_5\}$, respectively, then \mathcal{H} is not box-Mengerian.

Proof It is clear that \mathcal{H} is not ESP as hyperedge collection $\{S_1, S_2, S_3\}$ does not admit any equitable subpartition. Let A be the \mathcal{E} - V incidence matrix of \mathcal{H} . Define $w \in \mathbb{Z}_+^V$ and $\mathbf{l}, \mathbf{u} \in \mathbb{Q}_+^V$ by setting $w(v_i)$ to be 1 if $i \leq 6$ and to 0 otherwise, setting $\mathbf{l}(v_i)$ to be $\frac{1}{2}$ if $i \leq 3$ and to 0 otherwise, and setting $\mathbf{u} = \mathbf{1}$. Let $\mathbf{x}_* \in \mathbb{Q}_+^V$ be defined by

$$x_*(v_1) = x_*(v_2) = x_*(v_3) = \frac{1}{2}, \quad x_*(v_4) = x_*(v_5) = x_*(v_6) = \frac{1}{4},$$

$$\text{and } x_*(v_i) = 1 \text{ for all } 7 \leq i \leq |V|.$$

If the vector $A\mathbf{x}_*$ has some coordinate smaller than 1, then \mathcal{H} has a hyperedge $S \in \mathcal{E}$ such that $S \in \{v_4, v_5, v_6\}$ or $S \in \{v_i, v_j\}$ for some $i \in \{1, 2, 3\}$ and some $j \in \{4, 5, 6\}$. Neither case is possible since $\{v_4, v_5, v_6\}$ does not intersect the hyperedge $\{v_1, v_2, v_3\}$ of $b(\mathcal{H})$, and $\{v_i, v_j\}$ does not intersect one of the three hyperedges $\{v_1, v_6\}$, $\{v_2, v_4\}$, $\{v_3, v_5\}$ of $b(\mathcal{H})$. It follows that $A\mathbf{x}_* \geq \mathbf{1}$ and further that

$$\begin{aligned} \mathbf{x}_* \text{ is a feasible solution to } & \min\{\mathbf{w}^T \mathbf{x} : A\mathbf{x} \geq \mathbf{1}, \mathbf{u} \geq \mathbf{x} \geq \mathbf{l}, \mathbf{x} \geq 0\} \\ & \text{with objective value } \mathbf{w}^T \mathbf{x}_* = 2.25. \end{aligned} \tag{11}$$

Observe that the maximization problem $\max\{\boldsymbol{\alpha}^T \mathbf{1} + \boldsymbol{\beta}^T \mathbf{l} - \boldsymbol{\gamma}^T \mathbf{u} : \boldsymbol{\alpha}^T A + \boldsymbol{\beta}^T - \boldsymbol{\gamma}^T \leq \mathbf{w}^T, \boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\gamma} \geq \mathbf{0}\}$ has a feasible solution $(\boldsymbol{\alpha}_*, \boldsymbol{\beta}_*, \boldsymbol{\gamma}_*)$ with $\alpha_*(S_i) = \frac{1}{2}$ for $i = 1, 2, 3$, $\alpha_*(S) = 0$ for all $S \in \mathcal{E} - \{S_1, S_2, S_3\}$, $\beta_*(v_i) = \frac{1}{2}$ for $i = 1, 2, 3$, $\beta_*(v_i) = 0$ for $4 \leq i \leq |V|$, and $\boldsymbol{\gamma}_* = \mathbf{0}$. By (11), it follows from $\boldsymbol{\alpha}_*^T \mathbf{1} + \boldsymbol{\beta}_*^T \mathbf{l} - \boldsymbol{\gamma}_*^T \mathbf{u} = 2.25 = \mathbf{w}^T \mathbf{x}_*$ that the maximization problem has optimal value 2.25 and therefore cannot have an integral optimal solution as \mathbf{l} and \mathbf{u} are both half-integral. \square

In a directed graph $D = (V, E)$ with $r, s \in V$, vertex r reaches vertex s , or equivalently s is reachable from r if there is an rs -directed path in D . The following definition gives the node covers (see Definition 8) of the r -cut hypergraph and the R - S bicut hypergraph.

Definition 28 Let $D = (V, E)$ be a directed graph with a specified vertex $r \in V$. An r -arborescence in D is a set E' of $|V| - 1$ arcs in E forming a spanning tree (V, E') in which r reaches every vertex of V . Let V be partitioned into two sets R and S . A subset $E' \subseteq E$ is an R - S bibranching in D if in the graph (V, E') , each vertex in S is reachable from a vertex in R , and each vertex in R reaches a vertex in S .

For every directed graph D as described in the above definition, the following (i) and (ii) hold:

- (i) The clutter \mathcal{A}_D of r -arborescences in D (see Definition 28) is the blocker of the hypergraph of r -cuts in D (see Definition 26). The clutter \mathcal{A}_D is Mengerian by Edmonds' disjoint arborescences theorem [39].

More generally,

- (ii) The clutter \mathcal{B}_D of R - S bibranchings in D (see Definition 28) is the blocker of the hypergraph of R - S bicuts in D (see Definition 26). The clutter \mathcal{B}_D is Mengerian by Schrijver's disjoint bibranchings theorem [98].

A directed graph is source-sink connected if for each strong component C not entered by any arc and each strong component C' not left by any arc in the directed graph, some vertex in C reaches some vertex in C' . So an acyclic directed graph is source-sink connected if each source reaches each sink.

Definition 29 Let directed graphs $D = (V, E)$ and $D_0 = (V, E_0)$ be as described in Definition 26. A strong connector for D_0 in D is a subset $E' \subseteq E$ such that the directed graph $(V, E_0 \cup E')$ is strongly connected.

For every pair of directed graphs D and D_0 as described in the above definition, the following holds:

- (iii) The clutter \mathcal{S}_{D_0} of strong connectors of D_0 in D (see Definition 29) is the blocker of the hypergraph of D_0 -cuts in D (see Definition 26). When D_0 is source-sink connected, the clutter \mathcal{S}_{D_0} is Mengerian [98].

A directed graph is *series-parallel* if its underlying undirected graph contains no subdivision of K_4 (cf. Sect. 2.5(iii) and (v)). Given a directed tree T , which is an orientation of an undirected tree, a directed graph $D = (V, E)$ is called a *transitive closure* of T if $V = V(T)$ and $xy \in E$ if and only if x reaches y in T . For every directed graph D , the following holds:

- (iv) The clutter \mathcal{J}_D of dijoins in D (see Definition 27) is the blocker of the hypergraph of dicuts in D (see Definition 26). When D is a series-parallel directed graph [79], or a source-sink connected directed graph [47, 98], or a transitive closure of a directed tree [103], the clutter \mathcal{J}_D is Mengerian.

For undirected graph G , the following holds:

- (v) The clutter \mathcal{F}_G of feedback vertex sets in G (see Definition 20) is the blocker of the hypergraph of cycles (vertex sets of cycles) in G . When G contains no induced subgraph isomorphic to a subdivision of an odd ring or a wheel or $K_{2,3}$ (see Fig. 1), the clutter \mathcal{F}_G is Mengerian [18].

The following corollary of Lemma 9 asserts that none of the above Mengerian blockers is ESP:

Corollary 8 *The following blockers of ESP hypergraphs are all Mengerian but not necessarily box-Mengerian. Nor are they ESP:*

- (i) *The clutter \mathcal{A}_D of r-arborescences in directed graph D*
- (ii) *The clutter \mathcal{B}_D of R-S bibranching in directed graph D*
- (iii) *The clutter \mathcal{S}_{D_0} of strong connectors for sink-source connected directed graph D_0*
- (iv) *The clutter \mathcal{J}_D of dijoins in series-parallel directed graphs D , source-sink connected directed graph D , or transitive closure D of a directed tree*
- (v) *The clutter \mathcal{F}_G of feedback vertex sets in undirected graphs G which contain no induced subgraph isomorphic to a subdivision of an odd ring or a wheel or $K_{2,3}$*

Proof The task is to exhibit examples satisfying Lemma 9. They are depicted in Fig. 6, where symbols v_1, v_2, \dots, v_6 are put close to the hypergraph nodes they represent. They represent arcs in directed graph D and vertices in undirected graph G .

(i) Figure 6(1) presents a directed graph D with root r for which \mathcal{A}_D is neither ESP nor box-Mengerian. (ii) The conclusion follows immediately from (i), since \mathcal{A}_D is a special case of \mathcal{B}_D as shown by setting $R = \{r\}$ and $S = V - \{r\}$ for directed graph $D = (V, E)$ with $r \in V$. With the setting, a minimal R-S bibranching is simply an r -arborescence. (iii) Consider clutter \mathcal{S}_{D_0} of strong connectors in D in Fig. 6(1) for D_0 in Fig. 6(2), where sink r of D_0 is connected to all other vertices (sources). Notice that S_1, S_2 , and S_3 in Lemma 9 are corresponding strong connectors, that is, hyperedges of \mathcal{S}_{D_0} . (iv) The directed graph D in Fig. 6(3) is both series-parallel and source-sink connected. A transitive closure D of directed tree T is shown in Fig. 6(4), where thick arcs are those of T . These directed graphs D give rise to clutters \mathcal{J}_D which satisfy all the conditions of Lemma 9 in place of \mathcal{H} . (v) Clearly the graph $G = (V, E)$ in Fig. 6(5) is free of the forbidden structures and gives the clutter \mathcal{F}_G to which Lemma 9 applies. \square

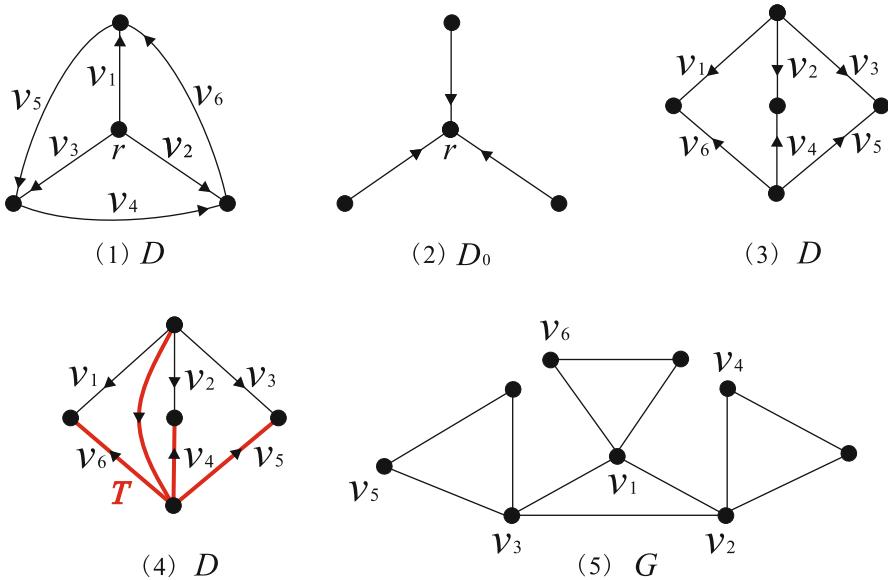

Fig. 6 Non-ESP blockers of ESP hypergraphs

A couple of blocking pairs possess Mengerian properties at the same time, for example, those in [Corollaries 6, 7, and 8](#), despite some exceptions, for example, dicuts vs. dijoins. In view that all hypergraphs in [Corollary 8](#) are Mengerian, it turns out much harder to preserve ESP property under taking blockers.

Remark 8 The ESP property is not closed under taking blockers nor is the box-Mengerian property.

It is even worse that in general no box- $\frac{1}{d}$ -Mengerian property with d bounded can be guaranteed for the blocker of an ESP hypergraph.

[Figure 7](#) gives extensions of the examples in [Fig. 6](#), which lead to the following negative statement on box- $\frac{1}{d}$ -Mengerian property for the Mengerian blockers of ESP hypergraphs.

Remark 9 Let \mathcal{H}_H denote the clutter in (i)–(v) of [Corollary 8](#). For any integer $d \geq 1$, there is graph H such that \mathcal{H}_H is not box- $\frac{1}{d}$ -Mengerian.

Proof In case of (i) and (ii), take H as the directed graph D in [Fig. 7\(1\)](#) with setting $R = \{r\}$ and $S = V(D) - \{r\}$ for case (ii). In case of (iii), take H as D_0 in [Fig. 7\(2\)](#) and consider \mathcal{H}_H the clutter of strong connectors for D_0 in the directed graph D in [Fig. 7\(1\)](#). In case of (iv), take H as D in [Fig. 7\(3\)](#) which is a transitive closure of the directed tree T in [Fig. 7\(4\)](#). In case of (v), consider H as the undirected graph G in [Fig. 7\(5\)](#).

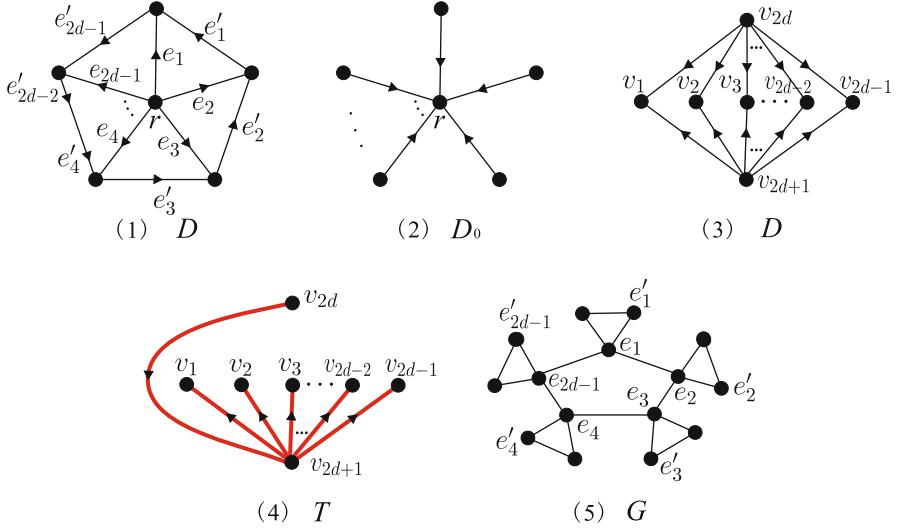

Fig. 7 Mengerian hypergraphs which are not box- $\frac{1}{d-1}$ -Mengerian

To verify the conclusion, investigate $\mathcal{H}_H = \mathcal{J}_D$ for the series-parallel directed graph D in Fig. 7(3). (The other cases of \mathcal{H}_H can be treated similarly). Observe that the directed graph D is an orientation of complete bipartite graph $K_{2,2d-1}$, $d \geq 2$, where $V(D)$ consists of bipartition $\{v_{2d}, v_{2d+1}\}$ of sources and $\{v_1, v_2, \dots, v_{2d-1}\}$ of sinks, and $E(D) = \{e_i, e'_i : i = 1, 2, \dots, 2d - 1\}$ is labeled in such a way that e_i and e'_i are incident with v_{2d} and v_{2d+1} , respectively, and have common head v_i , $i = 1, 2, \dots, 2d - 1$. Think of the clutter $\mathcal{J}_D = (E(D), \mathcal{E})$ of dijoints in D . Define $w, u \in \mathbb{Z}_+^{E(D)}$ and $l \in \mathbb{Q}_+^{E(D)}$ by setting

$$w = \mathbf{1}, u = \mathbf{1} \text{ and } l(e_i) = \frac{2d-3}{2d-2} \text{ and } l(e'_i) = 0 \text{ for } i = 1, 2, \dots, 2d-1.$$

Let A be the \mathcal{E} - $E(D)$ incidence matrix of \mathcal{J}_D . Note that the minimization problem $\min\{w^T x : Ax \geq \mathbf{1}, u \geq x \geq l, x \geq 0\}$ has a feasible solution x_* with $x_*(e_i) = \frac{2d-3}{2d-2}$ and $x_*(e'_i) = \frac{1}{(2d-2)^2}$, $i = 1, 2, \dots, 2d-1$, yielding objective value

$$w^T x_* = \frac{2d-3}{2d-2}(2d-1) + \frac{1}{(2d-2)^2}(2d-1) = \frac{(4d^2-10d+7)(2d-1)}{(2d-2)^2}.$$

On the other hand, D has dijoints $J_i := \{e_i\} \cup \{e'_1, e'_2, \dots, e'_{2d-1}\} - \{e'_i\} \in \mathcal{E}$ for $i = 1, 2, \dots, 2d-1$. It is easy to see that the maximization problem $\max\{\alpha^T \mathbf{1} + \beta^T l - \gamma^T u : \alpha^T A + \beta^T - \gamma^T \leq w^T, \alpha, \beta, \gamma \geq \mathbf{0}\}$ has a feasible solution $(\alpha_*, \beta_*, \gamma_*)$ given by $\alpha_*(J_i) = \frac{1}{2d-2}$ for $i = 1, 2, \dots, 2d-1$, $\alpha_*(J) = 0$ for all $J \in \mathcal{E} - \{J_i : i = 1, 2, \dots, 2d-1\}$; $\beta_*(e_i) = \frac{2d-3}{2d-2}$, $\beta_*(e'_i) = 0$ for $i = 1, 2, \dots, 2d-1$; and

$\gamma_* = \mathbf{0}$. From

$$\begin{aligned}\alpha_*^T \mathbf{1} + \beta_*^T \mathbf{l} - \gamma_*^T \mathbf{u} &= \frac{1}{2d-2}(2d-1) + \frac{2d-3}{2d-2} \cdot \frac{2d-3}{2d-2}(2d-1) \\ &= \frac{(4d^2 - 10d + 7)(2d-1)}{(2d-2)^2} = \mathbf{w}^T \mathbf{x}_*,\end{aligned}$$

it follows that the maximization problem has optimal value $\frac{(4d^2 - 10d + 7)(2d-1)}{(2d-2)^2}$, and hence cannot have any optimal solution that is $\frac{1}{d-1}$ -integral, as $\mathbf{u} = \mathbf{1}$ and \mathbf{l} is $\frac{1}{2d-2}$ -integral. \square

Definition 30 A clutter is *diadic* if each of its hyperedge intersects each of its minimal node cover in at most two nodes.

Consider the Mengerian clutter \mathcal{J}_D of dijoins (cf. Corollary 8(iv)) in the series-parallel directed graph D in Fig. 6(3). It is routine to check that \mathcal{J}_D is diadic. Particularly, \mathcal{J}_D is a circulant clutter [28] with node set $\{u_1, u_2, u_3, u_4, u_5, u_6\}$, where $u_1, u_2, u_3, u_4, u_5, u_6$ are arcs $v_1, v_2, v_3, v_6, v_4, v_5$ in Fig. 6(3), respectively, and hyperedge set $\{\{u_i, u_{i+1}, u_{i+2}\} : i = 1, 2, 3, 4\} \cup \{\{u_5, u_6, u_1\}, \{u_6, u_1, u_2\}\}$. Corollary 8(iv) says that \mathcal{J}_D is not box-Mengerian. This, together with a result of Cornuégols et al. [30], makes the following remark:

Remark 10 Ideal diadic clutters are Mengerian, but not necessarily box-Mengerian.

5 Total Dual Integral Systems

This section briefly reviews TDI systems established for edge covers and stars in Sect. 5.1, for feedback vertex sets and cycles in Sect. 5.2, for stable marriage in Sect. 5.3, for weighted restricted 2-matching in Sect. 5.4, for ordered submodular games in Sect. 5.5, for network design with orientation constraints in Sect. 5.6, for rooted k -connections in Sect. 5.7, and for cyclicly ordered directed graphs in Sect. 5.8. The results in the first two subsections are characterizations of both sufficiency and necessity for systems under investigation to be TDI, while the TDI-ness addressed in the third subsection with respect to stable marriage polytopes can be viewed as a sufficient condition of bipartiteness imposed on general stable matching polytopes to obtain total dual integrality. The fourth subsection provides a TDI description of the convex hull of $\{0, 1, 2\}$ -incidence vector of restricted perfect 2-matchings. The description involves complicate inequalities which have large coefficients. The TDI systems in the fifth subsection helps to prove the nonemptiness of cores of ordered submodular games. The total dual integrality established in the sixth and seventh subsections relies on positive intersecting supmodularity and intersecting supermodularity, where the latter property often yields the polynomial time solvability of the optimization problems over the TDI

systems despite their exponentially large dimension. The TDI systems presented in the last subsection concerns with cycle packing and covering in directed graphs whose vertices are given with cyclic orders, where so-called winding numbers are involved.

Every TDI system $Ax \geq b, x \geq \mathbf{0}$ is associated with one or more beautiful min–max theorems. When A is the hyperedge-node incidence matrix of a hypergraph \mathcal{H} , system $Ax \geq b, x \geq \mathbf{0}$ being TDI amounts to saying that $\tau(\mathcal{H}, w) = v(\mathcal{H}, w)$, that is, there holds the *min–max relation*:

“The minimum weight of a node cover of \mathcal{H} equals the maximum

$$\text{size of a } w\text{-packing of } \mathcal{H}.\quad (12)$$

One of the fundamental topics in combinatorial optimization is to identify scenarios under which the problems of such a covering-packing type enjoy the beautiful min–max relations. Results reviewed in Sects. 5.1 and 5.2 come in this flavor. In addition, both subsections state the characterizations for Mengerian hypergraphs and Mengerian blockers in the same theorem, with the aim of emphasizing the special features of the blocking pairs. Roughly speaking, edge covers and stars discussed in Sect. 5.1 share essentially (but not exactly) the same graphical characterization for Mengerian property, which stands in contrast with feedback vertex sets and cycles whose Mengerian hypergraphs exclude exactly the same forbidden structures, as described in Sect. 5.2.

5.1 Edge Covers and Stars

Two classical min–max theorems on edge cover and edge coloring of bipartite graphs have recently been extended to general graphs.

Definition 31 Let $G = (V, E)$ be a simple undirected graph. A *star* centered at a vertex $v \in V$ consists of all edges incident with v in G .

Let $w \in \mathbb{Z}_+^E$ be a nonnegative integral weight function defined on E . As defined in Schrijver [103], a w -stable set of G is a nonnegative integral vector $y \in \mathbb{Z}_+^V$ satisfying $y_u + y_v \leq w(e)$ for each edge $e = uv \in E$. Recalling Definition 8, it is easy to see that such an integral y corresponds to a w -star packing \mathcal{S} in G such that for each $v \in V$, packing \mathcal{S} contains exactly $y(v)$ copies of the star centered at v . The clutter of edge covers (see Definition 13) and the clutter of stars (see Definition 31) in an undirected graph form a blocking pair (cf. Definition 10). The weighted versions of Kőnig-Rado edge cover theorem [94] (see Theorem 19.4 of [103]) and Gupta’s edge cover packing theorem [70] (see Theorem 20.5 of [103]) state that the hypergraph of stars in a bipartite graph and the hypergraph of edge covers in a bipartite graph are Mengerian, respectively. The bipartiteness sufficient conditions for the total dual integrality (min–max relations (12)) have been recently

improved by Ding et al. [35] who showed that the same min–max relation holds on a graph if and only if the graph is essentially a quasi-bipartite graph (cf. [Definition 17](#)).

Theorem 22 *Let G be an undirected graph. The following statement holds:*

- (i) *For any nonnegative integral weight function $w \in \mathbb{Z}_+^E$, the minimum weight of an edge cover in G is equal to the maximum size of a w -star packing in G (i.e., the hypergraph of stars in G is Mengerian) if and only if G is quasi-bipartite, and no component of G contains K_4 as a spanning subgraph.*
- (ii) *For any nonnegative integral weight function $w \in \mathbb{Z}_+^E$, the minimum weight of a star in G is equal to the maximum size of a w -edge cover packing in G (i.e., the hypergraph of edge covers in G is Mengerian) if and only if G is quasi-bipartite.*

5.2 Feedback Vertex Sets and Cycles

It was proved by Lehman [80] that a clutter is ideal if and only if its blocker is ideal. Since the clutter of feedback vertex sets (abbreviated to FVSs, see [Definition 20](#)) and the clutter of cycles (more accurately, vertex sets of cycles) are blockers of each other, it follows from [Theorems 17](#) and [18](#) that both clutters of FVSs and cycles are ideal if and only if the underlying graphs free of the forbidden subgraphs specified in statements (i) of the two theorems. However, as far as the stronger property of being Mengerian is concerned, a blocking pair may fail to have a common characterization; see, for instance, the blocking pair of the edge cover clutter and the star clutter discussed in [Theorem 22](#) above. In other words, Mengerian property of hypergraphs is not closed under taking blockers (cf. [Theorem 8](#)).

Packing FVSs turns out not so amenable as its “blocker” counterpart—packing cycles whose associated min–max relation has been “characterized” in [Sect. 4.3](#). For instance, the FVS clutter in [Corollary 8\(v\)](#) is neither ESP nor box-Mengerian, while its cycle counterpart in [Theorem 17](#) is. Despite the gap between FVSs and cycles on box-Mengerian property, somewhat surprisingly, the same combinatorial structure assures the Mengerian property for both FVS clutter and cycle clutter, which gives the min–max relations of (12) type, as [Theorems 23](#) and [25](#) below state.

Theorem 23 *The following two statements are equivalent for every simple undirected graph $G = (V, E)$:*

- (i) *For any nonnegative integral weight function $w \in \mathbb{Z}_+^V$, the minimum weight of an FVS in G is equal to the maximum size of a w -cycle packing in G .*
- (ii) *For any nonnegative integral weight function $w \in \mathbb{Z}_+^V$, the minimum weight of a cycle in G is equal to the maximum size of a w -FVS packing in G .*
- (iii) *Graph G contains no induced subgraph isomorphic to a subdivision of an odd ring, or a where, or $K_{2,3}$ (see [Fig. 1](#)).*

For convenience, let \mathfrak{L} denote the class of simple undirected graphs G satisfying (iii). Ding and Zang [36] proved (i) \Leftrightarrow (iii), whose strengthening has been discussed

in [Theorem 17](#), and Chen et al. [18] proved (i) \Leftrightarrow (iii), whose proof relied heavily on the structural characterization of graphs in \mathfrak{L} [36] described as follows.

Let G_1 and G_2 be two undirected graphs. The *0-sum* of G_1 and G_2 is obtained by taking the disjoint union of these two graphs; the *1-sum* is obtained by identifying a vertex of G_1 with a vertex of G_2 . A *2-sum* of G_1 and G_2 is obtained by first choosing a triangle $r_i s_i t_i$ from G_i ($i = 1, 2$) such that t_i has degree two in G_i , then deleting t_i from G_i ($i = 1, 2$), and, finally, identifying $r_1 s_1$ with $r_2 s_2$. A triangle T of an undirected graph G is called *stable* if $G \setminus V(T)$ is connected and every vertex in T has degree at least three in G . A *3-sum* of G_1 and G_2 is obtained by identifying a stable triangle in G_1 with a stable triangle in G_2 .

A *rooted graph* consists of an undirected graph G and a specified set R of edges such that each edge in R belongs to a triangle and each triangle in G contains at most one edge from R . The operation of *adding pendent triangles* to the rooted graph G works as follows: For each edge uv in R , introduce a new vertex t_{uv} and two new edges ut_{uv} and vt_{uv} . The following reformulation of Theorem 3.1 in [36] gives the “decomposition” characterization of graphs in \mathfrak{L} .

Theorem 24 *For any graph $G \in \mathfrak{L}$, either (a) G is a k -sum of two smaller graphs, for $k = 0, 1, 2, 3$; or (b) G is obtained from a rooted 2-connected line graph by adding pendent triangles. (In the latter case (b), G is referred to as a prime graph).*

As mentioned at the beginning of [Sect. 5.2](#), condition (iii) $G \in \mathfrak{L}$ is necessary for the idealness of the FVS clutter of G , so by [Corollary 1](#) condition (iii) must be necessary for the min–max relation (i) which says that the clutter is Mengerian. To verify sufficiency of (iii) for (i), Chen et al. [18] resorted to [Theorem 24](#), which asserts that every graph in \mathfrak{L} can be constructed from *prime graphs* in (b) by “summing” operations in (a). In comparison with the proof for ESP cycle hypergraphs in [36] (cf. [Theorem 17](#)) which adopted the same decomposition-sum strategy by virtue of [Theorem 24](#), more complicated arguments and techniques were used in [18] to prove that FVS clutter being Mengerian is preserved under the “summing” operations and all prime graphs have Mengerian FVS clutters. A trade-off here is the algorithmic consequence.

- The nonconstructive proof by Ding and Zang [36] does not imply an algorithm for the cycle packing problem (see [Definition 20](#)) on graphs in \mathfrak{L} .
- The constructive proof by Chen et al. [19] can be converted into a polynomial time algorithm to find a maximum FVS w -packing for any graph $G = (V, E) \in \mathfrak{L}$ and any $w \in \{0, 1\}^V$. Roughly, the algorithm starts with an arbitrary collection \mathcal{F} of subsets of V such that $|\mathcal{F}|$ equals the minimum weight of a cycle G and every vertex v belongs to exactly $w(v)$ members of \mathcal{F} . Then the algorithm adjusts the collection to make it more efficient, meaning to make sets in, that is, members of, \mathcal{F} to meet as many induced cycles as possible while keeping the size $|\mathcal{F}|$ of the collection unchanged. The algorithm first makes members of \mathcal{F} meet all triangles and then other cycles in G . One of the key steps for making these adjustments is to find a better partition of the union of two members of \mathcal{F} (cf. Lemma 4.1 of [18]), where the structure stated in [Theorem 24\(b\)](#) plays

an important role. Finally the algorithm terminates when \mathcal{F} turns out to be a w -packing of FVSs in G and therefore a maximum one in view of the invariant $|\mathcal{F}|$ which equals the w -covering number (cf. inequality (2)).

Although in general the blocker of a Mengerian hypergraph does not have to be Mengerian (see, e.g., Remark 7 for Q_6), the famous max-flow min-cut theorem and a Fulkerson theorem [56] (see page 115 of [101]) assert that both the hypergraph of st -paths in a graph and its blocker are Mengerian (Corollary 7(ii) in this chapter strengthens the result), so are the hypergraph of r -arborescences and its blocker by Edmond's disjoint arborescence theorem [39] and Fullerson's optimum arborescence theorem [58] (cf. Corollary 8 in this chapter). These classes of hypergraphs \mathcal{H} certainly satisfy the condition:

$$\text{“}\mathcal{H}\text{ is Mengerian if and only if so is } b(\mathcal{H})\text{.”}$$

However, the satisfaction is trivial in the sense that no hypergraph in these classes are non-Mengerian. In contrast, Theorem 23 exhibits nontrivial satisfaction by the class of FVS hypergraphs and the class of cycle hypergraphs on undirected graphs, so does the following theorem on cycle packing and FVS packing in tournaments (cf. Sect. 4.3.2).

Theorem 25 *The following two statements are equivalent for every tournament $G = (V, E)$:*

- (i) *For any nonnegative integral weight function $w \in \mathbb{Z}_+^V$, the minimum weight of a FVS in G is equal to the maximum size of a w -cycle packing in G .*
- (ii) *For any nonnegative integral weight function $w \in \mathbb{Z}_+^V$, the minimum weight of a cycle in G is equal to the maximum size of a w -FVS packing in G .*
- (iii) *Tournament G has no subtournament isomorphic to F_1 nor F_2 (see Fig. 2).*

Note that the word “cycle” in this theorem can be replaced with “triangle,” meaning a directed cycle of length three in the tournament. The equivalence (i) \Leftrightarrow (iii) was established by Cai et al. [13] who obtained a structural description of tournaments satisfying (iii) (cf. Theorem 18 and the two paragraph succeeding it). Based on the structural description, Chen et al. [21] proved (i) \Leftrightarrow (iii).

Corollary 9 *Let \mathcal{H} be the FVS (resp. cycle) hypergraph on a undirected graph or a tournament. Then \mathcal{H} is Mengerian if and only if $b(\mathcal{H})$ is Mengerian.*

Complementary to the NP-hardness of the FVS packing problem on tournaments (cf. Theorem 13), Chen et al. [21] designed an exact algorithm running in quartic time for the FVS packing problem on tournaments with no F_1 nor F_2 . By exploiting the structural characterization given in Theorem 25 and using the exact algorithm as a subroutine, the authors provided a $\frac{2}{5}$ -approximation algorithm for the FVS packing problem on general tournaments based on the subgraph removal technique.

5.3 Stable Marriage Polytopes

Let $G = (V, E)$ be a graph. For each $v \in V$, let \prec_v be a strict linear order on $\delta(v)$ (cf. [Definition 14](#)). Let \prec be the collection of all these \prec_v for $v \in V$. The pair (G, \prec) is referred to as a *preference system*, and a *bipartite preference system* if G is a bipartite graph. An edge $e \in E$ is said to *dominate* an edge $f \in E$ if they have a common end v such that $e \preceq_v f$, meaning either $e = f$ or $e \prec_v f$. A matching of G is called *stable* if each edge of G is dominated by some edge in the matching. The *stable matching problem* is to determine if a given preference system admits a stable matching. The origin of this problem can be traced back to 1962 when Gale and Shapley [59] proposed the well-known *stable marriage problem* (which corresponds to the case of bipartite preference system); since then the stable matching problem and its variants have been subjects of extensive research. Of particular interest is the *minimum weight stable matching problem*, which takes a preference system (G, \prec) and an integral weight function w defined on $E(G)$ as input, and aims to find a stable matching of (G, \prec) with minimum total weight as output. This problem is NP-hard in general as shown by Feder [46] and is polynomial time solvable for bipartite preference system, since it was discovered by Rothblum [95] that the convex hull of stable matchings of a bipartite preference system can be described by a very simple system of linear inequalities, that is, [\(14\)](#)–[\(16\)](#) below. More specifically, the *minimum weight stable marriage problem* amounts to solving the following LP, where $\varphi(e)$ denotes the set of all edges of $G = (V, E)$ that dominate edge e :

$$\min \quad w^T x \tag{13}$$

$$\text{s.t.} \quad x(\delta(v)) \leq 1 \quad \forall v \in V \tag{14}$$

$$x(\varphi(e)) \geq 1 \quad \forall e \in E \tag{15}$$

$$x \geq \mathbf{0} \tag{16}$$

The integrality of Rothblum's system [\(14\)](#)–[\(16\)](#) with respect to bipartite preference system has recently been strengthened to total dual integrality (cf. [Theorem 1](#)) by Király and Pap [76], as the following theorem states:

Theorem 26 *If (G, \prec) is a bipartite system, then linear system [\(14\)](#)–[\(16\)](#) is TDI.*

Rothblum's system does not seem to fit easily into the known general framework for deriving total dual integrality, such as submodular flows and lattice polyhedra. Király and Pap [76] proved the TDI-ness by showing that an integral optimal solution to the LP-dual of the minimization [\(13\)](#)–[\(16\)](#) can be derived from the dual solutions of the associated rotation system, which has a totally unimodular matrix. Their constructive proof gives rise to a strongly polynomial algorithm for finding an integral optimal dual solution.

It should be noted that the system of Rothblum does not have the property that the two types of inequalities [\(14\)](#) and [\(15\)](#) separately define TDI systems (which holds, e.g., in the case of polymatroid intersection, or for any system described by

a totally unimodular matrix). In fact, neither the system of (14) and (16) nor the system of (15) and (16) is integral (cf. Theorem 1). This can be seen, respectively, from a triangle with all one weight and the example given by Király and Pap [76].

5.4 Weighted Restricted 2-Matching Polytopes

Let $G = (V, E)$ be an undirected graph, with possible loops or parallel edges. Fix an arbitrary collection \mathcal{C} of some (maybe none) cycles in G , each of which has an odd length in terms of the number of edges, and is called an *odd cycle* in G . A loop is regarded as an odd cycle.

Definition 32 A \mathcal{C} -*matching* of G is the edge set of a subgraph of G the components of which are single edges and cycles in \mathcal{C} . A \mathcal{C} -matching is *perfect* if it covers all vertices in V . The $\{0, 1, 2\}^E$ -*incidence vector* x of a \mathcal{C} -matching M is given by $x|_{E-M} = \mathbf{0}$, $x(e) = 1$ if edge $e \in E$ is in a cycle component of M , and $x(e) = 2$ if $\{e\}$ is a single edge component of M .

This subsection makes no difference between the \mathcal{C} -matching and its $\{0, 1, 2\}^E$ -incidence vector. Let P denote the convex hull of perfect \mathcal{C} -matchings, which is referred to as the *perfect \mathcal{C} -matching polytope* of G . When $\mathcal{C} = \emptyset$, the integral vectors multiplied by $1/2$ in P are precisely the perfect matchings of G , and $\frac{1}{2}P$ is known as the *perfect matching polytope* of G . When \mathcal{C} consists of all odd cycles in G , the integral vectors in P are precisely the perfect 2-matchings of G , and P is called the *perfect 2-matching polytope* of G . So, a *perfect 2-matching* of G is a vector assigning values 0, 1, or 2 to the edges in E such that the sum of values of edges incident with any vertex in V is equal to 2.

Pulleyblank and Edmonds [93] gave a TDI description of the perfect matching polytope (see, e.g., (25.20) and Corollary 25.4b of [103]), which is essential to solve the minimum weight perfect matching problem. This approach has been generalized to extensions of matching, one of which is a TDI description of the triangle-free perfect 2-matching polytope by Cornuéjols and Pulleyblank [32] (see also Theorem 30.14 of [103]), and a strongly polynomial time algorithm to find a minimum weight triangle-free perfect 2-matching. Thus, a natural question is whether one can also find a minimum weight pentagon-free perfect 2-matching, which was proposed by Schrijver [103] (see page 544), with the remark that the approach to the triangle-free problem does not extend to the pentagon-free problem. In 2009, Pap [90] solved the pentagon-free problem, and, more generally, solved a whole bunch of weighted restricted 2-matching problems.

A main result of [90] is a complete TDI description of restricted 2-matchings given Theorem 27 below. The polyhedral description is quite technical and involves so-called valid systems to be defined via a couple of definitions as follows.

An undirected graph $G = (V, E)$ is called *factor-critical* if the deletion of any vertex from G leaves a graph with a perfect matching. Given $F \subseteq E$, the set of ends of edges in F is written as $V(F)$; given $U \subseteq V$, the set of edges in E with both ends in U is written as $E(U)$.

Definition 33 A family of sets is called *laminar* if any two of the sets are disjoint or one of them is a subset of the other.

Definition 34 Let $G = (V, E)$ be an undirected graph. A set \mathcal{L} is called a *nice family* if the following conditions are satisfied:

- (i) $\mathcal{L} \subseteq 2^E$ is a laminar family.
- (ii) The subgraph $G(F) = (V(F), F)$ is factor-critical for all $F \in \mathcal{L}$.
- (iii) $\{V(F) : F \in \mathcal{L}\}$ is a laminar family.
- (iv) For every vertex $v \in V$, there exists a matching M in G such that v is exposed in M , and $|M \cap F| = (|V(F)| - 1)/2$ for all $F \in \mathcal{L}$.

A pair $(\mathcal{L}, \mathbf{m})$ of nice family \mathcal{L} and a nonnegative function $\mathbf{m} \in \mathbb{R}_+^{\mathcal{L}}$ is called a *nice system*. Given a set \mathcal{C} of some odd cycles in G , a nice system $(\mathcal{L}, \mathbf{m})$ is called a *valid* system if $\sum_{F \in \mathcal{L}} m(F)x(F) \leq \sum_{F \in \mathcal{L}} m(F)(|V(F)| - 1)$ holds for any \mathcal{C} -matching x of G (cf. [Definition 32](#)).

Theorem 27 Let $G = (V, E)$ be an undirected graph and \mathcal{C} be a set of odd cycles in G . The following is a TDI description of the perfect \mathcal{C} -matching polytope of G , which has integer coefficients:

$$\begin{aligned} x(\delta(v)) &= 2 && \forall v \in V \\ x(E(u)) &\leq |U| && \forall U \subseteq V \\ \sum_{F \in \mathcal{L}} m(F)x(F) &\leq \sum_{F \in \mathcal{L}} m(F)(|V(F)| - 1) && \forall \text{ valid system } (\mathcal{L}, \mathbf{m}) \text{ with } \mathbf{m} \in \mathbb{Z}_+^{\mathcal{L}} \end{aligned} \tag{17}$$

The TDI description also may be regarded as a generalization of its unweighted min–max formula [\[31\]](#) (see also Theorem 5 of [\[90\]](#)). While most known TDI descriptions only have 0, 1, 2 or 0 ± 1 coefficients, the last set of inequalities, called *valid inequalities*, in the above system (17) has arbitrarily large coefficients. To get a finite TDI description with integer coefficients, one may only put the valid inequalities for $(\mathcal{L}, \mathbf{m})$ corresponding to a Hilbert base of some $\{\mathbf{m} \geq \mathbf{0} : (\mathcal{L}, \mathbf{m}) \text{ is valid}\}$.

Besides the large coefficients, system (17) is not given explicitly; thus, polynomial time separation or optimization is not straightforward. In order to have such an algorithm, one has to specify explicitly the odd cycles in \mathcal{C} . On the other hand, the following algorithmic result of [\[90\]](#) shows the strong polynomial time solvability for a bunch of special cases.

Theorem 28 Let k be a fixed nonnegative integer. Given undirected graph G with edge-weights and a set \mathcal{C} of odd cycles in G , suppose that either:

- (i) \mathcal{C} contains all odd cycles longer than k and maybe some shorter cycles.
- (ii) \mathcal{C} can be enumerated in polynomial time (e.g., every member of \mathcal{C} has length less than k).

Then there is a strongly polynomial time algorithm for finding a minimum weight perfect \mathcal{C} -matching of G .

The solved special cases stated in [Theorem 28](#) include minimum weight perfect matching, minimum weight triangle-free and/or pentagon-free perfect 2-matching, and several other relaxations of the traveling salesman problem.

[Theorems 27](#) and [28](#) were proved in [90] by a primal-dual method, using the polynomial time algorithm of Cornuéjols and Hartvigsen [31] for the unweighted (i.e., unit weight) case as a subroutine. Specifically, the following principle was applied iteratively: maintain a dual solution, and either find a primal solution that satisfies the complementary slackness conditions (which is equivalent with an instance of the unweighted problem) or improve on the dual solution (which is done by using the unweighted min–max formula [31]). To obtain a polynomial time algorithm, Pap [90] showed how to implement oracles to test critical subgraphs in strongly polynomial time.

5.5 Ordered Submodular Games

Faigle and Kern [45] introduced a general order theoretic LP model, which combined with total dual integrality finds applications to the existence of the core in cooperative game theory, among others.

Let E be a finite set and let (E, \preceq) be a (partial) order on E . An element $e \in S$ is called an *upper neighbor* of the other element $f \in E$ if $f \prec e$ and there is no $g \in E$ with $f \prec g \prec e$. An *antichain* is a set of pairwise incomparable elements with respect to \prec . Let \mathcal{S} denote the set of antichains of (E, \preceq) . A distributive lattice $(\mathcal{S}, \vee, \wedge)$ can be defined by for all $S, T \in \mathcal{S}$ setting

$$\begin{aligned} S \vee T &= \text{the set of maximal elements of } \{e \in E : e \prec f \text{ for some } f \in S \cup T\}, \\ S \wedge T &= \text{the set of maximal elements of } \{e \in E : e \prec f \text{ and } e \prec g \text{ for} \\ &\quad \text{some } f \in S, g \in T\}. \end{aligned} \tag{18}$$

Let $b : \mathcal{S} \rightarrow \mathbb{R}$ or equivalently $\mathbf{b} \in \mathbb{R}^{\mathcal{S}}$ be a function on \mathcal{S} . The function \mathbf{b} is said to be *weakly increasing* relative to (E, \preceq) if for every $e \in E$ with at least two upper neighbors, the following property holds: $b(S) < b(S \cup \{e\})$ for every $S \in \mathcal{S}$ with $S \cup \{e\} \in \mathcal{S}$. The function \mathbf{b} is said to be *submodular* relative to (E, \preceq) if

$$b(S \vee T) + b(S \wedge T) \leq b(S) + b(T) \text{ for all } S, T \in \mathcal{S}.$$

Theorem 29 Let A be the \mathcal{S} - E incidence matrix of (E, \preceq) . If $\mathbf{b} \in \mathbb{R}^{\mathcal{S}}$ is a submodular and weakly increasing function on \mathcal{S} , then the following hold:

- (i) $Ax \leq b$ is a box-TDI system.
- (ii) For any function $c \in \mathbb{R}^E$, both $\max\{c^T x : Ax \leq b\}$ and the dual program $\max\{y^T b : y^T A = c, y \geq 0\}$ can be solved optimally in time polynomial in the dimension of A .

Proof It can be seen from the proof of Faigle and Kern [45, page 489–490] that the condition of [Theorem 2](#) has been satisfied, which establishes (i). The matroid-type greedy algorithm [44] (see also the (dual) greedy algorithm in [45]) finds the optimal solutions for both programs in (ii). \square

Similarly, Faigle and Kern [45] generalized the intersection theorem of Edmonds and Giles [41] from unordered ground sets to rooted forests. If an order (E, \preceq) is a rooted forest, then every function $b \in \mathbb{R}^S$ is trivially weakly increasing because every element of E has at most one upper neighbor relative to (E, \preceq) .

Theorem 30 Let A be the S - E incidence matrix of rooted forest (E, \preceq) . If $g, h \in \mathbb{R}^S$ are submodular and $b \in \mathbb{R}^S$ satisfies $b(S) = \min\{g(S), h(S)\}$ for all $S \in \mathcal{S}$, then $Ax \leq b$ is a box-TDI system.

The basic model of cooperative game theory comprises a set N of players. Subsets of N are called *coalitions*. There is a *characteristic function* $v : 2^N \rightarrow \mathbb{R}$ that assigns to each coalition S its value $v(S)$, where $v(\emptyset) = 0$. One may think of $v(S)$ as the *cost* generated by S . A solution concept is a method to divide the total cost $v(N)$ among the individual players in a “fair” way. The concept of the *core* [86] suggests to allocate a vector $x \in \mathbb{R}^N$ such that no coalition S is allocated more than its true cost $v(S)$. The *core* is defined as $Core(v) = \{x \in \mathbb{R}^N : x(S) \leq v(S) \text{ for all } S \subset N \text{ and } x(N) = v(N)\}$. Given a subfamily \mathcal{E} of essential coalitions, v induces the characteristic function $\tilde{v} : 2^N \rightarrow \mathbb{R}$ via

$$\tilde{v}(S) = \min\{\sum_j v(E_j) : E_j \in \mathcal{E} \text{ and } E_j \text{'s partition } S\} \text{ for every } S \subseteq N \quad (19)$$

with the understanding that $\tilde{v}(\emptyset) = 0$ and $\tilde{v}(S) = \infty$ if S cannot be partitioned into members of \mathcal{E} . The cooperative game (N, \tilde{v}) arising from (N, \mathcal{E}, v) is called a *partition game*. The following necessary and sufficient condition [45] for nonempty core states the existence condition of an integral optimal solution for a related LP.

Theorem 31 Let (N, \mathcal{E}, v) be a partition game, and let A be the \mathcal{E} - N incidence matrix. Then $Core(\tilde{v}) \neq \emptyset$ if and only if $\min\{(v|_{\mathcal{E}})^T y : y^T A = \mathbf{1}, y \geq 0\}$ has an integral optimal solution.

This theorem can be proved easily by using \tilde{v} ’s definition (19) and observing that nonempty $Core(\tilde{v})$ is exactly the set of optimal solution to the LP dual of $\min\{(v|_{\mathcal{E}})^T y : y^T A = \mathbf{1}, y \geq 0\}$. The following turns out a corollary of [Theorems 29, 1](#), and [31](#).

Corollary 10 Let $(N, \mathcal{E}, \mathbf{v})$ be a partition game. If the value function $\mathbf{v} \in \mathbb{R}^{\mathcal{E}}$ is submodular and weakly increasing relative to some (partial) order (N, \preceq) , then $\text{Core}(\tilde{\mathbf{v}}) \neq \emptyset$.

Along the same line, games whose value functions satisfy the conditions of [Theorem 30](#) also have nonempty cores.

Corollary 11 Let $(N, \mathcal{E}, \mathbf{v})$ be a partition game. If there exist rooted forest (N, \preceq) whose set of antichains is \mathcal{E} and submodular functions $\mathbf{g}, \mathbf{h} \in \mathbb{R}^{\mathcal{E}}$ such that the value function $\mathbf{v} \in \mathbb{R}^{\mathcal{E}}$ satisfies $v(S) = \min\{g(S), h(S)\}$ for all $S \in \mathcal{E}$, then $\text{Core}(\tilde{\mathbf{v}}) \neq \emptyset$.

The first prerequisite for applying [Corollaries 10](#) and [11](#) to cooperative games is to define appropriate partial orders (N, \preceq) which are seldom given in original game settings but constitutes basis where submodularity and weak increasing property can be discussed. Faigle and Kern [\[45\]](#) illustrated an application of [Corollary 11](#) to a generalization of the classical assignment games to three dimensions. Generalizations to higher dimensions are then straightforward to obtain.

Example 3 (3-Dimensional-Assignment Game). Let the player set N be the disjoint union of three sets I , J , and K , where $|I| = |J| = |K| = n$. The players are to form teams (i, j, k) with one member from each set. The “cost” incurred at forming such a team is $v(i, j, k) \geq 0$. How should the teams be formed and the total cost be allocated among the $3n$ players in the best possible way?

Assume that I , J , and K are geometrically represented as points on three parallel lines in \mathbb{R}^2 and the points are ordered in the same direction along the lines. Each team (i, j, k) is associated with a real number $\gamma(i, j, k) \in \mathbb{R}_+$ equal to the Euclidean circumference of the triangle on the three points corresponding to i, j, k , respectively. The number $\gamma(i, j, k)$ can be interpreted as a possible cost of forming team (i, j, k) .

Define partial order (N, \preceq) to be the union of three unrelated copies of the chain $\{1 < 2 < \dots < n\}$, one for each of I, J, K . Clearly, (N, \preceq) is a rooted forest, and the set $\mathcal{E} = \{(i, j, k) : 1 \leq i, j, k \leq n\}$ of all 3-element antichains is closed under the operations \vee and \wedge (cf. [\(18\)](#)) relative to (N, \preceq) . Moreover $\gamma(i, j, k)$ is a submodular function relative to (N, \preceq) . If the constant $\varsigma \geq 0$ offers an alternative cost per team (due to another cost scheme for which a team may opt), then the induced cost function $v(i, j, k) = \min\{\varsigma, \gamma(i, j, k)\}$, $(i, j, k) \in \mathcal{E}$ satisfies the conditions of [Corollary 11](#), which implies a nonempty core $\text{Core}(\tilde{\mathbf{v}})$ of the partition game $(N, \mathcal{E}, \mathbf{v})$.

5.6 Orientation Constrained Network Design

Khanna et al. [\[75\]](#) studied directed network design problems on mixed networks with orientation constraints in the following more general framework: Given a

directed graph $G = (V, E)$ with a *cost* function $\mathbf{w} \in \mathbb{Z}^E$, a *requirement* function $\mathbf{r} : 2^V \rightarrow \mathbb{Z}$ defined over all subsets of V , and \mathcal{R} a family of disjoint *constrained* arc pairs (e, e^-) , each of which induces a *digon*, that is, two arcs $e, e^- \in E$, arcs in E and pairs in \mathcal{R} are associated with nonnegative integral upper bounds given by $\mathbf{u}, \mathbf{l} \in \mathbb{Z}_+^{E \cup \mathcal{R}}$. The *orientation constrained network design* (OCND) problem consists of finding an optimal integral solution of the following LP, where $\delta^{\text{out}}(S)$ denotes the set of arcs in E that leave $S \subseteq V$:

$$\min \quad \mathbf{w}^T \mathbf{x} \quad (20)$$

$$\text{s.t.} \quad x(\delta^{\text{out}}(S)) \geq r(S) \quad \forall S \subset V \quad (21)$$

$$u((e, e^-)) \geq x(\{e, e^-\}) \geq l((e, e^-)) \quad \forall (e, e') \in \mathcal{R} \quad (22)$$

$$\mathbf{u}|_E \geq \mathbf{x} \geq \mathbf{l}|_E \quad (23)$$

A typical setting that falls within the general OCND framework was described in [75]: given a mixed graph $G = (V, F \cup E)$, where F consists of (undirected) edges and E consists of (directed) arcs. An orientation of an undirected edge is obtained by replacing it by one of two possible directed arcs parallel to it. Network designers often wish, at minimum cost, to fulfill a given connectivity requirement in a network by selecting a subgraph and orienting its undirected edges (i.e., satisfying orientation constraint $x(\{e, e'\}) = 1$). The typical case generalizes a couple of well-known NP-hard problems, including the problem of finding a minimum cost 2-edge-connected subgraph of an undirected graph and the problem of finding a minimum cost strongly-connected subgraph of a directed graph. In this subsection, the set function $r : 2^V \rightarrow \mathbb{Z}$ is always assumed to satisfy $r(\emptyset) = r(V) = 0$.

Definition 35 On a ground set V , two subsets $X, Y \subseteq V$ are called *intersecting* if none of $X - Y$, $Y - X$, and $X \cap Y$ is empty. A set function $r : 2^V \rightarrow \mathbb{R}$ is *intersecting supermodular*, if $r(X) + r(Y) \leq r(X \cap Y) + r(X \cup Y)$ for any intersecting pair $X, Y \subseteq V$; it is *positively intersecting supermodular* if $r(X) + r(Y) \leq r(X \cap Y) + r(X \cup Y)$ holds whenever $r(X) > 0, r(Y) > 0$ and $X, Y \subseteq V$ are intersecting.

Khanna et al. [75] proved that if the requirement function in the OCND problem is positively intersecting supermodular, then the polyhedron $\{\mathbf{x} \in \mathbb{R}^E : \mathbf{x}$ satisfies (21)–(23)\} is integral. Actually, by virtue of Theorem 2, their argument [75] suffices to prove the following stronger statement:

Theorem 32 *If the requirement function $r : 2^V \rightarrow \mathbb{Z}_+$ is positively interesting submodular, then the system (21)–(22) is box-TDI.*

The integrality of $\{\mathbf{x} \in \mathbb{R}^E : \mathbf{x}$ satisfies (21)–(23)\} naturally suggests the use of the ellipsoid method together with an oracle for \mathbf{r} to design a polynomial time algorithm for the OCND problem. As remarked in [75], the LP (20)–(23) needs

not be solvable in polynomial time for every positively intersecting supermodular function, although this is the case for most common applications. This is because usually such functions arise from intersecting supermodular functions by truncating them to be nonnegative. However, it was shown that this is not true for all such functions r .

In contrast to the “intractability” in connection with positively intersecting submodularity, intersecting submodular requirement functions have a stronger and nicer property, by which the OCND problem can be solved to optimality in polynomial time. Moreover, the results can be extended from graphs to directed hypergraphs, as shown by Frank et al. [53].

Definition 36 A *directed hypergraph* is a pair $\mathcal{H} = (V, \mathcal{E})$, where V is a finite set whose elements are called *nodes*, and \mathcal{E} a finite collection of so-called *hyperarcs* (possibly with repetition). A hyperarc $a \in \mathcal{E}$ consists of a subset $S_a \subseteq V$ and a designated head node $h_a \in S_a$.

Clearly, a directed graph is a directed hypergraph where every hyperarc has two nodes. Let $\mathcal{H} = (V, \mathcal{E})$ be a directed hypergraph and let $S \subseteq V$. It is convenient to view collection $\mathcal{E}|_V = \{S_a : a \in \mathcal{E}\}$ as the “restriction” of \mathcal{E} to V that contain underlying hyperedges, and consider $\delta^{\text{in}}(S) = \{S_a \in \mathcal{E}|_V : h_a \in S \text{ and } S_a \not\subseteq S\}$ consisting of hyperarcs that “enter” S . [Theorem 32](#) is clearly a corollary of the following more general result by Frank et al. [53], which also treats function property for tractability.

Theorem 33 Let $\mathcal{H} = (V, \mathcal{E})$ be a directed hypergraph for which $\mathcal{E}|_V$ can be partitioned into $\mathcal{E}_1, \mathcal{E}_2, \dots, \mathcal{E}_k$ such that sets (underlying hyperedges) in \mathcal{E}_i are the same for $i = 1, 2, \dots, k$. Given integers $u_i \geq l_i$, $i = 1, 2, \dots, k$, and set function $r : 2^V \rightarrow \mathbb{Z} \cup \{-\infty\}$, if r is positively intersecting submodular, then the linear system

$$\begin{aligned} x(\delta^{\text{in}}(S)) &\geq r(S) \quad \forall S \subseteq V \\ u_i &\geq x(\mathcal{E}_i) \geq l_i \quad \forall i = 1, 2, \dots, k \end{aligned} \tag{24}$$

is box-TDI. If r is intersecting submodular, then for any given $w, \tilde{u}, \tilde{l} \in \mathbb{Z}^{\mathcal{E}|_V}$ and the minimization problem

$$\min\{w^T x : \tilde{u} \geq x \geq \tilde{l} \text{ and } x \text{ satisfies (24)}\} \tag{25}$$

can be formulated as a submodular flow problem, solvable in polynomial time.

Frank et al. [53] showed that the so-called *orientation constraints* $u_i \geq x(\mathcal{E}_i) \geq l_i$, $\forall i = 1, 2, \dots, k$ can be incorporated into a construction of Schrijver [100] that transforms the minimization problem without orientation constraints

into a submodular flow problem which has efficient combinatorial algorithms (see, e.g., [55]).

Theorems 33 and 1 imply that the polyhedron $\{x : \tilde{u} \geq x \geq \tilde{l}$ and x satisfies (24)} is integral, and for every integral cost function w there exists an integral optimal solution to the dual of (25) where the family of the sets with positive dual variable is laminar (see [53] and page 313 of [101] for more details). This helps to formulate min–max relations for some graph problems. For example, what is the maximum number of undirected edges or the maximum number of arcs, that can be removed from a mixed graph such that the obtained subgraph has an orientation satisfying the requirements set by the requirement function r ? The following min–max formula due to Frank et al. [53] involves both of these problems. Let $G = (V, E)$ be an undirected graph, and let \mathcal{V} be a set of some subsets of V . Associate \mathcal{V} with the number

$$e_E(\mathcal{V}) = \max \left\{ \sum_{S \in \mathcal{V}} (\text{the number of arcs in orientation } \vec{G} \text{ that enter } S) : \right. \\ \left. \vec{G} \text{ is an orientation of } G \right\}.$$

Corollary 12 *Let $G = (V, F \cup E)$ be a mixed graph, where F is the set of undirected edges and E is the set of arcs. Let $w \in \{0, 1\}^{F \cup E}$ be a 0–1 cost function, and let $r : 2^V \rightarrow \mathbb{Z}_+$ be a positively intersecting supermodular set function. Then the minimum cost (with respect to w) of a subgraph that has an orientation satisfying requirement set by r equals*

$$\max \left\{ \sum_{S \in \mathcal{V}} r(S) - e_F(\mathcal{V}) - \sum_{S \in \mathcal{V}} |\delta_E^{\text{in}}(S)| + q(\mathcal{V}) : \mathcal{V} \subseteq 2^V \text{ is laminar} \right\}$$

where $\delta_E^{\text{in}}(S)$ is the set of arcs in E entering S , and $q(\mathcal{V})$ is the sum of the costs of the edges and arcs that enter at least one member of \mathcal{V} .

5.7 Rooted k -Connections in Directed Graphs

Let $G = (V, E)$ be a directed graph and $r_0 \in V$ be a specified vertex of G called the *root*. Graph G is called *rooted k -edge-connected* (resp. *rooted k -vertex-connected*) from r_0 if for every vertex $v \in V - \{r_0\}$, there exists at least k edge-disjoint (resp. openly disjoint) r_0v -paths in G . Suppose that G is endowed with a nonnegative arc cost function $w \in \mathbb{Z}_+^E$. Using polyhedral approaches, Frank [51] studied the *minimum cost rooted k -edge-connection* (resp. *minimum cost rooted k -vertex-connection*) problem which consists of finding a cheapest (with respect to w) subgraph $G' \subseteq G$ so that D' is rooted k -edge-connected (resp. rooted k -vertex-connected) from r_0 . Both problems have been solved to optimality in

polynomial time by Edmonds [38] and Frank and Tardos [54]. The contribution of [51] was highlighted by TDI descriptions of the rooted k -vertex-connected subgraphs and its generalizations, which were derived by using supermodular functions on bi-sets.

Definition 37 Let V be a ground set. A *bi-set* is a pair (S_O, S_I) with $S_I \subseteq S_O \subseteq V$. The set S_O is called the *outer member* of the bi-set, while S_I is called the *inner member*. A bi-set is *trivial* if $S_O = V$ or $S_I = \emptyset$, and is *void* if $S_I = \emptyset$.

Given a directed graph $G = (V, E)$, let \mathcal{B}_V denote the set of all bi-sets of V . An arc in E *enters* a bi-set (S_O, S_I) if its head belongs to S_O and its tail belongs to $V - S_O$. For any bi-set S , let $\delta^{\text{in}}(S)$ denote the set of arcs in E that enter S . Given two bi-sets $X = (X_O, X_I)$ and $Y = (Y_O, Y_I)$, their *intersection* and *union* are defined by $X \cap Y = (X_O \cap Y_O, X_I \cap Y_I)$ and $X \cup Y = (X_O \cup Y_O, X_I \cup Y_I)$, respectively.

Functions defined on \mathcal{B}_T are called *bi-set functions*. The bi-sets functions discussed in this subsection are assumed to be integer-valued and have zero value on void bi-sets. Analogous notions to those in [Definition 35](#) can be introduced for bi-set function as follows.

Definition 38 A bi-set function $r \in \mathbb{Z}^{\mathcal{B}_V}$ is *intersecting supermodular* if $r(X) + r(Y) \leq r(X \cap Y) + r(X \cup Y)$ holds for any two bi-sets X and Y with $X \cap Y$ nontrivial; it is *positively intersecting supermodular* if $r(X) + r(Y) \leq r(X \cap Y) + r(X \cup Y)$ holds whenever $r(X) > 0, r(Y) > 0$, and $X \cap Y$ nontrivial.

The combination of Frank’s “uncrossing” argument [51] and [Theorem 2](#) provides the following box-TDI system (26) under positively intersecting supermodularity. When further restricted to intersecting supermodular bi-set functions, the system defines a submodular flow polyhedron. A polyhedron P is said to be a *submodular flow polyhedron* if there exist directed graph $G = (V, E)$, an intersecting family \mathcal{V} of subsets of V (cf. [Definition 35](#)), an intersecting submodular function $s \in \mathbb{Z}^{\mathcal{V}}$, and vectors \mathbf{u} and \mathbf{l} in \mathbb{Z}^E (possibly having $-\infty$ coordinates and $+\infty$ coordinates, respectively) such that $P = \{\mathbf{x} : x(\delta^{\text{in}}(S)) - x(\delta^{\text{out}}(S)) \leq s(S) \text{ for all } S \in \mathcal{V}, \mathbf{l} \leq \mathbf{x} \leq \mathbf{u}\}$.

Theorem 34 Let $G = (V, E)$ be a directed graph. If $r \in \mathbb{Z}^{\mathcal{B}_V}$ is a positively intersecting supermodular function, then the linear system

$$x(\delta^{\text{in}}(S)) \geq r(S) \text{ for every bi-set } S \in \mathcal{B}_V \quad (26)$$

is box-TDI. If r is intersecting supermodular, then $\{\mathbf{x} : \mathbf{u} \geq \mathbf{x} \geq \mathbf{l} \text{ and } \mathbf{x} \text{ satisfies (26)}\}$ is a submodular flow polyhedron for any $\mathbf{u}, \mathbf{l} \in \mathbb{Z}^E$, where coordinates of \mathbf{u} and \mathbf{l} are allowed to be $+\infty$ or $-\infty$.

Let $G = (V, E)$ be a directed graph with root $r_0 \in V$. Considering the intersecting supermodular bi-set function $s \in \{-\infty, k\}^{\mathcal{B}_V}$ defined as

$$s(S) = \begin{cases} k & \text{if } \emptyset \neq S_O = S_I \subseteq V - \{r_0\} \\ -\infty & \text{otherwise} \end{cases}$$

from the integrality implied by the box-TDI system in [Theorem 34](#), it is easy to see that the minimum cost rooted k -edge-connected problem amounts to solving the following LP:

$$\begin{aligned} & \min\{w^T x : \mathbf{1} \geq x \geq \mathbf{0} \text{ and } x(\delta^{\text{in}}(S)) \geq s(S) \text{ for every bi-set } S \in \mathcal{B}_V\} \\ &= \min\{w^T x : \mathbf{1} \geq x \geq \mathbf{0} \text{ and } x(\delta^{\text{in}}(S)) \geq k \text{ for every nonempty } S \subseteq V - \{r_0\}\} \end{aligned}$$

This fact has been extended by Frank [\[51\]](#) to the following corollary of [Theorem 34](#):

Corollary 13 *Let $G = (V, F \cup E)$ be a directed graph with root $r_0 \in V$ and terminal set $T \subseteq V - \{r_0\}$ so that the head of each edge in E is in T . Then the convex hull of incidence vectors of the arc set $E' \subseteq E$, such that the directed graph $(V, F \cup E')$ is rooted k -edge-connected from r_0 to T , is equal to the polyhedron defined by the following TDI system:*

$$\mathbf{1} \geq x \geq \mathbf{0} \text{ and } x(\delta^{\text{in}}(S)) \geq k - (\delta^{\text{in}}(S) \cap F) \text{ for every } S \subseteq V - \{r_0\} \text{ with } S \cap T \neq \emptyset.$$

Furthermore, the polyhedron is a submodular flow polyhedron.

For the minimum cost rooted k -vertex-connected problem, Frank [\[51\]](#) gave a common generalization on rooted k -connection for both vertex and edge, where the notion rooted (k, g) -connectivity was introduced. Let $G = (V, E)$ be a directed graph with root r_0 . For $\mathbf{g} \in \mathbb{Z}_+^V$, G is said to be rooted (k, \mathbf{g}) -connected from r_0 if for every $v \in V - \{r_0\}$ there are at least k openly disjoint r_0v -paths in G where each vertex $u \in V - \{r_0, v\}$ is used by at most $g(u)$ of these paths.

Corollary 14 *Let $G = (V, E)$ be a directed graph with root $r_0 \in V$. Then the convex hull of incidence vectors of the arc set $E' \subseteq E$, such that the directed graph (V, E') is rooted (k, \mathbf{g}) -connected from r_0 , is equal to the polyhedron defined by the following TDI system:*

$$\begin{aligned} & \mathbf{1} \geq x \geq \mathbf{0} \text{ and } x(\delta^{\text{in}}(S)) \geq k - g(S_O - S_I) \text{ for every bi-set } S \in \mathcal{B}_V \text{ with} \\ & \quad \emptyset \neq S_I \subseteq S_O \subseteq V - \{r_0\}. \end{aligned}$$

Furthermore, the polyhedron is a submodular flow polyhedron.

5.8 Cyclic Orders in Directed Graphs

Seb   [105] proved a range of min–max theorems about cycle packing and covering in directed graphs whose vertices are cyclically ordered.

Let $G = (V, E)$ be a directed graph with its n vertices ordered by a *cyclic order* on V which arises from a linear order v_1, \dots, v_n of V with the additional relation that v_n is followed by v_1 . Every arc $a = uv \in E$ can be considered going forward (or clockwise) in this order and can be associated with the corresponding interval $\langle u, v \rangle$ of the circle between its tail u and its head v in clockwise direction, which consists of vertices that follow u and precede v in the clockwise order, including u and v . The number of vertices in the interval $[u, v]$ minus one is defined as the *length* of a , written as $\text{length}(a) = |\langle u, v \rangle| - 1$. Let C be a cycle of G and Λ be a collection of cycles in G ; then the *winding numbers* $\text{ind}(C)$ of C and $\text{ind}(\Lambda)$ of Λ are, respectively, defined as

$$\text{ind}(C) = \frac{1}{n} \sum_{a \in E(C)} \text{length}(a), \text{ and } \text{ind}(\Lambda) = \sum_{C' \in \Lambda} \text{ind}(C').$$

A cyclic order of V has n *openings*, described by two consecutive vertices u, v in the cyclic order: It is the linear order whose first element is v , and it is followed by the elements of V in clockwise order with u as the last element. Given directed graph $G = (V, E)$, a linear order of V is said to be *compatible* with G if every arc in E that is contained in a cycle of G is also contained in a cycle with exactly one backward arc, and arcs not contained in any cycle of G are forward arcs. A cyclic order is said to be *compatible with* G , if it has an opening which is compatible with G . Two cyclic orders are *equivalent* if one arises from the other by a sequence of elementary changes, that is, interchanges between nonadjacent vertices that are consecutive in the cyclic order. Given a directed graph $G = (V, E)$ with a cyclic order, $S \subseteq V$ is called a *cyclic stable set* if S is a stable set of G , and it forms an interval in some equivalent cyclic order. Directed graphs with every vertex contained in some cycle are called *simplified*.

The results by Seb   [105] provide a bunch of min–max relations between cycle packing and covering, concerning with various objects in cyclic directed graphs such as stable sets, their unions, feedback vertex sets and feedback arc sets. Of particular interest was the establishment of two classes of box-TDI systems.

Theorem 35 *Let $G = (V, E)$ be a simplified strongly connected directed graph given with a compatible cyclic order. Then, for every positive integer d , the following linear system (27) and system (28) are both box-TDI:*

$$\text{System: } x(V(C)) \leq d \cdot \text{ind}(C) \text{ for every cycle } C \text{ of } G \quad (27)$$

$$\text{System: } x(V(C)) \geq d \cdot \text{ind}(C) \text{ for every cycle } C \text{ of } G \quad (28)$$

Sebö [105] showed that integral solutions to (27) with $d = 1$ are precisely the characteristic (incidence) vectors of acyclic stable sets. Thus, the box-TDI-ness of (27) implies the following min–max theorem (cf. [Theorem 1](#)).

Theorem 36 *Let $G = (V, E)$ be a strongly connected directed graph given with a compatible cyclic order, and let $w \in \mathbb{Z}_+^V$. A w -cover of G is a collection Λ of cycles in G such that for every $v \in V$ at least $w(v)$ cycles in Λ each contain v . Then $\max\{w(S) : S \text{ is a cyclic stable set of } G\} = \min\{\text{ind}(\Lambda) : \Lambda \text{ is a } w\text{-cover of } G\}$.*

An interesting application of this min–max theorem gives a simple proof [105] for Bessy and Thomassé’s result [5] which confirmed Gallai’s conjecture: The vertices of a strongly connected directed graph can be covered by at most as many cycles as the stability number of the graph.

All min–max relations presented in [105] were proved using cyclic orders and a unique elementary argument based on network flows. In this way, antiblocking and blocking relations were established, leading to a combination of “integer decomposition, integer rounding” and “dual integrality” that particularly contains the matroid partition theorem and Dilworth’s theorem (see, e.g., [103]). Sebö [105] provided a common reason for all these min–max equalities to hold and some possible other ones which satisfy the same abstract properties.

Using the duality theorem of linear programming, total unimodularity, Charbit and Sebö [15] obtained the following theorem “polar to” [Theorem 36](#).

Theorem 37 *Let $G = (V, E)$ be a simplified directed graph with a cyclic order. Then*

$$\begin{aligned} \min\{\text{ind}(\Lambda) : \Lambda \text{ is a 1-cover of } G\} &= \max\{w(V) : w \in \mathbb{Z}^V \text{ and } w(C) \\ &\leq \text{ind}(C) \text{ for every cycle } C \text{ of } G\}. \end{aligned}$$

6 The Dual Half-Integrality

Recall from [Definition 5](#) that a linear system $Ax \geq b, x \geq \mathbf{0}$ is $\frac{1}{2}$ -TDI if the maximum in the LP-duality equation (1) has a half-integral optimal solution, for every integral vector w for which the optimum is finite. The following statement is an instant corollary of [Lemma 7](#).

Lemma 10 *The system $Ax \geq \mathbf{1}, x \geq \mathbf{0}, u \geq x \geq I$ is $\frac{1}{2}$ -TDI if and only if $\text{Max}(A, I, u, 4w; \mathbb{Z}) \leq 2 \text{Max}(A, I, u, 2w; \mathbb{Z})$ for any integer vector w for which $\text{Max}(A, I, u, w)$ is finite.*

This section focuses the dual half-integrality in the context of hypergraphs, namely, (box-)half-Mengerian property (see [Definition 11](#)). Well-known half-Mengerian (but not necessarily Mengerian) hypergraphs include the hypergraph of

T -cuts (see [Definition 23](#)) in undirected graphs (see Corollary 29.2d of [\[103\]](#)), the hypergraph of two-commodity paths (see [Definition 24](#)) in undirected graphs (see Hu's 2-commodity flow theorem [\[72\]](#)), and the hypergraph of odd cycles in signed graphs (see [Definition 22](#)) that do not have odd K_5 -minors (see the Geelen-Guenin theorem on evenly bipartite signed graphs [\[61\]](#)). [Section 6.1](#) develops an analogue to the ESP property, so-called quasi-ESP property, which is sufficient for box-half-Mengerian property, and helps to identify box-half-Mengerian hypergraphs of graphical edges and stars. [Section 6.2](#) deals with matroids, where matroids are considered as hypergraphs of their circuits, and (box-)Mengerian matroids are characterized in terms of excluded minors.

6.1 The Quasi-ESP Property

The ESP property is sufficient for box-Mengerian hypergraphs (see [Theorem 14](#)). Based on this property, several classes of box-Mengerian hypergraphs have been established (see [Sects. 4.2–4.5](#)). This approach can be naturally extended to hypergraphs with certain half-integrality properties.

Definition 39 Let $\mathcal{H} = (V, \mathcal{E})$ be a hypergraph and let Λ be a hyperedge collection of \mathcal{H} . A *quasi equitable subpartition* of Λ consists of two collections Λ_1 and Λ_2 of hyperedges in \mathcal{E} (which are not necessarily in Λ) such that:

- (i) $|\Lambda_1| + |\Lambda_2| \geq |\Lambda|$.
- (ii) $d_{\Lambda_1 \cup \Lambda_2}(v) \leq d_\Lambda(v)$ for all $v \in V$.
- (iii') $\max\{d_{\Lambda_1}(v), d_{\Lambda_2}(v)\} \leq 2\lceil d_\Lambda(v)/4 \rceil$ for all $v \in V$.
- (iv') $|d_{\Lambda_1}(v) - d_{\Lambda_2}(v)| \leq 2$ for all $v \in V$ with $d_{\Lambda_1 \cup \Lambda_2}(v) = d_\Lambda(v)$.

The hypergraph \mathcal{H} is called *quasi equitably subpartitionable*, abbreviated quasi-ESP, if every collection of its hyperedges admits a quasi equitable subpartition. We refer to the above (i), (ii), (iii'), and (iv') as *quasi-ESP property*.

Note that condition (iii) specified in ESP property (see [Definition 18](#)) implies conditions (iii') and (iv') of the quasi-ESP property. In general, conditions (i), (ii), and (iii') are not sufficient for box-half-Mengerian hypergraphs, though they do imply half-Mengerian property (see [\[37\]](#) for a proof).

Theorem 38 Let $\mathcal{H} = (V, \mathcal{E})$ be a hypergraph. If for every hyperedge collection Λ of \mathcal{H} , there exist two collections Λ_1 and Λ_2 of hyperedges in \mathcal{E} satisfying (i), (ii), and (iii'), then \mathcal{H} is half-Mengerian.

A counterpart of [Theorem 14](#) reads as follows:

Theorem 39 Every quasi-ESP hypergraph is box-half-Mengerian.

Obviously, the theorem is a corollary of the following stronger result.

Theorem 40 Let $\mathcal{H} = (V, \mathcal{E})$ be a hypergraph and let A be the $\mathcal{E} - V$ incidence matrix. Suppose that for any $\mathbf{l}, \mathbf{u} \in \mathbb{Q}^V$ and $\mathbf{w} \in \mathbb{Z}^V$ with finite $\text{Max}(A, \mathbf{l}, \mathbf{u}, \mathbf{w})$, there exists an optimal solution $(\boldsymbol{\alpha}^*, \boldsymbol{\beta}^*, \boldsymbol{\gamma}^*)$ to $\text{Max}(A, \mathbf{l}, \mathbf{u}, 4\mathbf{w}; \mathbb{Z})$ such that the hyperedge collection corresponding to $\boldsymbol{\alpha}^*$ (cf. Definition 19) admits a quasi equitable subpartition. Then \mathcal{H} is box-half-Mengerian.

Proof Let $(\boldsymbol{\alpha}^*, \boldsymbol{\beta}^*, \boldsymbol{\gamma}^*)$ be an optimal solution to $\text{Max}(A, \mathbf{l}, \mathbf{u}, 4\mathbf{w}; \mathbb{Z})$ such that the hyperedge collection Λ corresponding to $\boldsymbol{\alpha}^*$ admits a quasi equitable subpartition (Λ_1, Λ_2) . By Definition 11 and Lemma 10, it suffices to find a feasible solution $(\boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\gamma})$ to $\text{Max}(A, \mathbf{l}, \mathbf{u}, 2\mathbf{w}; \mathbb{Z})$ such that $\boldsymbol{\alpha}^T \mathbf{1} + \boldsymbol{\beta}^T \mathbf{l} - \boldsymbol{\gamma}^T \mathbf{u} \geq [(\boldsymbol{\alpha}^*)^T \mathbf{1} + (\boldsymbol{\beta}^*)^T \mathbf{l} - (\boldsymbol{\gamma}^*)^T \mathbf{u}] / 2$. Without loss of generality, it can be assumed that:

- (1) $\beta^*(v)\gamma^*(v) = 0$ for all $v \in V$.
- (2) $\beta^*(v) = 0$ for all $v \in V$ with $l(v) < 0$.
- (3) $d_\Lambda(v) + \beta^*(v) - \gamma^*(v) = 4w(v)$ for all $v \in V$ with $\beta^*(v) + \gamma^*(v) > 0$.

For $i = 1, 2$, let $\boldsymbol{\alpha}_i \in \mathbb{Z}_+^{\mathcal{E}}$ correspond to Λ_i . It follows from (i) of the quasi-ESP property that $\boldsymbol{\alpha}_1^T \mathbf{1} + \boldsymbol{\alpha}_2^T \mathbf{1} \geq (\boldsymbol{\alpha}^*)^T \mathbf{1}$. Considering Λ of $\sum_{v \in V} d_\Lambda(v)$ as small as possible, it can be deduced that

- (4) $|\Lambda_1| + |\Lambda_2| = |\Lambda|$ (i.e., $\boldsymbol{\alpha}_1^T \mathbf{1} + \boldsymbol{\alpha}_2^T \mathbf{1} = \boldsymbol{\alpha}^T \mathbf{1}$) and $d_{\Lambda_1}(v) + d_{\Lambda_2}(v) = d_\Lambda(v)$ for all $v \in V$.

It remains to show that for each $v \in V$, there exist nonnegative integers $\beta_1(v), \beta_2(v), \gamma_1(v), \gamma_2(v)$ such that

- (5) $\beta_1(v) + \beta_2(v) = \beta^*(v), \gamma_1(v) + \gamma_2(v) = \gamma^*(v)$ and $d_{\Lambda_i}(v) + \beta_i(v) - \gamma_i(v) \leq 2w(v)$ for $i = 1, 2$.

Upon obtaining (5), for $i = 1, 2$, set $\boldsymbol{\beta}_i = (\beta_i(v) : v \in V)$ and $\boldsymbol{\gamma}_i = (\gamma_i(v) : v \in V)$. By (4), it is easy to see that either $(\boldsymbol{\alpha}_1, \boldsymbol{\beta}_1, \boldsymbol{\gamma}_1)$ or $(\boldsymbol{\alpha}_2, \boldsymbol{\beta}_2, \boldsymbol{\gamma}_2)$ is a solution to $\text{Max}(A, \mathbf{l}, \mathbf{u}, 2\mathbf{w}; \mathbb{Z})$ as desired.

To verify (5), suppose $d_{\Lambda_s}(v) \leq d_{\Lambda_t}(v)$, where $\{s, t\} = \{1, 2\}$. If $d_{\Lambda_t}(v) \leq \lceil d_\Lambda(v)/2 \rceil$, then by $d_\Lambda(v) + \beta^*(v) - \gamma^*(v) \leq 4w(v)$, it can be seen from (1) to (4) that (5) is satisfied by setting $\beta_s(v) = \lceil \beta^*(v)/2 \rceil, \gamma_s(v) = \lfloor \gamma^*(v)/2 \rfloor, \beta_t(v) = \lfloor \beta^*(v)/2 \rfloor, \gamma_t(v) = \lceil \gamma^*(v)/2 \rceil$. Therefore, the proof reduces to the case where

- (6) $d_{\Lambda_t}(v) > \lceil d_\Lambda(v)/2 \rceil$.

If $\beta^*(v) = \gamma^*(v) = 0$, then (5) follows from setting $\beta_1(v), \beta_2(v), \gamma_1(v)$, and $\gamma_2(v)$ all equal to zero, as $\max\{d_{\Lambda_1}(v), d_{\Lambda_2}(v)\} \leq 2\lceil d_\Lambda(v)/4 \rceil \leq 2w(v)$ by (iii') of the quasi-ESP property. Hence, it remains to consider

- (7) $\beta^*(v) + \gamma^*(v) > 0$.

From (6) and (iii') of the quasi-ESP property, it follows that $\lceil d_\Lambda(v)/2 \rceil + 1 \leq d_{\Lambda_t}(v) \leq 2\lceil d_\Lambda(v)/4 \rceil$. By considering possible congruence of $d_\Lambda(v)$ modulo four and comparing the lower and upper bounds of the preceding inequality, it is easy to see that

- (8) $\lceil d_\Lambda(v)/2 \rceil + 1 = d_{\Lambda_t}(v) = 2\lceil d_\Lambda(v)/4 \rceil$ and $d_\Lambda(v) \equiv 1$ or $2 \pmod{4}$.

Observe further that

- (9) If $\gamma^*(v) > 0$, then $\gamma^*(v) \geq 2$.

Otherwise, $\gamma^*(v) = 1$. Statements (1) and (3) imply $d_\Lambda(v) \equiv 1 \pmod{4}$. It follows from (8) that $d_{\Lambda_t}(v) = [d_\Lambda(v) + 3]/2$, and it turns from (ii) of the quasi-ESP property that $d_{\Lambda_s}(v) \leq d_\Lambda(v) - [d_\Lambda(v) + 3]/2 = [d_\Lambda(v) - 3]/2$. So $d_{\Lambda_t}(v) - d_{\Lambda_s}(v) \geq 3$, which together with (4), gives a contradiction to (iv') of the quasi-ESP property. Thus, (9) is established.

By (8), $d_\Lambda(v) \equiv k \pmod{4}$, where $k = 1$ or 2 , and $d_{\Lambda_t}(v) = [d_\Lambda(v) + 4 - k]/2$. Set $\beta_t(v) = 0$ if $\beta^*(v) = 0$ and $[\beta^*(v) - 4 + k]/2$ otherwise, and set $\gamma_t(v) = 0$ if $\gamma^*(v) = 0$ and $[\gamma^*(v) + 4 - k]/2$ otherwise. From (1), (7), (3), and (9), it can be deduced that

$$(10) \quad 0 \leq \beta_t(v) \leq \beta^*(v), \quad 0 \leq \gamma_t(v) \leq \gamma^*(v), \text{ and } d_{\Lambda_t}(v) + \beta_t(v) - \gamma_t(v) = 2w(v).$$

Set $\beta_s(v) = \beta^*(v) - \beta_t(v)$ and $\gamma_s(v) = \gamma^*(v) - \gamma_t(v)$. Then, $0 \leq \beta_s(v) \leq \beta^*(v)$ and $0 \leq \gamma_s(v) \leq \gamma^*(v)$. If (5) were violated by $i = s$, then $d_\Lambda(v) + \beta^*(v) - \gamma^*(v) \geq \sum_{i=1}^2 [d_{\Lambda_i}(v) + \beta_i(v) - \gamma_i(v)] > 4w(v)$ by (10), contradicting (3). So (5) holds for $i = 1$ and 2 .

In characterizing (box-)Mengerian hypergraphs, the Q_6 -minor plays an important role (see, e.g., Corollaries 4 and 5). Although Q_6 is not ESP, an easy case analysis shows that it is quasi-ESP. Thus by Theorem 39, clutter Q_6 is box- $\frac{1}{2}$ -Mengerian. Sections 6.1.1 and 6.1.2 below show applications of quasi-ESP property to obtaining box-half-total dual integrality on packing edges and stars of undirected graphs.

6.1.1 Undirected Graphs

Let $G = (V, E)$ be an undirected graph with a nonnegative integral weight function w defined on V .

Definition 40 The *vertex cover problem* is to find a vertex cover in G (see Definition 13) with minimum total weight with respect to w .

As is well known, this NP-hard problem can be approximated within a factor of two. Despite tremendous research effort, no $(2 - \epsilon)$ -approximation algorithm has been found to date, no matter how small the positive constant ϵ is. Actually it is a widespread belief that 2 is the best approximation ratio we can achieve. One 2-approximation algorithm for the vertex cover problem is based on the following Balinski theorem [2] (see, e.g., Theorem 64.11 in [103]): Let A be the E - V incidence matrix. Then the polytope $P = \{x : Ax \geq \mathbf{1}, \mathbf{1} \geq x \geq \mathbf{0}\}$ is half-integral (cf. Definition 4). The algorithm proceeds by finding a half-integral optimal solution x^* to the LP problem $\min\{w^T x : Ax \geq \mathbf{1}, \mathbf{1} \geq x \geq \mathbf{0}\}$. Set $U = \{v : x^*(v) \geq 1/2\}$. Then U is a vertex cover as desired. In the literature P is called the *fractional vertex cover polytope*.

In view that box- $\frac{1}{2}$ -TDI-ness implies $\frac{1}{2}$ -TDI-ness, which in turn implies half-integrality, the following theorem presents a strengthening of Balinski theorem [2].

Theorem 41 Every graph is quasi-ESP, so it is box-half-Mengerian (by Theorem 39).

Proof Let $G = (V, E)$ be a graph and let Λ be an edge collection of G . To show that Λ admits a pseudo-equitable subpartition, let U be the set of all vertices of G that are incident with some edges in Λ and let $H = (U, \Lambda)$ (possibly H contains multiple edges). It can be assumed without loss of generality that H is connected (otherwise, turn to considering the components of H). Let $H' = H$ if H is Eulerian and let H' be obtained from H by adding a new vertex v^* and then making it adjacent to all vertices of odd degree in H otherwise. Then the degree of each vertex of H' is even, so H' admits an Eulerian tour T . Let a be the starting vertex of T . Clearly it can be guaranteed that:

- Vertex a is precisely v^* , if any, and $d_\Lambda(a) \equiv 2 \pmod{4}$ if H is Eulerian and has an odd number of edges.

Let E_1 consist of all odd-numbered edges in T and let E_2 consist of all even-numbered edges in T . It is easy to see that $d_{E_1}(v) = d_{E_2}(v)$ for all vertices v of H' , except possibly vertex a when H' has an odd number of edges; in this case $d_{E_1}(a) - d_{E_2}(a) = 2$. Set $\Lambda_i = \Lambda \cap E_i$ for $i = 1, 2$. Then:

- $|\Lambda_1| + |\Lambda_2| = |\Lambda|$.
- $d_{\Lambda_1 \cup \Lambda_2}(v) = d_\Lambda(v)$ for all vertices v of H .
- $\max\{d_{\Lambda_1}(v), d_{\Lambda_2}(v)\} \leq \lceil d_\Lambda(v)/2 \rceil$ for all vertices v in H , except possibly a when H is Eulerian and has an odd number of edges; in this case $\max\{d_{\Lambda_1}(a), d_{\Lambda_2}(a)\} = 1 + d_\Lambda(a)/2 = 2\lceil d_\Lambda(a)/4 \rceil$.
- $|d_{\Lambda_1}(v) - d_{\Lambda_2}(v)| \leq 2$ for all vertices v of H .

So (i), (ii), (iii'), and (iv') of the quasi-ESP property (see Definition 39) are all satisfied by Λ_1 and Λ_2 , and hence, (Λ_1, Λ_2) is a quasi equitable subpartition of Λ .

Corollary 15 Let A be a 0–1 matrix with precisely two 1s in each row. Then the linear system $Ax \geq \mathbf{1}$, $x \geq \mathbf{0}$ is box- $\frac{1}{2}$ -TDI.

6.1.2 Star Hypergraphs

Let $G = (V, E)$ be a simple undirected graph. Let \mathcal{S} be the set of all stars in G (see Definition 31). The *star hypergraph* $\mathcal{H} = (E, \mathcal{S})$ of G has its \mathcal{S} - E incidence matrix A identical with the V - E incidence matrix of G . The blocker of \mathcal{H} is the clutter of edge covers of G (see Definition 13). Clearly, G has an edge cover if and only if G contains no isolated vertex. In the literature $\{x : Ax \geq \mathbf{1}, x \geq \mathbf{0}\}$ is called the *fractional edge cover polyhedron* of G , which is half-integral as shown by Balinski [2] (see Theorem 30.10 in [103]). A closely related result of Schrijver asserts that $Ax \geq \mathbf{2}$, $x \geq \mathbf{0}$ is $\frac{1}{2}$ -TDI (see Corollary 30.11a in [103]), where $\mathbf{2}$ is the all-two vector. The next theorem strengthens these two results.

Theorem 42 Every star hypergraph is quasi-ESP, so it is box-half-Mengerian (by Theorem 39).

Proof Let $\mathcal{H} = (E, \mathcal{S})$ be the star hypergraph of a graph $G = (V, E)$ and let Λ be a hyperedge collection of \mathcal{H} . To show that Λ admits a quasi equitable subpartition, for convenience, Λ is viewed as a star collection of G . Let $S(v)$ denote the star of G centered at v , let $m_\Lambda(v)$ denote the multiplicity of $S(v)$ in Λ , let X be the set of all vertices v of G with $m_\Lambda(v) \equiv 3 \pmod{4}$, and let $Y = V - X$. Now let Λ_1 be the star collection such that $S(v)$ appears $\lceil m_\Lambda(v)/2 \rceil$ times for any $v \in X$ and $\lfloor m_\Lambda(v)/2 \rfloor$ times for any $v \in Y$, and let Λ_2 be the star collection such that $S(v)$ appears $\lfloor m_\Lambda(v)/2 \rfloor$ times for any $v \in X$ and $\lceil m_\Lambda(v)/2 \rceil$ times for any $v \in Y$. Clearly:

- (1) $|\Lambda_1| + |\Lambda_2| = |\Lambda|$.
- (2) $d_{\Lambda_1 \cup \Lambda_2}(e) = d_\Lambda(e)$ for all edges e of G .
- (3) $|d_{\Lambda_1}(e) - d_{\Lambda_2}(e)| \leq 2$ for all edges e of G .

Moreover, for any edge $e = uv$ of G and $i = 1, 2$, the equation $d_{\Lambda_i}(e) = m_{\Lambda_i}(u) + m_{\Lambda_i}(v)$ holds. Furthermore,

- (4) $d_{\Lambda_i}(e) \leq 2\lceil d_\Lambda(e)/4 \rceil$ for all edges e of G .

Assume the contrary: $d_{\Lambda_i}(e) \geq 2\lceil d_\Lambda(e)/4 \rceil + 1$ for some edge $e = uv$ of G and $i = 1$ or 2 . Set $j = 3 - i$. By (2), we have $d_{\Lambda_j}(e) \leq 2\lceil d_\Lambda(e)/4 \rceil - 1$. Since $d_{\Lambda_i}(e) - d_{\Lambda_j}(e) \geq 2\lceil d_\Lambda(e)/4 \rceil + 1 - (2\lceil d_\Lambda(e)/4 \rceil - 1) = 2$, from (3) it follows that $d_{\Lambda_i}(e) = 2\lceil d_\Lambda(e)/4 \rceil + 1$ and $d_{\Lambda_j}(e) = 2\lceil d_\Lambda(e)/4 \rceil - 1$. Hence, both $d_{\Lambda_i}(e)$ and $d_{\Lambda_j}(e)$ are odd numbers.

On the other hand, $d_{\Lambda_i}(e) - d_{\Lambda_j}(e) = 2$ if and only if $m_{\Lambda_i}(u) - m_{\Lambda_j}(u) = 1$ and $m_{\Lambda_i}(v) - m_{\Lambda_j}(v) = 1$ if and only if $m_{\Lambda_i}(u) = \lceil m_\Lambda(u)/2 \rceil = \lfloor m_\Lambda(u)/2 \rfloor + 1 = m_{\Lambda_j}(u) + 1$ and $m_{\Lambda_i}(v) = \lceil m_\Lambda(v)/2 \rceil = \lfloor m_\Lambda(v)/2 \rfloor + 1 = m_{\Lambda_j}(v) + 1$. So both $m_\Lambda(u)$ and $m_\Lambda(v)$ are odd. From the definition of Λ_1 and Λ_2 , it follows that either $\{u, v\} \subseteq X$ or $\{u, v\} \subseteq Y$. Thus, $m_\Lambda(u) \equiv m_\Lambda(v) \equiv 3$ or $1 \pmod{4}$ and therefore $d_{\Lambda_i}(e) = m_{\Lambda_i}(u) + m_{\Lambda_i}(v)$ is even. This contradiction justifies (4).

By (1)–(4), it is clear that (i), (ii), (iii'), and (iv') of the quasi-ESP property (see Definition 39) are all satisfied by Λ_1 and Λ_2 , and hence, (Λ_1, Λ_2) is a quasi equitable subpartition of Λ . \square

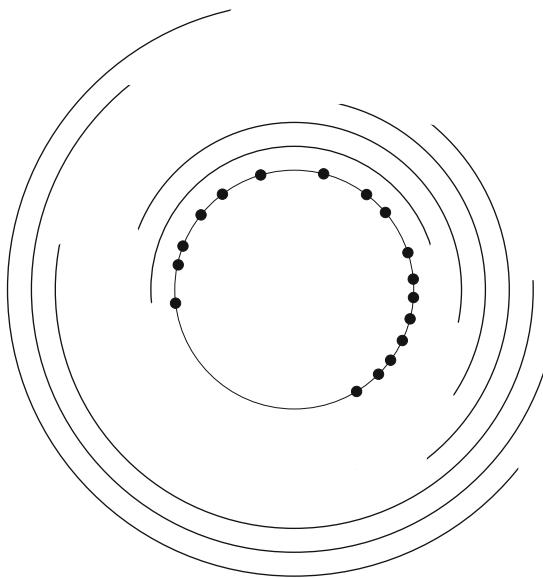

Corollary 16 *Let A be a 0–1 matrix with precisely two 1s in each column. Then the linear system $A\mathbf{x} \geq \mathbf{1}$, $\mathbf{x} \geq \mathbf{0}$ is box- $\frac{1}{2}$ -TDI.*

In the concluding part of Sect. 6.1, two examples show hypergraphs without quasi-ESP property.

Example 4 Circular arc clutters (clutters with hyperedges consecutive subsets of a set of nodes arranged in circle) are known to be diadic [34] (see Definition 30). Figure 8 presents such a clutter, where every arc represents an hyperedge in way of going through the nodes in the hyperedge. The example shows that diadic clutters are not necessarily quasi-ESP.

Example 5 A 0–1 matrix is a *hole matrix* if it contains exactly two 1s per row and per column and has no proper submatrix with this property. A *totally balanced matrix* is a 0–1 matrix in which every hole submatrix is the 2×2

Fig. 8 A circular arc clutter that is not quasi-ESP

submatrix of all 1s [27]. A hypergraph $\mathcal{H} = (V, \mathcal{E})$ is *totally balanced* if the \mathcal{E} - V incidence matrix is totally balanced [103]. For instance, a totally balanced hypergraph \mathcal{H} is given by setting $V = \{1, 2, \dots, 12\}$ and $\mathcal{E} = \{\{1, 5, 6\}, \{2, 5, 7\}, \{3, 5, 8\}, \{4, 5, 9\}, \{1, 2, 3, 4, 5, 10\}, \{1, 2, 3, 4, 5, 11\}, \{1, 2, 3, 4, 5, 12\}\}$. This hypergraph is not quasi-ESP since \mathcal{E} admits no quasi equitable subpartition.

6.2 Half-Integral Circuit Packing in Matroids

Let $M = (E, \mathcal{C})$ be a matroid (which is also viewed as a hypergraph with node set E and hyperedge set \mathcal{C}), and let $w \in \mathbb{Z}_+^E$ be a nonnegative integral weight function on E . It is not difficult to verify that hypergraph M of circuits is Mengerian (cf. Definition 9) if and only if M is the direct sum of circuits and coloops [37]. Let A be the $E - \mathcal{C}$ incidence matrix of M . It is nature to investigate the total dual half-integrality of the system $Ax \geq \mathbf{1}, x \geq \mathbf{0}$. Let

$$\begin{aligned} v_2(M, w) &= \max\{k : M \text{ has } k \text{ circuits (repetition allowed) such that each element } e \text{ of } M \text{ is used at most } 2w(e) \text{ times by these circuits}\} \\ &= \text{the maximum size of a } 2w\text{-circuit packing in } M; \\ \tau_2(M, w) &= \min\{w(X) : X \text{ is a collection of elements (repetition allowed) of } M \text{ such that every circuit in } M \text{ meets } X \text{ at least twice}\}. \end{aligned}$$

Then one may think of $v_2(M, \mathbf{w})$ as the maximum size of \mathbf{w} -“half-integral”-circuit packing in M .

6.2.1 Half-Mengerian Matroids

Recalling [Definition 11](#) and [Theorem 4](#), it is easy to obtain the following equivalence:

$$\begin{aligned} M \text{ is half-Mengerian} &\Leftrightarrow A\mathbf{x} \geq \mathbf{1}, \mathbf{x} \geq \mathbf{0} \text{ is } \frac{1}{2}\text{-TDI} \\ &\Leftrightarrow \frac{1}{2}A\mathbf{x} \geq \mathbf{1}, \mathbf{x} \geq \mathbf{0} \text{ is } \frac{1}{2}\text{-TDI} \\ &\Leftrightarrow v_2(M, \mathbf{w}) = \tau_2(M, \mathbf{w}) \text{ for all } \mathbf{w} \in \mathbb{Z}_+^E. \end{aligned} \quad (29)$$

Let $U_{2,4}$ be the uniform matroid of rank two on four elements. Let F_7 and F_7^* be the Fano matroid and its dual, respectively. Let K_n^- denote the graph obtained from K_n by deleting an edge, and let K be the first graph depicted in [Fig. 9](#). Ding and Zang [37] characterized all matroids that are half-Mengerian by proving the following theorem:

Theorem 43 *Let M be a matroid and let A be the circuit-element incidence matrix of M . Then the following statements are equivalent:*

- (i) *None of $U_{2,4}$, F_7 , F_7^* , $M(K_{3,3})$, $M(K_n^-)$ and $M(K)$ as a minor of M .*
- (ii) *The linear system $\frac{1}{2}A\mathbf{x} \geq \mathbf{1}, \mathbf{x} \geq \mathbf{0}$ is TDI.*
- (iii) *The polyhedron $\{\mathbf{x} : \frac{1}{2}A\mathbf{x} \geq \mathbf{1}, \mathbf{x} \geq \mathbf{0}\}$ is integral.*

Observe that if M is the cographic matroid of an undirected graph G , then circuits of M are precisely cuts of G and therefore A is the cut-edge incidence matrix of G . In this case, Ding and Zang’s [37] work is closely related to the *graphical traveling salesman problem* (GTSP), which, given a graph $G = (V, E)$ and a length function on E , is to find a tour of G with minimum total length, where a tour of G is an alternating sequence $T = v_0e_0v_1e_1\dots v_{k-1}e_{k-1}v_k$ of its vertices and edges such that $v_0 = v_k$, $e_i = v_iv_{i+1}$ for all $i < k$ and that each vertex of G appears in T at least once. GTSP is a relaxation of the classical TSP where a minimum Hamiltonian cycle is sought. The reader is referred to [29, 49] for a variety of motivations for investigating this graphical version. Due to its theoretical interest and practical value, the GTSP has been a subject of extensive research over the past two decades.

Let $G = (V, E)$ be an undirected graph. Each tour T of G is associate to its *incidence vector* $\mathbf{x} = (x(e) | e \in E)$, where $x(e)$ is the number of times that edge e occurs in the tour. Recalling the definition of cuts in G ([Definition 14](#)), it is easy to see that \mathbf{x} satisfies the following:

$$\begin{aligned} x(C) &\geq 2 \text{ for every cut } C \text{ of } G \\ x(e) &\in \mathbb{Z}_+ \text{ for all } e \in E. \end{aligned} \quad (30)$$

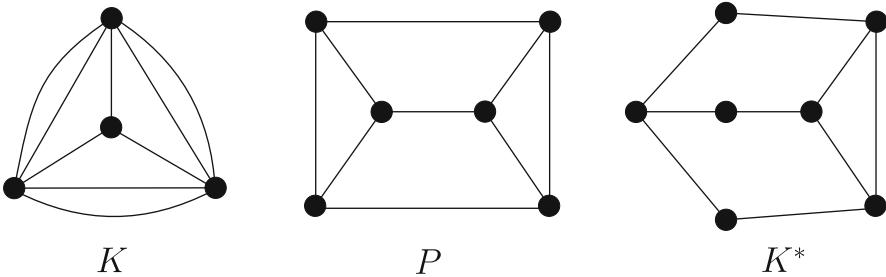

Fig. 9 Graphs K , P , and K^*

However, not every vector satisfying (30) is an incidence vector of a tour of G . In fact, it is easy to see that a vector \mathbf{x} satisfies (30) if and only if replacing each $e \in E$ with $x(e)$ parallel edges (e is actually deleted if $x(e) = 0$) results in a 2-edge-connected graph with vertex set V . (Such a graph $G_{\mathbf{x}}$ corresponds a tour of G only when $G_{\mathbf{x}}$ is Eulerian.)

Given a graph G with cut-edge incidence matrix A , let $P_0(G)$ be the convex hull of the incidence tours of G , let $P_1(G)$ be the convex hull of the incidence vectors of 2-edge-connected subgraphs of G where edges can be used several times (i.e., the convex hull of all vectors satisfying (30)), and let

$$P_2(G) = \{\mathbf{x} : \frac{1}{2}A, \mathbf{x} \geq \mathbf{1}, \mathbf{x} \geq \mathbf{0}\}. \quad (31)$$

The polyhedron $P_2(G)$ plays an important role in various polyhedral approaches to the GTSP; it is also closely related to several network design problems (see, for instance, [66, 67, 83–85]). Clearly, $P_0 \subseteq P_1(G) \subseteq P_2(G)$ and equalities need not hold in general. Observe that the classical traveling salesman polytope (the convex hull of the incidence vectors of all Hamiltonian cycles) is a subset of $P_0(G)$, and the integral vectors in $P_2(G)$ are precisely those satisfying (30).

Cornuéjols et al. [29] proposed the problem of characterizing all graphs G for which $P_1(G) = P_2(G)$ (equivalently $P_2(G)$ is integral). They also showed that all series-parallel graphs G enjoy this property, where a graph is called *series-parallel* if it does not contain K_4 as a minor (cf. Sect. 2.5(ii)). It is worthwhile pointing that, when restricted to cographic matroids, the equivalence of (i) and (iii) in Theorem 43 gives a complete solution to this research problem, which was independently solved by Vandenbussche and Nemhauser in [113]. Ding and Zang's [37] approach is different from that in [113]. They determined the complete structure of matroids that satisfy (i), and proved (ii) using this structure. Then they derived the equivalence of (i) and (iii) as a corollary. As is well known, (ii) is much stronger than (iii).

Let P and K^* , shown in Fig. 9, be the planar duals of K_5 and K , respectively. From Theorem 43 it can be seen that a graph G has an integral $P_2(G)$ if and only if it contains neither P nor K^* as a minor. With the same excluded minors, actually Ding and Zang [37] have drawn a much stronger statement as elaborated in the following

theorem, which establishes the implication (i) \Rightarrow (ii) of [Theorem 43](#) when M is cographic:

Theorem 44 *Let G be an undirected graph. Then the cographic matroid of G is half-Mengerian (cf. (29)) if and only if G contains neither P nor K^* as a minor.*

A one-page proof [37] showed that [Theorem 43](#) follows from [Theorem 44](#). To establish the latter theorem, Ding and Zang [37] proved that graphs without P and K^* minors can be expressed as sums of some prime graphs, which provides a structural characterization of half-Mengerian matroids. Then the authors proved that possessing the half-Mengerian property is preserved under summing operations on matroids. In turn, they introduced a packing property associated with cuts in graphs which is sufficient for the corresponding cographic matroids to be half-Mengerian. Finally they proved that each prime graph enjoys the packing property, from which [Theorem 44](#) follows. In order to verify the packing property on a few small graphs, the authors used computer to exhaust all the (about 2,700) possibilities.

6.2.2 Box-Half-Mengerian Matroids

Given undirected graph G with cut-edge incidence matrix A , integral vectors in $P_2(G)$ (see (31)) or equivalently vectors that satisfy (30) do not have to be 0–1 vectors, since they may have coordinates exceeding one. This could cause problems in certain applications. Clearly, a natural fix for this problem is to impose the box condition $\mathbf{1} \geq \mathbf{x} \geq \mathbf{0}$. This is what Mahjoub did in [83, 84], where he investigated the convex hull of incidence vectors of 2-edge-connected spanning subgraphs of G (with no edge repetition), and proved that if G is a series-parallel graph, then $P_3(G) = \{\mathbf{x} : \frac{1}{2}A\mathbf{x} \geq \mathbf{1}, \mathbf{1} \geq \mathbf{x} \geq \mathbf{0}\}$ is an integral polytope. Chen et al. [19] recently found the following common strengthening of the integrality of $P_2(G)$ [29] and the integrality of $P_3(G)$ [83] on series-parallel graphs G .

Theorem 45 *Let A be the cut-edge incidence matrix of a connected undirected graph G . Then the linear system $\frac{1}{2}A\mathbf{x} \geq \mathbf{1}, \mathbf{x} \geq \mathbf{0}$ is box-TDI if and only if G is a series-parallel graph.*

Since there are big differences between systems that are integral, that are TDI, and that are box-TDI (see, e.g., [103] and [Sects. 4.4–4.6](#) of this chapter), [Theorem 45](#) does discover much nicer feature of the series-parallel structure. One key to the proof [19] is the fact that every series-parallel graph is constructed from a forest by repeatedly adding loops and making series extension and/or parallel extensions (meaning that replacing an edge by two edges in series or in parallel). The other key consists of the operations under which box-total dual integrality is maintained, namely, column deletion, column addition, column series extension, and column parallel extension (see [Sect. 2.4](#)). The first key enables one to start with a forest and build up the whole picture step by step via series and parallel extensions, while the second key inductively guarantees the system at every step is box-TDI. A generalization of [Theorem 45](#) thinks of matrix A as circuit-element matrix of a

matroid. Chen et al. [19] characterized in terms of “excluded minor” the matroid M for which $\frac{1}{2}Ax \geq \mathbf{1}, x \geq \mathbf{0}$ is a box-TDI system.

Theorem 46 *Let M be a matroid and let A be the circuit-element incidence matrix of M . Then the following statements are equivalent:*

- (i) M is box-half-Mengerian.
- (ii) $\frac{1}{2}Ax \geq \mathbf{1}, x \geq \mathbf{0}$ is a box-TDI system.
- (iii) M has neither $U_{2,4}$ -minor nor $M(K_4)$ -minor.

Proof The equivalence (ii) \Leftrightarrow (iii) has been established in [19]. Definition 11 and Lemma 1 give (ii) \Rightarrow (i). If M has $U_{2,4}$ or $M(K_4)$ as a minor, then as argued in [19], the polytope $\{x : \frac{1}{2}Ax \geq \mathbf{1}, \mathbf{1} \geq x \geq \mathbf{0}\}$ is not integral, and (i) does not hold by Lemma 2. Hence, (i) \Rightarrow (iii). \square

7 Conclusion

In addition to the three-volume monograph by Schrijver [103], excellent treatments of the dual integrality with respect to combinatorial optimization problems include survey papers by Pulleyblank [92], Schrijver [99, 101, 102], and Frank and Király [52]. Aside from what has been reviewed in this chapter, many other recent works on dual integrality and its related topics have attracted considerable research attentions.

TDI Description. Pia and Zambelli [91] studied systems of the form $\mathbf{b} \leq Ax \leq \mathbf{d}$, $\mathbf{l} \leq x \leq \mathbf{u}$, where A is obtained from a totally unimodular matrix with two nonzero elements per row by multiplying by 2 some of its columns and where $\mathbf{b}, \mathbf{d}, \mathbf{l}, \mathbf{u}$ are integral vectors. They gave an explicit TDI description for the integer hull of the polyhedron P defined by the above inequalities. Since the inequalities of such a TDI system are Chvátal inequalities for P , their result implies that the matrix A has cut-rank 1. The authors also derived a strongly polynomial time algorithm to find an integral optimal solution for the dual of the problem of minimizing a linear function with integer coefficients over the TDI system.

Approximate min–max Relations. Samuel et al. [48] studied the ratio between the minimum size of an odd cycle vertex transversal and the maximum size of a collection of vertex-disjoint odd cycles in a planar graph. They showed that this ratio is at most 10. They also gave a shorter proof of the ratio 2 for the corresponding edge version of the problem, which was originally proved by Král and Voss [77].

Excluded Minor Characterizations. A 0–1 matrix is *balanced* if it contains no square submatrix of odd order with exactly two 1s per row and per column. Balanced matrices lead to ideal formulations for both set packing and set covering problems. Balanced graphs are those graphs whose clique-vertex incidence matrix is balanced. While forbidden induced subgraph characterization of balanced graphs was obtained by [7], there is no such characterization by minimal forbidden induced

subgraphs. Bonomo et al. [10] provided minimal forbidden induced subgraph characterizations of balanced graphs restricted to some graph classes which also lead to polynomial time or even linear time recognition algorithms within the corresponding subclasses.

A graph G is *clique-perfect* if the cardinality of a maximum clique-independent set of H equals the cardinality of a minimum clique-transversal of H , for every induced subgraph H of G . A graph G is *coordinated* if the minimum number of colors that can be assigned to the cliques of H in such a way that no two cliques with nonempty intersection receive the same color equals the maximum number of cliques of H with a common vertex, for every induced subgraph H of G . Coordinated graphs are a subclass of perfect graphs. Finding the complete lists of minimal forbidden induced subgraphs for the classes of clique-perfect and coordinated graphs turns out to be a difficult task. However, some (partial) characterizations have been obtained for several special classes of graphs [8, 9, 11].

Fractional Packing. Given an undirected graphs G , a k half-integral packing of an H -minor, where H is a fixed graph, is a collection of k H -minors of G such that each vertex of G is used at most twice. Ken-ichi [73] showed that the problem of deciding whether or not G has k half-integral packing of an H -minor for fixed k and graph H is polynomial time solvable when $H = K_6$ or $H = K_7$. The author also showed that Erdős–Pósa property holds for k half-integral packing of a K_6 -minor (resp. a K_7 -minor). Latter Ken-ichi and Bruce [74] studied the half integral k disjoint paths packing problem for which they provided an $O(n \log n)$ time algorithm for this problem for fixed k , improving upon Kleinberg’s $O(n^3)$ algorithm.

Consider an ideal clutter with a nonnegative capacity function on its vertices. It follows from idealness that for any nonnegative capacity the total multiplicity of an optimal fractional packing is equal to the minimum capacity of a node cover. Yuji [115] presented a polyhedral framework for fractional packing in ideal clutters. Given an n -node clutter, this framework finds an optimal hyperedge packing using at most n hyperedges with positive multiplicities, performing at most n times minimizations for the clutter and at most n^2 times minimizations for its blocker. Applied to the clutter of dijoints, the framework gave the first combinatorial polynomial time algorithm for fractional packing of dijoints.

Bounded Fractionality. Harai [71] gave a complete characterization of the class of weighted maximum multiflow problems whose dual polyhedra have bounded fractionality, which is a common generalization of two fundamental results of Karzanov for metric weight and 0–1 weight. Harai characterized not only the commodity graphs H for which the dual of maximum multiflow problem with respect to H has bounded fractionality but also the metrics on terminals for which the dual of metric-weighed maximum multiflow problem has bounded fractionality. Apart from the fractionality issues, the design of combinatorial or practical algorithms specialized to general multiflow problems is still a challenging

problem. The tight-span dual problem and the geometry of explored in [71] might give a basis against this challenge.

In concluding this chapter, it is worthwhile noting that there are many exciting and important problems on dual integrality yet to be solved. Among the other topics of interest are the following:

- (a) For the complexity of recognizing (box-)TDI systems, the question whether [Problems 2](#) and [3](#) are in NP or co-NP is still unanswered.

All tournaments G with Mengerian cycle hypergraphs \mathcal{H}_G and those with Mengerian FVS clutters $b(\mathcal{H}_G)$ have been characterized in terms of “forbidden subtournaments” (see [Theorem 25](#)). Coincidentally, $b(\mathcal{H}_G)$ is Mengerian if and only if \mathcal{H}_G is (see [Corollary 9](#)).

- (b) Major open problems in this research direction are to characterize all directed graphs G with Mengerian \mathcal{H}_G and those with Mengerian $b(\mathcal{H}_G)$. The arc versions of these problems are equally interesting.

While these problems are extremely hard in general, Guenin and Thomas [69] successfully characterized all directed graphs that pack, where a directed graph G *packs* if for any sub-directed graph H of G , the maximum number of vertex-disjoint cycles is equal to the minimum number of vertices in an FVS in H . Guenin strongly believes that the blocker version of their theorem holds on exactly the same class of directed graphs.

- (c) A directed graph G packs if and only if for any subgraph H of G , the maximum number of disjoint feedback vertex sets is equal to the minimum number of vertices in a cycle in H .

The comparison of statements (i) and (ii) of [Theorems 23](#) and [25](#) shows a preservation of the min–max relation under the interchange of the roles of feedback vertex sets and cycles. Similar interchange arises in the celebrated Lucchesi–Younger theorem [82] and Woodall’s conjecture [114]. The planar version of Lucchesi–Younger theorem asserts that in any planar directed graph, the minimum size of a transversal is equal to the maximum number of arc-disjoint cycles, where a *transversal* is a set of arcs which intersects every cycle in the directed graph.

- (d) Correspondingly, Woodall conjectured in 1978 that in a planar directed graph, the length of a shortest cycle is equal to the maximum cardinality of a collection of disjoint transversals. The conjecture has been a long-standing open problem.

Based on Ding and Zang’s [36] “excluded minor” characterization for cycle Mengerian undirected graphs (see [Theorem 17](#)), Chen and Chen [16] developed an efficient algorithm for finding a maximum w -cycle packing in cycle Mengerian undirected graphs. The algorithm, which employs the ellipsoid algorithm of Grötschel et al. [64] as a subroutine, is not strongly polynomial time.

- (e) It is challenging to design a combinatorial algorithm for the cycle packing problem (see [Definition 20](#)) on cycle Mengerian undirected graphs.

Abstract

Several dynamical system approaches to combinatorial optimization problems are described and compared. These include dynamical systems derived from penalty methods; the approach of Hopfield and Tank; self-organizing maps, that is, Kohonen networks; coupled selection equations; and hybrid methods. Many of them are investigated analytically, and the costs of the solutions are compared numerically with those of solutions obtained by simulated annealing and the costs of a global optimal solution.

Using dynamical systems, a solution to the combinatorial optimization problem emerges in the limit of large times as an asymptotically stable point of the dynamics. The obtained solutions are often not globally optimal but good approximations of it. Dynamical system and neural network approaches are appropriate methods for distributed and parallel processing. Because of the parallelization, these techniques are able to compute a given task much faster than algorithms which are using a traditional sequentially working digital computer.

This chapter focuses on dynamical system approaches to the linear two-index assignment problem and the \mathcal{NP} -hard three-index assignment problem. These and extensions thereof can be used as models for many industrial problems like manufacturing planning and optimization of flexible manufacturing systems. This is illustrated for an example in distributed robotic systems.

1 Introduction

The key idea of a dynamical system approach to combinatorial optimization problems is that the reached asymptotically stable point of a dynamical system is identified with a solution to the combinatorial optimization problem. Clearly, this stable point has to be a feasible solution to the combinatorial optimization problem, that is, all constraints have to be respected in order to get a global optimal solution or at least a good approximation of it. The discrete positions of the asymptotically stable points allow the use of continuous dynamical systems for discrete optimization problems. Here, the question arises of how to define a dynamical system with appropriate properties.

There are many different dynamical system approaches to combinatorial optimization. The most fundamental differences are, first, the initial conditions; second, the set of stable points and the shape of the basins of attraction; and, third, the deterministic and stochastic properties, that is, the presence or absence of additional stochastic terms in the dynamical system.

To initialize the dynamical system, one can use random or calculated initial values. The detailed information about the specific optimization problem like costs of a single assignment can be used as initial values and/or for the definition of the dynamics, that is, the equation of motion. Examples of approaches with random initial values are penalty methods [66], the neural network approach of Hopfield and Tank [73], and variations of it. In [21], initial values with identical elements for different alternatives are used. In contrast to this, the approaches of coupled selection equations in [63, 118, 124] use calculated initial values which contain problem information.

The second difference, which deals with the stability properties of the dynamical system, is the most crucial point. In order to make dynamical systems without cost terms in the equation of motion applicable to combinatorial optimization problems, there must be a one-to-one mapping from the set of asymptotically stable points of the dynamical system to the set of feasible solutions to the combinatorial optimization problem. The reason for this is that they have to be universal for all problems of the same size. Methods which contain cost terms in the equation of motion do not require this one-to-one mapping, that is, not every feasible solution has to be represented as a stable point. This is due to the fact that the cost terms define for each problem a specific dynamical system. Nevertheless, both approaches, with or without cost terms in the equation of motion, must not have stable states which are no feasible solution. These important stability conditions of the dynamical system that are necessary to obtain always feasible solutions are fulfilled only in some approaches (see, e.g., [63, 118, 124]). Others, like [73], may produce spurious states.

The third difference is about the use of additional stochastic terms to prevent the system from getting stuck in a local minimum of the objective function. For this purpose, stochastic terms and simulated annealing techniques are used in [133, 134] to improve the solutions of [73].

The resulting solutions are usually not global optimal but nonetheless good approximations. Compared to other heuristics (see, e.g., [55] in [53]), the advantage of dynamical system approaches which include neural networks is that they are appropriate for distributed and parallel processing. The reason for this is that the dynamical system can be distributed among many coupled simple processing units. Because the communication effort is low, the parallelization is very effective. The use of parallel hardware for dynamical system approaches results therefore in very fast problem solvers. Another advantage of many dynamical system and neural network approaches is their error resistivity, that is, the process of finding a solution can be continued even after disturbances which often appear, for example, in robotics (see, e.g., [94, 123, 125]). This will be explained in Sect. 11.

To be able to compare different approaches, the following analysis focuses on two- and three-index assignment problems (also called two- and three-dimensional assignment problems). Nevertheless, most of the methods described below can be adapted to other combinatorial optimization problems. For solving maximum clique problems with so-called replicator equations, it is referred to [21] and [22]. Furthermore, it is worth mentioning that some of the approaches like penalty methods have their origin in continuous optimization. To apply these methods to combinatorial optimization problems, the set of solutions is restricted to discrete variables by using specific constraints.

2 Assignment Problems

In this section, two important special cases of assignment problems [29], the linear two-index assignment problem and the linear \mathcal{NP} -hard three-index assignment problem, are considered. Assignment problems are simple models for industrial optimization problems from the simple assignment of jobs to machines up to the organization of complex flexible manufacturing systems. This practical relevance justifies and motivates the investigation of assignment problems.

The linear two-index assignment problem allows comparison of the results with the optimal solution even for large problem sizes by using polynomial time algorithms, for example, the dual forest algorithm [2] or the Hungarian method [28, 40, 100]. As a second test example, the three-index assignment problem is investigated as representative of \mathcal{NP} -hard problems.

Definition 1 For given costs $(c_{ij}) \in \mathbb{R}^{n \times n}$, the task of the linear two-index assignment problem (two-dimensional assignment problem) is to find Boolean variables $x_{ij} \in \{0, 1\}$ with $i, j \in N := \{1, \dots, n\}$ so that the total costs

$$c := \sum_{i,j} c_{ij} \cdot x_{ij} \quad (1)$$

are minimal with respect to the constraints

$$\sum_i x_{ij} = 1 \quad \forall j \in N \quad \text{and} \quad (2)$$

$$\sum_j x_{ij} = 1 \quad \forall i \in N. \quad (3)$$

The constraints (2) and (3) imply that (x_{ij}) has to be a permutation matrix.

In graph theory, the assignment problem is known as the weighted bipartite matching problem. The standard example is the assignment of jobs to machines.

Here, n jobs are given which can be worked on each of n machines. The real number c_{ij} defines the costs which are incurred by the execution of job i on machine j :

$$\begin{array}{ccc} \text{job } i & \xrightarrow{\quad \text{machine } j \quad} & \\ \downarrow & \left(\begin{array}{c} c_{11} \cdots c_{1n} \\ \vdots \qquad \vdots \\ c_{n1} \cdots c_{nn} \end{array} \right) & \end{array}$$

The Boolean matrix

$$x_{ij} := \begin{cases} 1 & \text{if job } i \text{ is worked on machine } j \\ 0 & \text{otherwise} \end{cases}$$

is a permutation matrix, that is, every job has to be done once and only once and every machine has to be used once and only once at the same time.

Lemma 1 *The assignment problem (1)–(3) is invariant by adding a constant to each element of a row or column.*

Proof The proof is straightforward: Suppose the constant α_i is added to all elements of row i and the constant β_j is added to all elements of column j . Using the Kronecker symbol

$$\delta_{ii'} := \begin{cases} 1 & \text{for } i = i' \\ 0 & \text{for } i \neq i' \end{cases}$$

and $G := \{x^{(1)}, \dots, x^{(n!)}\}$ which is the set of all $n!$ permutation matrices, it follows with (2) and (3) that

$$\begin{aligned} (x_{kl})^{\text{opt}} &= \arg \min_{x^{(r)} \in G} \left(\sum_{i,j} (c_{ij} + \alpha_{i'} \delta_{ii'} + \beta_{j'} \delta_{jj'}) \cdot x_{ij}^{(r)} \right) \\ &= \arg \min_{x^{(r)} \in G} \left(\sum_{i,j} c_{ij} \cdot x_{ij}^{(r)} + \sum_{i,j} \alpha_{i'} \delta_{ii'} \cdot x_{ij}^{(r)} + \sum_{i,j} \beta_{j'} \delta_{jj'} \cdot x_{ij}^{(r)} \right) \\ &= \arg \min_{x^{(r)} \in G} \left(\sum_{i,j} c_{ij} \cdot x_{ij}^{(r)} + \alpha_i \sum_j x_{ij}^{(r)} + \beta_j \sum_i x_{ij}^{(r)} \right) \end{aligned}$$

$$\begin{aligned}
&= \arg \min_{x^{(r)} \in G} \left(\sum_{i,j} c_{ij} \cdot x_{ij}^{(r)} + \alpha_i + \beta_j \right) \\
&= \arg \min_{x^{(r)} \in G} \left(\sum_{i,j} c_{ij} \cdot x_{ij}^{(r)} \right). \quad \square
\end{aligned}$$

This property is used for the solution of the assignment problem by the Hungarian method [28, 40, 100] to transform the cost matrix into an appropriate form to be used during further steps. Without loss of generality, it can be assumed that $c_{ij} \geq 0 \quad \forall i, j$. Using the above-described transformation, one can always obtain a cost matrix with nonnegative entries so that a permutation matrix can be selected out of the vanishing entries. The necessary computation time of the Hungarian method is of order $O(n^4)$ instead of the exponential dependence of n by comparing all $n!$ feasible solutions using exhaustive search.

Alternative to the minimization problem (1), it is sometimes useful to work with the dual maximization problem, where

$$w := \sum_{i,j} w_{ij} \cdot x_{ij} \quad (4)$$

has to be maximized with winnings $w_{ij} \geq 0$ and the constraints (2) and (3) for $x_{ij} \in \{0, 1\}$. One gets (4) from (1) with the linear transformation

$$w_{ij} = -a \cdot c_{ij} + b \quad \text{with } a > 0 \quad \forall i, j. \quad (5)$$

The condition $w_{ij} \geq 0$ is no restriction, because of Lemma 1: The optimization problems (1) and (4) are invariant by adding a constant to every element of a specific row or column, so that $w_{ij} \geq 0$ can always be fulfilled.

Definition 2 In the (axial) three-index assignment problem (three-dimensional assignment problem), the Boolean variables $x_{ijk} \in \{0, 1\}$ with $i, j, k \in N := \{1, \dots, n\}$ have to be determined such that the total costs

$$c := \sum_{i,j,k} c_{ijk} \cdot x_{ijk} \quad (6)$$

are minimal with respect to the constraints

$$\sum_{i,j} x_{ijk} = 1 \quad \forall k \in N, \quad (7)$$

$$\sum_{i,k} x_{ijk} = 1 \quad \forall j \in N, \quad (8)$$

$$\sum_{j,k} x_{ijk} = 1 \quad \forall i \in N. \quad (9)$$

In a variant of this, the so-called planar three-index assignment problem, the constraints (7)–(9) are replaced with

$$\sum_i x_{ijk} = 1 \quad \forall j, k \in N, \quad (10)$$

$$\sum_j x_{ijk} = 1 \quad \forall i, k \in N, \quad (11)$$

$$\sum_k x_{ijk} = 1 \quad \forall i, j \in N. \quad (12)$$

Both variants of the three-index assignment problem are \mathcal{NP} -hard [29, 47, 115].

The standard example to the axial three-index assignment problem is the assignment of jobs, machines, and workers. A generalization of three-index assignment problems leads to multi-index assignment problems. Assignment problems of different types can be used to model some problems in flexible manufacturing systems, distributed autonomous robotic systems, and cellular robotic systems [118, 121, 123]. Additional details of such applications are given in Sect. 11.

3 Dynamical Systems

Dynamical systems are defined by the change of a state $x(t) \in \mathbb{R}^n$ with respect to the time t . For example, in physical systems, the state vector $x(t) \in \mathbb{R}^6$ may indicate the time-dependent position in space and velocity of a mass point.

In the case of continuous time, the time evolution of the state $x(t)$ is given by the equation of motion

$$\dot{x} = f(x) \quad (13)$$

with $t \in \mathbb{R}$. Here, \dot{x} denotes the time derivative $\frac{d}{dt}x$ of the state x , and $f : \mathbb{R}^n \mapsto \mathbb{R}^n$ determines this change in dependence of the state x . In the case of discrete time, the equation of motion is given by

$$x(t+1) = f(x(t)) \quad (14)$$

with $t \in \mathbb{Z}$.

In this chapter, mainly continuous time systems are considered. Starting with an initial condition $x(0)$, the equation of motion leads to a solution curve $x(t)$ in the state space which is called trajectory; the set of all solution curves is called phase flow of the dynamical system. For large times, the trajectory is often restricted to a

low-dimensional attractor. There exist several kinds of attractors, like limit cycles or strange attractors. The most simple but nevertheless important case of an attractor is an asymptotically stable point. Various techniques for the analysis of the asymptotic behavior are developed. For details see, for example, [7, 9–11, 68, 136], or [110].

In the dynamical system approach to combinatorial optimization, one can restrict to systems with asymptotically stable points x^* . This asymptotic behavior is defined as the limit of large times, that is, $x^* = \lim_{t \rightarrow \infty} x(t)$. These asymptotically stable points are taken as candidates of solutions of the combinatorial optimization problems. As it was already pointed out in the introduction, for some dynamical system approaches, there exists a one-to-one mapping of the asymptotically stable points to the solution of the combinatorial optimization problem (see, e.g., [118]). Others like the replicator dynamics [21] are metastable with respect to the space of feasible solutions (i.e., that the solution is lying on a simplex) or may produce spurious states which are no feasible solution (see, e.g., [73]).

4 Dynamical Systems Based on Penalty Methods

Nonlinear optimization problems are defined by a cost function which has to be minimized and by separately given constraints which have to be respected. By adding the cost function and further terms which contain the constraints, an optimization problem without separately given constraints is obtained. Clearly, by regarding a minimization problem, these terms have to vanish if the constraints are respected and have to be large, that is, have to cause costs or penalties, if the constraints are violated. Therefore, this procedure is called penalty method. Related to penalty methods are barrier methods (see, e.g., [89] and [75]) and interior-point methods (see, e.g., [78, 96]).

4.1 Classical Approach

Penalty methods can be used to solve optimization problems with constraints which are given as equalities or inequalities. Here, only problems with equality constraints are considered. Furthermore, this section focuses on nonlinear optimization problems, that is, either the objective function or cost function itself or the constraints are nonlinear. For further readings, see, for example, [13, 54, 66, 75, 114].

Suppose, the function which has to be minimized is given by $f : \mathbb{R}^n \mapsto \mathbb{R}$, and the equality constraints are given by $h : \mathbb{R}^n \mapsto \mathbb{R}^m$. Thus, the set of feasible points is defined as $G := \{x \in \mathbb{R}^n : h(x) = 0\}$. By using the penalty method, the nonlinear optimization problem

$$x^{\text{opt}} = \arg \min_{x \in G} f(x) \quad (15)$$

where the constraints are given by G is transformed in the unrestricted optimization problem

$$x^{\text{opt}} = \arg \min_{x \in \mathbb{R}^n} \tilde{f}(x) \quad (16)$$

with

$$\tilde{f}(x) = f(x) + \tilde{h}(x). \quad (17)$$

The function $\tilde{h}(x)$ contains the constraints and has to fulfill the condition:

$$\tilde{h}(x) = \begin{cases} 0 & \text{for } h(x) = 0 \\ \text{large positive value} & \text{for } h(x) \neq 0. \end{cases} \quad (18)$$

In order to fulfill the conditions (18), often the square of $h(x)$ multiplied by a large constant p is used:

$$\tilde{h}(x) = p \cdot (h(x))^2. \quad (19)$$

The following theorem states that the penalty method converges globally to a minimum with respect to the constraints (see, e.g., [66]):

Theorem 1 *Let $x(p)$ be a minimum point of (17) with (19), that is,*

$$\tilde{f}(x, p) = f(x) + p \cdot (h(x))^2 \quad (20)$$

on a compact set. Then

$$\lim_{p \rightarrow \infty} x(p) = x_0 \quad \text{and} \quad (21)$$

$$\lim_{p \rightarrow \infty} p \cdot h(x(p)) = 0, \quad (22)$$

where x_0 is the minimum point of f on G . From $0 \leq p < p'$, it follows that the inequalities

$$\tilde{f}(x(p), p) \leq \tilde{f}(x(p'), p') \leq f(x_0), \quad (23)$$

$$f(x(p)) \leq f(x(p')) \leq f(x_0), \quad \text{and} \quad (24)$$

$$h(x(p)) \geq h(x(p')) \geq 0 \quad (25)$$

are fulfilled.

See [66] for a proof.

In spite of this theorem, for the numerical handling of the penalty method, the constant p has to be chosen appropriately in dependence of the finite step size of numerical schemes like the gradient descent method. This is the weak point of these methods.

The large positive value in (18), which has to be fulfilled by the function \tilde{h} , causes a fast relaxation of the initial point $x(0)$ to the set of feasible solutions which respect the constraint $h(x) = 0$. This initial point $x(0)$ contains usually no problem information and is chosen, for example, randomly. See Sect. 9.3.1 for an exception of this. The penalty term $\tilde{h}(x)$ has to be chosen smooth in order to be able to apply gradient descent methods

$$\dot{x} = -\frac{\partial \tilde{f}}{\partial x} \quad (26)$$

to find the minimum. By using a digital computer, a finite step size is necessary, which makes the use of gradient descent methods problematic [75, 89], and one often has to accept low convergence rates because of the unfavorable eigenvalue structure of the problem. To improve the convergence rate conjugate gradient methods, the Newton method or variants of it can be used (see, e.g., [89]).

4.1.1 Constraints of Assignment Problems

The constraints of two-index assignment problems are considered in this section in detail. Other constraints can be treated similarly.

The constraint of Boolean variables $x \in \{0, 1\}$ can be achieved by using

$$x_{ij} \cdot (x_{ij} - 1) = 0 \Leftrightarrow x_{ij} = 0 \text{ or } x_{ij} = 1. \quad (27)$$

To satisfy the condition (18) for all values of x_{ij} , instead of (27), the condition

$$\tilde{h}_{ij}^{(1)} = x_{ij}^2 \cdot (x_{ij} - 1)^2 = 0 \quad (28)$$

can be used. Certainly, this is in some sense just arbitrary; there are many more ways to respect (18) than just to take the square. For an alternative, see the next section.

Dealing with the two-index assignment problem, the constraints (2) and (3) are rewritten as

$$\tilde{h}_j^{(2)} = \left(\sum_i x_{ij} - 1 \right)^2 = 0 \quad \text{and} \quad (29)$$

$$\tilde{h}_i^{(3)} = \left(\sum_j x_{ij} - 1 \right)^2 = 0. \quad (30)$$

Again, for $\tilde{h}_j^{(2)}$ and $\tilde{h}_i^{(3)}$, the square can be used so that the constraints of the two-index assignment problem are respected with the penalty term

$$\tilde{h}(x) = p_1 \sum_{i,j} \tilde{h}_{ij}^{(1)} + p_2 \sum_j \tilde{h}_j^{(2)} + p_3 \sum_i \tilde{h}_i^{(3)}. \quad (31)$$

Because of the symmetry, the constraints $\tilde{h}_j^{(2)}$ and $\tilde{h}_i^{(3)}$ have to be weighted equally. Therefore, the same constant p_2 is chosen for both terms.

The cost function (1) of the two-index assignment problem is treated as function

$$f(x) = \sum_{ij} c_{ij} x_{ij} \quad (32)$$

which has to be minimized. Using a gradient descent method to minimize (17), the resulting equation of motion is

$$\begin{aligned} \dot{x}_{ij} &= -c_{ij} - p_1 \left(4x_{ij}^3 - 6x_{ij}^2 + 2x_{ij} \right) \\ &\quad - 2p_2 \left(\sum_{i'} x_{i'j} - 1 \right) - 2p_2 \left(\sum_{j'} x_{ij'} - 1 \right). \end{aligned} \quad (33)$$

4.2 Variants of Penalty Terms

As mentioned before, there are many ways to respect (18). Instead of just taking the square of the constraints h , one can use several kinds of functions \tilde{h} (see [54, 114], or [132] for examples).

Furthermore, one can use the fact that (27) implies $x_{ij} = x_{ij}^2$ to obtain the penalty term, resulting in

$$\begin{aligned} \tilde{h}(x) &= p_1 \sum_j \left(\sum_i x_{ij}^2 - 1 \right)^2 + p_1 \sum_i \left(\sum_j x_{ij}^2 - 1 \right)^2 \\ &\quad + p_2 \sum_{i,j} \sum_{i' \neq i} x_{ij}^2 \cdot x_{i'j}^2 + p_2 \sum_{i,j} \sum_{j' \neq j} x_{ij}^2 \cdot x_{ij'}^2. \end{aligned} \quad (34)$$

Similarly, because of $x_{ij} = x_{ij}^2$, the original cost function can be changed into

$$f(x) = \sum_{ij} c_{ij} x_{ij}^2. \quad (35)$$

The resulting equation of motion by using a gradient descent method to minimize (17) with \tilde{h} defined in (34) is

$$\dot{x}_{ij} = (8p_1 - 2c_{ij})x_{ij} + 8p_2 x_{ij}^3 - 4(p_1 + p_2)x_{ij} \left(\sum_{j'} x_{ij'}^2 + \sum_{i'} x_{i'j}^2 \right). \quad (36)$$

The penalty term (34) is used in [62] to assign buildings to appropriate sites in regional planning. See in this respect also [31, 32] for describing settlement and occupation processes.

By using a gradient descent method of \tilde{h} in (34), that is, minimizing just the penalty terms without the original objective function, one obtains a dynamical system which is identical to the coupled selection equations described in Sect. 9 where the data of the original optimization problem is contained in the initial values. Utilizing methods from dynamical systems theory such as investigations of stability, attractors and their basins of attraction allow further analysis of the effect of the penalty terms, pointed out in detail in Sect. 9.3.1.

5 Statistical Approaches

The following statistical approaches are usually not regarded as dynamical systems but can be interpreted as very special cases of stochastic dynamical systems with discrete time dynamics. Furthermore, stochastic methods are often used in addition to deterministic methods to avoid stagnation of the dynamics in spurious states. For this reason, their inclusion is regarded in this chapter as justified. The Metropolis algorithm, simulated annealing, evolutionary strategies, and genetic algorithms are considered as a small selection of statistical approaches. Further examples are the greedy randomized adaptive search procedure for the three-index assignment problem proposed in Lidstrom et al. (1996, An approximation algorithm for the three-index assignment problem, unpublished) and the so-called tabu search (see, e.g., [30, 49–51]). See [56] for an overview of several stochastic methods applied to optimization.

5.1 Metropolis Algorithm

The Metropolis algorithm [92] is a modified Monte Carlo method. By the so-called importance sampling, the number of random points in promising areas of the state space is increased. The cost function which has to be minimized is called energy E because of the physical problem considered in the original article [92]. An ensemble of states is considered of which each state is assigned to an energy value. Starting from an initial state x , a randomly chosen test state x' in its local neighborhood is considered. If the energy $E(x')$ of the test state x' is less or equal than the energy $E(x)$ of the old state x , the test state will be used as new state. In the other case, that is, if the energy of the test state is larger, this state is taken with probability proportional to $e^{-\Delta E/T}$. Herein, $\Delta E = E(x') - E(x)$ is the energy difference between the test state and the current state. The parameter $T \in \mathbb{R}_+$ is called temperature. This behavior can be summarized by using the conditional probability

$$P(x \rightarrow x') = \begin{cases} 1 & \text{for } \Delta E = E(x') - E(x) \leq 0 \\ e^{-\Delta E/T} & \text{otherwise} \end{cases} \quad (37)$$

which gives the probability for changing from state x to state x' .

The fact that states with higher energy values can be taken gives the possibility for escaping from a spurious state. By repetition of this procedure, an (thermodynamic) equilibrium is reached. If a number of elements are considered in this energy landscape, this ensemble of elements reaches a Boltzmann distribution $n_r \propto e^{-E_r/T}$ [92]. Herein, n_r is the number of elements of the ensemble in the state r .

5.2 Simulated Annealing

The method of simulated annealing is a special case of a Metropolis algorithm. The idea is taken from material sciences. There, defects in crystals are eliminated by heating and a slow cooling process afterwards. A state of a crystal with defects has higher energy than a state without defects. Fast cooling processes result in the movement of the current state into a state with defects which correspond to a local energy minimum.

The basic idea is identical with the idea of the Metropolis algorithm. But in contrast to the Metropolis algorithm, in simulated annealing, the temperature T is decreased slowly. During this process of decreasing the temperature T , the acceptance of energetically unfavorable states becomes more and more improbable until $T = 0$, where only energetically better states can be accepted. See Fig. 1 for the energy E in dependence of the time t . One can observe that the height of the jumps to larger energy values is decreasing with the time t which is due to the decrease of the temperature T .

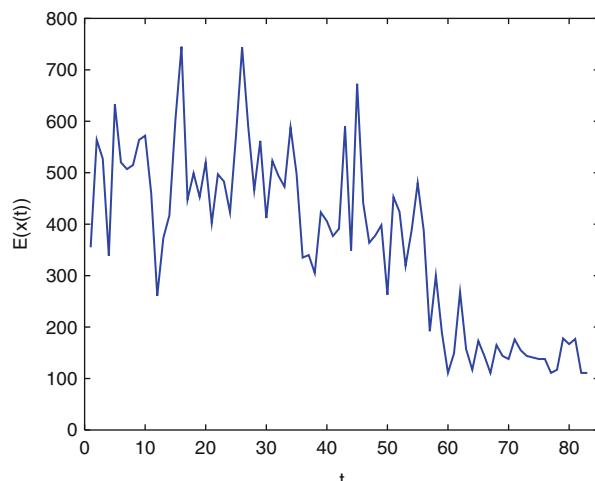

Fig. 1 Energy E over time t of an example of simulated annealing

The method of simulated annealing was used for the traveling salesman problem by Kirkpatrick [81–83]. It is possible to get good results with little computing power. The monotonically decreasing function of the temperature T has to be adapted to the optimization problem and the problem size. This has to be done empirically.

It can be proven that infinitely slow cooling results in a global optimal solution. This and further detailed analysis of simulated annealing can be found in [135]. Clearly, this fact does not help very much in practical applications because only finite computing time is available.

5.3 Evolutionary Strategies and Genetic Algorithms

Nature shows many different kinds of adaptation of several species to specific environmental conditions in biological evolution. Keeping this in mind, one can interpret evolution as optimization method. The basic principles of biological evolution are used by so-called evolutionary strategies (ES) and genetic algorithms (GA) for optimization problems. Rechenberg suggested evolutionary strategies to optimize technical systems like the shape of a jet [109]. The systems which have to be optimized are represented by a set of parameters. These have to be adapted in order to optimize some function like the thrust of the jet. The parameters are represented as real numbers which define some vector. This vector is copied and mutated with a given probability distribution like the deoxyribonucleic acid (DNA) in biological systems. The best of these variants are selected and copied and mutated again. The selection corresponds to Darwin's "survival of the fittest." This procedure results in a more detailed examination of the area in search space around successful variants. This method is used with a different number of parallel existing individuals, descendants, and selected individuals. These evolutionary strategies were developed further and compared with other methods by Schwefel [111].

Genetic algorithms are due to Holland [70]. In contrast to evolutionary strategies, they use a binary coding of the parameters which have to be optimized. The kind of coding is essential for the success of the approach of genetic algorithms. The so-called genetic operator is defined by point mutation, crossover, and inversion. This genetic operator is used to mutate the individuals. The composition of the genetic operator is in some sense arbitrary and requires a lot of experience in applications of these methods. No strict rules are known to construct this operator. Except of the parameter representation, the two approaches are quite similar. They are not distinguished precisely in literature.

In [36, 37], aspects of information theory and entropy concerning evolution and optimization methods are considered. Applications of evolutionary strategies and genetic algorithms to the traveling salesman problem can be found, for example, in [16, 99]. Further applications are published, for example, in [33, 52], and [93].

6 Neural Networks

Systems consisting of a large number of connected simple units are called distributed systems or (artificial) neural networks. The units are able to perform only simple operations. One fundamental advantage of these distributed systems is their error resistivity. An overview can be found in [95] or [65]. Many historically important papers on this topic are collected in [4] and [5]. A short discussion of the use of neural networks for combinatorial optimization is presented in [105, 106, 126, 139], and [113].

6.1 Hopfield Model

In [71], Hopfield points out the analogy between pattern recognition or correcting associative memories and the phase flow in state space of physical dynamical systems with several stable states. In particular, Hopfield suggests an associative memory similar to the Ising model of spin glass theory [19]. The two-state elements are called neurons, and the whole system is called an artificial neural network.

A similar model with continuous states is introduced in [72]. This model is the basis for the approach of Hopfield and Tank for combinatorial optimization in the example of the traveling salesman problem (TSP), wherein one has to find the shortest tour such that each of n given cities is visited once and only once and the tour starts and ends in the same city [73, 74].

The Hopfield model proposed in [72] can be realized in hardware using analog electronic circuits. These consist of a set of electronic nonlinear amplifiers which are interconnected by resistors. Using such a hardware, a parallel processing is natural. The nonlinear amplifiers transform an input (voltage) signal u_i in an output (voltage) signal V_i by

$$V_i = g_i(u_i). \quad (38)$$

The transfer function g_i which increases strictly monotonically with u_i has range $[0, 1]$ for $u_i \in [-\infty, \infty]$, and a well-defined inverse

$$u_i = g_i^{-1}(V_i). \quad (39)$$

Usually, the sigmoidal function $g_i(u_i) = (1 + \tanh(u_i))/2$ is used. For details of the electronic circuit, see [72] or [95]. The equation of motion of the electronic circuit and respectively of the Hopfield model can be written as

$$\tau_i \cdot \dot{u}_i = -u_i + \sum_j w_{ij} \cdot g_j(u_j) \quad (40)$$

with local time constants $\tau_i = C_i R_i$ and synaptic strengths $w_{ij} = R_i / R_{ij}$. The C_i represent capacitors, and R_i and R_{ij} are resistors.

To be able to apply the Hopfield model to optimization problems, the stability properties of the output V_i are important. This is discussed in the following theorem [72] before applications to combinatorial optimization problems are treated in the next sections:

Theorem 2 *For symmetric synaptic strengths $w_{ij} = w_{ji}$, the equation of motion (40) of the Hopfield network will tend to an asymptotically stable point for any initial value.*

Proof The proof is based on a construction of a so-called Lyapunov function E . In this context, this function is often called energy function even if it does not represent the physical energy of the electronic circuit which is modeled by the equation of motion (40). The Lyapunov function

$$E = -\frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n \frac{1}{R_{ij}} \cdot V_i \cdot V_j + \sum_{i=1}^n \frac{1}{R_i} \int_0^{V_i} g_i^{-1}(V) dV$$

is decreased monotonically by (40) because of

$$\begin{aligned} \dot{E} &= - \sum_i \dot{V}_i \left(\sum_j \frac{1}{R_{ij}} \cdot V_j - \frac{1}{R_i} g_i^{-1}(V_i) \right) \\ &= - \sum_i \dot{V}_i C_i \dot{u}_i \\ &= - \sum_i C_i \frac{dg_i^{-1}(V_i)}{dV_i} \cdot (\dot{V}_i)^2. \end{aligned}$$

The function $g_i^{-1}(V_i)$ increases strictly monotonically which implies that $dg_i^{-1}(V_i)/dV_i$ is positive. The constants C_i are positive for all i . Because of that, $\dot{E} \leq 0$ holds. Furthermore, E is bounded from below if the sigmoidal function is used for $g_i(u_i)$. Therefore, $\dot{E} = 0$ is equivalent to $\dot{V}_i = 0$ and $\dot{u}_i = 0$. This proves the theorem. \square

In the following, all g_i are assumed to be identical, that is, $g_i = g \forall i$. The high-gain limit of the amplifier, that is, an approximation of a step function for $g(u_i)$, gives the quadratic Lyapunov function or energy function

$$E = -\frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n \alpha_{ij} \cdot V_i \cdot V_j - \sum_{i=1}^n \beta_i \cdot V_i \quad (41)$$

with $\alpha_{ij}, \beta_i \in \mathbb{R}$ which depend on the resistors and capacitors of the electronic circuit. If they are chosen appropriate, the Hopfield model minimizes a

quadratic function which may be defined in dependence of a given Boolean, that is, 0/1-combinatorial optimization problem. Because of the approximation of a step function for $g(u_i)$ in the high-gain limit, the outputs agree only approximately with the values 0 and 1.

6.1.1 The Hopfield Model for the Traveling Salesman Problem

In [73], the energy function (41) for the traveling salesman problem (TSP) with distances $c_{ii'} \in \mathbb{R}_+$ between city i and city i' is given by

$$\begin{aligned} E = & \frac{A}{2} \sum_i \sum_j \sum_{j' \neq j} V_{ij} V_{ij'} + \frac{B}{2} \sum_i \sum_j \sum_{i' \neq i} V_{ij} V_{i'j} + \frac{C}{2} \left(\sum_i \sum_j V_{ij} - n \right)^2 \\ & + \frac{D}{2} \sum_i \sum_{i' \neq i} \sum_j c_{ii'} \cdot V_{ij} (V_{i',1+j \bmod n} + V_{i',1+(j-2+n) \bmod n}). \end{aligned} \quad (42)$$

The modulo formulation $1 + j \bmod n$ and $1 + (j - 2 + n) \bmod n$ is used instead of $j + 1$ and $j - 1$ to obtain properly defined indices in the set $N = \{1, \dots, n\}$. The constants $A, B, C, D \in \mathbb{R}_+$ are positive real numbers. The condition $V_{ij} = 1$ indicates the visit to the i th city at position j of the path in the total tour. To describe a tour which starts and ends at the same city and each city is visited once and only once, V has to be a permutation matrix. The first term in (42) causes high energy values for two nonvanishing elements in the same row i , the second term for two nonvanishing elements in the same column j , while the third term causes high energy values for a number of nonvanishing elements larger or smaller than n . The last term consists of the costs or distances c_{ij} . Therefore, this energy function can be regarded as cost function with penalty terms of a penalty method.

The terms in E result in so-called frustrated states. This expression is common in spin glass theory and designates several competing couplings between variables in the sense of low energetic states which cannot all be satisfied simultaneously. This results in several local minima where the system gets trapped in and does not reach a global minimum. As consequence, the approach does not only result in tours which are not the shortest ones but also in unfeasible solutions which do not represent a tour.

The equation of motion of the Hopfield network for the TSP [72, 73] is defined by

$$\begin{aligned} \dot{u}_{ij} = & -\frac{u_{ij}}{\tau} - A \sum_{j' \neq j} V_{ij'} - B \sum_{i' \neq i} V_{i'j} - C \left(\sum_{i'} \sum_{j'} V_{i'j'} - \tilde{n} \right) \\ & - D \sum_{i' \neq i} c_{ii'} (V_{i',1+j \bmod n} + V_{i',1+(j-2+n) \bmod n}) \end{aligned} \quad (43)$$

with $\tau \in \mathbb{R}_+$. The functions $V_{ij} = V_{ij}(u_{ij})$ are sigmoid functions of the form

$$V_{ij}(u_{ij}) = \frac{1}{2} \left(1 + \tanh \left(\frac{u_{ij}}{u_0} \right) \right) \quad (44)$$

where u_0 is a scaling factor. The constant \tilde{n} is used instead of n to adjust the operating point of the amplifiers [73]. The initial values $u_{ij}(0)$ are randomly chosen by

$$u_{ij}(0) = u_{00} + u_0 \left(\Theta - \frac{1}{2} \right) \quad (45)$$

around some center value u_{00} where Θ is a random number in the interval $[0, 1]$. The equation of motion (43) drives the system to the local minima of the energy function E [72]. The spurious states of E cause solutions which do not fulfill the given constraints. In other words, $\lim_{t \rightarrow \infty} V$ may not be a valid tour in the traveling salesman problem.

The problems of the above-mentioned local minima of the energy function E are reported in detail in [137] and [77], among others. The stagnation of the neural network dynamics in local minima of the energy function E can be avoided by using some additional stochastic terms. This was done in [133, 134] with annealing and normalization of the output. Theoretical investigations of stability of the Eq. (43) depending on the parameters A, B, C , and D and supplementary remarks are given in [77] and [90]. In [131], the objective function is written in normal form and is investigated. An analysis of the linearized dynamic of the Hopfield network is done in [48]. Further adaptations of the Hopfield network to special problems are made in [91]. The influence of the initial values is reported in [137] and [131]. The approach of Hopfield and Tank to the TSP is extended to an A/D converter, a signal decision, circuit and a linear programming circuit in [128].

The above-mentioned disadvantages of randomly chosen initial values, parameter sensitivity, and spurious states are avoided in other methods [26, 118] which are reported below. As already mentioned, another possible approach to avoid the stagnation of the dynamics in spurious states is the additional use of statistical methods.

6.1.2 Adaptation to the Assignment Problem

The adaptation of (41) to the two-index assignment problem can also be done easily. This results in the energy function

$$\begin{aligned} E = & \frac{A}{2} \sum_i \sum_j \sum_{j' \neq j} V_{ij} V_{ij'} + \frac{B}{2} \sum_i \sum_j \sum_{i' \neq i} V_{ij} V_{i'j} + \frac{C}{2} \left(\sum_i \sum_j V_{ij} - n \right)^2 \\ & + \frac{D}{2} \sum_i \sum_j c_{ij} \cdot V_{ij}^2, \end{aligned} \quad (46)$$

and the following equation of motion:

$$\dot{u}_{ij} = -\frac{u_{ij}}{\tau} - A \sum_{j' \neq j} V_{ij'} - B \sum_{i' \neq i} V_{i'j} - C \left(\sum_{i'} \sum_{j'} V_{i'j'} - \tilde{n} \right) - D \cdot c_{ij} \cdot V_{ij}. \quad (47)$$

Again, \tilde{n} is used instead of n . The output, which has to be a permutation matrix, is given by the $n \times n$ matrix (V_{ij}).

The choice of the energy function E for the two-index assignment problem is not unique, but the presented one is most similar to the energy function for the TSP presented by Hopfield and Tank.

6.2 Self-Organizing Maps and Kohonen Networks

Another neural network approach to combinatorial optimization is done in [35] and [6] for the TSP by using Kohonen networks, that is, self-organizing maps [84, 85]. This approach is also called elastic net or elastic snake method because of the fit of an initial elastic ring to the cities in the city space.

6.2.1 Self-Organizing Maps for the Traveling Salesman Problem

The elastic ring contains marked points which are iteratively moved to the cities. The initial ring is located in the center of the city positions. The marked points are finally mapped to the locations of the cities. Each marked point of the ring is mainly shifted in the direction of the nearest city. The other cities have a smaller influence which is decreasing with larger distance to the marked point. Eventually each city is assigned to one and only one marked point.

The description of the elastic net method in [35] is quite similar to a penalty method where the objective function

$$E = -\alpha K^2 \sum_i \ln \sum_j \phi(\|x_i - y_j\|, K) + \beta \sum_j \|y_{j+1} - y_j\|^2 \quad (48)$$

with

$$\phi(d, K) = e^{\frac{-d^2}{2K^2}} \quad (49)$$

and parameters α , β , and K has to be minimized. Using the gradient descent method

$$\dot{y}_j = -\frac{\partial E}{\partial y_j} \quad (50)$$

to minimize E , one obtains for the change of the space positions y_j of the marked points

$$\dot{y}_j = \alpha \sum_i \frac{\phi(\|x_i - y_j\|, K)}{\sum_{j'} \phi(\|x_i - y_{j'}\|, K)} (x_i - y_j) + \beta K(y_{j+1} - 2y_j + y_{j-1}). \quad (51)$$

The second term in (51) can be interpreted as elastic force which explains the name “elastic net method.” In [6], one can find a more algorithmic formulation which is also based on the idea of self-organizing maps. These approaches intuitively lead to a short tour of the TSP. The application of the self-organizing maps to the TSP produces also good results for large problems with up to 1,000 cities [6]. There are variants of this approach where the equation of motion cannot be written as gradient descent system (see, e.g., [42]).

6.3 Adaptation to the Assignment Problem

To our best knowledge, there is nothing published about the application of self-organizing maps or Kohonen networks to assignment problems. In principle, it should work to use the above-described strategy with vectors of a canonical basis for x_i , that is,

$$x_{ii'} := \delta_{ii'} \quad (52)$$

with the Kronecker symbol $\delta_{ii'}$ and $i, i' \in \{1, \dots, n\}$. The initial values for the vectors $y_j \in \mathbb{R}^n$ can either be chosen randomly or all equal.

Using an adapted cost term $\beta K \sum_{i,j} c_{ij} y_{ij}$ in (48), the resulting equation of motion is

$$\dot{y}_j = \alpha \sum_i \frac{\phi(\|x_i - y_j\|, K)}{\sum_{j'} \phi(\|x_i - y_{j'}\|, K)} (x_i - y_j) - \beta K(c_{1j}, c_{2j}, \dots, c_{nj})^T. \quad (53)$$

Like in the case of the TSP, where the marked points y_j tend to the cities x_i , the marked points y_j have to tend to the canonical basis vectors x_i . All vectors x_i together define a permutation matrix which is a feasible solution to the two-index assignment problem.

7 Double-Bracket Flows

Brockett introduces in [25] dynamical systems, so-called double-bracket flows, of the form

$$\dot{X} = [X; [X; Y]]$$

to diagonalize symmetric matrices, sort lists, and solve linear programming problems. Here, X and Y are symmetric $n \times n$ matrices, and $[X; Y] := XY - YX$ denotes the commutator. Such a double-bracket flow is used in [26] to solve the two-index assignment problem and is applied in [138] to \mathcal{NP} -hard combinatorial optimization problems. In these references, no numerical results are presented nor compared with other methods. See [20, 25, 26, 64, 127, 138, 140], and references there for further details.

8 Replicator Equations

A biological motivated dynamical system approach was used as heuristics for finding a maximum clique in a graph [22]. The so-called replicator equation

$$\dot{x}_i = x_i ((Wx)_i - x^T W x) \quad (54)$$

is used there to select from a graph the maximum clique [21]. The elements of the vector (x_1, \dots, x_N) describe the species. The weights $W = A + I$ are computed with the adjacency matrix A of the considered graph G and the identity matrix I .

The replicator dynamics is used in theoretical biology to describe an evolution process or a selection behavior of different species over time. The differential equation (54) has the nice property that the standard simplex $S_N = \{x \in \mathbb{R}^N : x_i \geq 0 \quad \forall i \text{ and } \sum_i x_i = 1\}$ is an invariant set with respect to its flow, that is, that its solutions stay on S_N . This fact simplifies certain types of analysis. Numerical results and extensions can be found, for example, in [23, 24, 101–104].

To our best knowledge, there are no results available about the application of replicator equations (54) to solve assignment problems. However, in [129] and [130], a synthesis of the replicator approach and the coupled selection equations described in Sect. 9 is used in a deterministic annealing procedure increasing iteratively the coupling strength between row and column elements and is applied to quadratic assignment problems.

Even though there is also a selection process involved, the approach should not to be mixed with the one of the coupled selection equations described in Sect. 9. The approach of the replicator equations does contain the detailed problem information only in the right-hand side of the equation of motion, and the vector $(1/N, \dots, 1/N)$ is used as initial value, that is, in contrast to the coupled selection equations, no problem information is used for the initial value.

9 Coupled Selection Equations

Using the method of coupled selection equations for combinatorial optimization problems, the initial conditions are calculated from the specific data of the problem, that is, the costs. They determine together with the basins of attraction the final solution. In contrast to standard penalty methods, the approach of Hopfield and

Tank, and the replicator dynamics approach, there are not necessarily cost terms, that is, specific problem data, in the equation of motion. The solution is obtained as output of the dynamical system in the limit of large times, when the state variables have reached the asymptotic stable points. Selection equations can be found in models of many biological, chemical, and physical systems [58, 59]. Below, the selection equations of pattern formation, which can be used for pattern recognition, are described first before going on to outline an approach to combinatorial optimization problems using coupled selection equations.

9.1 Selection Equations

The neural network approaches to associative memories which are described in [72, 80] and are motivated by physical spin glasses show many spurious states, that is, the dynamic ends often in patterns which are not stored. This unwanted behavior led to investigations about the storage capacity of these networks by means of statistical analysis (see, e.g., [3, 65, 95]).

To avoid the spurious states, Haken introduced a dynamical system where the stored patterns are the only asymptotically stable points of the dynamics. This dynamical system is called synergetic computer (see [57, 60, 61], and references there). The patterns are stored as vectors $\mu_i = (\mu_{i1}, \dots, \mu_{in})^T \in \mathbb{R}^n$ of the pixels for all $i \in M = \{1, \dots, m\}$. The vector component μ_{ij} represents the gray value of the corresponding pixel j of pattern i .

It is assumed that the vectors of the patterns are linear independent and that the number m of patterns is at most n , the number of pixels. The dynamics can be described with so-called order parameters ξ_i which are coefficients of the expansion of the test pattern $v \in \mathbb{R}^n$ with respect to the stored patterns μ_i and a rest vector ϱ

$$v = \sum_{i=1}^m \xi_i \mu_i + \varrho. \quad (55)$$

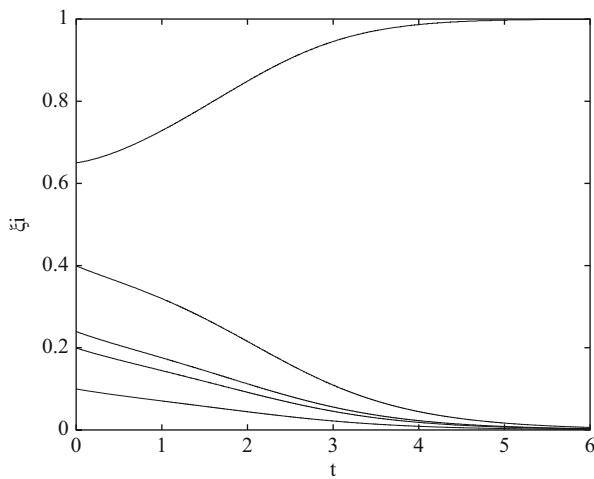

The equation of motion of the order parameters is defined by

$$\dot{\xi}_i = \xi_i - \xi_i^3 - \beta \cdot \xi_i \sum_{i' \neq i} \xi_{i'}^2 \quad \forall i \in M \quad (56)$$

with $\beta > 1$. To avoid the stagnation at some stationary but instable point, some noise is added to (56). To get a visual impression of the selection behavior of (56), see Fig. 2 for an example of the solution $\xi(t)$ over time. The selection behavior is formulated in the following theorem:

Theorem 3 *The dynamical system (56) is a selection equation, that is, one and only one mode survives, namely, the mode with the largest corresponding initial value ($\xi_{i'} \rightarrow 1$ for $t \rightarrow \infty$), and all others decay to zero ($\xi_i \rightarrow 0$ with $i \neq i'$ for $t \rightarrow \infty$).*

Fig. 2 Presentation of the components of the solution $\xi(t)$ over time t showing the selection behavior for $\beta = 2$. The component with the largest initial value wins the competition and converges to one, while all others decay to zero

Proof The proof is based on linear stability analysis and the fact that from $\xi_i > \xi_j$ it follows that $\dot{\xi}_i > \dot{\xi}_j$. See [60] for details. Equation (56) can be formulated as gradient flow $\dot{x}_i = -\frac{\partial \phi}{\partial \xi_i}$ with the potential ϕ which is plotted in Fig. 4. Further explanations can be found in Sect. 9.3 about the coupled selection equations. \square

A corresponding dynamical system can be found in the Bénard problem of fluid dynamics. There, it describes the selection behavior of roll patterns. The similarity between pattern formation and pattern recognition was pointed out by Haken [18, 57]. In [14, 67], a similar approach to an associative memory and related systems can be found which uses a linear mapping to a dynamical system with well-known asymptotic properties. Further selection equations can be found in models of biological selection of autocatalytic macromolecules. See the work of Eigen and Schuster in [38, 39] and work based on these in [37, 69].

Concerning coupled selection equations which set of asymptotically stable points is identical with the set of permutation matrices, a similar result to Theorem 3 will be stated below.

9.2 How the Coupled Selection Equations Work

The coupled selection equation approach (see, e.g., [63, 116–118, 124]) to combinatorial optimization is based on the idea of the competition between several modes or variables with respect to the constraints. By regarding dynamical systems which allow not only one but several modes to survive, it is possible to get complex solutions by composing several single modes. This competition of parts of the whole solution simultaneously operating in continuous space by the coupled selection equations leads to a significant reduction of the computational complexity. In contrast to this, a

comparison of all feasible solutions is impossible for problem sizes $n > 15$ because of the exponential growth of the number of all feasible solutions.

In the following, the maximization problems (4) which are transformations of two-index assignment problems are treated as well as the corresponding three-index problems. The maximization of the total winnings, that is, the minimization of the total costs, is done by a selection of the largest single winnings. The single modes or variables are initialized by the single winnings, that is, transformed costs. Therefore, the largest initial values have to win the competition. The total procedure can be regarded as a heuristic method to maximize the total winnings, that is, the sum of the single winnings.

This approach is similar to the intuitive approach of a human problem solver. Several alternatives which are parts of the total solution, are compared during the process of decision making, that is, the decisions for the alternatives are competing against each other.

9.2.1 Problem Information as Initial Values

The detailed problem information can be found in the valuation $w \in \mathbb{R}_+^n$ and in the constraints. The valuations are given by initial values to the dynamical system and are not included in the equation of motion itself. The constraints are respected by specific coupling terms of the dynamical system. The solution to the combinatorial optimization problem emerges as limit of large times $t \rightarrow \infty$. The ω -limit set of the dynamical systems considered here contains stable and unstable points only. There are no limit cycles or more complicated attractors. The position of the asymptotically stable points guarantees the emergence of feasible solutions only. The other way around, every feasible solution corresponds to one and only one asymptotically stable point.

The dynamical process changes the single continuous, that is, real-valued, winnings in Boolean values. This describes the selection of suitable, that is, as large as possible, single winnings as part of the total solution. The Boolean value 1 marks the choice of the corresponding single decision with corresponding winnings, while the Boolean value 0 marks that this alternative was not chosen.

In the following sections, two different types of coupled selection equations are considered each for the two- and three-index assignment problems as well as a hybrid method between coupled selection equations and a penalty approach. These are the coupled selection equations of pattern formation and the coupled, piecewise continuous selection equations. For an adaptation of the coupled selection equations to other optimization problems, appropriate coupling terms have to be used which lead to asymptotically stable points which respect the constraints.

9.3 Coupled Selection Equations of Pattern Formation

By numbering the variables with two indices and using specific coupling terms, the selection equation (56) can be adapted such that they can be used for two-index assignment problems.

9.3.1 Two-Index Assignment Problem

The given matrix (w_{ij}) of nonnegative winnings of the dual two-index assignment problem, that is, the maximization problem (4), is used to initialize the coupled selection equations with variables $(\xi_{ij}) \in \mathbb{R}_+^{n \times n}$, as it is described before, that is,

$$\xi_{ij}(0) := w_{ij} \quad \forall i, j. \quad (57)$$

For calculating w_{ij} , the transformation (5) is used so that w_{ij} lies on the interval $[0, 1]$.

To summarize the procedure of the coupled selection equation approach to combinatorial optimization again, the final solution of the optimization problem emerges in the limit ξ^* for $t \rightarrow \infty$ as a Boolean variable $x_{ij} \in \{0, 1\}$ for each element from the problem information $c_{ij} \in \mathbb{R}$, that is, the given costs:

$$c_{ij} \mapsto w_{ij} = \xi_{ij}(0) \longrightarrow \xi_{ij}(t) \longrightarrow \xi_{ij}^* = x_{ij}. \quad (58)$$

Extending the selection equations of pattern formation (56) with further coupling terms, the dynamical system

$$\dot{\xi}_{ij} = \xi_{ij} - \xi_{ij}^3 - \beta \cdot \xi_{ij} \sum_{i' \neq i} \xi_{i'j}^2 - \beta \cdot \xi_{ij} \sum_{j' \neq j} \xi_{ij'}^2, \quad (59)$$

results. All variables ξ_{ij} in the same row and same column are coupled with each other. For references, see [63, 116–118, 124]. Even though these equations were developed by the author of this chapter from scratch and independently, similar equations appeared already before in the context of an algorithmic procedure for the traveling salesman problem [15] but without detailed analytical investigations.

Theorem 4 *The set of asymptotically stable points of the dynamical system (59) is identical with the set of permutation matrices for nonnegative initial values and $\beta > 1/2$.*

Proof The proof is based on the examination of the Hesse matrix of the corresponding potential function. See Sect. 9.3.2 for the potential function and [118] for further details. \square

This theorem states that there always emerges a feasible solution in the limit of large times if a little bit noise is assumed to be present which prevents the system to stay at saddle points. Figure 3 shows this behavior in four steps of the evolution for the problem sizes $n^2 = 5^2$ and $\beta = 2$.

As described above, the specific problem definition is represented by the initial values and not by the dynamical system itself. That is, in contrast to penalty methods or the approach of Hopfield and Tank, for all transformed linear assignment problems (4), the same dynamical system (59) is used.

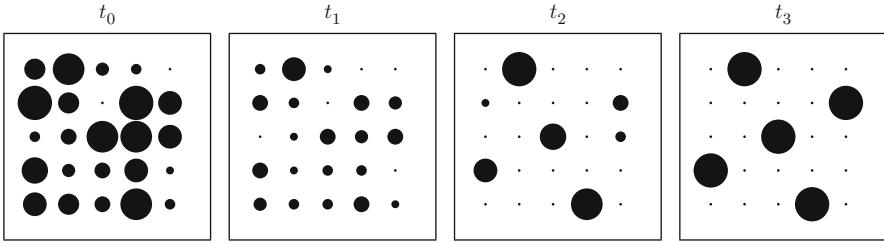

Fig. 3 Four time steps of a simulation of the coupled selection equations (59) solving a two-index assignment problem. The *dots* are arranged as a matrix (ξ_{ij}). The size of the *dots* is proportional to the values ξ_{ij} . The time t_0 indicates the initial state. At time t_3 , a stable point emerges which corresponds to a permutation matrix

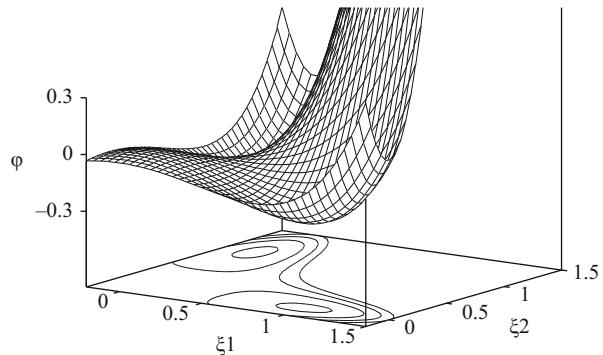

Fig. 4 Potential function φ for two variables $\xi_1, \xi_2 \geq 0$ with $\beta = 4$

9.3.2 Corresponding Gradient Flow and Potential Function

To get a visual impression of how the stability properties work, one can rewrite the equation of motion (59) as gradient flow

$$\dot{\xi}_{ij} = -\frac{\partial \varphi}{\partial \xi_{ij}} \quad \forall i, j \quad (60)$$

with the corresponding potential function

$$\varphi = -\frac{1}{2} \sum_{i,j} \xi_{ij}^2 + \frac{1}{4} \sum_{i,j} \xi_{ij}^4 + \frac{\beta}{4} \sum_{i,j} \sum_{i' \neq i} \xi_{ij}^2 \cdot \xi_{i'j}^2 + \frac{\beta}{4} \sum_{i,j} \sum_{j' \neq j} \xi_{ij}^2 \cdot \xi_{ij'}^2. \quad (61)$$

Figure 4 shows a plot of φ for two variables in one row (or column) which are denoted with ξ_1 and ξ_2 . This corresponds to the selection equation (56) discussed before. The manner in which the coupled selection equations work can be illustrated for the two variables ξ_1 and ξ_2 by a decomposition of the potential function φ in two parts φ_1 and φ_2 with $\varphi = \varphi_1 + \varphi_2$, where

Fig. 5 Potential function φ_1 for two variables $\xi_1, \xi_2 \geq 0$

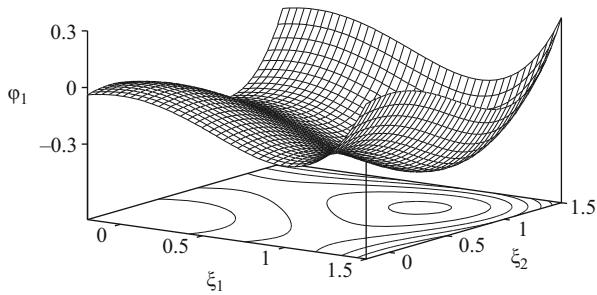

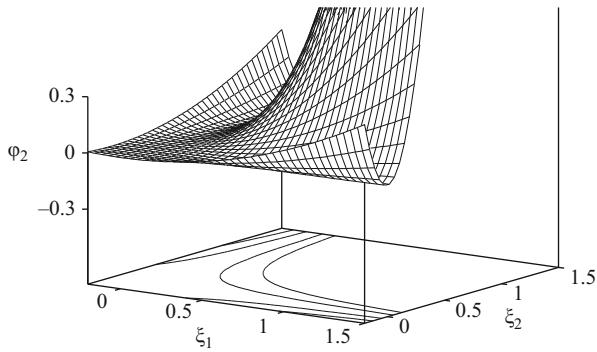

Fig. 6 Potential function φ_2 for two variables $\xi_1, \xi_2 \geq 0$ with $\beta = 4$

$$\varphi_1 = -\frac{1}{2} \sum_{i=1}^2 \xi_i^2 + \frac{1}{4} \sum_{i=1}^2 \xi_i^4 \quad (62)$$

and

$$\varphi_2 = \frac{\beta}{4} \sum_{i=1}^2 \sum_{i' \neq i} \xi_i^2 \cdot \xi_{i'}^2. \quad (63)$$

The potential function φ_1 is shown in Fig. 5. As one can see in Fig. 6, the potential function φ_2 prevents both of the variables ξ_1 and ξ_2 from being nonvanishing in a stable state by putting a “hill” in the corresponding area. This function φ_2 describes the coupling terms in the coupled selection equations. The superposition of φ_1 and φ_2 causes the minimum of φ_1 to be replaced by two minima in the total potential function φ . They are placed at the two saddle points of φ_1 . See Figs. 4–6 for illustration.

9.3.3 Interpretation as Penalty Terms

There is an amazing correlation of the coupled selection equations of pattern formation (59) to a penalty method with specific penalty terms. By adding $\frac{1}{4}$ to the potential (61), it can be written as

$$\tilde{\varphi} = \varphi + \frac{1}{4} \quad (64)$$

$$\begin{aligned} &= p_1 \sum_j \left(\sum_i \xi_{ij}^2 - 1 \right)^2 + p_1 \sum_i \left(\sum_j \xi_{ij}^2 - 1 \right)^2 \\ &\quad + p_2 \sum_{i,j} \sum_{i' \neq i} \xi_{ij}^2 \cdot \xi_{i'j}^2 + p_2 \sum_{i,j} \sum_{j' \neq j} \xi_{ij}^2 \cdot \xi_{ij'}^2 \end{aligned} \quad (65)$$

with $p_1 = \frac{1}{8}$ and $p_2 = \beta/4 - p_1$. Therefore, the potential (65) can be interpreted as penalty terms (18) of a penalty method and is identical to (34).

9.3.4 Hybrid Method: Coupled Selection Equations and Penalty Method

By using the objective function (35) together with these penalty terms and a gradient descent method, one obtains the equation of motion (36) as described in Sect. 4.2. The specific choice for the penalty terms which lead to Eq. (36) was certainly made to obtain this correspondence and to take advantage of mathematical tools from dynamical systems theory in particular the stability properties of (59). See [63] and [124] for further details.

Due to the cost term in (36), their stability properties change compared to those reported in Theorem 4 of the dynamical system (59). Because of the cost term in the equation of motion, the stability properties depend on the cost values. Also the basins of attraction of the dynamical system (18) are deformed compared with those of the coupled selection equations (59). A rough calculation can be done to demonstrate this fact. Assuming a stationary point has one and only one nonvanishing element in each row and each column, it follows from (36) that

$$0 = 2c_{ij} - 8p_1 + 8p_1\xi_{ij}^2 \quad \Leftrightarrow \quad \xi_{ij} = \sqrt{1 - \frac{c_{ij}}{4p_1}} \quad (66)$$

for these nonvanishing elements of the stationary points. This gives the deviation of the non-vanishing elements from 1 in dependence of p_1 and the costs c_{ij} . In [44], the stability investigations are extended for the case of larger costs c_{ij} shifting the position of the asymptotically stable positions.

Using the equation of motion (36), that is, coupled selection equations of pattern formation with an additional cost term, and the calculated initial values (57), one obtains a hybrid method between the coupled selection equations and the penalty method. As mentioned above, the basins of attraction are deformed compared to those of the coupled selection equations of pattern formation. This implies an advantageous change in the solution behavior which is discussed in Sect. 10.

9.3.5 Smooth Exact Penalty Function

The downside of having a dynamical system like (36) with asymptotically stable states which are just approximative permutation matrices can be overcome by

choosing yet another formulation of the penalty method or the dynamical system, respectively. A fourth-order objective function is used for this purpose in the following which is identical to the linear one in (1) or (32) at the positions of the Boolean variables, that is, for $x_{ij} \in \{0, 1\}$:

$$f(x) = \sum_{i,j} c_{ij} x_{ij} = \sum_{i,j} c_{ij} (2x_{ij}^2 - x_{ij}^4). \quad (67)$$

It can be observed that for $x_{ij} = 0$ and $x_{ij} = 1$, it holds that $(2x_{ij}^2 - x_{ij}^4) = x_{ij}$. The change of the originally linear objective function (32) to a nonlinear one with second- and fourth-order terms in (67) would usually be considered as disadvantageous, and it would be expected that this results in additional unwanted local minima corresponding to unfeasible solutions. Nevertheless, in the special case which is considered here, it is of big advantage, and it can be proven that there are only minima at feasible points.

The effective objective function of the penalty method can with (67) be written as

$$\begin{aligned} \tilde{\varphi} = & p_0 \sum_{i,j} c_{ij} (2\xi_{ij}^2 - \xi_{ij}^4) \\ & + p_1 \sum_i \left(\sum_j \xi_{ij}^2 - 1 \right)^2 + p_1 \sum_j \left(\sum_i \xi_{ij}^2 - 1 \right)^2 \\ & + p_2 \sum_{i,j} \left(\sum_{i' \neq i} \xi_{ij}^2 \xi_{i'j}^2 + \sum_{j' \neq j} \xi_{ij}^2 \xi_{ij'}^2 \right). \end{aligned}$$

Using as before a gradient descent method to minimize $\tilde{\varphi}$ results in the equation of motion

$$\frac{d}{dt} \xi_{ij} = (1 - \alpha c_{ij}) (\xi_{ij} - \xi_{ij}^3) - \beta \xi_{ij} \left(\sum_{j' \neq j} \xi_{ij'}^2 + \sum_{i' \neq i} \xi_{i'j}^2 \right), \quad (68)$$

where $\alpha > 0$ is small and the condition $\beta > 1/2(1 - \alpha \min_{i,j} c_{ij})$ has to be satisfied to be able to guarantee permutation matrices as asymptotically stable points. The initial values are chosen as before:

$$\xi_{ij}(0) = w_{ij} = -a \cdot c_{ij} + b \quad \forall i, j \quad \text{with } a > 0. \quad (69)$$

The fact that the inhomogeneity of the growth rates α_{ij} affects in (68) not only the linear term but also the cubic one leads in contrast to [43, 63, 124], and [44] to the wanted behavior. The ratio of the coefficients of these two terms is one, and the stable points are therefore located exactly at permutation matrices with $\xi_{ij} = 0$ or

$\xi_{ij} = 1$ (suppose the coupling strength is strong enough) and not at intermediate values. This is not only mathematically more elegant but simplifies also practical applications. This is formulated in the following:

Theorem 5 *The set of asymptotically stable points of the gradient flow (68) for the smooth exact penalty function with nonnegative initial values and $\beta > 1/2(1 - \alpha \min_{i,j} c_{ij})$ is identical to the set of feasible solutions of the two-index assignment problem (permutation matrices).*

Proof The proof is based on examination of the Hesse matrix $\left(\frac{\partial^2 \tilde{\varphi}}{\partial \xi_{ij} \partial \xi_{i'j'}}\right)$ for the gradient flow $\frac{d}{dt} \xi_{ij} = \frac{-\partial V}{\partial \xi_{ij}}$. The key point here is the scaling of $(\xi_{ij} - \xi_{ij}^3)$ with $(1 - \alpha c_{ij})$ as the ratio of the coefficients determines the positions of the asymptotically stable points. \square

9.3.6 Three-Index Assignment Problem

To treat the axial three-index assignment problem (6)–(9) or the corresponding dual problem, that is, the maximization problem, a three-index variable $(\xi_{ijk}) \in \mathbb{R}_+^{n \times n \times n}$ is necessary. Apart from that, the line of proceeding is identical with the introduced approach of coupled selection equations for the two-index assignment problem. As in the two-index case, the initial values are calculated by

$$\xi_{ijk}(0) := w_{ijk} \quad \forall i, j, k \quad (70)$$

using the winnings w_{ijk} . The equation of motion is defined by

$$\begin{aligned} \dot{\xi}_{ijk} &= \xi_{ijk} + (3\beta - 1)\xi_{ijk}^3 \\ &- \beta \cdot \xi_{ijk} \left(\sum_{i',j'} \xi_{i'j'k}^2 + \sum_{i',k'} \xi_{i'jk'}^2 + \sum_{j',k'} \xi_{ij'k'}^2 \right) \end{aligned} \quad (71)$$

such that the coupling terms ensure asymptotically stable points which respect the constraints of the axial three-index assignment problem. These couplings lead to a competition between all elements in the same plane. The stability properties can be formulated by:

Theorem 6 *The asymptotically stable points of (71) respect the constraints $\xi_{ijk} \in \{0, 1\} \forall i, j, k$, and (7)–(9). In addition, all points which respect these constraints are asymptotically stable points of (71).*

A proof can be found in [118].

The decision variables (x_{ijk}) can therefore be identified with the asymptotically stable points (ξ_{ijk}^*) of the dynamical system (71) as it is done in the two-index case.

The approach works similar for the planar three-index assignment problem with constraints (10)–(12), but in contrast to (71), the coupling terms are reduced from

index planes which are characterized by two varying indices to pillars with only one varying index:

$$\begin{aligned}\dot{\xi}_{ijk} &= \xi_{ijk} + (3\beta - 1)\xi_{ijk}^3 \\ &\quad - \beta \cdot \xi_{ijk} \left(\sum_{i'} \xi_{i'jk}^2 + \sum_{j'} \xi_{ij'k}^2 + \sum_{k'} \xi_{ijk'}^2 \right).\end{aligned}\quad (72)$$

The following comparison of numerical results in Sect. 10 includes the axial three-index assignment problem but not the planar one.

Coupled selection equations for multi-index assignment problems can be defined similarly to the extension of the two-index assignment problem to the (axial and planar) three-index one.

9.4 Coupled, Piecewise Continuous Selection Equations

Using coupled, piecewise continuous selection equations, more far-reaching analytical results can be obtained than with the smooth dynamical systems (59) and (71) with nonlinear right-hand sides consisting of polynomials up to third order.

A criterion is given which shows whether a solution obtained by the coupled selection equations is global optimal (Starke and Hirsch, 1996, Combinatorial optimization based on coupled piecewise continuous selection equations, unpublished). See also [118] for further details. Such a criterion is very useful, since it tells whether the solution can or cannot be improved by further trials with different optimization methods. Again, there are no spurious states in the coupled, piecewise continuous selection equations introduced in the following.

9.4.1 Two-Index Assignment Problem

The dynamical system for handling the transformed two-index assignment problem (4), that is, the coupled, piecewise continuous selection equations, is defined for all i, j as

$$\dot{\xi}_{ij} = \begin{cases} 1 - \xi_{ij} - \beta \sum_{i' \neq i} \xi_{i'j} - \beta \sum_{j' \neq j} \xi_{ij'} & \text{for } \xi_{ij} > 0 \\ 0 & \text{for } \xi_{ij} = 0 \\ \chi & \text{for } \xi_{ij} < 0 \end{cases}\quad (73)$$

with the constant $\chi > 0$.

Theorem 7 *The set of asymptotically stable points of the coupled, piecewise continuous selection equations (73) is identical with the set of permutation matrices for nonnegative initial values and $\beta > 1/2$.*

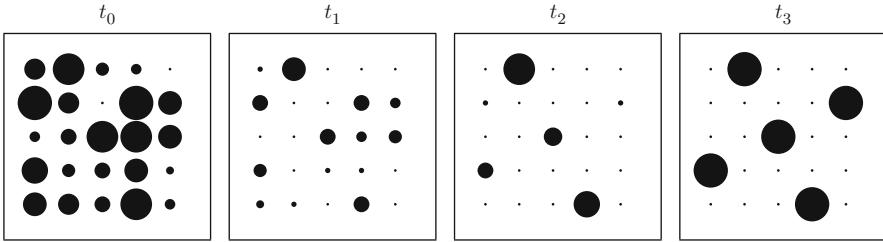

Fig. 7 Four time steps of a simulation of the coupled, piecewise continuous dynamical system (73) solving a two-index assignment problem. The *dots* are arranged as a matrix (ξ_{ij}). The size of the *dots* is proportional to the values ξ_{ij} . The time t_0 indicates the initial state. At time t_3 , a stable point emerges which corresponds to a permutation matrix

The proof is based on examining the neighborhood of the stationary points. The piecewise continuous dynamical system does not allow standard stability analysis (Starke and Hirsch, 1996, Combinatorial optimization based on coupled piecewise continuous selection equations, unpublished). See [118] for details.

The initial values are chosen as in the case of the coupled selection equations of pattern formation by (57). The emergence of a permutation matrix by using the dynamical system (73) is shown in Fig. 7. Some minor differences to Fig. 3 can be observed in the time evolution. Due to the jump in the equation of motion (73) of the coupled, piecewise continuous selection equations, some elements decay to zero after a finite time. In the case of coupled selection equations of pattern formation (59), the decay to zero is exponential.

It should be remarked that for all $\xi_{ij} > 0$, due to the linearity of the system in the form $\dot{x} = Ax$ with a matrix $A \in \mathbb{R}^{n \times n}$, it is possible to give the analytical solution as $x(t) = \exp(At)x(0)$. After an element ξ_{ij} reaches zero, one has to reduce the system with respect to this variable, and one can repeat the procedure. Nevertheless, the numerical comparison in the following did not take advantage of this.

The system (73) can be adapted to three- or multi-index assignment problems. Likewise, the following analysis of (73) can be extended to these problems, that is, also to the \mathcal{NP} -hard three-index assignment problem.

9.4.2 Analysis of the Basins of Attraction

The ability of the piecewise continuous dynamical system to solve assignment problems is determined by the position of the stable points and the basins of attraction like in all other dynamical system approaches. Therefore, the analysis of the basins of attraction is important.

Theorem 8 *For the dynamical system (73), the following relations are true with two permutation matrices $x^{(r)}$ and $x^{(s)}$:*

$$\sum_{i,j} \xi_{ij} x_{ij}^{(r)} \leqq \sum_{i,j} \xi_{ij} x_{ij}^{(s)} \quad \Rightarrow \quad \sum_{i,j} \dot{\xi}_{ij} x_{ij}^{(r)} \leqq \sum_{i,j} \dot{\xi}_{ij} x_{ij}^{(s)}, \quad (74)$$

if $\beta > 1/2$ and for all i, j $(x_{ij}^{(r)} = 1 \vee x_{ij}^{(s)} = 1) \Rightarrow \xi_{ij} \neq 0$. This means that the hyperplane

$$\sum_{i,j} \xi_{ij} x_{ij}^{(r)} = \sum_{i,j} \xi_{ij} x_{ij}^{(s)} \quad (75)$$

is repelling and separates the two basins of attraction of the asymptotically stable points $\xi^* = x^{(r)}$ and $\xi^* = x^{(s)}$.

The following definition is used in the proof:

Definition 3 The index sets N^2 , I^2 , and R^2 are defined by:

$$\begin{aligned} N^2 &:= N \times N. \\ I^2 &:= \{(i, j) \in N \times N : \xi_{ij} > 0\}. \\ R^2 &:= \{(i, j) \in N \times N : \xi_{ij} = 0\}. \end{aligned}$$

Proof of Theorem 8. Using the dynamical system (73) with $\beta > 1/2$ and the constraints of permutation matrices (2) and (3), it follows that

$$\begin{aligned} \sum_{i,j} \dot{\xi}_{ij} x_{ij}^{(r)} &= \sum_{(i,j) \in I^2} \left(1 + (2\beta - 1)\xi_{ij} - \beta \sum_{i' \in N} \xi_{i'j} - \beta \sum_{j' \in N} \xi_{ij'} \right) x_{ij}^{(r)} \\ &= |I^2| + (2\beta - 1) \sum_{(i,j) \in I^2} \xi_{ij} x_{ij}^{(r)} - \beta \sum_{(i,j) \in I^2} \sum_{i' \in N} \xi_{i'j} x_{ij}^{(r)} \\ &\quad - \beta \sum_{(i,j) \in I^2} \sum_{j' \in N} \xi_{ij'} x_{ij}^{(r)} \\ &= |I^2| + (2\beta - 1) \sum_{(i,j) \in N^2} \xi_{ij} x_{ij}^{(r)} - \beta \sum_{i',j} \xi_{i'j} \sum_i x_{ij}^{(r)} \\ &\quad - \beta \sum_{i,j'} \xi_{ij'} \sum_j x_{ij}^{(r)} \\ &= |I^2| + (2\beta - 1) \sum_{i,j} \xi_{ij} x_{ij}^{(r)} - 2\beta \sum_{i,j} \xi_{ij} \\ &\stackrel{\leq}{\geq} |I^2| + (2\beta - 1) \sum_{i,j} \xi_{ij} x_{ij}^{(s)} - 2\beta \sum_{i,j} \xi_{ij} \\ &= \sum_{i,j} \dot{\xi}_{ij} x_{ij}^{(s)}. \end{aligned}$$

□

By using this theorem, a criterion can be given to check if a solution to the two-index assignment problem obtained by the coupled, piecewise continuous selection equations is optimal or not.

9.4.3 Criterion for Global Optimal Solutions

The quality of the solutions of dynamical systems approaches is decisively given by the shape of the basins of attraction. Suppose the selection described by the coupled, piecewise continuous selection equations changes variables permanently to zero one after another, that is, variables are permanently eliminated as candidates for nonvanishing elements in the solution of the optimization problem. Then a recursive application of [Theorem 8](#) to the remaining nonvanishing elements guarantees an optimal solution. This fact is described in the following theorem:

Theorem 9 *The solution, that is, the reached asymptotically stable point of the dynamical system (73), is optimal in the sense of the two-index assignment problem (4) if for all t' it follows that*

$$\xi_{ij}(t') = 0 \quad \Rightarrow \quad \forall t > t' \quad \xi_{ij}(t) = 0 \quad (76)$$

is true for all ξ_{ij} , that is, if an element becomes zero and is staying at zero.

Proof The proof follows directly from [Theorem 8](#) concerning the basins of attraction and [Theorem 7](#) concerning the asymptotically stable points of the coupled, piecewise continuous selection equations. \square

The set of all linear, two-index assignment problems where an optimal solution can be guaranteed by using the coupled, piecewise continuous selection equations is given as

$$L^{\text{opt}} = \left\{ \xi(0) \in \mathbb{R}_+^{n \times n} : \forall t' \quad \xi_{ij}(t') = 0 \quad \Rightarrow \quad \forall t > t' \quad \xi_{ij}(t) = 0 \right\}$$

where $\xi_{ij}(t)$ is the solution of the dynamical system (73). In future work, a criterion for the initial values $\xi(0)$ must be sought which allows one to determine L^{opt} without simulation of the coupled, piecewise continuous selection equations.

9.4.4 Three-Index Assignment Problem

The extension of (73) to the axial three-index assignment problem results in

$$\dot{\xi}_{ijk} = \begin{cases} 1 + (3\beta - 1)\xi_{ijk} - \beta \left(\sum_{i',j'} \xi_{i'j'k} + \sum_{i',k'} \xi_{i'jk'} + \sum_{j',k'} \xi_{ij'k'} \right) & \text{for } \xi_{ijk} > 0 \\ 0 & \text{for } \xi_{ijk} = 0 \\ \chi & \text{for } \xi_{ijk} < 0 \end{cases} \quad (77)$$

with the constant $\chi > 0$.

Theorem 10 Let $\beta > 1/3$. The asymptotically stable points of (77) respect the constraints $\xi_{ijk} \in \{0, 1\}$ $\forall i, j, k$, and (7)–(9). In addition, all points which respect these constraints are asymptotically stable points of (77).

See [118] for a proof.

The decision variables (x_{ijk}) correspond to the asymptotically stable points (ξ_{ijk}^*) of the dynamical system (77).

9.4.5 Criterion for Global Optimal Solutions

The above-described investigations of the two-index assignment problem can be adapted to the three-index assignment problem.

Theorem 11 For the dynamical system (77), the following relation is true with two feasible solutions $x^{(r)}$ and $x^{(s)}$ which respect the constraints (7)–(9):

$$\sum_{i,j,k} \xi_{ijk} x_{ijk}^{(r)} \leqq \sum_{i,j} \xi_{ijk} x_{ijk}^{(s)} \Rightarrow \sum_{i,j} \dot{\xi}_{ijk} x_{ijk}^{(r)} \geqq \sum_{i,j} \dot{\xi}_{ijk} x_{ijk}^{(s)}, \quad (78)$$

if $\beta > 1/3$ and $\forall i, j, k \quad (x_{ijk}^{(r)} = 1 \vee x_{ijk}^{(s)} = 1) \Rightarrow \xi_{ijk} \neq 0$. This means that the hyperplane

$$\sum_{i,j,k} \xi_{ijk} x_{ijk}^{(r)} = \sum_{i,j,k} \xi_{ijk} x_{ijk}^{(s)} \quad (79)$$

is repelling and separates the two basins of attraction of the asymptotically stable points $\xi^* = x^{(r)}$ and $\xi^* = x^{(s)}$.

The proof is similar to the proof of [Theorem 8](#).

As in the case of the two-index assignment problem, a criterion can be given to check if a solution to the \mathcal{NP} -hard three-index assignment problem obtained by the coupled, piecewise continuous selection equations is optimal or not, that is, the piecewise linear structure of (77) allows the following theorem.

Theorem 12 The dynamical system (77) solves the corresponding maximization problem of the linear assignment problem (6) optimally if the condition

$$\xi_{ijk}(t') = 0 \Rightarrow \forall t > t' \quad \xi_{ijk}(t) = 0 \quad (80)$$

holds for all t' and for all i, j , and k .

Proof The proof is based on the examination of the basins of attraction described in [Theorem 11](#) and the position of the asymptotically stable points of the coupled, piecewise continuous selection equations (77) described in [Theorem 10](#). \square

By this theorem, one obtains a criterion for the \mathcal{NP} -hard three-index assignment problem (6) if the solution obtained by using the coupled, piecewise continuous selection equations is globally optimal.

10 Numerical Results

Numerical results are very important, in that they enable us to compare different methods for combinatorial optimization. Clearly, these results depend on the data sets, the kind of the combinatorial optimization problem, and the parameters of the method. There is no way to get rid of this drawback. Furthermore, the presentation of numerical results causes many problems with regard to the scientific demands. To make the simulations reproducible, all data sets used should be published as well. There are many cases in the history of science where the disregard of this rule has caused disputes. As an example, see the attempts in [137] to reproduce the results published in [73]. Because of the large amount of data, it is not possible to present them all in printed form. Electronic publishing of the data sets is one way of getting around this problem, but often, the further support of the provided material on the Internet is not guaranteed for a long time. Therefore, a pseudorandom number generator with integer arithmetic is used here in order to get reproducible data sets for the simulations.

10.1 Generation of Data Sets

In many algorithms running on a computer, random numbers are needed. However, the deterministic working principle of computers allow the production of only pseudorandom numbers. Algorithms producing these pseudo-random numbers can be found, for example, in [107]. For probabilities in the interval $[0, 1]$, real numbers or floating point numbers in computers have to be used. Because of rounding errors, these algorithms are not reproducible. In contrast, reproducibility can be achieved by using integer arithmetic. This is used in the following to obtain pseudorandom cost matrices (c_{ij}) and pseudorandom cost tensors (c_{ijk}).

The discrete time dynamic

$$x_{n+1} = (a \cdot x_n) \bmod m \quad (81)$$

with $x_n, a, m \in \mathbb{N}$ is applied. To produce the data sets, the initial value $x_0 = 111,111$ and the parameters $a = 1,233$ and $m = 260,669$ are used. The parameters a and m are chosen so that their product $a \cdot m$ is smaller than the largest 4-byte signed integer (`long int` in the programming language C), that is, $a \cdot m < 2^{31} - 1$. By using these parameters, a period of length 129,822 is obtained. This means that after 129,822 pseudorandom numbers, the sequence is repeating. The first pseudorandom number used for the data set is x_1 . Starting with x_0 , the time discrete dynamical system (81) produces the following sequence: 111,111, 148,638, 20,347, 63,627, 251,391, 29,662, 79,586, 117,994, 33,300, 133,867, 54,534, 248,489, 100,862, 23,733, 67,861, ...

The elements of the cost matrix and cost tensor are chosen in the set $\{0, 1, \dots, 99\}$ of integer values. To obtain this set of integer values, the function

$$\tilde{x}_n = \left\lfloor \frac{x_n}{m} \cdot 100 \right\rfloor \quad (82)$$

is used, where the Gauß bracket $\lfloor \cdot \rfloor$ cuts off the decimals. This derives the sequence 57, 7, 24, 96, 11, 30, 45, 12, 51, 20, 95, 38, 9, 26, 99, 89, 29, ... of pseudorandom numbers.

For the purpose of using this pseudorandom sequence for the elements of the cost matrices c_{ij} and cost tensors c_{ijk} , the uniform distribution of these elements in every length scale of the data set is favored. To illustrate that the distributions produced by the pseudorandom numbers are uniform, the relative frequency $r(\tilde{x}_n)$ is plotted in Fig. 8 for the first 100, 1,000, 10,000, and 100,000 pseudorandom numbers. In these plots, the relative frequency $r(\tilde{x}_n)$ is defined by the product of the number of pseudorandom numbers falling at intervals of a given length which contain \tilde{x} and the number of elements in the set $\{0, \dots, 99\}$, that is, 100, divided by the product of the total number of pseudorandom numbers and the length of the intervals. The plots show a good uniform distribution for every length scale of the data set.

The elements of the cost matrix $c_{ij}^{(l)}$ with $i, j \in N = \{1, \dots, n\}$ of data set l are defined by

$$c_{ij}^{(l)} := \tilde{x}_{((l-1) \cdot n^2 + (i-1) \cdot n + j)} \quad (83)$$

using the produced sequence of pseudorandom numbers. Similarly, the elements of the cost tensor $c_{ijk}^{(l)}$ with $i, j, k \in N = \{1, \dots, n\}$ of data set l are defined by

$$c_{ijk}^{(l)} := \tilde{x}_{((l-1) \cdot n^3 + (i-1) \cdot n^2 + (j-1) \cdot n + k)}. \quad (84)$$

The entries of the first cost matrices or cost tensors of each data set for a given problem size n start with the element \tilde{x}_1 of the pseudorandom sequence. The subsequent cost matrices or cost tensors use consecutively the elements of the pseudorandom number sequence.

As an example, the first 10×10 cost matrix

$$\left(c_{ij}^{(1)} \right) = \begin{pmatrix} 57 & 7 & 24 & 96 & 11 & 30 & 45 & 12 & 51 & 20 \\ 95 & 38 & 9 & 26 & 99 & 89 & 29 & 68 & 46 & 67 \\ 23 & 54 & 13 & 26 & 40 & 30 & 50 & 79 & 45 & 97 \\ 53 & 42 & 28 & 5 & 89 & 98 & 1 & 61 & 72 & 97 \\ 92 & 59 & 64 & 43 & 78 & 14 & 87 & 82 & 1 & 24 \\ 67 & 90 & 59 & 16 & 75 & 71 & 73 & 86 & 90 & 81 \\ 32 & 89 & 63 & 86 & 73 & 11 & 71 & 81 & 40 & 0 \\ 67 & 66 & 79 & 5 & 67 & 72 & 35 & 64 & 36 & 16 \\ 74 & 56 & 74 & 37 & 85 & 85 & 65 & 5 & 25 & 44 \\ 5 & 40 & 81 & 95 & 51 & 91 & 52 & 37 & 87 & 9 \end{pmatrix} \quad (85)$$

is given.

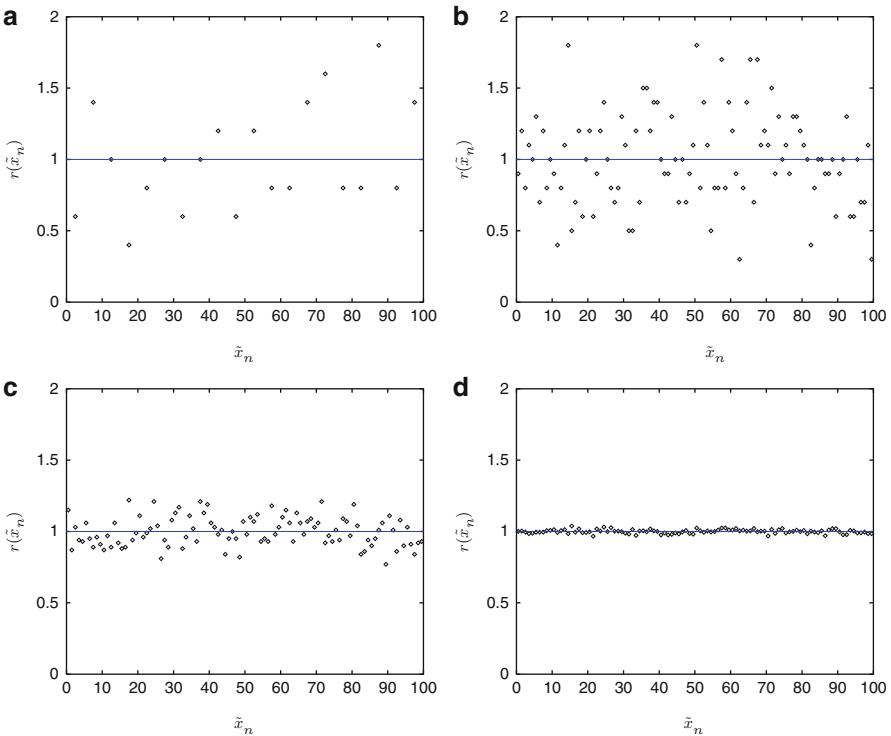

Fig. 8 Distribution of the pseudorandom numbers produced by the described algorithm in the interval $[0, 99]$. The relative frequency $r(\tilde{x}_n)$ of the first k pseudorandom numbers, where the pseudorandom numbers falling at intervals of length l are counted, is plotted over \tilde{x}_n and compared with the horizontal line $r = 1$. (a) With $k = 100$ and $l = 5$. (b) With $k = 1,000$ and $l = 1$. (c) With $k = 10,000$ and $l = 1$. (d) With $k = 100,000$ and $l = 1$

10.2 Generation of Pseudo Random Initial Values

For those methods which have to be initialized with random initial values, the same procedure as for the generation of the data sets is used to generate pseudorandom initial values. The reason for this effort is again the reproducibility of the simulations. This time, the discrete dynamics (81) is used with the initial value $x_0 = 72,664$ as well as the parameters $a = 1,233$ and $m = 260,669$. By using these parameters, a period of length 129,822 is obtained. Again, the first pseudorandom number used for the data set is x_1 . Starting with x_0 , the time discrete dynamical system (81) produces the following sequence: 72,664, 185,245, 61,041, 190,881, 232,835, 88,986, 238,758, 93,313, 99,900, 140,932, 163,602, 224,129, 41,917, 71,199, 203,583, 254,261, ...

The pseudorandom initial values have to lie in the interval $[0, 1]$. The accuracy of these values is chosen as 5 decimals. Therefore, the function

$$\tilde{x}_n = \left\lfloor \frac{x_n}{m} \cdot 100,000 \right\rfloor \frac{1}{100,000} \quad (86)$$

is used. This produces the sequence 0.71065, 0.23417, 0.73227, 0.89322, 0.34138, 0.91594, 0.35798, 0.38324, 0.54066, 0.62762, 0.85982, 0.16081, 0.27314, 0.78100, 0.97542, 0.68928, ... as pseudorandom initial values.

The elements of the initial $n \times n$ matrix and the initial $n \times n \times n$ tensor are defined equivalent to (83) and (84), respectively. As in the case of cost matrices and cost tensors, the entries are chosen consecutively from the sequence of pseudorandom numbers.

10.3 Numerical Solution of Dynamical Systems

The dynamical systems are solved numerically by using the explicit (forward) Euler method

$$\xi(t_{k+1}) = \xi(t_k) + \sigma \cdot \dot{\xi}(t_k)$$

with discrete time steps t_k and step size σ . This simple numerical method is sufficient because the dynamical systems considered are defined as gradient flows and their attractors are asymptotically stable points only and no limit cycles or even more complicated attractors occur. Furthermore, the method allows also for a simple implementation of the piecewise continuous dynamical systems. To avoid the stagnation at stationary but unstable points, some noise is added if the maximal component $\max_{i,j} |\dot{\xi}_{ij}|$ in the case of two-index assignment problems and $\max_{i,j,k} |\dot{\xi}_{ijk}|$ in the case of three-index assignment problems is smaller than 0.00001.

The integration was aborted if the constraints are fulfilled with accuracy of Δ which is given below, that is, elements which fall at interval $[-\Delta, \Delta]$ are taken as 0 and elements which fall at interval $[1 - \Delta, 1 + \Delta]$ are taken as 1. If this condition was not fulfilled after a given number of steps, the computation was stopped as well.

For parameter values, see the detailed description in the next section.

10.4 Parameter Settings for the Numerical Simulations

In order to allow a verification of our numerical results, the parameter settings for the investigated methods are specified below. Nevertheless, even by using reproducible data sets, there may occur some deviation of the obtained results to those computed on other machines due to numerical rounding errors, but these are negligible in the total comparison.

10.4.1 Dual Forest Algorithm

To evaluate the solutions of the methods used, the results are compared with global optimal solutions. In the case of the two-index assignment problem, the global optimal solutions are obtained by a dual forest algorithm [2], for which the C code of P. Kleinschmidt, A. Hefner, and H. Achatz has been used. Another possibility is the well-known Hungarian method [28, 100].

10.4.2 Branch and Bound

In the case of the \mathcal{NP} -hard axial three-index assignment problem, a branch and bound method has been used. Because of bounding conditions, the entire search tree is truncated which reduces the total number of computations compared with exhaustive search. The so far best solution found is used as bound for the subsequent branches. For unfavorable data sets, not enough bounding conditions can be found, which results in long computing times (see, e.g., [55]).

10.4.3 Penalty Methods

For the numerical integration of the equations of motion (33) and (36) which are derived from a penalty method, the explicit (forward) Euler scheme has been used.

For the classical penalty method (33), the step size $\sigma = 0.00001$ and the parameters $p_1 = 10$ and $p_2 = 10$ have been used, which seem to be appropriate for the two-index assignment problems of size 10×10 . In order to get parameter settings which are independent of the range of the data sets, the given costs are normalized on the interval $[0, 1]$. The accuracy of $\Delta = 0.2$ was chosen to stop the integration.

The parameters $p_1 = 1$ and $p_2 = 0.1$ and the step size $\sigma = 0.001$ have been used for the variant with squared variables (36) for the problem sizes 10×10 , 20×20 , and 30×30 .

10.4.4 Simulated Annealing

For the method of simulated annealing, an adapted routine of [107] has been used. The original pseudorandom generator included in this routine has been kept for the simulations. In the two-index case, the assignment, that is, the permutation matrix, is represented by an ordered list of the integer numbers $1, \dots, n$. This ordering is rearranged by reversing the order of a part of the list or replacing a part of the list between two arbitrary elements of the list in the simulated annealing procedure. For the three-index assignment problem, two of these lists have been used.

The cooling function $T(m) = 0.95^m \cdot T(0)$, where m denotes a step in the cooling procedure, has been chosen with the initial temperature $T(0) = 500$. The temperature is decreased if either the maximum number of reconfigurations of $1,000 \cdot n$ or maximum number of successful reconfigurations $100 \cdot n$ is reached. Further details can be found in [107].

10.4.5 Hopfield and Tank Approach

The costs of the data sets are normalized also for the Hopfield and Tank approach on the interval $[0, 1]$ for the same reason as mentioned in Sect. 10.4.3. For the equation

of motion (47) of the approach of Hopfield and Tank adapted to the two-index assignment problem, the parameter settings $A = B = 10$, $C = 2$, $D = 20$, $u_0 = 0.02$, $\tau = 1$, and $\tilde{n} = 15$ are used. These parameters have been found by successive determination of $A = B$ and C to obtain permutation matrices as output. After that, D is increased as long as possible so that a permutation matrix is maintained as output. Furthermore, $u_{00} = u_0 \cdot \operatorname{atanh}\left(\frac{2}{n} - 1\right)$ has been used which gives initial values where the sum over the elements of each row and column is equal to 1. These settings result in better solutions to the two-index assignment problem than the settings given in [73]. For the integration of the dynamical system, the step size $\sigma = 0.001$ has been used.

10.4.6 Coupled Selection Equations

The following description applies for both the coupled selection equations of pattern formation and the coupled, piecewise continuous selection equations.

For the two-index assignment problem, the initial values are calculated by using the transformation (5) with a and b so that the winnings w_{ij} are bounded by zero from below and by one from above. For this, it is possible to use the transformation $w_{ij} = 1 - \frac{c_{ij} - \min_{i,j} c_{ij}}{\max_{i,j} c_{ij}}$ or $w_{ij} = 1 - \frac{c_{ij} - \min_{i,j} c_{ij}}{\max_{i,j} c_{ij} - \min_{i,j} c_{ij}}$. The first is confined on the interval $[\min_{i,j} c_{ij} / \max_{i,j} c_{ij}, 1]$ and the latter on $[0, 1]$. For both, the coupled selection equations of pattern formation and the coupled, piecewise continuous selection equations, the coupling parameter $\beta = 1$ and the step size $\sigma = 0.001$ are chosen.

For the three-index assignment problem, the initial values are determined similarly to these of the two-index case. Again, the coupling parameter $\beta = 1$ has been chosen. For problems of size $10 \times 10 \times 10$, the fixed step size $\sigma = 0.002$ has been used for both methods, the coupled selection equations of pattern formation and the coupled, piecewise continuous selection equations.

Due to gradients of large Euclidean norm in the case of the $20 \times 20 \times 20$ problems using the coupled selection equations of pattern formation, the absolute values of the components of the gradient were confined to 0.01, while the used step size was $\sigma = 0.01$. This was not necessary for the coupled, piecewise continuous selection equations because of the piecewise linear equation of motion instead of the terms of order three in the previous case. Therefore, the fixed step size $\sigma = 0.001$ has been used.

10.4.7 Coupled Selection Equations with Cost Terms: Hybrid Method

In the case of the hybrid method between the coupled selection equations and the penalty method, that is, selection equations with cost terms, the cost values are used for the equation of motion as well as for the initial values. For the equation of motion, they are used in the same manner as for the penalty methods. For the initial values, the same normalization on the interval $[0, 1]$ as for the above-described selection equations has been done.

For the numerical simulation, the evolution equation (36) is used in the form

$$\dot{x}_{ij} = x_{ij} \left(\alpha_{ij} + (2\beta - 1)x_{ij}^2 - \beta \left(\sum_{j'} x_{ij'}^2 + \sum_{i'} x_{i'j}^2 \right) \right) \quad (87)$$

with the cost-dependent individual growth rates

$$\alpha_{ij} = \frac{3}{4} + \frac{1}{4} \left(1 - \frac{c_{ij} - \min_{i,j} c_{ij}}{\max_{i,j} c_{ij}} \right), \quad (88)$$

the parameter $\beta = 0.55$, and the step size $\sigma = 0.001$.

10.5 Comparison of Several Methods

The following tables show and compare the results of a dual forest algorithm; branch and bound; classical penalty method; a variation of the penalty method; simulated annealing; the approach of Hopfield and Tank; coupled selection equations of pattern formation; coupled, piecewise continuous selection equations; and a hybrid method that is a coupled selection equations with an additional cost term.

Several simulation results are presented in the following for the two- and axial three-index assignment problem with different problem sizes and various optimization methods. The data sets used for the numerical analysis are those described in Sect. 10.1. The corresponding pseudorandom initial values described in Sect. 10.2 are used for the methods which need randomly chosen initial values. These are the classical penalty method (33), the penalty method (36) with modified terms and the approach (47) of Hopfield and Tank. The presented results are the total costs $c^{(k)}$ of each used data set k in Tables 1 and 4 and the mean of the total costs \bar{c} of m investigated data sets in Tables 2, 3, and 5. The mean value is defined by

$$\bar{c} = \frac{1}{m} \sum_{k=1}^m c^{(k)}. \quad (89)$$

Furthermore, the standard deviation

$$s = \sqrt{\frac{1}{m} \sum_{k=1}^m (c^{(k)} - \bar{c})^2} = \sqrt{\frac{1}{m} \sum_{k=1}^m (c^{(k)})^2 - \left(\frac{1}{m} \sum_{k=1}^m c^{(k)} \right)^2} \quad (90)$$

is shown to give a measure for the spread of the obtained solutions compared to the spread of the global optimal solution. The ratio of these standard deviations indicates whether the quality of the obtained solutions is the same for all data sets

or whether it is varying strongly. The mean and the standard deviation are rounded with an accuracy up to the first decimal.

It has to be remarked that the computation time of the investigated optimization methods is not compared. There are several reasons for this. First, our main interest is not to find the fastest algorithm if the total amount of time is within a reasonable range. Instead, we focus upon the investigation of the method's optimization principle. Second, the comparison of CPU times of computer codes is problematic. This depends strongly on the art of programming, the compiler and compiler options used, and the hardware.

10.5.1 Two-Index Assignment Problem

[Table 1](#) shows numerical results for data set 1–10 obtained by the dual forest algorithm; the classical penalty methods; a penalty method using modified terms with squared variables; simulated annealing; the approach of Hopfield and Tank; coupled selection equations of pattern formation; coupled, piecewise continuous selection equations; and coupled selection equations of pattern formation with an additional cost term. A global optimal solution, which is obtained by the dual forest algorithm, gives a comparative value to the solutions obtained by the approximation methods. The symbol “–” in [Table 1](#) indicates that no feasible solution was found for this data set.

A summary of the results for data set 1–100 in the case of the problem sizes $n^2 = 10^2$ and $n^2 = 20^2$ and for data set 1–50 in the case $n^2 = 30^2$, respectively, can be found in the [Tables 2](#) and [3](#). The mean of the solutions and the standard deviation are given for every method. Furthermore, the number of feasible solutions obtained by the used methods is indicated.

In [Tables 2](#) and [3](#), the classical penalty method and the approach of Hopfield and Tank show obvious bad results. The quality of the solutions of the coupled selection equations of pattern formation and of the coupled, piecewise continuous selection equations is comparable with the quality of the solutions of simulated annealing. The hybrid method, that is, the coupled selection equations of pattern formation with calculated initial values and with cost terms in the equation of motion, produces remarkable good results. Compared with the coupled selection equations of pattern formation, this is due to the deformation of the basins of attraction caused by the cost term in the equation of motion. It is also much better than the penalty method with the same equation of motion but with randomly chosen initial values because the calculated initial values start the dynamics in a promising region. It should be remarked that the results of the coupled, piecewise continuous selection equations improve considerably if the initial state is shifted with the saddle point of the dynamics.

A comparison of the hybrid coupled selection equation approach with simulated annealing is done in [\[63\]](#). The results are summarized in [Fig. 9](#) where the scaling of the relative deviation of the optimization results compared to the optimal solutions is plotted against the problem size. The hybrid method scales with respect to the problem size remarkably better than simulated annealing.

Table 1 Results of the simulations for 10 data sets of the two-index assignment problems of size $n^2 = 10^2$ where the objective function (1) has to be minimized. The global optimal solution obtained by the dual forest algorithm serves as comparative value to the solutions obtained by the approximation methods

10.5.2 Three-Index Assignment Problem

For the \mathcal{NP} -hard axial three-index assignment problem, only the most promising approaches of Sect. 10.5.1 have been used. The solutions of the penalty methods and the approach of Hopfield and Tank are either not feasible or result in very high total costs. The hybrid method is not included here in the comparison, but detailed investigations can be found in [124].

Table 4 shows the results for the first 10 data sets for branch and bound, simulated annealing, coupled selection equations of pattern formation, and coupled, piecewise continuous selection equations. A summary of the results of data set 1–100 in the case of problem size $n^3 = 10^3$ and data set 1–10 in the case of problem size $n^3 = 20^3$ is presented in Table 5. The global optimal solution of the \mathcal{NP} -hard

Fig. 9 Scaling behavior of the relative deviation r of the obtained solutions compared to the optimal solutions by using simulated annealing (rhombs) and the hybrid method of coupled selection equations (triangles) over the problem size n . The hybrid method shows a remarkable better scaling than simulated annealing. Each point represents the mean of results of 10 data sets (Reprinted from [63])

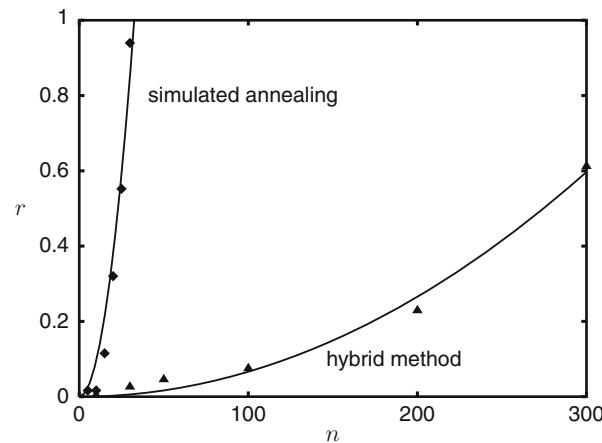

Table 4 Results of the simulations for 10 data sets of three-index assignment problems of size $n^3 = 10^3$. The global optimal solution obtained by a branch and bound method serves as comparative value to the solutions obtained by the approximation methods

Method	Branch and bound	Simulated annealing	Selection equations	
			Pattern formation	Piecewise continuous

Standard deviation	5.3	22.1	38.4	48.0

three-index assignment problem was obtained by branch and bound which is still practicable for the considered problem sizes. This gives a comparative value to the costs of the other solutions. The results obtained by simulated annealing and the coupled, piecewise continuous selection equations presented in Table 5 show a bad scaling behavior with respect to the problem size. The reason for the bad results of the coupled, piecewise continuous selection equations is due to the violation of condition (80) which is unfortunately the case in many numerical simulations. Further investigations under which conditions there exist elements which do not fulfill (80) and appropriate transformations to avoid these elements could improve the results of the coupled, piecewise continuous selection equations [118]. In opposite, the coupled selection equations of pattern formation show acceptable results.

Table 5 Summary of the results of three-index assignment problems for $n^3 = 10^3$ and $n^3 = 20^3$

11 Assignments in Distributed Robotic Systems and Flexible Manufacturing

Traditional manufacturing processes are typically based on specialized machines and factories which are built and optimized to produce sometimes only one specific kind of product. In contrast to this, the demand for a production with high variety, small batch size, and short delivery periods requires flexible and modular manufacturing processes [87]. This modularity requires to optimize the combination of many subsystems and leads naturally to assignment problems. Together with flexibility due to modularity increases also the complexity and by that the error rate which exceeds the capabilities of traditional control methods [41, 112] and demands alternative approaches. A promising strategy is to adapt robust and flexible concepts from nature and to use self-organization and pattern formation principles [58, 98] in engineering [27, 34, 86]. By using selection processes as one of the main principles of pattern formation, namely, using different variants of coupled selection equations for assignment problems as described in Sect. 9, it is possible to control distributed robotic systems to perform certain tasks at manufacturing targets in a very robust way. The concept and first basic ideas are described in [123] and are further developed in [94]. An extension to situations with underlying three-index assignments are presented in [121] and [17]. Dynamic environments and time-dependent assignments are considered in [119] and [120] where sequential manufacturing tasks in logical order are fully considered with guaranteed feasibility of the assignment solutions. Practical and experimental tests with real robots are shown in [76] and [125].

11.1 Modeling Flexible Manufacturing Systems

In the area of flexible manufacturing systems and distributed robotic systems, the key of the problem is often to assign robots to manufacturing targets. The idea

to use cooperative autonomous robots (see, e.g., [12, 45, 46]) is discussed for a while with different viewing angles but often lacks in this area a formalization and general mathematical framework and description. On the other hand, the formalization by job shop problems results usually in too complicated setups and is therefore typically not used. One option for a relatively simple description with a mathematical model is to use assignment problems as basic building blocks. In particular, time-dependent robot-target assignments appear in the production processes of flexible manufacturing systems where sequences of tasks have to be machined. To simplify the situation compared to general job shop problems, the problem will be divided in several subproblems which are considered in not specified time intervals, that is, a treatment is taken which works local in time. This can be used to model a large class of application problems.

In extension to the two-index assignment problem (1) with constraints (2) and (3), it is also possible to consider situations with unequal number of targets and robots so that after the assignment there are spare targets or robots. Furthermore, at a given time, targets can be set active or inactive to capture sequential task processing in a logical order. Thus, time-dependent robot-target assignment problems are obtained, that is, in a given time interval, each active target has to be served by one robot.

11.2 Ad Hoc Assignments with Coupled Selection Equations

The term ad hoc assignments refers to the fact that there is no preexisting structure of robots and manufacturing targets available at a given time. This structure evolves in time depending on the current situation like sudden changes in demands, breakdowns of single robots, or obstacles in the way of maneuvering robots. Self-organization approaches like the one of coupled selection equations are in particular suited for this class of problems where flexibility and robustness are of importance.

To assign the robots to the manufacturing targets while considering time-dependent sequential manufacturing tasks in logical order with guaranteed feasibility of the assignment solutions, the coupled selection equations (59) can be extended with time-dependent parameters $\alpha_{ij}(t)$ and $\lambda_{ij}(t)$. The dynamical system results then to

$$\frac{d}{dt} \xi_{ij} = \kappa \xi_{ij} \left(\alpha_{ij} (\lambda_{ij} - \xi_{ij}^2) - \beta \sum_{i' \neq i} \xi_{i'j}^2 - \beta \sum_{j' \neq j} \xi_{ij'}^2 \right) \quad (91)$$

which defines the time evolution of preferences $\xi_{ij}(t)$ for robot i to manufacturing target j . Details can be found in [120]. Please note the similarity to Eq. (68) which was derived as penalty approach for assignment problems, where $(1 - \alpha c_{ij})$ corresponds to α_{ij} in the present equation and λ_{ij} was identical to one for all i, j . The initial conditions are chosen as the specific winnings w_{ij} which was described already in Sect. 9, that is, as $\xi_{ij}(0) = w_{ij}$ for all i, j . The w_{ij} can all be chosen nonnegative without loss of generality so that nonnegative initial values are obtained.

The extended coupled selection equations (91) serve as robust heuristic optimization strategy for the introduced time-dependent assignment problems. Similarly as described for Eq. (59), the dynamical system approach optimizes the assignment problem by choosing the largest single manufacturing profits for each robot-target assignment from the set of available robots and active targets so that the total profits are maximized. The solution $\xi_{ij}(t)$ tends to the unknown decision variables x_{ij} . For equal numbers of robots and targets, the system converges to a permutation matrix; for unequal numbers of targets and robots, the column or row elements of spare targets or robots tend to zero. This requires the assumption that there is a little bit noise present so that there is no stagnation at stationary but unstable points.

In addition to (59), the extended coupled selection equations (91) use a number of parameters: κ adjusts the time scales of the selection equation and its decision-making process with those of the velocities of the robots. The weight parameter $\alpha_{ij}(t) > 0$ captures updates of sudden problem changes by deviations from the default value $\alpha_{ij}(t) = 1$ for all i, j, t . This favors or penalizes the individual selection for the assignment preferences ξ_{ij} . Finally, changing the sign of the activation parameter $\lambda_{ij}(t) \in \{-10, 1\}$ switches over active and inactive targets: Positive $\lambda_{ij}(t)$ stabilizes the selection for active targets, and negative $\lambda_{ij}(t)$ destabilizes it for inactive targets. This allows for the modeling of sequential manufacturing steps and changes in demands of time-dependent assignment problems.

Similarly to the coupled selection equations (59), the feasibility of solutions can be guaranteed also for Eq. (91) if the coupling strength is large enough, that is, if $\beta > \frac{1}{2} \max_{i,j,t} \alpha_{ij}(t)$. This can be proven under the assumption that $\alpha_{ij}(t)$ and $\lambda_{ij}(t)$ tend to constants in the course of time until a target is served. These assumptions are necessary because otherwise, for example, fast oscillating demands would lead to situations where the tasks cannot be finished. In contrast to [43, 63], and [44], the inhomogeneity of the growth rates α_{ij} takes effect in (91) not only on the linear but also the cubic term. Therefore, the ratio of the coefficients of these two terms is one, and for large-enough couplings, the stable points are located at $\xi_{ij} = 0$ or $\xi_{ij} = 1$.

A distributed instead of a centralized control is possible by exchanging information of the row and column elements of (ξ_{ij}) , that is, $\sum_i \xi_{ij}^2$ and $\sum_j \xi_{ij}^2$ from time to time between the cooperative robots. By this, additional robustness against hardware failures is achieved [125].

The flexibility and fault tolerance of the approach are due to the continuous decision process which works locally in time of the manufacturing sequence. This means that sudden changes in the demands can still be considered in the selection process without the need of a restart and more profitable upcoming active targets can replace already assigned ones.

11.3 Navigation of the Robots

The navigation of autonomous robots in space is implemented in the following by combining a specifically constructed behavioral force model [8] with the extended coupled selection equations (91). The equation of motion

$$\frac{d}{dt} \mathbf{r}_i = v_i^0 \mathbf{e}_i^0(\mathbf{r}_i, \xi) + \mathbf{f}_i(\mathbf{r}_i) \quad (92)$$

describes the positions $\mathbf{r}_i \in \mathbb{R}^3$ of the robots i in space with velocity constant v_i^0 and the destination vector $\mathbf{e}_i^0(\mathbf{r}_i, \xi)$ [120]. The direction of the destination vector \mathbf{e}_i^0 tends towards the selected target as the preference matrix $\xi = (\xi_{ij}(t))$ converges to a decision matrix with elements equal to zero or one.

The definition of the destination vector

$$\mathbf{e}_i^0(\mathbf{r}_i, \xi) = \mathbf{N}_{\gamma\delta} \left(\sum_j \xi_{ij}(t) \mathbf{N}_{\gamma'\delta'} (\mathbf{g}_j - \mathbf{r}_i(t)) \right) \quad (93)$$

is based on the normed linear combination of the normed difference vectors of the position $\mathbf{r}_i(t)$ to all target positions \mathbf{g}_j weighted with $\xi_{ij}(t)$. Due to this property, its direction tends in the course of time towards the selected target. The operator $\mathbf{N}_{\gamma\delta}(\mathbf{y}) = \frac{1}{\|\mathbf{y}\|+1/(\gamma\|\mathbf{y}\|+\delta)} \cdot \mathbf{y}$ with $\gamma, \delta > 0$, where $\|\cdot\|$ is the Euclidean norm, mainly normalizes the vector \mathbf{y} and avoids singularities for the numerical integration at $\mathbf{y} = \mathbf{0}$.

The collision avoidance term

$$\mathbf{f}_i(\mathbf{r}_i) = \sum_{i' \neq i} \mathbf{f}_{ii'}^r(\mathbf{d}_{ii'}^r) + \sum_k \mathbf{f}_{ik}^o(\mathbf{d}_{ik}^o) \quad (94)$$

consists of a part for collision avoidance between robot i and other robots $i' \neq i$ and one between robot i and obstacles k . The terms $\mathbf{f}_{ii'}^r(\mathbf{d}_{ii'}^r) \in \mathbb{R}^3$ depend on distance vectors $\mathbf{d}_{ii'}^r$ between the surfaces of the objects obtained by the robots' sensors. They tend to infinity for small distances and have finite range, that is, they are identical zero for distances over a given threshold $\sigma^{r,o}$. This avoids that for large distances, small residuals of the collision avoidance terms could add up to unwanted spurious states, that is, unfeasible stable points of the dynamical system [94] at which the robots would be trapped. This is obtained by the choice

$$\mathbf{f}_{ii'}^r(\mathbf{d}) = \begin{cases} s^{r,o} (\tan \psi(\|\mathbf{d}\|) - \psi(\|\mathbf{d}\|)) \frac{\mathbf{d}}{\|\mathbf{d}\|}, & \|\mathbf{d}\| \leq \sigma^{r,o} \\ 0, & \|\mathbf{d}\| > \sigma^{r,o}, \end{cases} \quad (95)$$

where $s^{r,o} \in \mathbb{R}$ is the strength of the collision avoidance term, $\psi(\|\mathbf{d}\|) = \frac{\pi}{2} \left(\frac{\|\mathbf{d}\|}{\sigma^{r,o}} - 1 \right)$, and $\|\cdot\|$ is the Euclidean norm.

Alternatively to the behavioral force approach (92), also other path-planning methods (see, e.g., [79, 88, 125]) can be combined with the coupled selection equations to take advantage of the robust and fault-tolerant assignment process.

11.4 Application Example: Assembling of a Space Station

The example of assembling a space station with autonomous robots demonstrates the capabilities of the proposed method (cf. Fig. 10) and intends to illuminate possible future concepts in various fields with complex requirements. The robot's task is to collect different components from a space shuttle and transport them to certain positions at the space station where bars and solar panels have to be assembled. Each of the 8 identical robots is equipped with distance sensors in order to avoid collisions and can detect the relative direction towards the manufacturing targets to maneuver using Eqs. (92)–(95). As initial values $\xi_{ij}(0)$, large profits w_{ij} were used for small Euclidean distances $d_{ij}(t) = \|\mathbf{g}_j - \mathbf{r}_i(t)\|$ between robots i and manufacturing targets j so that the total travel distance is used as objective function which has to be minimized and the result can easily be evaluated by visual inspection. The same choice was done for the weight parameter $\alpha_{ij}(t)$ which respects by that time delays from maneuvering around obstacles in the selection process. Therefore, the linear transformation $W_{ij}^{a,b}(t) = a - b \frac{d_{ij}(t) - \min_{i',j'} d_{i'j'}(t)}{\max_{i',j'} d_{i'j'}(t) - \min_{i',j'} d_{i'j'}(t)}$ with $a, b > 0$ and $a \geq b$ such that $W_{ij}^{a,b}(t) \in [a - b, a]$ is used for the initial values $\xi_{ij}(0) = w_{ij} = W_{ij}^{a,b}(0)$ and weight parameters $\alpha_{ij}(t) = W_{ij}^{a',b'}(t)$.

The activation parameter $\lambda_{ij}(t)$ is chosen +1 for active and -10 for inactive manufacturing targets at each time t so that the decision variables are finally either zero or one and that there is a 10 times faster destabilization than stabilization of selections. To capture the manufacturing in the logical order of the sequential processing, each of the 44 manufacturing targets, either at the space station or at the material depot of the space shuttle, becomes active for the period where the requirements and prerequisites for the corresponding task are given and until the task is done. To exclude certain configurations, for example, to model breakdowns of robots, the corresponding activation parameters λ_{ij} can be switched to negative values. This results in the growth of preferences of an alternatively available robot and a subsequent replacement by the usual selection process of the equations.

Figure 10 shows the simulation results for the assembling of a space station. Active targets are green, and inactive targets are red boxes (see the online version for colors). Short histories of the robots' trajectories are plotted to visualize their movements in space. Between subfigures (a) and (b), the first assignment has been developed in the preference matrix. In Fig. 10d–f, the completion of the mission is shown including an automatic and self-organized replacement of a robot after a triggered breakdown which demonstrates the robustness. Subfigure (e) shows how collisions with obstacles are avoided, that is, two robots maneuver around the space station. The last figure (f) shows the completely assembled space station. The numerical solutions of (91) and (92) were calculated with the parameters $\kappa = 15$, $\beta = 4$, $a = 0.9$, $b = 0.8$, $a' = 1.5$, $b' = 1$ and $v_i^0 = 0.3$, $\sigma^r = 0.1$, $\sigma^o = 0.02$, $s^{r,o} = 1$, $\gamma = 10$, $\delta = 1$, $\gamma' = 10^6$, and $\delta' = 10^6$.

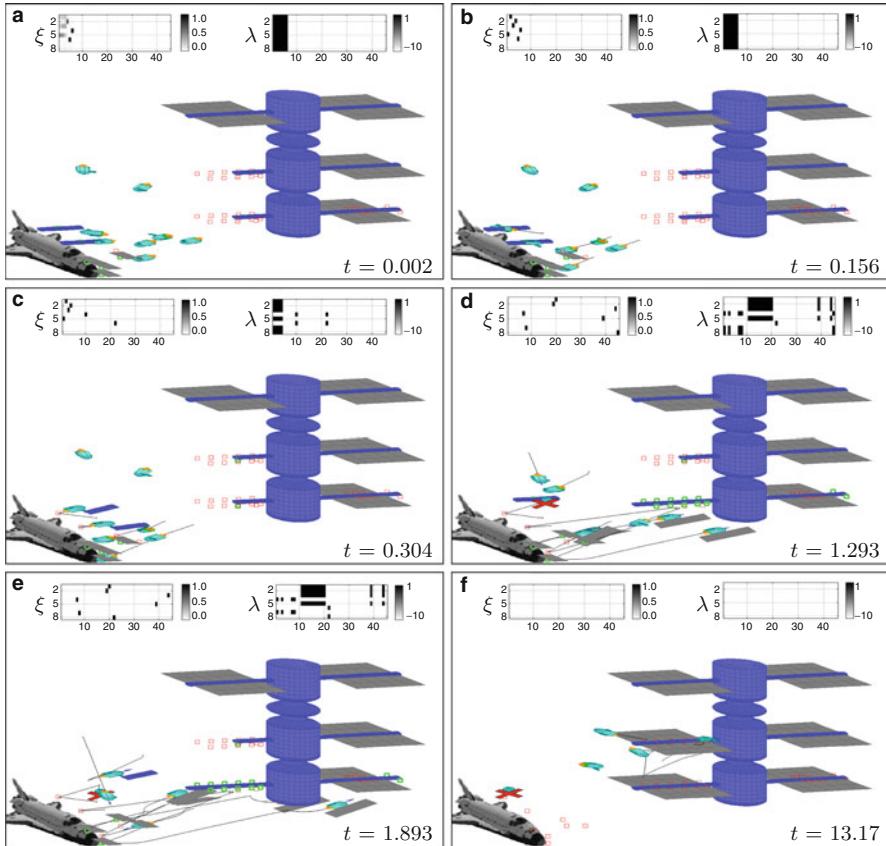

Fig. 10 Application example of the coupled selection equations (91) for a complex time-dependent manufacturing process with ad hoc assignments of robots to manufacturing targets. The presented snapshots show a simulation of assembling solar panels of a space station. The robustness of the approach is demonstrated by a triggered breakdown of a robot in (d) and the following transfer of the task to another robot while the whole process continues. The preference matrix ξ and the activation matrix λ are given, respectively, in the upper left and right corner of each snapshot (Reprinted from [120])

The simulation results show the successful application of the coupled selection equation approach to a complex manufacturing problem where flexible, modular, and decentralized structures are required. The extended selection equations (91) can be tailored to a wide range of applications by adapting the activation parameter $\lambda_{ij}(t)$ to the respective engineering problem. The approach is therefore very promising in a large number of problems in flexible manufacturing as well as distributed robotics, microrobotics, and nanorobotics, in particular where it is important that the total process continues even if the risk of partial failures is high.

12 Conclusion

This chapter about dynamical system approaches to combinatorial optimization problems focuses on the two- and on the \mathcal{NP} -hard three-index assignment problem. In addition to many other application examples, they can be used as simple models for manufacturing planning and distributed robotic systems. Therefore, there is an important practical relevance of assignment problems in general. The dynamical system approaches provide approximate solutions to the combinatorial optimization problems. These approximate solutions to the optimization problems emerge in the limit of large times as asymptotically stable states of the dynamical systems.

The classical penalty method and the approach of Hopfield and Tank cause problems in fulfilling the constraints, that is, even for the two-index assignment problem of size 10×10 , feasible solutions are not obtained for all investigated data sets. Furthermore, these methods are very parameter sensitive. Therefore, they cannot be used in practical applications. An adaptation of the parameters to new optimization problems is very time consuming, and there is neither a straightforward way nor a guarantee to find parameter settings which work well. Because these methods use random initial values, one can get good and bad solutions for the same specific combinatorial optimization problem. In contrast to real statistical approaches like simulated annealing, this does not at all seem to be a necessary ingredient of the approach but is used only because of the lack of a formula to calculate initial values. Calculated initial values allow the dynamics to start in a promising, problem corresponding basin of attraction instead of a randomly chosen one.

The results and comparisons presented in Sect. 10.5 show clearly that if there exists a polynomial time algorithm based on discrete operations, this is the best choice. The dynamical system approaches cannot compete against them except for special applications where error resistivity is relevant during the solution process. For cases where there are no polynomial time algorithms, the dynamical system approaches can be a good alternative to other approaches such as statistical ones. The comparison in Sect. 10.5 showed that the coupled selection equation approach outperforms the other tested dynamical system approaches. Remarkable good results are obtained by the hybrid method, that is, the coupled selection equations of pattern formation with calculated initial conditions and an additional cost term in the equation of motion. In the case of the \mathcal{NP} -hard three-index assignment problem, the results of the coupled selection equations of pattern formation are better than the results obtained by simulated annealing. For the coupled, piecewise continuous selection equations, a criterion for the global optimality of the obtained solutions is given.

An implementation in hardware, that is, an analog computer concept, could provide a big advantage concerning the computing time. One of the most promising hardware implementations is an optical computer. See [1, 108] for a recurrent laser system which is able to reconstruct a pattern out of a given set of patterns which are stored in a hologram. The nonlinearity there is based on a photorefractive crystal

which causes a selection process and favors the most similar stored pattern. In [97], an alternative optical system showing pattern formation is introduced using liquid-crystal light valves as nonlinear elements. These might be promising concepts for the construction of an optical computer for coupled selection equations.

Furthermore, dynamical system approaches are suitable for the adaptation to self-organizing structures like cellular and distributed robotic systems and flexible manufacturing systems which are error resistant and flexible with respect to changing demands. The robustness and capabilities with respect to flexibility to sudden problem changes are demonstrated for the coupled selection equation approach applied to control a distributed robotic system in a manufacturing process. The results are promising and include even recovery from breakdowns of parts of the system and a continuous functioning of the whole system.

This leads to the conclusion that the approaches of the coupled selection equations, in particular the coupled, piecewise continuous selection equations and the hybrid method, are promising approaches and worth for future investigations.

Abstract

Computing shortest paths in a geometric environment is a fundamental topic in computational geometry and finds applications in many other areas. The problem of processing geometric shortest path queries is concerned with constructing an efficient data structure for quickly answering on-line queries for shortest paths connecting any two query points in a geometric setting. This problem is a generalization of the well-studied problem of computing a geometric shortest path connecting two specified points. This chapter covers several effective

algorithmic paradigms for processing geometric shortest path queries and related problems. These general paradigms have led to efficient techniques for designing algorithms and data structures for processing a variety of queries on exact and approximate shortest paths in a number of geometric and graph-theoretic settings. Some open problems and promising directions for future research are also discussed.

1 Introduction

The problems of computing optimal or near-optimal paths in a certain environment arise in many disciplines and in fact are one of the several most powerful tools for modeling combinatorial optimization problems. A well-known example of path-planning problem is to compute shortest paths in a graph [45, 53]. A geometric version of this shortest path problem is, given a d -dimensional space scattered with geometric obstacles, to compute a path connecting two specified locations such that the path does not intersect the interior of any obstacle and such that the total length of the path (based on a certain metric such as the Euclidean or L_p for a positive value p) is minimized. There are many variations and generalizations of this geometric shortest path problem. Figure 1 gives an example of a shortest obstacle-avoiding path in the plane.

Computing geometric shortest paths is a very fundamental topic in computational geometry, a field that studies the development of algorithms and analysis of complexity for problems with useful geometric structures [47, 49, 80, 84]. Geometric path-planning problems play an important role in solving other geometric problems and in many practical applications, such as computer-aided design, geographical information systems, intelligent transportation systems, operations research, pattern matching, plant and facility layout, robotics, and VLSI. Furthermore, geometric path-planning problems have significant connections with other fundamental topics in computational geometry (e.g., convexity, geometric graphs, geometric optimization, triangulation, visibility, and Voronoi diagrams) and with other disciplines (e.g., graph theory, combinatorial optimization, and networks). Problems in these areas or geometric topics often appear as subproblems in solving some geometric shortest path problems and vice versa. For example, geometric path-planning problems address quite naturally the combinatorial and algorithmic aspects of robot motion and navigation.

Consequently, a great deal of work has been done on solving various geometric shortest path problems with respect to different types of environment specifications, path constraints, obstacle natures, and optimization criteria, especially for planar and 3-dimensional (3-D) settings [74, 75, 77]. In particular, for computing shortest paths in the plane with polygonal obstacles, Hershberger and Suri [63] obtained an optimal $O(n \log n)$ -time algorithm (where n is the total number of obstacle vertices). For computing shortest paths in the 3-D space with polyhedral obstacles, Canny and Reif [23] showed that the problem is NP-hard, and several efficient approximation algorithms have been discovered [40, 41, 81].

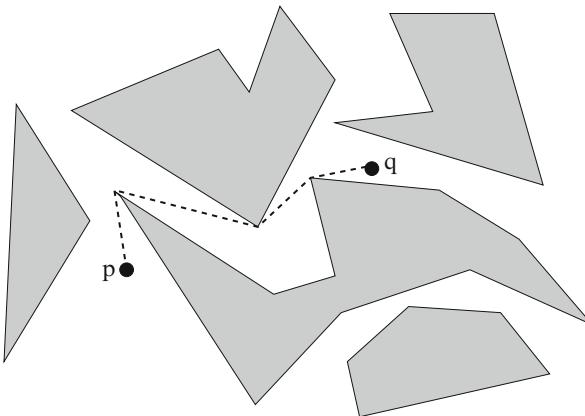

Fig. 1 A shortest obstacle-avoiding path connecting points p and q

This chapter mainly considers the following version of *geometric shortest path query problem*:

Given a set of (possibly weighted) obstacles in a geometric space S , construct an efficient data structure so that on-line queries on shortest paths (and their lengths) connecting any two query points in S can be quickly answered (e.g., in polylogarithmic time for a length query). If one of the two points for a path query is fixed, then the queries are called *single-source* path queries.

Despite the fact that there are numerous geometric algorithms known for computing a shortest path between two specified points and for computing single-source shortest paths, few results were known, until recently, for solving geometric shortest path *query* problems, even in the plane. In fact, the only known geometric path query algorithms before the results discussed in this chapter are for several cases of shortest paths inside a *simple polygon* [12, 39, 46, 54, 56, 57, 62, 87] (the optimal algorithms for these cases take $O(n)$ time and space to build a data structure for a simple polygon of n vertices; using such a data structure, a length query for any two query points can be answered in $O(\log n)$ time, and an actual shortest path connecting the two query points can be reported in $O(\log n + k)$ time, where k is the number of vertices on the output path). Clearly, the general problems which are concerned with geometric shortest path queries among *many* obstacles are of much more theoretical and practical interest and are certainly much more challenging than the simple polygon case.

It is obvious that geometric shortest path *query* problems are natural generalizations of the well-studied problem of computing a geometric shortest path connecting two specified points. Geometric shortest path queries are useful in databases for several application areas such as geographical information systems and intelligent transportation systems. These problems model the practical situations in which good quality routes (under certain criteria) between many pairs of different locations or between two constantly changing locations in a geometric environment are sought. For example, it is very common for a police car patrolling an area to quickly get to

a spot where an accident has occurred. In this situation, it is natural to treat both the locations of the police car and the accident as on-line input data to a path query. In graph theory, a common solution to the shortest path query problem is nothing more than computing and storing the all-pairs shortest paths in a graph. However, in a geometric environment, a solution based straightforward on computing and storing all-pairs geometric shortest paths will not work well because normally there are uncountably infinitely many points in a geometric space. Furthermore, unlike the graph version of the problems, it was not immediately clear until recently how to use geometric single-source shortest path query algorithms and data structures to obtain reasonably efficient solutions for processing geometric shortest path queries between arbitrary points.

This chapter discusses several effective algorithmic paradigms for processing geometric shortest path queries and related problems. (The author of this chapter was involved in many of the known results on geometric shortest path query problems.) These general paradigms have led to very efficient techniques for designing algorithms and data structures for a variety of queries on exact and approximate geometric shortest paths in planar settings. More importantly, these frameworks offer the promise of achieving new efficient algorithmic techniques for geometric shortest path queries and for other related problems. This chapter also discusses some open problems and promising directions for future research on geometric shortest path problems.

The focus of discussion in this chapter will be on the planar settings that contain polygonal obstacles. Let n denote the number of obstacle vertices in the plane.

It should be pointed out that it is possible to solve some geometric shortest path query problems in the plane by using known computational geometry techniques (e.g., by reducing such a problem to higher-dimensional point location). However, such an approach tends to yield data structures with a storage space and construction time of polynomials of rather high degrees, which would hardly be usable to practical applications. In contrast, the algorithmic solutions presented in this chapter all take either near-quadratic or even subquadratic space and construction time, and support in most cases polylogarithmic query time. Hence, in addition to their theoretical merit, the solutions in this chapter are likely to provide an impact to practical applications.

This chapter will focus on discussing *length queries* (i.e., reporting the length of a shortest or approximate shortest path). The length of a geometric path is often determined by the L_p metric for some positive value p (p is usually a positive integer). Recall that for two points a and b in the plane, the L_p distance $D_p(a, b)$ between a and b is defined as $D_p(a, b) = (|a_x - b_x|^p + |a_y - b_y|^p)^{1/p}$, where q_x and q_y denote the x - and y -coordinates of a point q . When an actual shortest path is desired, the algorithms discussed in this paper, after finding its length, can also report such an actual path P in an additional $O(|P|)$ time, where $|P|$ is the number of vertices of P .

The rest of the chapter is organized as follows. [Section 2](#) presents a general paradigm, called the *gateway paradigm*, for processing geometric shortest path queries. [Section 3](#) applies this paradigm to several problems of processing *exact*

geometric shortest path queries. [Section 4](#) applies this paradigm to problems of processing *approximate* geometric shortest path queries. [Section 5](#) sketches some recent developments on solving geometric shortest path query problems. [Section 6](#) discusses some open problems and promising directions for future research.

This chapter is a revised and updated version of the paper [28].

2 The Gateway Paradigm

The following paradigm, which was introduced in [30, 32], is a key to the algorithmic techniques for processing geometric shortest path queries presented in this chapter. Let s and t be two query points between which a shortest path in a geometric environment S is sought.

The Gateway Paradigm: For a query point s , identify a point set W_s in the geometric space S such that a shortest path in S connecting s and the other query point t passes through some point in W_s . The points in W_s are called the *gateways* of s . Once W_s is available, a shortest path between s and t can be obtained from the single-source path query data structures for the gateways of s (with each point in W_s being the source of such a data structure).

For the gateway paradigm to work well, several difficulties must be resolved:

1. W_s must have a reasonably small size because this will give rise to an $\Omega(|W_s| \times f(n))$ query time, where $f(n)$ is the time for a single-source path query and $|W_s|$ is the size of W_s .
2. It must be possible to quickly identify the gateway points of W_s for any query point s (this is part of the cost for the query time).
3. It must be known how to build efficient single-source data structures for the desired shortest paths (this is a key factor to the overall complexity bounds of the shortest path query data structure).
4. Let $W = \cup_{s \in S} W_s$, where S is the geometric space (i.e., W is the union of gateways for all possible query points in S). The size of W must be finite and, furthermore, cannot be too large (this is because for each point of W , it needs to build a single-source path query data structure).

Several different forms of the above general gateway paradigm arise in the solutions below to various geometric shortest path query problems, due to the specific constraints and geometric structures of each of these problems. These solutions will be discussed in the next two sections.

3 Exact Shortest Path Queries

This section discusses efficient algorithmic techniques for processing various length queries on *exact* geometric shortest paths among polygonal obstacles in the plane. The lengths of the paths considered here are determined according to the L_1 and L_2 (i.e., the Euclidean), the link (i.e., the number of edges) metric, or some combinations of these metrics. The algorithms in this chapter are crucially based on the gateway paradigm.

One thing needs to be mentioned before the discussion proceeds: For any two query points s and t , if the line segment \overline{st} whose end points are s and t does not cross any obstacle boundary edge, then the shortest path between s and t in the L_2 metric is simply \overline{st} . In this case, it says that s and t are *visible* to each other. It is easy to detect whether s and t are visible to each other by using the ray-shooting technique [1–3] in computational geometry. A *ray-shooting* operation is that given a point p in an obstacle scene and a direction d , “shoot” a ray $Ray(p, d)$ from p in the direction d , until $Ray(p, d)$ hits for the first time an obstacle boundary. To find out whether two query points s and t are visible to each other, one only needs to shoot a ray from s in the direction of t . It is known [1–3] that for a given polygonal obstacle scene, one can build a data structure in $O(n^2)$ space and $O(n^2 \log n)$ time that supports any ray-shooting operation in logarithmic time. Hence, it is easy to handle the case in which s and t are visible to each other by using a ray-shooting data structure. In the rest of this section, it assumes without loss of generality (WLOG) that the two query points s and t are *not* visible to each other.

3.1 The Visibility-Sensitive Approach

A general technique, called the *visibility-sensitive approach* [30], is first discussed for various geometric path queries. This approach is based on the computation of visibility polygons of query points s and t .

The *visibility polygon* Q_s of a point s is the (possibly unbounded) polygonal region in the plane that is visible from s , with the obstacle boundaries being the “opaque” objects (see Fig. 2 for an example). The polygon Q_s is represented as a counterclockwise sequence of vertices of the obstacle scene that are visible from s when scanning around s a ray that originates at s .

The simple observation used here is that when the query points s and t are not visible to each other, various optimal paths between s and t pass through one of the vertices visible from s (resp., t). Therefore, it can use the vertices of Q_s (resp., Q_t) as the gateways of s (resp., t). In this way, the set of gateways for the whole obstacle scene consists of all the n obstacle vertices.

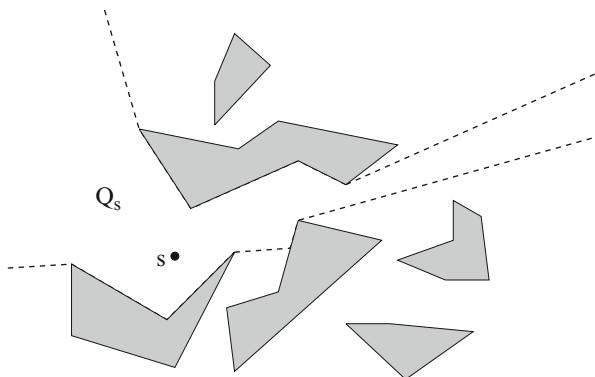

Based on the *visibility complex* of Pocchiola and Vegter [82, 83], it was developed in [30] the following *visibility-sensitive approach*:

Construct a geometric path data structure that supports, for any two query points s and t in the plane, an $O(\min\{|Q_s|, |Q_t|\} \times \log n)$ query time on path lengths.

This approach enables one to identify and use only $O(\min\{|Q_s|, |Q_t|\})$ instead of $O(|Q_s| + |Q_t|)$ gateway points, without having to compute both Q_s and Q_t completely. Note that $\min\{|Q_s|, |Q_t|\}$ can be much smaller than n and can be as small as $O(1)$. The visibility complex of a polygonal obstacle scene with n vertices can be constructed in $O(n^2)$ time and space [83].

Using this approach, data structures for length queries on various geometric paths were achieved that support a query time of $O(\min\{|Q_s|, |Q_t|\} \times \log n)$. In [30], this approach has been applied for solving three path query problems among polygonal

Fig. 2 The visibility polygon Q_s of a point s

obstacles: (1) Euclidean shortest paths, (2) approximate minimum-link paths, and (3) monotone paths (among convex polygonal obstacles).

- Euclidean shortest obstacle-avoiding paths among polygonal obstacles. The data structure uses $O(n^2 \log n)$ time and $O(n^2)$ space. This solution makes use of Hershberger and Suri's single-source path data structure [63].
- Approximate minimum-link paths among polygonal obstacles. The problem is to compute an obstacle-avoiding approximate minimum-link path between any two query points. The path obtained has at most two more links than the exact optimal path. The data structure takes $O(n((|E| + \ln)^{2/3} n^{2/3} l^{1/3} \log^{3.11} n + |E| \log^3 n))$ time and $O(n^2)$ space to build, where E is the edge set of the visibility graph of the obstacle scene and l is the longest link length among all the minimum-link paths between any two obstacle vertices. This solution makes use of Mitchell, Rote, and Woeginger's single-source path data structure [78].
- Monotone paths among convex polygonal obstacles. The problem is to find a direction d such that there is an obstacle-avoiding path between two query points that is monotone to d (it was shown in [11] that for convex polygonal obstacles, such a direction always exists). The data structure uses $O(n^2 \log n)$ time and $O(n^2)$ space to build. This solution makes use of Arkin, Connelly, and Mitchell's single-source path data structure [11].

3.2 The Reduced Visibility Graph Approach

The visibility-sensitive approach discussed in the previous subsection is quite general and gives rise to several reasonably efficient path query data structures. But, the query time of these data structures depends on the size of the smaller visibility polygon of the query points, which can still be as big as n in the worst case. In an attempt to reduce this query time while still maintaining the efficiency of the path query data structures, a different approach, called *reduced visibility graph approach*, was developed [30, 32]. This approach is particularly useful to queries on various rectilinear optimal paths and has yielded data structures that use near-quadratic construction time and space and support polylogarithmic query time.

A *rectilinear* geometric object is one whose boundary edges are parallel to a Cartesian coordinate axis (i.e., horizontal or vertical). Note that in rectilinear path problems, the polygonal obstacles need not be rectilinear. Since rectilinear shortest paths have many applications, especially in VLSI design, considerable work has been done on designing a variety of rectilinear shortest path algorithms [68]. Notably, Mitchell [71, 72] obtained an optimal $O(n \log n)$ -time algorithm for building an $O(n)$ -space data structure for planar rectilinear single-source shortest path queries among general (nonrectilinear) polygonal obstacles.

The reduced visibility graph approach is quite powerful and has been applied to the following optimal path query problems [30, 32]:

- L_1 shortest paths amid general polygonal obstacles.
- Shortest A -distance paths amid general polygonal obstacles. A -distance paths are paths whose edges can be in arbitrary directions but whose edge lengths are measured based on $|A|$ given orientations, where A is a finite set of allowed orientations [89].
- Rectilinear shortest paths amid *weighted* rectilinear polygonal obstacles such that the paths are allowed to penetrate “obstacles” with “weight factors” by paying higher costs for the path lengths (more on this later).
- A rectilinear path with the minimum number of links among all the rectilinear shortest paths between any two query points s and t , amid rectilinear polygonal obstacles.
- A rectilinear shortest path among all the rectilinear minimum-link paths between s and t , amid rectilinear polygonal obstacles.
- The rectilinear minimum-cost path between s and t amid rectilinear polygonal obstacles, where the cost is a nondecreasing function of the number of links and the length of a path.

The above paths whose “lengths” are determined according to a combination of the L_1 and link metrics are called *bicriteria* paths.

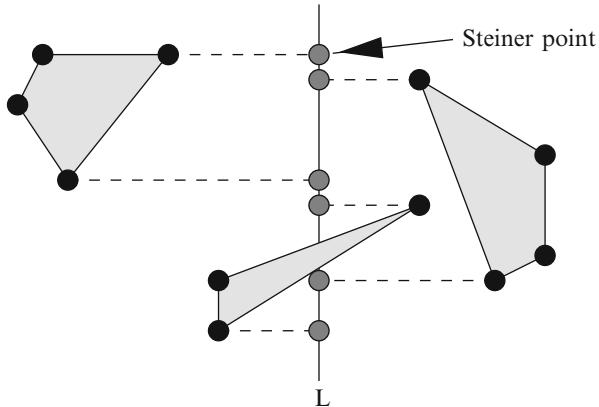

In a plane with *weighted* obstacles, each obstacle is associated with a nonnegative *weight* factor so that a path in the plane, if it intersects the interior of an obstacle, is charged extra cost based on the weight of that obstacle in addition to the cost of the L_1 length of the path. Specifically, the “length” of a path in the interior of an obstacle with a weight factor of W is $(1 + W)D_1$, where D_1 is the length of the path in the L_1 metric. Weighted obstacles often appear in path-planning problems in real applications. The weight factors, for example, can represent speed limits or traffic conditions of streets in a city. Note that shortest paths amid weighted obstacles are in fact a generalization of the shortest paths that completely avoid the interior of obstacles because shortest paths become obstacle-avoiding if one allows the weight of each obstacle be $+\infty$.

The rest of this subsection discusses the reduced visibility graph approach and the resulting optimal path query algorithms.

3.2.1 Reduced Visibility Graphs

A key component of the rectilinear path query data structures is the *reduced visibility graph* $G = (V(G), E(G))$, which captures the necessary information about shortest paths among the n obstacle vertices. This graph was introduced by Clarkson

Fig. 3 Creating Steiner points on the cut line L

et al. [42, 43] for computing L_1 shortest paths amid general polygonal obstacles and was generalized by Lee et al. [67] to computing rectilinear shortest paths amid weighted rectilinear polygonal obstacles. Yang et al. [90] also used this graph to compute rectilinear optimal bicriteria paths amid rectilinear polygonal obstacles.

The vertex set $V(G)$ of the reduced visibility graph G can be partitioned into the set V_O of obstacle vertices and the set V_S of *Steiner points*. The following recursive procedure is used to generate Steiner points for the graph G :

1. Draw a vertical (resp., horizontal) line L , which is called a *cut line*, at the median of the x -(resp., y -)coordinates of all the vertices in V_O .
2. Project all the vertices in V_O that are visible in the horizontal (resp., vertical) direction from the cut line L onto L . The projection points of V_O on L are the Steiner points of V_S on L . [Figure 3](#) gives an example of this step.
3. Use the cut line L to partition V_O into two subsets S_1 and S_2 , one on each side of L .
4. Perform this procedure recursively on the vertex sets S_1 and S_2 , respectively, until the size of each vertex set becomes 1.

Because the recursive procedure above has $O(\log n)$ recursion levels, it clearly generates $O(n \log n)$ Steiner points in V_S . Since $|V_O| = O(n)$, there are totally $O(n \log n)$ vertices in $V(G) = V_O \cup V_S$. Each cut line L is associated with a *level number*, which is the number of the recursion level at which L is used in the above procedure (with the root level being level 1).

The edge set $E(G)$ of G consists of the set E_V of line segments between every Steiner point in V_S and its corresponding vertex in V_O and the set E_L of line segments between consecutive Steiner points on every cut line if the two consecutive Steiner points are visible to each other. Clearly, $|E(G)| = O(n \log n)$.

The algorithms in [42, 67] run Dijkstra's shortest path algorithm on G [53] to find a shortest path between two points s and t in the plane (with both s and t being included in $V(G)$), in $O(n \log^2 n)$ time and $O(n \log n)$ space. A modified version G' of the graph G was then used in [43, 67] such that G' consists of $O(n \sqrt{\log n})$ vertices and $O(n \log^{1.5} n)$ edges. Consequently, running Dijkstra's shortest path algorithm on G' [53] takes $O(n \log^{1.5} n)$ time and space.

As will be seen in the next subsubsection, the vertex set $V(G)$ of G is used as the gateways for the whole plane. Hence, it needs to compute shortest paths in the reduced visibility graph G (with $O(n \log n)$ vertices and edges). In [30, 32], single-source and all-pairs shortest paths in G are computed without having to straightforwardly apply the shortest path algorithm in [53] to the graph G . Actually, by exploiting the special structures of G , it computes single-source shortest paths in G in $O(n \log^{1.5} n)$ time and $O(n \log n)$ space and all-pairs shortest paths in G in $O(n^2 \log^2 n)$ time and space, both of which are improvements over the previous algorithms in [42, 43, 67].

3.2.2 Characterization of Gateways

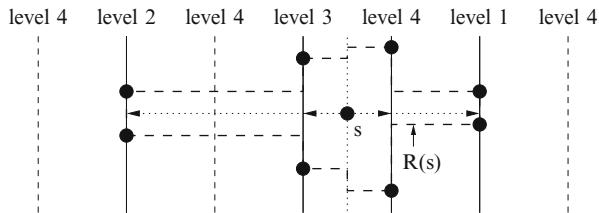

The idea for computing a set W_s of gateways for a query point s is that of “inserting” s into the reduced visibility graph G . That is, s is treated as if it were one of the obstacle vertices, and compute the edges in G adjacent to s that would have resulted if the graph construction procedure in the previous subsubsection for constructing G were applied to s . Note that such an “insertion” of a point into G does not essentially change the shortest path information contained in G (i.e., s is not a new obstacle); furthermore, the resulting “graph” (after the “insertions”) contains shortest path information among the inserted points and the vertices of G , if a shortest path between the inserted points does intersect some vertices of G . Also, note that the “insertion” process does not actually modify the graph G because the points are never truly inserted into G .

To “insert” a point s into the reduced visibility graph G , it is necessary to project the point s onto the relevant cut lines based on the graph construction procedure. A fixed set of $O(n)$ cut lines are used in the construction of G . These cut lines subdivide the plane recursively, and each cut line is associated with a particular recursion level. In consequence, all points in each region of the resulting planar subdivision can be projected onto the same subset of cut lines. If, according to the graph construction procedure, s would have been projected onto a cut line L , then it says L is a *projection cut line* of s . Note that if a cut line L is a projection cut line of s , then s is visible in the horizontal or vertical direction from L . But, not every cut line visible from s is a projection cut line of s . It is sufficient for the discussion to use vertical cut lines only.

The lemmas and observations in this subsection are proved in [30, 32].

The set W_s of gateways for a point s is determined as follows: For each projection cut line L of s , if z is the vertex of G on L that is immediately above (resp., below) the projection point of s on L , then $z \in W_s$ (see Fig. 4). Observe that if s were “inserted” into G , then the only edges adjacent to s in the graph would be those connecting s with its projection points. Because each projection point of s is adjacent to at most two neighboring vertices of G on its cut line, W_s controls every path in G from s to any other vertex of G . Since, at each recursion level of the graph construction procedure, s can be projected onto at most one cut line, there are $O(\log n)$ projection cut lines for s . Along each projection cut line of s , there can be at most two neighboring vertices of G . Therefore, the following two lemmas follow.

Fig. 4 The gateways and gateway region $\mathcal{R}(s)$ of a point s

Lemma 1 For each point s in the plane, $|W_s| = O(\log n)$.

Lemma 2 For each point s and each vertex v of G , there is a shortest s -to- v path in the plane that goes through a vertex of W_s .

For every vertex $z \in W_s$, an “edge” (s, z) in the graph is defined as follows: Let z be on a projection cut line L of s ; then, the edge (s, z) consists of the segments $sp(s)$ and $p(s)z$, where $p(s)$ is the projection point of s on L .

A gateway region $\mathcal{R}(s)$ (Fig. 4) of a point s is the area defined by an interconnection of the vertices in W_s . WLOG, it is only shown how the gateways of W_s that are in the first quadrant of s are connected together:

1. Let a vertical “pseudo” cut line pass through s .
2. For each vertex v of W_s in the first quadrant of s , project v horizontally to the projection cut line L of s that is immediately to the left of v (it can be shown that such a projection is always possible even among weighted obstacles). Note that L can be the “pseudo” cut line passing s .
3. Let the projection point of v on L be $p(v)$ and the vertex of W_s that is on L and in the first quadrant of s be u (if u exists).
4. Connect u and v by line segments $up(v)$ and $p(v)v$.
5. If v is the rightmost gateway of s , then connect v with the point (v_x, s_y) by a segment.
6. If L is the pseudo cut line passing through s (and hence u does not exist on L), then connect v and $p(v)$ by a segment.

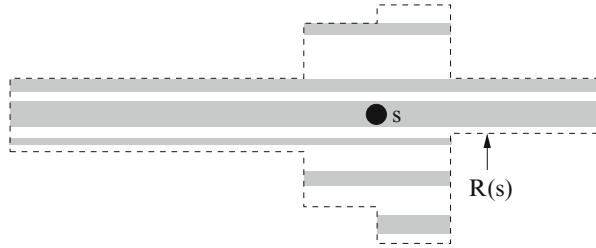

The area in the first quadrant of s enclosed together by the polygonal chain so defined, the x -axis and y -axis (with s as the origin), is part of $\mathcal{R}(s)$. $\mathcal{R}(s)$ is the union of the areas so defined in the four quadrants of s .

A region \mathcal{R} in the plane is said to be *rectilinearly convex* if \mathcal{R} is a connected region and, for any horizontal or vertical line L , $L \cap \mathcal{R}$ is either a single segment or empty. The following lemma characterizes some crucial structures of $\mathcal{R}(s)$.

Lemma 3 The gateway region $\mathcal{R}(s)$ of any point s has the following structures:

- $\mathcal{R}(s)$ is rectilinearly convex.
- For any point z in $\mathcal{R}(s)$, the points (z_x, s_y) and (s_x, z_y) are both in $\mathcal{R}(s)$.
- $\mathcal{R}(s)$ contains no vertices of $V_O \cup V_I$ in its interior.

Fig. 5 Horizontal obstacle strips across the gateway region $\mathcal{R}(s)$

[Lemma 3](#) implies that when obstacles are unweighted (i.e., their weights are all ∞), the interior of $\mathcal{R}(s)$ is either completely free of obstacle or is completely contained within an obstacle. However, when obstacles are weighted, there is an additional case in which the interior of $\mathcal{R}(s)$ contains parallel “strips” of obstacles which are all across $\mathcal{R}(s)$ (see [Fig. 5](#)).

From the above discussion, one can see that the set of gateways for the whole plane is the vertex set $V(G)$ of the reduced visibility graph G .

3.2.3 Algorithms for Rectilinear Path Queries

By making use of the structures of a gateway region $\mathcal{R}(s)$ ([Lemma 3](#)), W_s can be computed efficiently for any query point s , especially when $\mathcal{R}(s)$ is completely free of obstacle or is completely contained within an obstacle (e.g., in $O(\log^2 n)$ time by doing a binary search on the vertices of G along each projection cut line of s or in $O(\log n)$ time by using a *fractional cascading* data structure [[24, 25](#)]). But, there are still some difficulties. For example, amid weighted obstacles, each edge connecting s with a gateway point in W_s can penetrate as many as $O(n)$ obstacle strips across the gateway region $\mathcal{R}(s)$ ([Fig. 5](#)), making the computation of such a weighted edge length seemingly quite costly. However, by exploiting numerous geometric observations on these path problems, it is possible to compute W_s and the costs of all the edges adjacent to s in $O(\log n)$ time [[30, 32](#)].

The algorithms for various path query problems are summarized as follows:

- L_1 shortest paths amid general polygonal obstacles [[32](#)]. Here, the path edges can be in arbitrary directions, but the edge lengths are measured in the L_1 metric. It makes use of Mitchell’s single-source L_1 shortest path data structure [[71, 72](#)]. This L_1 path query data structure takes $O(n^2 \log^2 n)$ time and $O(n^2 \log n)$ space to build and supports a length query in $O(\log^2 n)$ time.
- Shortest A -distance paths amid general polygonal obstacles [[30](#)]. It constructs a generalized reduced visibility graph, which has $O(|A|n \log n)$ vertices and edges. It is shown that there are $O(|A| \log n)$ gateways for each query point. Since single-source shortest path data structure was not available before, both the single-source and general path query data structures need to be developed. The general path query data structure takes $O(|A|^2 n^2 \log^2 n)$ time and space to build and supports a length query in $O(|A|^2 \log^2 n)$ time.
- Rectilinear shortest paths amid weighted rectilinear polygonal obstacles [[32](#)]. It needs to develop both the single-source and general path query data structures.

The general path query data structure takes $O(n^2 \log^2 n)$ time and space to build and supports a length query in $O(\log^2 n)$ time.

- Rectilinear optimal bicriteria paths amid rectilinear polygonal obstacles based on combinations of the L_1 and link metrics [30]. It needs to develop both the single-source and general path query data structures. In addition, Yang, Lee, and Wong's special *segment-dragging* data structure [90] is generalized for the gateway-based procedure of answering path queries. This general path query data structure takes $O(n^2 \log^2 n)$ time and space to build and supports a length query in $O(\log^2 n)$ time.

3.3 Other Related Path Problems

In [15, 16], a simpler case of the problem of processing geometric shortest path queries was studied: Process rectilinear shortest path queries among disjoint *rectangular* rectilinear obstacles. The techniques developed involve a fast parallel computation of *staircase separators* and a parallel scheme for partitioning the boundaries of the obstacles in a way that ensures that the resulting path length matrices have a special *monotonicity property* that was apparently absent before applying the partitioning scheme. In particular, it was presented in [15, 18] optimal parallel algorithms for partitioning a set of m disjoint rectangles into two subsets of size $m/2$ each, by using an obstacle-avoiding staircase, called a *staircase separator* (see Fig. 6 for an example). It was shown that for rectilinear shortest path queries among rectangular obstacles, each query point needs to use at most two gateway points. The data structure was constructed sequentially in $O(n^2)$ time and space and in parallel in $O(\log^2 n)$ time using $O(n^2 / \log n)$ CREW PRAM processors, for supporting an $O(\log n)$ length query time [15, 16].

The staircase separator algorithms have been used, by the author and by others, in solving various geometric paths and Voronoi diagram problems sequentially and in parallel [18, 29, 50, 55, 79].

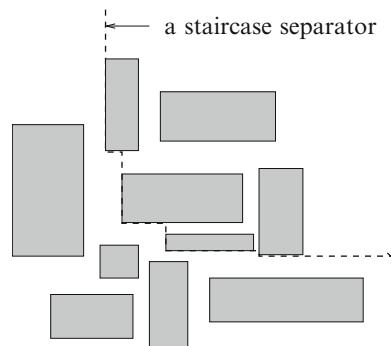

Fig. 6 A staircase separator partitioning a set of rectangular obstacles

Matrices with the special monotonicity property that are used in [15, 16] are called *monotone matrices* or *Monge matrices* [5, 6, 9]. Monotone matrices can be multiplied in the $(\min, +)$ semiring very efficiently, even in parallel. For example, two $n \times n$ monotone matrices can be multiplied in parallel in $O(\log n)$ time and $O(n^2 / \log n)$ CREW PRAM processors [5, 9]. Monotone matrices find numerous applications in many areas. In particular, it has been discovered that monotone matrices appear in many geometric and graph shortest path problems, yielding very efficient algorithms for such path problems [15–17, 19, 20, 64].

4 Approximate Shortest Path Queries

This section discusses a family of efficient algorithmic solutions for processing various length queries on *approximate* geometric shortest obstacle-avoiding paths among polygonal obstacles in the plane. The lengths of the paths considered are determined according to the L_p metric, where p is any positive integer. These algorithms achieve an interesting trade-off between the approximation factor, the query time, and the space and construction time of the data structures. In addition to the gateway paradigm, the algorithms are also based on other important paradigms for approximation of geometric and graph shortest paths.

Note that in a plane with multiple polygonal obstacles, the best-known data structures for even relatively simple cases of exact shortest path queries take super-quadratic space, as shown in the previous section. However, solutions of super-quadratic space can still be too expensive for many practical applications. Moreover, solutions suitable for many practical problems (e.g., in data compression and geographical information systems) often need not use exact shortest paths. In such situations, practitioners may be willing to sacrifice, to a certain degree, the optimality of their solutions to gain algorithmic simplicity and efficiency. Therefore, it makes sense to develop efficient solutions (e.g., of subquadratic space) for queries on approximate geometric shortest paths whose lengths are within a guaranteed small constant factor c of their corresponding exact shortest paths. Such approximate shortest paths will be referred to as *c-short paths* or simply *short paths*. For example, the *exact* shortest paths are 1-short paths.

One of the goals in this section, therefore, is to illustrate some trade-off between the approximation factor, the query time, and the space and construction time of the approximate shortest path query data structures developed in [10, 26].

Very few previous results were known for computing approximate geometric shortest paths in the plane. Notably, Clarkson [41] presented an algorithm for processing Euclidean $(1 + \epsilon)$ -short path queries amid polygonal obstacles, for any positive constant ϵ . Clarkson's algorithm uses $O(n \log n)$ time and $O(n)$ space for building the data structure and answers a short path query in $O(n \log n)$ time. As was mentioned in [41], it is possible to extend Clarkson's result as follows: In $O(n^2 \log n)$ time, an $O(n^2)$ -space data structure can be constructed for supporting a length query in $O(\log n)$ time; the details of this solution

is actually provided in [26]. Mitchell [71, 72] gave a different approach for computing $(1 + \epsilon)$ -short obstacle-avoiding paths in the plane.

4.1 Main Ideas

The main ideas of the approximation solutions are first discussed. Let V denote the set of n obstacle vertices. Let $G_V = (V, E)$ be the visibility graph of the obstacle scene with vertex set V and edge set E such that for any two distinct vertices u and $v \in V$, (u, v) is an edge in E if and only if the line segment \overline{uv} does not intersect the interior of any obstacle. The cost of edge $(u, v) \in E$ is the L_p distance $d(u, v)$ between u and v for a metric L_p . Clearly, $|E| = O(n^2)$ in the worst case. Let $Length(P)$ denote the length of an obstacle-avoiding path P .

It will use the vertex set V of the visibility graph G_V as the set of gateway points for the whole plane. To be able to compute efficiently a c -short path $P_S(p, q)$ between any two query points p and q in the plane, two difficulties need to be overcome:

1. “Discretize” the computation of $P_S(p, q)$, that is, compute $P_S(p, q)$ based on short paths $P_S(u, v)$, for some obstacle vertices u and $v \in V$.
2. Obtain short paths between obstacle vertices quickly.

To handle difficulty (1) in a fast manner (e.g., in polylogarithmic time) for each pair of query points requires the query procedure to examine $P_S(u, v)$ for only a small number of pairs of obstacle vertices u and v . To answer short path queries between arbitrary query points in the plane in polylogarithmic time and with a data structure in subquadratic space and construction time, a problem that one must get around is to avoid using general *ray shooting*. (In contrast, recall that many of the solutions for processing *exact* path queries in the previous section do make use of general ray shooting.) When two query points are visible to each other, the true shortest path between them is found naturally by ray shooting (in polylogarithmic time). However, a data structure that supports general ray-shooting operations in logarithmic time takes $O(n^2)$ space and $O(n^2 \log n)$ time to build [1], or one can use subquadratic space data structures and perform ray-shooting operations in superpolylogarithmic time (e.g., see [1–3]). Neither of those ray-shooting data structures gives a satisfactory solution.

Difficulty (2), in a sense, is the problem of finding a good “spanner.” Given a set S of n points in a d -dimensional space, a t -spanner is a graph G whose vertex set includes the points of S such that for any two points u and v of S , there is a u -to- v path in the graph G of length at most t times the distance between u and v in a chosen L_p metric. The problem of constructing various “good” spanners has attracted a considerable amount of attention recently (e.g., see [13] and the references given there). The “spanner” is not only for a finite set of points (which is the case for most spanner results) but for the entire obstacle-scattered plane. To resolve difficulty (2), it needs an efficient scheme for computing and maintaining short paths between any two obstacle vertices using only subquadratic space and time. Actually, the scheme involved makes use of certain spanners for discrete points.

The scheme for resolving difficulty (2), called *approximation of approximation*, is outlined as follows:

Approximation 1: Use a *planar spanner* for the gateway point set V , to approximate shortest paths between any two gateway points in the plane.

Approximation 2: Develop efficient algorithms and data structures for computing approximate shortest paths in such a spanner graph.

The rest of this section unfolds the solutions for resolving these difficulties.

4.2 Planar Spanners

As will be shown in the next subsection, planar spanners are particularly useful for computing geometric short paths. For the gateway point set V , a *planar spanner* is a graph $G_P = (V_P, E_P)$ such that:

1. The set V of obstacle vertices is a subset of V_P .
2. The edges of G_P represent straight-line segments that do not intersect the interior of any obstacle.
3. For any two obstacle vertices u and $v \in V$, there is a u -to- v path in G_P which corresponds to a c -short obstacle-avoiding path in the plane in an L_p metric;
4. G_P is a planar graph.

If $V_P = V$, then it calls G_P a *planar L_p c-spanner*. Otherwise, if G_P contains additional vertices (called *Steiner vertices*), then it calls G_P a *planar Steiner L_p c-spanner*. The real number $c \geq 1$, representing the approximation factor of short paths, is called the *stretch factor* of the spanner. [Figure 7](#) gives an example of a planar spanner of the visibility graph for a point set in the plane with no obstacle.

There were already several algorithms that construct planar L_2 c -spanners in $O(n \log n)$ time. The best-known stretch factor in L_2 is $c = 2$, which was discovered by Chew [[34, 36](#)].

Ideally, one would like to have planar spanners with a stretch factor of $1 + \epsilon$ for any given positive constant ϵ . So one interesting question is: What kind of planar spanners can achieve a $1 + \epsilon$ stretch factor? The following lemma, proved in [[10](#)], sheds some light on the answer to this question.

Lemma 4 *There exist point sets of size n in the plane such that any planar L_1 spanner that is a subgraph of the visibility graph on such a point set (modeling the L_1 distances among the given points) has a stretch factor ≥ 2 . Furthermore, the stretch factor of 2 is tight, since there is an $O(n \log n)$ -time algorithm for constructing such a planar L_1 2-spanner for the vertices of any polygonal obstacle scene in the plane.*

The $O(n \log n)$ -time algorithm for constructing a planar L_1 2-spanner (without using any Steiner vertices) hinges on computing a *constrained Delaunay triangulation* using a convex distance function [[35–37](#)] based on an isosceles triangle which

Fig. 7 The visibility graph (a) and a planar spanner (b) of five points in the plane

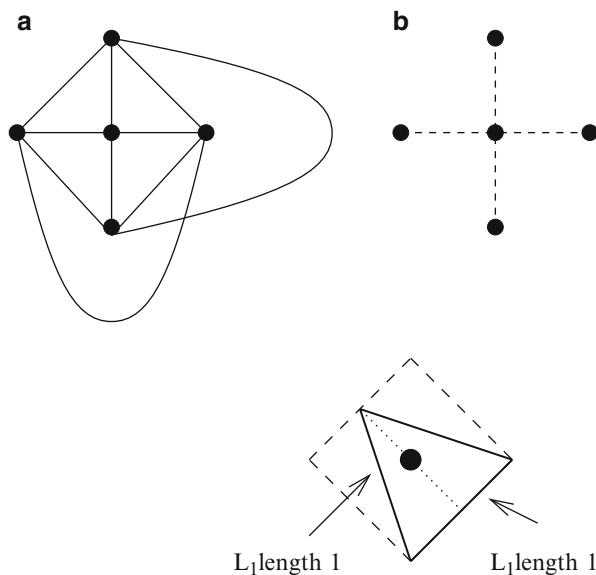

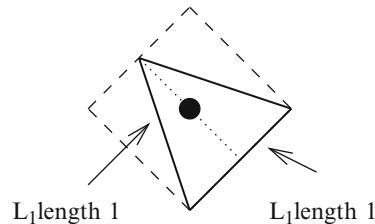

Fig. 8 The convex distance function is based on the isosceles triangle within an L_1 unit diamond

is within an L_1 unit diamond (shown in Fig. 8). This approach is similar to those used in [34–36].

Lemma 4 shows that if one wants a planar L_1 spanner with a stretch factor less than 2, then it is *necessary* to use Steiner vertices. Since any L_p metric is related to the L_1 metric by a fixed constant factor, this conclusion also holds for planar L_p spanners (i.e., Steiner vertices are needed for achieving planar L_p spanners with a $1 + \epsilon$ stretch factor).

The following lemma, proved in [10], shows that planar Steiner L_1 $(1 + \epsilon)$ -spanners exist and can be constructed efficiently.

Lemma 5 *Given a collection of disjoint polygonal obstacles in the plane with n vertices and given any constant $\epsilon > 0$, a planar L_1 $(1 + \epsilon)$ -spanner with $O(n/\epsilon^2)$ Steiner vertices can be constructed in $O(n \log n + n/\epsilon^2)$ time.*

The results of Lemma 5 have been extended to the L_2 metric (the constant factor associated with the number of Steiner vertices used by the resulting planar L_2 spanner depends on a higher-degree polynomial of $1/\epsilon$). It seems possible to even further extend this lemma to any L_p metric.

The $O(n \log n)$ -time algorithm for Lemma 5 is quite involved. It is based on a special *planar subdivision* introduced by Arya et al. [14], which was originally used for solving nearest neighbor searching problems. Interestingly, it is possible to apply this planar subdivision to constructing planar Steiner spanners for obstacle vertices. In [10], it first constructs the planar subdivision of Arya et al. [14] for a polygonal obstacle scene. Doing so in a straightforward manner, however, may result in a planar subdivision with $O(n^2)$ regions. It can be shown that it is possible

to group the $O(n^2)$ regions into only $O(n)$ regions, in $O(n \log n)$ time. Finally, it carefully creates grids on the resulting $O(n)$ regions of the subdivision. This gives a planar Steiner spanner with a $1 + \epsilon$ stretch factor.

In comparison with the planar L_1 and L_2 2-spanners (without any Steiner vertices) in [10, 34, 36], the planar Steiner $(1 + \epsilon)$ -spanners obtained in Lemma 5 have a better stretch factor but at a price of possibly using a large number of Steiner vertices.

Before concluding this subsection, it should be mentioned that all the presented $O(n \log n)$ -time algorithms for constructing planar spanners (with or without using Steiner vertices) are optimal in the algebraic computation tree model [22]. Specifically, the following lower-bound results were proved in [31]:

Lemma 6 *The problem of constructing geometric spanners, possibly containing Steiner points, for sets of points in the d -dimensional space, and the problem of computing approximate shortest paths amid a collection of polygonal obstacles in the plane, for any given approximation factor, all take $\Omega(n \log n)$ time to solve in the algebraic computation tree model.*

4.3 Short Paths in Planar Graphs

This subsection discusses several algorithmic techniques for computing and maintaining approximate shortest paths in weighted undirected planar graphs with nonnegative real edge costs. The algorithms all construct certain data structures for short path queries in planar graphs in subquadratic time and space and achieve an interesting trade-off between the approximation factor, the query time, and the space and construction time of the data structures. These solutions, of course, are immediately applicable to the planar spanners discussed in the previous subsection because such planar spanners are simply instances of weighted undirected planar graphs.

Let $G = (V, E)$ be a weighted undirected planar graph with nonnegative real costs on its edges, and let n denote the number of vertices of G . Note that one cannot simply store the all-pairs shortest paths in G , since that would require $O(n^2)$ space. Hence, different approaches for computing short paths in G must be used.

4.3.1 A General Approximation Paradigm

The first approach for computing short paths in undirected planar graphs hinges crucially on the following key observation which was proved in [26].

Lemma 7 *For two elements p and q in an environment \mathcal{R} , let \mathcal{R}' be a subset of \mathcal{R} such that a shortest path $P(p, q)$ between p and q in \mathcal{R} goes through an element in \mathcal{R}' . For p (resp., q), let p' (resp., q') be an element in \mathcal{R}' such that the length of the shortest path $P(p, p')$ (resp., $P(q, q')$) in \mathcal{R} is the shortest among all the paths between p (resp., q) and the elements*

in \mathcal{R}' ; that is, $\text{Length}(P(p, p')) = \min\{\text{Length}(P(p, w)) \mid w \in \mathcal{R}'\}$ (resp., $\text{Length}(P(q, q')) = \min\{\text{Length}(P(q, w)) \mid w \in \mathcal{R}'\}$). Then, $\text{Length}(P(p, p') \cup P(p', q') \cup P(q', q)) \leq 3 \times \text{Length}(P(p, q))$.

Lemma 7 states that the concatenation of the three shortest paths $P(p, p')$, $P(p', q')$, and $P(q', q)$ is a good approximation of the shortest path $P(p, q)$ (within at most *three times*). This observation is quite general since the environment \mathcal{R} can be geometric or graph-theoretic, so long as the paths involved in the observation are *undirected*. It immediately leads to the following general paradigm for processing short path queries in \mathcal{R} :

1. Find a subset \mathcal{R}' of \mathcal{R} (\mathcal{R}' is called a *separator* of \mathcal{R}), and use \mathcal{R}' to partition \mathcal{R} into connected components $\mathcal{R}_1, \mathcal{R}_2, \dots, \mathcal{R}_k$. Ideally, \mathcal{R}' would give rise to a “balanced” partition of \mathcal{R} .
2. Compute and store shortest paths in \mathcal{R} from each element of \mathcal{R}' to other elements of \mathcal{R}' (i.e., an all-pairs shortest path computation among the elements of \mathcal{R}'). Also, compute and store, for each element p of \mathcal{R} , a shortest path in \mathcal{R} from p to its closest element p' in \mathcal{R}' (i.e., the Voronoi diagram on \mathcal{R} whose sites are the elements of \mathcal{R}'). Then, the shortest path information so prepared is sufficient for reporting an approximate shortest path (within a factor of 3 of the exact shortest path) between any $p \in \mathcal{R}_i$ and $q \in \mathcal{R}_j$, $1 \leq i < j \leq k$.
3. For every $i = 1, 2, \dots, k$, build the data structure recursively for \mathcal{R}_i , until \mathcal{R}_i becomes easily manageable.

In addition to the above general approximation paradigm, **Lemma 7** has several other important implications. For example, the size of a short path query data structure that is based on the above paradigm can be affected greatly by the size of the separator \mathcal{R}' because the all-pairs shortest paths among the elements of \mathcal{R}' may need to be represented explicitly. Therefore, “small-sized” separators such as Lipton and Tarjan’s planar separators [69] are particularly useful in this framework. However, large-sized separators, such as the *staircase separators* [15, 16, 18], can also be appropriate, especially when the all-pairs shortest paths among the elements of such separators can be made available without paying high computational costs. Hence, with this framework, results on various graph-theoretic and geometric separators can have a significant impact on algorithms for computing approximate shortest paths.

Now it is clear that this approximation paradigm is especially applicable to undirected planar graphs, due to Lipton and Tarjan’s *separator theorem* [69]. In fact, the approximation paradigm has led to a number of results on computing short geometric and graph paths in [10, 26].

4.3.2 3-Short Paths in Planar Graphs

When this paradigm is applied to a weighted undirected planar graph G , a two-phase recursive algorithm was developed for constructing a 3-short path query data structure [26]. At each recursion level of the algorithm, a planar separator [69], denoted by S , is computed and is used to partition a region of the graph G into

smaller regions. The Voronoi diagram on the region of G whose sites are the vertices of S is computed, based on Mehlhorn's notion of *Voronoi regions* in graphs [70] and making use of the optimal single-source shortest path algorithm in planar graphs by Klein et al. [66]. The (global) all-pairs shortest paths among the vertices of S are computed in the bottom-up and top-down phases of the algorithm, by repeatedly using Dobosiewicz's all-pairs shortest path algorithm [48]. The algorithm maintains a structure for the recursive graph-partitioning process, called the *partition tree* of G . Queries on 3-short paths between any two vertices of G are answered by first computing their *lowest common ancestor* [61, 85] in the partition tree.

As a result, the algorithm in [26] builds the 3-short path query data structure in $O(n \log n)$ space and $O(n^{3/2} / \sqrt{\log n})$ time, supporting a length query in $O(1)$ time. The data structure construction algorithm is further improved by using Frederickson's *hammock decomposition* technique [52], to $O(n \log n)$ space and $O(n \log n + q^{3/2} / \sqrt{\log q})$ time, where q , with $1 \leq q \leq n$, is the minimum number of faces needed to cover all the vertices of the planar graph.

4.3.3 c -Short Paths in Planar Graphs

The ideas and algorithm for computing 3-short paths in [26] inspired a further study of c -short paths in weighted undirected planar graphs, where $1 \leq c \leq 3$ [10]. In particular, the following results are presented in [10].

Lemma 8 *Given an n -vertex planar graph G and an arbitrary integer ρ with $1 \leq \rho \leq \sqrt{n}$, it is possible to construct a data structure in $O(n^2/\rho)$ time and space such that a length query on the exact shortest path between any two vertices in G can be answered in $O(\rho)$ time.*

Note that the algorithm for Lemma 8 is for computing *exact* shortest paths (i.e., 1-short paths) in G . It is based on the planar separators [69] and Frederickson's notion of r -division [51]. It partitions the planar graph G into a division consisting of a number of regions (depending on the value of ρ) and then computes shortest path trees in the entire graph G , with each of these shortest path trees rooting at a vertex on the boundary of such a region.

The following lemma, proved in [10], is for computing 2-short paths in planar graphs.

Lemma 9 *Let u and v be any two vertices of a planar graph G , and let S be a separator of G . If a shortest u -to- v path in G passes through a vertex in S , then $\min\{\text{Length}(P(u, b_u)) + \text{Length}(P(b_u, v)), \text{Length}(P(v, b_v)) + \text{Length}(P(b_v, u))\} \leq 2 \times \text{Length}(P(u, v))$, where $P(u, v)$ is a shortest u -to- v path in G and b_u , called a closest separator vertex of u on the separator S , is a vertex in S which satisfies $\text{Length}(P(u, b_u)) \leq \text{Length}(P(u, w))$ for any vertex w in S .*

Based on Lemma 9, an algorithm is developed for constructing a data structure for 2-short path queries in planar graphs. The 2-short path data structure construction algorithm, actually, is somewhat similar to the algorithm for the 3-short paths

in the previous subsubsection. One main difference between these two algorithms is that the computation of a Voronoi diagram in a region of G with the separator vertices as the sites is replaced by the computation of single-source shortest path trees in the region rooted at each separator vertex. The 2-short path algorithm achieves the following result.

Lemma 10 *Given an n -vertex planar graph G , it is possible to construct a data structure in $O(n^{3/2})$ time and space such that a length query on a 2-short path between any two vertices in G can be answered in $O(\log n)$ time.*

The query procedure supported by this 2-short path data structure takes $O(\log n)$ time because it needs to perform an $O(1)$ time computation (based on Lemma 9) at each of the $O(\log n)$ levels of the partition tree of G .

4.4 Short Path Queries Amid Obstacles in the Plane

This subsection shows how to put together the results on planar Steiner L_p c -spanners (Sect. 4.2) and on all-pairs short path queries in undirected planar graphs (Sect. 4.3), as well as other useful geometric structures, to solve the problem of processing L_p short path queries amid disjoint polygonal obstacles in the plane (with $p = 1, 2$). Several algorithms and data structures for the problem are given, which differ from each other in the approximation factors of the short paths they obtain and in their complexity bounds. The complexity bounds of these solutions also depend on a given value $\epsilon > 0$.

The L_p short path query data structures are also based on the gateway paradigm (Sect. 2). Recall that the gateway points in this case are simply all the n obstacle vertices. These path query data structures all consist of the following two major components:

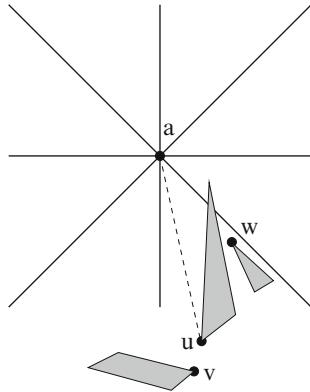

Part I. A data structure for answering queries on all-pairs short paths in a planar Steiner L_p c -spanner as discussed in Sect. 4.2

Part II. A data structure that, given any two query points s and t in the plane, quickly reduces the computation of a short s -to- t path in the plane to the computation of short paths between a constant number of pairs of gateway points (the number of pairs of gateway points involved depends on the value of ϵ)

Given the results in Sects. 4.2 and 4.3, the data structure of Part I can be easily constructed as follows. Let $\epsilon_1 > 0$ be a value depending on the given ϵ (ϵ_1 will be decided later). It first obtains a planar Steiner L_p $(1 + \epsilon_1)$ -spanner with $O(n)$ Steiner vertices, denoted by G_P , and then builds a data structure for answering all-pairs short path queries in the planar graph G_P .

Assume that, in $O(\log n)$ time, one can reduce the computation of a short path query between any two query points in the plane to the computation of short paths between $O(1)$ pairs of gateways (it will be shown later how to perform this $O(\log n)$ -time reduction with the $O(n)$ -space data structure of Part II). Once the

Fig. 9 Clarkson's cone system: to apex a , u is the closest visible obstacle vertex in the cone containing u

data structures of Parts I and II are available, it can, for example, process a short path query between any two query points in the plane in $O(n)$ time. This is done by first reducing such a query to computing $O(1)$ exact shortest paths in G_P and then applying to G_P the $O(n)$ -time single-source shortest path algorithm of [66]. Note that, in this case, the data structure of Part I needs to consist of only the graph G_P itself, and hence, it takes only $O(n)$ space and $O(n \log n)$ time to build. This $O(n)$ -time query-answering algorithm compares favorably with Clarkson's $O(n \log n)$ -time and $O(n)$ -space algorithm for L_2 $(1 + \epsilon)$ -short path queries among polygonal obstacles in the plane [41]. If the data structure of Part I supports queries on c -short paths in G_P (Sects. 4.3.2 and 4.3.3), then the length query time for a short path between any two query points in the plane is $O(\log n + f_c)$, where f_c is the length query time for a c -short path in G_P .

Let $\epsilon_2 > 0$ be a value depending on the given ϵ (ϵ_2 will be decided later). The data structure of Part II takes $O((n \log n)/\epsilon_2)$ time and $O(n/\epsilon_2)$ space to build. This data structure serves the purpose of, given two query points s and t in the plane, computing a c -short s -to- t path from the short paths between $O((1/\epsilon_2)^2)$ pairs of obstacle vertices. This data structure is given in [26] for processing L_2 short path queries in the plane. It is based on a modified version of Clarkson's cone system [41], as sketched below.

For a given value ϵ' , $0 < \epsilon' \leq 1$, Clarkson [41] constructed a set of cones in the plane with a common corner point a , called the *apex*, as follows: Let $\psi = \min\{\pi/12, \epsilon'\pi/2\}$ if $\epsilon' < 1/2$ and $\psi = \epsilon'\pi/6$ if $1/2 \leq \epsilon' \leq 1$; partition the plane into a set \mathcal{F}_ψ^a of cones with the point a as their apex such that the angle of each cone $C_a \in \mathcal{F}_\psi^a$ is smaller than ψ (see Fig. 9 for an example). If no particular apex point is referred to, the set of cones is denoted by \mathcal{F}_ψ . For two points a and b that are visible to each other, with b lying inside a cone $C_a \in \mathcal{F}_\psi^a$, the *approximate L_2 distance* $D_{a,b}^{C_a}$ from a to b is defined by $D_{a,b}^{C_a} = (b - a) \cdot U_{C_a}$, where U_{C_a} is a fixed unit vector contained in C_a . Based on this cone system, Clarkson built a sparse subgraph $G_{\epsilon'}$ of the visibility graph G_V in a plane with polygonal obstacles such that for any two obstacle vertices a and u , (a, u) is an edge of $G_{\epsilon'}$ if u is visible from a and there is

a cone $C_a \in \mathcal{F}_\psi^a$ containing u with $D_{a,u}^{C_a}$ being the minimum (approximate) distance among all the obstacle vertices in $C_a - \{a\}$ that are visible from a (see Fig. 9 for an example). $G_{\epsilon'}$ hence consists of all the vertices of G_V and of $O(n/\epsilon')$ edges and can be obtained in $O((n \log n)/\epsilon')$ time by using certain variants of Voronoi diagrams in the plane, called *conical Voronoi diagrams*, whose sites are the vertices of G_V [41]. By using $G_{\epsilon'}$ and an $O(n/\epsilon')$ -space data structure for a set of $O(1/\epsilon')$ conical Voronoi diagrams, a $(1 + \epsilon')$ -short path between any two points in the plane can be reported in $O(n \log n + n/\epsilon')$ time [41]. The geometric short path query data structures here include a modified version of Clarkson's cone system and several additional components, such as those for *oriented ray shooting* and for planar point location used in [26]. One of the needed modifications to Clarkson's cone system is to carefully choose a set of unit vectors for computing the approximate L_p distances in each cone (the choices of these unit vectors ensure the correctness of the query procedure [26]).

The data structure for Part II enables one to perform the following computation in $O((\log n)/\epsilon_2)$ time: Given any point s in the plane, compute a set P_s of $O(1/\epsilon_2)$ gateway points such that P_s is a subset of the obstacle vertices and such that each $v \in P_s$ ($v \neq s$) is the closest point among all the obstacle vertices in a cone $C_s \in \mathcal{F}_\psi^s$ (based on the approximate L_p distance defined by a unit vector for C_s) that are visible from s .

Given Parts I and II of the data structures, it can answer the length query for a geometric short path $P_S(s, t)$ between any two query points s and t as follows:

1. Compute the gateway point sets P_s and P_t using the set of $O(1/\epsilon_2)$ conical Voronoi diagrams.
2. For each of the $O((1/\epsilon_2)^2)$ pairs of gateway points $u \in P_s$ and $v \in P_t$, compute the length of a short u -to- v path in the planar spanner G_P (with the desired stretch factor).
3. Find the shortest length among all the short obstacle-avoiding paths from s to t via u and v so obtained. This gives the length of the short path $P_S(s, t)$.

The time complexity of this query procedure is $O((\log n)/\epsilon_2)$ (for step 1) plus $O((1/\epsilon_2)^2)$ times the time for a short path length query in the planar graph G_P (for step 2).

To complete the discussion of the geometric short path query data structures, it must be decided the values of ϵ_1 and ϵ_2 based on ϵ . Note that because G_P is a planar Steiner L_p $(1 + \epsilon_1)$ -spanner with $O(n)$ Steiner vertices and because the stretch factors of the short paths in G_P that the all-pairs short path query data structures report are $k \in \{1, 2, 3\}$, a short path in G_P so computed corresponds to a short obstacle-avoiding path in the plane with a stretch factor of $k(1 + \epsilon_1) = k + k\epsilon_1$. Also, note that another approximation error is induced by the above geometric short path query procedure and this error depends on ϵ_2 . The stretch factor of the short obstacle-avoiding paths thus computed, therefore, can be bounded by $k + k(\epsilon_1 + \epsilon_2)$, and one would like to have $k + k(\epsilon_1 + \epsilon_2) \leq k + \epsilon$. Choosing $\epsilon_1 = \epsilon_2 = \epsilon/(2k)$ will be sufficient, and this only increases the time and space complexity bounds of the geometric short path query data structures by a constant factor.

Table 1 The results for the geometric short path query data structures in the L_1 and L_2 metrics. Here, ϵ is an arbitrarily small positive constant, ρ is an arbitrary integer such that $1 \leq \rho \leq \sqrt{n}$, and q is the minimum number of faces needed to cover all the vertices of the planar spanner used by a data structure and $1 \leq q \leq n$

Stretch factor	Construction time	Space	Query time
$1 + \epsilon$	$O(n^2/\rho)$	$O(n^2/\rho)$	$O(\log n + \rho)$
$1 + \epsilon$	$O(n \log n)$	$O(n)$	$O(n)$
$2 + \epsilon$	$O(n^{3/2})$	$O(n^{3/2})$	$O(\log n)$
$3 + \epsilon$	$O(n \log n + q^{3/2}/\sqrt{\log q})$	$O(n \log n)$	$O(\log n)$

The results of the geometric short path query data structures presented above are summarized in [Table 1](#).

4.5 A Special Case

As mentioned in [Sect. 4.3.1](#), not only small-sized separators (e.g., [69]) are useful in the approximation paradigm but also large sized graph-theoretic and geometric separators can be effective. For example, Mitra and Bhattacharya [79] and Chen and Klenk [29] have used the *staircase separators*, which was introduced for parallel geometric shortest path algorithms and for other geometric path problems in [15, 16, 18], in designing data structures for approximate rectilinear shortest path queries among rectilinear rectangular obstacles. Mitra and Bhattacharya's data structure in [79] takes $O(n \log^2 n)$ space and $O(n \log^3 n)$ construction time and supports an $O(\log^2 n)$ time on length queries for 7-short paths. An improved data structure was given that takes $O(n \log n)$ space and $O(n \log^2 n)$ construction time and supports an $O(\log n)$ -time length query for 3-short paths [29]. Observe that an obstacle-avoiding staircase separator S (e.g., see [Fig. 6](#)), although can be of size $O(n)$, has the nice property that for any two points on S , there is a rectilinear shortest obstacle-avoiding path connecting the two points along S . Hence, the data structures for approximate shortest path queries in [29, 79] need not explicitly compute and store the all-pairs shortest paths among points on any such staircase separator, resulting in a significant saving in their space and construction time. It was also shown in [29] that in this special case, each query point needs to use at most two gateway points.

5 Some Other Geometric Shortest Path Query Results

This section sketches some other results for geometric shortest path query problems in the plane and in the 3-D space. Unless otherwise specified, we assume that the distance metric used in this section is Euclidean.

If the planar geometric environment contains only one simple polygon of n vertices, then a data structure can be constructed optimally in $O(n)$ time and space, which answers shortest path queries in $O(\log n)$ time each [56, 57].

In a planar geometric environment S that contains h (in the worst case, $h = O(n)$) polygonal obstacles of totally n vertices, the general shortest path query problem becomes much more difficult. While the single-source shortest path queries in S can be handled by a data structure which takes $O(n \log n)$ time to build and processes each query in $O(\log n)$ time [63], the general (two-point) query version has much higher time and space complexities. Known solutions for general two-point queries in S often reduce the problem to a higher-dimensional point location problem [88]. Chiang and Mitchell [38] presented several data structures for the general two-point query problem in this setting, including a data structure built in $O(n^{11})$ (resp., $O(n^{10} \log n)$) time and space for answering any query in $O(\log n)$ (resp., $O(\log^2 n)$) time and a data structure built in $O(n^{5+\epsilon})$ time and space with a sublinear query time, where $\epsilon > 0$ is any small constant. But, these time and space bounds are usually very high for practical usage. Even for some special cases on the planar geometric environment S with multiple polygonal obstacles, solutions for general two-point queries are still very expensive. For example, when both query points are constrained to lie on the boundaries of the obstacles in S , it takes $\tilde{O}(n^5)$ (resp., $O(n^{3+\epsilon})$) time and space to build a data structure with an $O(\log n)$ (resp., sublinear) query time, where the notation \tilde{O} hides a polylogarithmic factor, by Bae and Okamoto [21].

Guo et al. [58] developed a data structure built in $O(n^2 \log n)$ time and $O(n^2)$ space with an $O(h \log n)$ query time. While the time and space bounds in [58] are (nearly) quadratic, the $O(h \log n)$ query time is still $O(n \log n)$ in the worst case, no better than the time bound for computing single-source shortest paths in S [63].

The shortest path query problem on 3-D polyhedral surfaces has also been studied. For two-point queries on a *convex* polytope of n vertices, Agarwal et al. [4] presented a data structure built in $O(n^6 m^{1+\epsilon})$ time and space with an $O(n^{1/2}/m^{1/4})$ query time, for any fixed $1 \leq m \leq n^2$ and any constant $\epsilon > 0$; when the query points are all on the edges of the convex polytope, the time and space bounds of the data structure can be reduced by a factor of n [4]. Recently, Cook and Wenk [44] improved the solutions in [4] (reducing the bounds by a factor of n) based on a kinetic Voronoi diagram approach. For single-source queries on a (possibly non-convex) polyhedral surface, a data structure can be built in $O(n^2)$ time and space, by Chen and Han [33] (an improvement on the solution in [76]), with an $O(\log n)$ query time. If the polyhedral surface is *convex*, then a data structure can be constructed in $O(n \log n)$ time and space, by Schreiber and Sharir [86]. There are also some interesting efficient techniques for processing *approximate* shortest path queries on 3-D polyhedral surfaces (e.g., see [8, 59, 60]).

6 Conclusion

This chapter has discussed several newly developed algorithmic paradigms for processing geometric shortest path queries and related problems. It has shown how these general paradigms lead to efficient techniques for designing algorithms and

data structures for processing a variety of queries on exact and approximate shortest paths in a number of geometric and graph-theoretic settings.

There are many exciting and important problems on computing various geometric shortest paths that are yet to be solved. In [27], a number of research issues were raised on geometric optimal path planning. In addition to the research issues discussed in [27], the following open problems and research directions are likely to receive considerable attention in the future:

- In [10], it was shown that for the L_1 metric, it is possible to achieve a planar spanner (without any Steiner vertices) with a stretch factor of 2, and this stretch factor is tight. However, what about other L_p metrics for $p > 1$? For example, it is already known how to construct planar spanners (without any Steiner vertices) for the L_2 metric with a stretch factor of 2 [34, 36]. Can this stretch factor be improved for the L_2 metric? What is the tight lower bound for this stretch factor?
- The visibility-sensitive approach for processing queries on exact geometric shortest paths (Sect. 3.1) relates the query time with the visibility polygons of the query points, whose sizes can still be big. Can one reduce this query time for exact geometric shortest paths in the L_2 metric while still being able to use a data structure with a near-quadratic space and construction time?
- The approaches for processing queries on approximate geometric shortest paths (Sect. 4) crucially hinge on efficient schemes for computing approximate shortest paths in *planar spanners* of the obstacle vertices. There are many other geometric spanners that have a variety of useful properties (e.g., see [13, 41]). Can one develop efficient schemes for computing approximate shortest paths in these geometric spanners?
- The geometric shortest path query algorithms in this chapter all assume that the plane is perfectly “flat.” However, path-planning problems in practical situations are likely to occur in non-flat planes or even terrains. Distances in such non-flat geometric settings are usually more than the standard L_p distances. For example, in [7], it defines a distance (called *skew distance*) in a non-flat plane as the Euclidean distance plus a signed difference in height between two points. The skew distance is a natural generalization of the Euclidean distance. Efficient algorithms for processing shortest path queries in non-flat geometric settings with such generalized distance functions need to be developed.
- It is well known that computing geometric shortest paths in the 3-D space with polyhedral obstacles is NP-hard [23]. Several efficient approximation algorithms have been discovered for computing 3-D shortest paths [40, 41, 81]. However, there is so far no efficient approximation algorithm known for processing 3-D shortest path *queries* among polyhedral obstacles, even for the L_1 metric.
- All geometric shortest path query algorithms in this chapter assume that the geometric settings are *static*. However, in real applications, the geometric environments are likely to be *dynamic* (e.g., obstacles are moving, the weight factors of the regions are changing). Shortest path problems in dynamic geometric environments are much harder than the static versions. So far, no efficient algorithm is known for processing shortest path queries in dynamic geometric environments.

- The known algorithms for general two-point Euclidean shortest path queries in a planar geometric environment with multiple polygonal obstacles (e.g., [21, 38]) and on 3-D polyhedral surfaces (e.g., [4, 38, 44]) tend to have high time and space complexities. Reducing the time and space bounds of these solutions is important to practical applications.

Abstract

Since batteries are power supply for devices in wireless networks, energy efficiency is an important issue. There are many combinatorial optimization problems in the study of wireless networks. They can be roughly divided into three classes, minimum total power with adjustable-power nodes, minimum total power with unadjustable-power nodes, and maximum lifetime with unadjustable-power nodes. In this survey, some classical problems are introduced together with their solutions in each class.

1 Introduction

Recently, *New York Times* [1] reported the following:

Mr. Obama is also asking Congress to make a one-time investment of \$5 billion to bring wireless coverage to rural areas, and is proposing to spend \$3 billion of the spectrum proceeds on research and development into new wireless technologies. And the president is calling for a \$10.7 billion commitment to support what the administration describes as a nationwide wireless broadband network for public safety.

This means that a high-speed next-generation wireless network is going to be constructed and the investigation and technology developments in wireless communication will get in another hot season.

There are many types of wireless networks. They all have advantage that it can be accessed at anywhere and anytime due to their mobility. They all involve many optimization problems in their developments. In particular, the wireless ad hoc network and the wireless sensor network usually consist of a collection of mobile hosts with limited resource supply and hence they have many optimization problems on resource distribution and management. *In this chapter, an overview on those problems is given. These problems will be classified based on their optimization objectives, and the relationship between them will be further introduced.*

There are two types of energy-saving techniques in the literature. In the first type, the transmission power level at each node is adjusted to minimize the total energy consumption [2–4]. In the second type, the transmission power level at each node is fixed, wireless nodes are scheduled into sleep or active state in order to minimize the total energy consumption [5–7] or to maximize the lifetime of network system [8–10]. Therefore, one can classify those optimization problems into three classes, total energy consumption minimization with adjustable power level ([Sect. 2](#)), total energy consumption minimization with fixed power level ([Sect. 3](#)), and lifetime maximization with fixed power level ([Sect. 4](#)). There is a very interesting relationship between [Sects. 3](#) and [4](#).

2 Minimum Energy with Adjustable Power

The energy of wireless devices is often supplied with batteries, which means the energy supply is usually limited. Due to this fact, the energy efficiency becomes an important issue in the study of wireless networks. The communication range of wireless station (node) is closely related to its energy consumption and antenna type. For omni-antenna at a station s , the signal power received at a location t is decreasing as the distance $d(s, t)$ is increasing. Suppose at s , the signal power is P_s . Then at location t , it is $\frac{P_s}{d(s,t)^\alpha}$ where α is a constant usually between 2 and 5 [11]. Suppose c is the quality threshold for the signal power, that is, in order to receive the signal correctly, the signal power has to be at least c . This means that for location t to receive the signal correctly, it must have $\frac{P_s}{d(s,t)^\alpha} \geq c$, that is,

$$P_s \geq c \cdot d(s, t)^\alpha.$$

Thus, the communication range at each station is a disk with radius r where r is determined by the power p through formula

$$p = cr^\alpha.$$

Often, the transmission quality threshold c is normalized to 1.

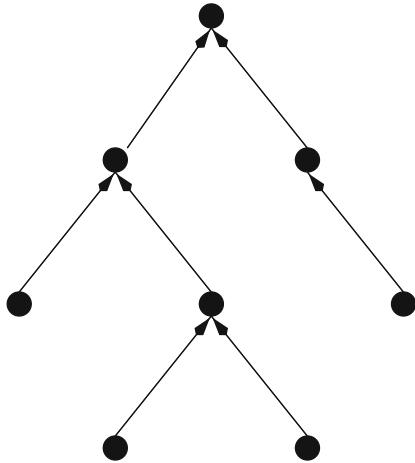

When the power p at each node is adjustable, one often studies the problem of minimizing the total energy consumption under certain network connection constraints in order to meet the requirement for certain duty. There exist many combinatorial optimization problems of this type in the literature. The following is a general mathematical formulation.

Consider a complete graph (or directed graph) $G = (V, E)$ with a distance table. For each $(u, v) \in E$, denote $w(u, v) = d(u, v)^\alpha$, the power requirement for arc (u, v) to be connected, that is, arc (u, v) is connected if and only if vertex u is assigned with a power $p(u) \geq w(u, v)$. The problem is to find a power assignment $p : V \rightarrow R^+$ such that the subgraph with vertex set V and edge set (or arc set) $\{(u, v) \mid p(u) \geq w(u, v), p(v) \geq w(v, u)\}$ (or $\{(u, v) \mid p(u) \geq w(u, v)\}$) satisfies certain property and total power $\sum_{u \in V} p(v)$ is minimized.

In this section, some examples will be presented. An interesting common aspect in those examples is that the minimum spanning tree plays an important role in design of good approximation algorithms for them.

2.1 Symmetric Topological Control

To keep nodes in a wireless network being able to communicate each other, the network is required to contain a spanning tree (in symmetric case) or a strongly connected spanning subgraph (in asymmetric case).

Fig. 1 An in-arborescence

In symmetric case, an (undirected) edge exists between two nodes u and v if and only if the communication range of u covers v and the communication range of v covers u . The topological control problem in this case can be stated as follows.

MIN-POWER SYMMETRIC CONNECTIVITY: Given a wireless network with power-adjustable nodes, find a power assignment to minimize the total power and to keep the network connected symmetrically.

The NP-hardness of this problem was first shown by Blough et al. [12]. To study its approximation solutions, consider a spanning tree T . The total required power for keeping the existence of T is

$$P(T) = \sum_{u \in V(T)} \max_{(u,v) \in E(T)} w(u, v)$$

where $V(T)$ is the node set of T and $E(T)$ is the edge set of T . Choose an arbitrary node as the root r . For every node u other than r , let e_u denote the edge incident to u on the path from u to r . Then e_u is unique and all e_u for $u \in V(T)$ form an in-arborescence A as shown in Fig. 1 and $P(T) \geq P(A)$.

Lemma 1 (In-Arborescence Lemma) *For any in-arborescence A , let T be the spanning tree obtained from removing all edge directions in A . Then,*

$$P(A) = w(T)$$

where $w(T) = \sum_{e \in E(T)} w(e)$ is the total weight of spanning tree T .

Proof

$$P(A) = \sum_{(v,u) \in E(A)} w(v, u) = w(T).$$

□

By In-Arborescence Lemma, it can be observed that $P(T) \geq \cdot w(T)$. On the other hand,

$$P(T) = \sum_{u \in V(T)} \max_{(u,v) \in E(T)} w(u, v) \leq \sum_{u \in V(T)} \sum_{v:(u,v) \in E(T)} w(u, v) = 2 \cdot w(T).$$

Suppose T^* is the minimum-weight spanning tree with edge weight $w(\cdot)$ and T^{opt} the optimal spanning tree for MIN-POWER SYMMETRIC CONNECTIVITY. Then,

$$P(T^*) \leq 2 \cdot w(T^*) \leq 2 \cdot w(T^{\text{opt}}) \leq 2 \cdot P(T^{\text{opt}}).$$

This means that T^* is a 2-approximation for MIN-POWER SYMMETRIC CONNECTIVITY.

The following lemma indicates that the minimum-weight spanning tree is actually the minimum-length spanning tree.

Lemma 2 *Let T and T^* be a spanning tree and the minimum-length spanning tree of a network, respectively. Then there is a one-to-one onto mapping $\sigma : E(T) \rightarrow E(T^*)$ such that for every $e \in E(T)$, $d(e) \geq d(\sigma(e))$.*

Proof For every edge $e \in E(T^*) \cap E(T)$, set $\sigma(e) = e$. Note that for each $e \in E(T) \setminus E(T^*)$, $e \cup T^*$ contains a cycle Q_e which contains edge e , and for every edge e' in Q_e , $d(e) \geq d(e')$. (Otherwise, it has $d(e) < d(e')$, which implies that $(T - e') \cup e$ would be a spanning tree with length smaller than T , contradicting the minimality of T).

One claims that for any subset $F \subseteq E(T) \setminus E(T^*)$, $\cup_{e \in F} Q_e$ contains at least $|F|$ edges in $E(T) \setminus E(T^*)$. For $|F| = 1$, it is trivial since, otherwise, T^* contains cycle Q_e for $e \in F$, contradicting that T^* is a tree. Next, consider $|F| \geq 2$. Fix an edge $e \in F$ and choose $e' \in Q_e \cap (E(T^*) \setminus E(T))$. Denote $T' = (T \cup e) - e'$. For any $\bar{e} \in F - \{e\}$, if $Q_{\bar{e}}$ does not contain e' , then set $Q'_{\bar{e}} = Q_{\bar{e}}$. If $Q_{\bar{e}}$ contains e' , then note that $Q_e \oplus Q_{\bar{e}}$ is a union of cycles in which there is one containing \bar{e} ; this one is defined to be $Q'_{\bar{e}}$. Clearly, $\cup_{\bar{e} \in F - \{e\}} Q'_{\bar{e}} \subset \cup_{e \in F} Q_e$. Each $Q'_{\bar{e}}$ is contained in $T' \cup \bar{e}$. By induction hypothesis, $\cup_{\bar{e} \in F - \{e\}} Q'_{\bar{e}}$ contains at least $|F| - 1$ edges in $E(T^*) \setminus E(T')$. Add back e' . It follows immediately that $\cup_{e \in F} Q_e$ contains at least $|F|$ edges in $E(T) \setminus E(T^*)$. This completes the proof of the claim.

From claim, one sees that there exists a one-to-one mapping σ from $E(T^*) \setminus E(T)$ to $E(T) \setminus E(T^*)$ such that for every $e \in E(T^*) \setminus E(T)$, $\sigma(e)$ is in Q_e and hence $d(e) \geq d(\sigma(e))$. \square

Now, it has the following.

Theorem 1 ([13]) *The minimum-length spanning tree is a polynomial-time 2-approximation for MIN-POWER SYMMETRIC CONNECTIVITY.*

Fig. 2 $2n$ points on a line

Remark This fact is significant because the minimum-length spanning tree in Euclidean plane can be computed in $O(n \log n)$ time while computing directly the minimum-weight spanning tree with edge weight $w(\cdot)$ may need more time.

The following example [14] shows that 2 is tight for the performance ratio of minimum-length spanning tree as an approximation for MIN-POWER SYMMETRIC CONNECTIVITY.

Let v_1, v_2, \dots, v_{2n} be $2n$ points lying along a line in Fig. 2 with the distance as follows:

$$\begin{aligned} d(v_1, v_2) &= d(v_3, v_4) = \dots = d(v_{2n-1}, v_{2n}) = 1, \\ d(v_2, v_3) &= d(v_4, v_5) = \dots = d(v_{2n-2}, v_{2n-1}) = \varepsilon, \end{aligned}$$

where ε is a sufficiently small positive number. The minimum power-cost for keeping symmetric connectivity is

$$nc(1 + \varepsilon)^\alpha + (n - 1)c\varepsilon^\alpha + c \rightarrow (n + 1)c \text{ as } \varepsilon \rightarrow 0$$

which is achieved when $v_1, v_3, \dots, v_{2n-1}$ are assigned with power $c(1 + \varepsilon)^\alpha$, $v_2, v_4, \dots, v_{2n-2}$ are assigned with power $c\varepsilon^\alpha$, and v_{2n} is assigned with power $c1^\alpha$. The minimum spanning tree is the path $(v_1, v_2, \dots, v_{2n})$ with power-cost

$$2nc1^\alpha = 2nc.$$

Therefore, the performance ratio is

$$\frac{2nc}{nc(1 + \varepsilon)^\alpha + (n - 1)c\varepsilon^\alpha + c} \rightarrow 2$$

as $\varepsilon \rightarrow 0$ and $n \rightarrow \infty$.

Is there a polynomial-time approximation with performance ratio less than 2 for MIN-POWER SYMMETRIC CONNECTIVITY? The answer is yes.

To see it, one introduced a type of decomposition for tree.

A k -restricted decomposition of a tree T is a partition of T into a set of edge-disjoint subtrees each with at most k nodes. Consider a k -restricted decomposition of T , $Q = \{T_1, T_2, \dots, T_q\}$. The power-cost of Q is defined by

$$P(Q) = \sum_{i=1}^q P(T_i).$$

Calinescu et al. [15] indicated that the k -restricted decomposition plays a role in the study of MIN-POWER SYMMETRIC CONNECTIVITY the same as the k -restricted Steiner tree in the network Steiner minimum tree problem [16–19]. Algorithms in [16–19] can be modified into approximation algorithms for MIN-POWER SYMMETRIC CONNECTIVITY with performance ratios less than 2. For example, let *gain* of a subtree H is defined by

$$\text{gain}(H) = 2 \cdot \text{mst}(V) - 2 \cdot \text{mst}(V/H) - P(H)$$

where $\text{mst}(V)$ is the power-cost of minimum-length spanning tree T on V , that is,

$$\text{mst}(V) = \sum_{e \in E(T)} w(e),$$

and V/H is the set of nodes after contracting H . Let *loss* of a subtree H be defined by

$$\text{loss}(H) = c(H) - (\text{mst}(V) - \text{mst}(V/H)).$$

Then the algorithm in [18] can be written as follows.

Loss-Contracting Algorithm

Input: A complete graph $G = (V, E)$ with edge cost $w(u, v) = d(u, v)^\alpha$ and integer $3 \leq k < |V|$.

$T \leftarrow$ the minimum-length spanning tree of G ;

$H \leftarrow G$;

$ok \leftarrow 1$;

while $ok = 1$ **do**

find a k -restricted tree K with maximum $r = \text{gain}(K)/\text{loss}(K)$;

if $r < 0$

then $ok \leftarrow 0$

else $H \leftarrow H \cup K$

$V \leftarrow V/K$;

output H (a k -restricted decomposition connecting all nodes in G .)

By an argument similar to that in [18], it can be obtained by the following.

Theorem 2 *The above Loss-Contracting Algorithm produces an approximation solution for MIN-POWER SYMMETRIC CONNECTIVITY with performance ratio at most $\rho_k \left(1 + \frac{\ln(4\rho_k^{-1}-1)}{2}\right)$ where ρ_k is defined by*

$$\rho_k = \sup_T \min_Q \frac{P(Q)}{P(T)}$$

where T is over all trees and Q is over all k -restricted decompositions of T .

Althaus et al. [20] showed that $\rho_3 = 5/3$ equal to the inverse of the k -Steiner ratio determined by Du [21]. Li et al. [22] showed that this fact holds for general k , that is, ρ_k is equal to the inverse of the k -Steiner ratio determined in [23].

Theorem 3 ([22]) *For any $k \geq 2$,*

$$\rho_k = \frac{(r+1)2^r + s}{r2^r + s}$$

where $k = 2^r + s$, $0 \leq s < 2^r$.

As $k \rightarrow \infty$, it can be obtained that $\rho_k \rightarrow 1$. Therefore,

$$\rho_k \left(1 + \frac{\ln(4\rho_k^{-1} - 1)}{2} \right) \rightarrow 1 + (\ln 3)/2 < 1.55.$$

Thus, the following is obtained.

Corollary 1 *For sufficiently large k , **Loss-Contraction Algorithm** produces an approximation solution for MIN-POWER SYMMETRIC CONNECTIVITY with performance ratio at most 1.55.*

Although some new technique [24, 25] has been introduced to study MIN-POWER SYMMETRIC CONNECTIVITY, 1.55 is still currently the best known performance ratio of polynomial-time approximation for MIN-POWER SYMMETRIC CONNECTIVITY. Not every technique for design of approximation for Network Steiner Tree Problem can be easily applied to MIN-POWER SYMMETRIC CONNECTIVITY. Indeed, polynomial-time approximation for Network Steiner Tree Problem has been improved by Byrka et al. [26] with a new technique. However, it is an open problem whether this new technique can be applied to MIN-POWER SYMMETRIC CONNECTIVITY.

2.2 Asymmetric Topological Control

It is interesting to note that the minimum spanning tree is also a polynomial-time 2-approximation in asymmetric case as follows.

MIN-POWER STRONG CONNECTIVITY: Given a wireless network with power-adjustable nodes, find a power assignment to minimize the total power and to keep the network strongly connected.

In asymmetric case, an arc (directed edge) (u, v) exists if and only if the communication range of node u covers node v , that is, $p(u) \geq w(u, v)$. This problem was initially studied by Chen and Huang [27]. They showed that the minimum-length spanning tree gives 2-approximation. Kirousis et al. [13] showed the NP-hardness of the problem in three-dimensional Euclidean space with $\alpha = 2$ and presented

a polynomial-time 2-approximation. Clementi et al. [28, 29] showed that the NP-hardness remains in two-dimensional Euclidean plane. Cheng et al. [30] showed an alternative proof for the NP-hardness of MIN-POWER STRONG CONNECTIVITY in the two-dimensional Euclidean plane. Earlier efforts were also made by Ramanathan et al. [31], Wattenhofer et al. [32], and Hajiaghayi et al. [33].

Consider a directed network H . The total power for keeping H survived is

$$P(H) = \sum_{u \in V(H)} \max_{(u,v) \in E(H)} w(u, v).$$

When H is strongly connected, it can construct an in-arborescence A as follows:

- Pick up a root r arbitrarily.
- For every node u , construct a shortest path $p(u)$ from u to r .
- Let A be the in-arborescence obtained from the union $\cup_{u \in V(H)} p(u)$ by the following simplification: for each node u , if u has more than one out-edges, then keep one and delete all others.

Since $P(H) \geq P(A)$, by In-Arborescence Lemma, the following can be obtained.

Lemma 3 *For any strongly connected graph H and a node r of H , there is an in-arborescence A with root r , contained in H , such that*

$$P(H) \geq w(A)$$

where $w(A) = \sum_{(u,v) \in E(A)} w(u, v)$.

Now, suppose T^* is a minimum-length spanning tree. By Lemma 2, it can be obtained that

$$\begin{aligned} P(T^*) &\leq 2 \sum_{(u,v) \in E(T^*)} w(u, v) \\ &\leq 2w(A) \\ &\leq 2P(H) \end{aligned}$$

for every strongly connected graph H where A is an in-arborescence contained in H . This means that the minimum-length spanning tree is a polynomial-time 2-approximation for MIN-POWER STRONG CONNECTIVITY.

Theorem 4 ([27]) *The minimum-length spanning tree is a polynomial-time 2-approximation for MIN-POWER STRONG CONNECTIVITY.*

Calinescu [14] indicated that 2 is tight upper bound for the performance ratio of the minimum-length spanning tree. Actually, the example for MIN-POWER SYMMETRIC CONNECTIVITY also works here although Calinescu [14] constructed

a different example. Indeed, the example for MIN-POWER SYMMETRIC CONNECTIVITY means that there exists a spanning tree T such that for the minimum-length spanning tree T^* ,

$$\frac{P(T^*)}{P(T)} \rightarrow 2 \text{ as } \varepsilon \rightarrow 0, n \rightarrow \infty.$$

Let opt_{mpsc} be the objective function value of optimal solution for MIN-POWER STRONG CONNECTIVITY. Then, $P(T) \geq opt_{\text{mpsc}}$ and $P(T^*) \leq 2 \cdot opt_{\text{mpsc}}$. Therefore,

$$2 \geq \frac{T^*}{opt_{\text{mpsc}}} \geq \frac{P(T^*)}{P(T)} \rightarrow 2$$

as $\varepsilon \rightarrow 0$ and $n \rightarrow \infty$. Hence,

$$\frac{T^*}{opt_{\text{mpsc}}} \rightarrow 2 \text{ as } \varepsilon \rightarrow 0, n \rightarrow \infty.$$

Although many efforts have been made to improve the performance of approximation algorithms [13, 34–36] and the performance ratio less than 2 has been established in several special cases, it was a long-standing open problem whether there is a polynomial-time approximation algorithm with performance ratio less than 2 for MIN-POWER STRONG CONNECTIVITY. Recently, this open problem is solved by Calinescu [14]. He presented a greedy approximation with performance 1.992. The following is a sketch of his work.

The algorithm is a greedy approximation with submodular potential function. This submodular potential function is defined as follows:

Consider a minimum-length spanning tree T on given graph $G = (V, E)$. Let \hat{T} be obtained from T by replacing each edge with two arcs of opposite directions. \hat{T} is called the bidirected version of T .

For any vertex $u \in V$ and a real number $p \in \{w(u, v) \mid (u, v) \in E\}$, $S(u, p)$ denotes the directed star with center u and all arcs (u, v) with $w(u, v) \leq p$ where recall that $w(u, v) = d(u, v)^\alpha$. Let $Q(u, p)$ be the set of edges of T on a path between two vertices of $S(u, p)$.

For a collection \mathcal{A} of directed stars $S(u_i, p_i)$, define $f(\mathcal{A}) = \sum_{e \in Q(\mathcal{A})} w(e)$ where $Q(\mathcal{A}) = \cup_{S(u_i, p_i) \in \mathcal{A}} Q(u_i, p_i)$.

Lemma 4 *f is submodular and monotone increasing, that is, for any two collections \mathcal{A} and \mathcal{B} of directed stars $S(u_i, p_i)$,*

$$f(\mathcal{A}) + f(\mathcal{B}) \geq f(\mathcal{A} \cup \mathcal{B}) + f(\mathcal{A} \cap \mathcal{B}),$$

and

$$\mathcal{A} \subset \mathcal{B} \Rightarrow f(\mathcal{A}) \leq f(\mathcal{B}).$$

Proof By Lemma 2.25 in [37], it suffices to prove

$$\mathcal{A} \subset \mathcal{B} \Rightarrow \Delta_S f(\mathcal{A}) \geq \Delta_S f(\mathcal{B})$$

where S is one of directed stars $S(u_i, w_i)$ and $\Delta_S f(\mathcal{A}) = f(\mathcal{A} \cup \{S\}) - f(\mathcal{A})$. Clearly,

$$\begin{aligned}\Delta_S f(\mathcal{A}) &= \sum_{e \in Q(\mathcal{A} \cup \{S\})} w(e) - \sum_{e \in Q(\mathcal{A})} w(e) \\ &= \sum_{e \in Q(\{S\}) \setminus Q(\mathcal{A})} w(e) \\ &\geq \sum_{e \in Q(\{S\}) \setminus Q(\mathcal{B})} w(e) \\ &= \Delta_S f(\mathcal{B}).\end{aligned}$$

□

Let $\hat{Q}(u, p)$ be the set of arcs on the path from u to v in \hat{T} for $(u, v) \in S(u, p)$. Let $I_{\mathcal{A}}(S(u, p))$ denote the set of arcs in $\hat{Q}(u, p)$, but its undirected version not in $Q(\mathcal{A})$. Denote $w(T) = \sum_{e \in E(T)} w(e)$. The following is the greedy algorithm proposed by Calinescu [14]:

Calinescu's Greedy Algorithm

Let T be a minimum spanning tree.

```

 $\mathcal{A} \leftarrow \emptyset,$ 
 $M \leftarrow \hat{T};$ 
while  $f(\mathcal{A}) < w(T)$  do
     $(u, p) \leftarrow \operatorname{argmax}_{(u', p')} \frac{\Delta_{S(u', p')}(\mathcal{A})}{p'}$ 
     $M \leftarrow M \setminus I_{\mathcal{A}}(S(u, p))$ 
     $\mathcal{A} \leftarrow \mathcal{A} \cup \{S(u, p)\}$ 
output  $\cup_{S \in \mathcal{A}} E(S) \cup M.$ 
```

The following lemma shows the correctness of above algorithm.

Lemma 5 $H = (V, \cup_{S \in \mathcal{A}} E(S) \cup M)$ is a strongly connected spanning subgraph during the computation of Calinescu's Greedy Algorithm.

Proof Remove from T all edges each having two corresponding arcs in M . Then T is broken into several connected components T_1, T_2, \dots, T_k . It can be observed that every $V(T_i)$ for $1 \leq i \leq k$ induces a strongly connected subgraph of H . Then, the lemma follows immediately from this fact.

Initially, $M = \hat{T}$. Thus, every edge of T has two corresponding arcs in M . This means that each T_i is a vertex of T and hence strongly connected. Now, suppose at some stage of the algorithm, every $V(T_i)$ induces a strongly connected subgraph H_i of H . It is shown that after adding $S(u, p)$ to \mathcal{A} , this fact still holds.

For each $v \in V(S(u, p) - \{u\})$, suppose on the path from u to v in T , there are h edges $(x_1, y_1), (x_2, y_2), \dots, (x_h, y_h)$ each having its two corresponding arcs (x_i, y_i) and (y_i, x_i) in M . Further, it can be assumed that u and x_1 are in the same connected component T_0 , y_1 and x_2 are in the same connected component T_1, \dots, y_h and v are in the same connected component T_h . When $S(u, w)$ is added to \mathcal{A} , arcs $(x_1, y_1), (x_2, y_2), \dots, (x_h, y_h)$ would be deleted from M ; however, arc (u, v) is added to $\cup_{S \in \mathcal{A}} E(S)$. Therefore, in new H , $V(T_0) \cup V(T_1) \cup \dots \cup V(T_h)$ would induce a strongly connected subgraph because arcs $(u, v), (y_h, x_h), \dots, (y_1, x_1)$ form a directed cycle connecting $h + 1$ strongly connected subgraphs H_0, H_1, \dots, H_h into a bigger strongly connected subgraph. Note that after deleting arcs $(x_1, y_1), (x_2, y_2), \dots, (x_h, y_h)$ from M , $T_0 \cup (u, x_1) \cup T_1 \cup \dots \cup T_h$ becomes a new connected component. This would complete our proof. \square

To analyze the performance of Calinescu's Greedy Algorithm, the general theory introduced in [37] should be recalled.

Consider a monotone nondecreasing, submodular function $f : 2^X \rightarrow R$. Denote $\Omega(f) = \{A \subseteq X \mid f(A) = f(X)\}$. Let $c : X \rightarrow R$ be a nonnegative cost function. Consider the following SUBMODULAR-COVER problem:

$$\begin{aligned} \min \quad & c(A) = \sum_{x \in A} c(x) \\ \text{subject to} \quad & A \in \Omega(f). \end{aligned}$$

To compute an approximation of this problem, the following greedy algorithm may be employed.

Greedy Algorithm G

```

 $A \leftarrow \emptyset;$ 
while  $f(A) < f(X)$  do
    choose  $x \in X$  to maximize  $\frac{\Delta_x f(A)}{c(x)}$ 
    and  $A \leftarrow A \cup \{x\}$ ;
output  $A$ .

```

There is a general theorem on the performance of above algorithm.

Theorem 5 Suppose in Greedy Algorithm G, selected x always satisfies

$$\frac{\Delta_x f(A)}{c(x)} \geq 1.$$

Then, Greedy Algorithm G produces an approximation solution for SUBMODULAR-COVER with performance ratio at most

$$1 + \ln \frac{f(X) - f(\emptyset)}{opt}$$

where opt is the objective function value of optimal solution for SUBMODULAR-COVER.

Consider the MIN-STARS problem as follows:

$$\min \sum_{S(u,p) \in \mathcal{A}} p$$

subject to $f(\mathcal{A}) = w(T).$

Note that Calinescu's Greedy Algorithm is the same as the **Greedy Algorithm G** for the MIN-STARS problem. Based on this observation, it is easy to obtain the following corollary.

Corollary 2 *If $opt_{\min\text{-stars}} \leq \alpha opt_{\text{mpsc}}$ where opt_{mpsc} is the objective function value of optimal solution for MIN-POWER STRONG CONNECTIVITY, then Calinescu's Greedy Algorithm is a polynomial-time approximation for MIN-POWER STRONG CONNECTIVITY with performance ratio at most*

$$1 + \alpha + \alpha(1 - \ln \alpha).$$

Proof Note that when $f(\mathcal{A}) < w(T)$, M contains two antiparallel arcs (x, y) and (y, x) . In such a case, S can be selected to satisfy

$$\frac{\Delta_{S(u,p)} f(\mathcal{A})}{p} \geq 1,$$

since set $w' = w((x, y))$, it has the following that

$$\frac{\Delta_{S(x,p')} f(\mathcal{A})}{p'} \geq 1.$$

By [Theorem 5](#),

$$\sum_{S(u,p) \in \mathcal{A}} p \leq opt_{\min\text{-stars}} \left(1 + \ln \frac{w(T)}{opt_{\min\text{-stars}}} \right).$$

Therefore, output of Calinescu's Greedy Algorithm has total power at most

$$\begin{aligned} & w(T) + \sum_{S(u,p) \in \mathcal{A}} p \\ & \leq opt_{\text{mpsc}} + opt_{\min\text{-stars}} \left(1 + \ln \frac{w(T)}{opt_{\min\text{-stars}}} \right) \\ & \leq opt_{\text{mpsc}} + opt_{\min\text{-stars}} \left(1 + \ln \frac{opt_{\text{mpsc}}}{opt_{\min\text{-stars}}} \right) \\ & \leq opt_{\text{mpsc}} \left(1 + \alpha \left(1 + \ln \frac{1}{\alpha} \right) \right) \\ & \leq opt_{\text{mpsc}} (1 + \alpha(1 - \ln \alpha)), \end{aligned}$$

where note that function $x \left(1 + \ln \frac{opt_{\text{mpsc}}}{x} \right)$ is monotone nondecreasing for $0 < x < opt_{\text{mpsc}}$. \square

Calinescu [14] showed the following.

Lemma 6 $opt_{\text{min-stars}} \leq (4/5)opt_{\text{mpsc}}$.

The following follows immediately from [Corollary 2](#) and [Lemma 6](#).

Theorem 6 *There exists a polynomial-time approximation for MIN-POWER STRONG CONNECTIVITY with performance ratio at most $1 + (4/5)(1 + \ln(5/4))$.*

2.3 Broadcast

A broadcasting routing is for transmitting data from a source node s to all other nodes. Mathematically, it is an out-arborescence T rooted at s . Let (u, v_i) , $i = 1, \dots, k$ be all out-edges at node u in T . Then, the power-cost of u in the routing equals $p(u) = \max_{1 \leq i \leq k} w(u, v_i)$. The power-cost of broadcasting routing T is the sum of power-costs at all nodes in T . In general graph setting, it is unlikely to have polynomial-time $o(\log n)$ -approximation for the minimum power broadcasting problem [38, 39]. However, for geometric setting, the situation may be different. For example, in one-dimensional Euclidean space, the problem is polynomial-time solvable [38, 40, 41], and in d -dimensional Euclidean space, the minimum-length spanning tree is still a good approximation. For instance, consider this problem in Euclidean plane as follows.

MIN-POWER BROADCAST: Given a set of points S in the Euclidean plane and a source node $s \in S$, find a broadcasting routing from s to minimize the total power-cost of the routing.

This is an NP-hard problem [40]. It is an interesting fact that the minimum Euclidean spanning tree T is also a constant approximation for MIN-POWER BROADCAST. This is because of the existence of the following lemma, which plays an important role for MIN-POWER BROADCAST, similar to the role of [Lemma 1](#) for MIN-POWER SYMMETRIC CONNECTIVITY and the role of [Lemma 3](#) for MIN-POWER STRONG CONNECTIVITY.

Lemma 7 [*Out-Arborescence Lemma*] *For any out-arborescence T , there exists a minimum Euclidean spanning tree T^* such that*

$$P(T) \geq \frac{1}{6} \sum_{e \in E(T^*)} c \|e\|^\alpha.$$

The proof of [Lemma 7](#) relies on the following fact.

Lemma 8 *Let C be a disk with center x and radius R and P be a set of points lying in C . Assume $x \in P$. Then, for minimum spanning tree T^* on P ,*

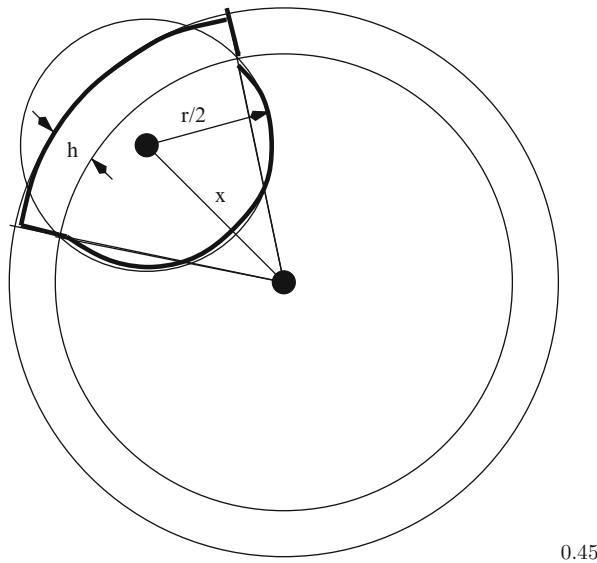

Fig. 3 Minimum spanning tree in a disk

$$\sum_{e \in T^*} \|e\|^\alpha \leq 6R^\alpha$$

where $\alpha \geq 2$.

To prove Lemma 7, for each node u of T , a smallest disk $D(u)$ to cover all out-edges at u is drawn. Let $V(u)$ be the set of all endpoints of out-edges at u . Let $T^*(u)$ be the minimum spanning tree on $V(u) \cup \{u\}$. By Lemma 8,

$$\sum_{e \in E(T^*(u))} c \|e\|^\alpha \leq 6cR(u)^\alpha$$

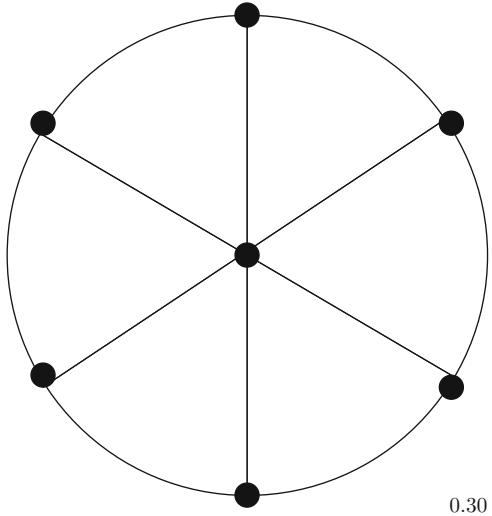

where $R(u)$ is the radius of $D(u)$. Note that $\cup_{u \in V} T^*(u)$ is a spanning tree on the given node set V . By Lemma 2,

$$\sum_{e \in E(T^*)} c \|e\|^\alpha \leq \sum_{u \in V} \sum_{e \in E(T^*(u))} c \|e\|^\alpha.$$

Therefore,

$$\sum_{e \in E(T^*)} c \|e\|^\alpha \leq \sum_{u \in V} 6cR(u)^\alpha = 6P(T).$$

This completes the proof of Lemma 7 (Fig. 3).

Fig. 4 6 is the best possible

The proof of [Lemma 8](#) given by Ambühl [\[42\]](#) is quite complicated. Actually, this result was obtained through a sequence of efforts [\[4, 43–46\]](#). Actually, Wan et al. [\[4\]](#) initiated this theoretical analysis, and they also indicated that the constant 6 is the best possible. An example which reaches this bound is shown in [Fig. 4](#).

The approach to establish the upper bound for this performance ratio is quite interesting. Here, a proof of a weaker bound is included to show the main idea.

Lemma 9 ([46]) Consider a circle C with center x and radius R in the Euclidean plane. Let P be a set of points lying in C . Assume $x \in P$. Then, for minimum Euclidean spanning tree T^* on P ,

$$\sum_{e \in E(T^*)} \|e\|^\alpha \leq 8R^\alpha$$

where $\alpha \geq 2$.

Proof Let $n(T^*, r)$ be the number of connected components of subgraph $T^*(r)$ of T^* where $T^*(r)$ has the node set P and the edge set consisting of all edges with length at most r . Note that $x \in P$ implies that every edge in T^* has length at most R . Therefore,

$$\sum_{e \in E(T^*)} \|e\|^\alpha = \alpha \int_0^R (n(T^*, r) - 1)r^{\alpha-1} dr.$$

For each node $u \in P$, draw a disk with center u and radius $r/2$. Then, for each connected component of $T^*(r)$, those disks form a connected region. Moreover, different connected components induce disjoint such regions. Note that each such

region contains at least one disk with radius $r/2$. Hence, its area is at least $\pi(r/2)^2$. It follows that the boundary of each connected region has length at least πr because circle gives the shortest boundary for surrounding a given amount of area. Let $a(P, r)$ denote the total area covered by those disks with radius $r/2$. Then, it has

$$\begin{aligned} a(P, R) &= \int_0^R d(a(P, r)) \\ &\geq \int_0^R n(T^*, r) \pi r d(r/2) \\ &= \frac{\pi}{2} \int_0^R (n(T^*, r) - 1) r dr + \frac{\pi R^2}{4} \\ &= \frac{\pi}{4} \sum_{e \in E(T^*)} \|e\|^2 + \frac{\pi R^2}{4}. \end{aligned}$$

Note that $a(P, R)$ is contained by a disk at x with radius $1.5R$. Thus,

$$\pi(1.5R)^2 \geq \frac{\pi}{4} \sum_{e \in E(T^*)} \|e\|^2 + \frac{\pi R^2}{4}.$$

Hence,

$$\sum_{e \in E(T^*)} \|e\|^2 \leq 8R^2.$$

Since for every $e \in E(T^*)$, $\|e\| \leq R$, one has

$$\sum_{e \in E(T^*)} (\|e\|/R)^\alpha \leq \sum_{e \in T} (\|e\|/R)^2 \leq 8.$$

□

By [Lemma 7](#), it is easy to see the following.

Theorem 7 *The minimum spanning tree induces a 6-approximation for MIN-POWER BROADCAST.*

All above results in this subsection are on networks with all nodes lying in the Euclidean plane. For networks with all nodes lying in the three-dimensional space, results are different.

For networks with all nodes lying in the d -dimensional Euclidean space, it has been shown that the minimum-length spanning tree would induce an 18.8-approximation for $d = 3$ [47] and $(3^d - 1)$ -approximation for $d > 3$ [44]. In [4, 40], it has been also shown that the lower bound for the performance ratio

of the minimum-length spanning tree is given by the d -dimensional kissing number n_d , which is the maximum number of nonoverlapping unit balls touching a unit ball. For $d = 3$, $n_d = 12$. In general, $n_d = 2^{cd(1+o(1))}$ where $0.2075 \leq c \leq 0.401$ for large d [48]; determination of exact value of n_d for large d is quite hard [49].

Is it possible to have an approximation with performance better than that of the minimum-length spanning tree for MIN-POWER BROADCAST? The answer is positive. Wan et al. [4] indicated that the BIP (Broadcasting Incremental Power) is a possible candidate because its performance ratio is between $13/3$ and 12 while the minimum-length spanning tree has performance ratio between 6 and 12 (note: in both cases, upper bound 12 has been improved to 6 by Ambühl [42]). To construct a BIP tree, starting from the source node, at each iteration, a new node is reached with smallest increasing power. Note that this increasing may have two ways. One is to assign power to an unassigned node, and the other one is to increase the power to a node with power assigned in previous iteration.

Caragiannis et al. [50] gave a greedy approximation with performance ratio 4.2 which is definitely better than both BIP and the minimum-length spanning tree. The result of Caragiannis et al. [50] is for any metric space that if the minimum-length spanning tree induces a ρ -approximation, then their greedy approximation has performance ratio $2 \ln \rho - 2 \ln 2 + 2$. It is 4.2 for $d = 2$, 6.49 for $d = 3$, and $2.20d + 0.61$ for $d \geq 4$. This greedy approximation is quite interesting, which is designed using the following properties of spanning tree.

Lemma 10 *Let T_1 and T_2 be two rooted spanning trees over the same set of nodes V . There exists a one-to-one mapping $\sigma : E(T_1) \rightarrow E(T_2)$ such that for any node u and its children v_1, \dots, v_k in T_1 , $(T_1 \cup \{(u, v_1), \dots, (u, v_k)\}) - \{\sigma((u, v_1)), \dots, \sigma((u, v_k))\}$ is a spanning tree.*

Lemma 11 *Let T be a spanning tree. Consider k edges $(u, v_1), \dots, (u, v_k)$. Suppose $(T \cup \{(u, v_1), \dots, (u, v_k)\}) - \{(w_1, y_1), \dots, (w_k, y_k)\}$ is a spanning tree. Then, for $\{(u, z_1), \dots, (u, z_h)\}$, there exists a subset F of h edges of T such that $(T \cup \{(u, v_1), \dots, (u, v_k), (u, z_1), \dots, (u, z_h)\}) - (\{(w_1, y_1), \dots, (w_k, y_k)\} \cup F)$ is a spanning tree.*

There is no proof for above two lemmas in [50]. They can be derived from the following.

Lemma 12 *Let T_1 and T_2 be two spanning trees. There exists a one-to-one onto mapping $\sigma : E(T_1) \rightarrow E(T_2)$ such that for any $A \subseteq E(T_1)$, $(E(T_2) \cup A) - \sigma(A)$ is the edge set of a spanning tree.*

However, it is an open problem whether Lemma 12 holds or not, which is an interesting open problem. Next, an application of above lemmas will be presented.

Consider a spanning tree T of a graph $G = (V, E)$ and an edge subset F of E . A *swap set* for T with F is an edge subset A of $E(T)$ such that $(E(T) \cup F) - A$ is the edge set of a spanning tree. Let $E(u, p) = \{(u, v) \in E(G) \mid w(u, v) \leq p\}$. $A(u, p)$ denotes a swap of T with $E(u, p)$. The greedy algorithm can be described as follows.

CFM Algorithm

```

 $T \leftarrow$  the minimum-length spanning tree of  $G$ .
 $ok \leftarrow 1$ ;
 $\mathcal{A} \leftarrow \emptyset$ ;
while  $ok = 1$  do begin
     $E(u, p) = \operatorname{argmax}_{E(u', p')} \frac{w(A(u', p'))}{p'}$ ;
    if  $\frac{w(A(u, p))}{p} > 2$ 
        then  $\mathcal{E} \leftarrow \mathcal{E} \cup \{E(u, p)\}$ 
             $(T \cup E(u, p)) \setminus A(u, p)$ 
            assign all edges in  $E(u, p)$  with weight 0
        else  $ok \leftarrow 0$ ;
output  $\mathcal{E}$  and  $T$ .

```

The following shows an upper bound for power-cost of broadcasting tree constructed from output of CFM Algorithm.

Lemma 13 *With output \mathcal{E} and T , a broadcasting tree can be constructed with powercost at most*

$$2 \sum_{E(u,p) \in \mathcal{E}} p + w(T).$$

Proof Suppose s is the source node. Turn tree T into a tree rooted at s and turn each edge into an arc by giving the direction from parent to child. This rooted tree (or out-arborescence) can be realized with the following power assignment. Consider an arc (x, y) in rooted tree T .

If edge (x, y) is not in $\cup_{E(u,p) \in \mathcal{E}} E(u, p)$, then assign $p(x) = w(x, y)$.

If $(x, y) \in E(u, p)$ for some $E(u, p) \in \mathcal{E}$, then assign $p(x) = p$. An important observation is that for each $E(u, p)$, there is at most one edge (u, v) in $E(u, p)$ such that arc (v, u) is in rooted tree T . In fact, if (v, u) is in the tree T with root s , then for every edge $(u, v') \in E(u, p)$, other than (u, v) , one can reach v' from u through arc (u, v') , that is, if (v', u) cannot be in T .

In above assignment, the total power is at most

$$2 \sum_{E(u,p) \in \mathcal{E}} p + w(T).$$

□

The performance of CFM is given in the following theorem.

Theorem 8 Suppose $\rho > 2$ is the performance ratio of the minimum-length spanning tree as an approximation for MIN-POWER BROADCAST. Then, the performance ratio of approximation solution obtained from CFM Algorithm is at most $2 \ln \rho - 2 \ln 2 + 2$.

Proof Let T_0 denote the minimum spanning tree at the initial step and T_i for $i = 1, \dots, k$ the tree obtained in the i th iteration. Let $E(u_i, p_i)$ be selected at the i th iteration. Clearly,

$$w(A(u_i, p_i)) = w(T_{i-1}) - w(T_i).$$

First, it can be observed that

$$\rho \leq \frac{w(T_{i-1}) - w(T_i)}{w(T_{i-1})} \cdot opt.$$

where opt is objective function value of optimal solution for MIN-POWER BROADCAST.

Suppose T^* is the optimal broadcast tree. Let $IN(T^*)$ denote the set of internal nodes of T^* . Denote by $B(u)$ the set of arcs going out from u . Then,

$$p(T^*) = \sum_{u \in IN(T^*)} \max_{(u,v) \in B(u)} w(u, v).$$

By Lemma 12, there exists a one-to-one onto mapping $\sigma : E(T^*) \rightarrow E(T_{i-1})$ such that $\sigma(B(u))$ is a swap set for T_{i-1} with $B(u)$. Denote $\rho_u = \max_{(u,v) \in B(u)} w(u, v)$. Then,

$$\frac{w(\sigma(B(u)))}{\rho_u} \geq \frac{\sum_{u \in IN(T^*)} w(\sigma(B(u)))}{\sum_{u \in IN(T^*)} \rho_u} = \frac{w(T_{i-1})}{opt}.$$

Therefore, there exists $u \in IN(T^*)$ such that

$$\frac{w(\sigma(B(u)))}{\rho_u} \geq \frac{w(T_{i-1})}{opt}.$$

Since $\sigma(B(u)) \subseteq A(u, \rho_u)$, it follows that

$$\frac{w(A(u, \rho_u))}{\rho_u} \geq \frac{w(T_{i-1})}{opt}.$$

It follows from greedy principle that

$$\frac{w(A(u_i, \rho_i))}{\rho_i} \geq \frac{w(A(u, \rho_u))}{\rho_u} \geq \frac{w(T_{i-1})}{opt},$$

that is,

$$\rho_i \leq \frac{w(T_{i-1}) - w(T_i)}{w(T_{i-1})} \cdot opt.$$

Now, by [Lemma 13](#), GFM Algorithm produces a broadcast tree with total power at most

$$\begin{aligned} & 2 \sum_{i=1}^k \frac{w(T_{i-1}) - w(T_i)}{w(T_{i-1})} \cdot opt + w(T_k) \\ & \leq 2 \sum_{i=1}^{k-1} \frac{w(T_{i-1}) - w(T_i)}{w(T_{i-1})} \cdot opt + 2\rho_k + w(T_k). \end{aligned}$$

Denote $\delta = 2opt - w(T_k)$. Note that

$$\frac{w(A(u_k, \rho_k))}{\rho_k} > 2.$$

Thus,

$$\begin{aligned} 2\rho_k + w(T_k) &= 2 \cdot \frac{w(A(u_k, \rho_k))}{w(A(u_k, \rho_k))/\rho_k} - \delta + 2opt \\ &\leq 2 \cdot \frac{w(A(u_k, \rho_k)) - \delta}{w(A(u_k, \rho_k))/\rho_k} + 2opt \\ &\leq 2 \cdot \frac{w(A(u_k, \rho_k)) - \delta}{w(T_{k-1})/opt} + 2opt \quad (*) \\ &= 2opt \cdot \left(\frac{w(A(u_k, \rho_k)) - \delta}{w(T_{k-1})} + 1 \right), \end{aligned}$$

Therefore, GFM Algorithm produces a broadcast tree with total power at most

$$\begin{aligned} & 2opt \left(\sum_{i=1}^{k-1} \frac{w(T_{i-1}) - w(T_i)}{w(T_{i-1})} + \frac{w(T_{k-1}) - 2opt}{w(T_{k-1})} + 1 \right) \\ &\leq 2opt \left(\sum_{i=1}^{k-1} \int_{w(T_0)-w(T_{i-1})}^{w(T_0)-w(T_i)} \frac{dt}{w(T_0)-t} + \int_{w(T_0)-w(T_{k-1})}^{w(T_0)-2opt} \frac{dt}{w(T_0)-t} + 1 \right) \\ &= 2opt \left(\int_0^{w(T_0)-2opt} \frac{dt}{w(T_0)-t} + 1 \right) \\ &= 2opt \left(\ln \frac{w(T_0)}{opt} - \ln 2 + 1 \right) \\ &\leq opt(2 \ln \rho - 2 \ln 2 + 2). \end{aligned}$$

□

The above proof contains a bug. The inequality sign at line (*) holds only if $w(A(u_k, \rho_k)) - \delta \geq 0$, that is, $w(T_{k-1}) \geq 2opt$. If $w(T_{k-1}) < 2opt$, is there some way to fix the proof? So far, nobody knows.

Dai and Wu [51], Li et al. [52, 53], and Guo and Yang [54] minimize the total energy cost of broadcast in wireless networks with directional antennas or adaptive antennas. Ghosh [55] designs distributed algorithm and Wu and Dai [56] design an broadcast algorithm with self-pruning technique. Agarwal et al. [57] study energy-efficient broadcast in wireless ad hoc network with hitch-hiking.

2.4 Asymmetric Power Requirement

In wireless networks studied in [58], each node x has its own rate $r(x)$ for power requirement to establish a link (x, y) , i.e., the power-cost for the existence of (x, y) is

$$p(x, y) = c\|(x, y)\|^\alpha / r(x)$$

instead of $c\|(x, y)\|^\alpha$. When $r(x) \neq r(y)$, it has the following that $p(x, y) \neq p(y, x)$.

Althaus et al. [20] also considered the case that arcs $p(u, v) \neq p(v, u)$ and studied the following problem:

MIN-POWER SYMMETRIC CONNECTIVITY WITH ASYMMETRIC POWER REQUIREMENT:

Given a complete graph $G = (V, E)$ and power requirement $p : V \times V \rightarrow R^+$, find a minimum power-cost spanning tree where an (undirected) edge (u, v) exists iff the power at u is at least $p(u, v)$ and the power at v is at least $p(v, u)$.

For this problem, they showed that the minimum spanning tree with respect to edge weight $p(u, v) + p(v, u)$ is a 2-approximation. However, the proof contains a flaw because the power-cost of an out-arborescence has not been proved to be lower-bounded by the sum of its edge power requirements. In fact, Lemma 7 indicates that the power-cost of an out-arborescence can be lower bounded by one-sixth of the sum of edge power requirements of a minimum spanning tree which is not the out-arborescence itself. Therefore, it is still an open problem whether MIN-POWER SYMMETRIC CONNECTIVITY WITH ASYMMETRIC POWER REQUIREMENT has a polynomial-time constant approximation or not.

Calinescu et al. [59] gave a positive answer in the case that

$$p(x, y) = cd(x, y)^\alpha / r(x),$$

where $d(x, y)$ is the distance between x and y in a metric space.

Theorem 9 *The minimum spanning tree with respect to edge weight $w(u, v) = p(u, v) + p(v, u)$ induces an approximation solution within a factor of*

$$\min_{r>1} 2 \max \left(2^\alpha + (r+1)^\alpha, \frac{r^\alpha}{r^\alpha - 1} \right)$$

from optimal for MIN-POWER SYMMETRIC CONNECTIVITY WITH ASYMMETRIC POWER REQUIREMENT.

This theorem follows immediately from the following lemma.

Lemma 14 [Rooted-Spanning Tree Lemma] For any rooted spanning tree T and a number $r > 1$, there exists a rooted spanning tree T_r such that

$$w(T_r) \leq 2 \max \left(2^\alpha + (r+1)^\alpha, \frac{r^\alpha}{r^\alpha - 1} \right) \cdot P(T)$$

where $w(T_r) = \sum_{(u,v) \in E(T_r)} (p(u,v) + p(v,u))$.

Proof Let $V^i(T)$ be the set of all internal nodes of T . Denote by $T(u)$ the subtree induced by an internal node u and all its children. Then,

$$\sum_{u \in V^i(T)} P(T(u)) \leq 2P(T).$$

For each $T(u)$, a tree $T_r(u)$ is constructed by modifying $T(u)$ in the following way:

- Sort all children x_1, x_2, \dots, x_k of u in ordering of nonincreasing in $d(u, x_i)$, that is, $d(u, x_1) \geq d(u, x_2) \geq \dots \geq d(u, x_k)$.
- For each $i = 1, \dots, k-1$, if $(d(u, x_i) \leq rd(u, x_{i+1}))$, then replace edge (u, x_i) by edge (x_i, x_{i+1}) .

Note that for each edge (x_i, x_{i+1}) in $T_r(u)$,

$$d(x_i, x_{i+1}) \leq d(u, x_i) + d(u, x_{i+1}) \leq (1+r)d(u, x_{i+1})$$

and

$$d(x_i, x_{i+1}) \leq d(u, x_i) + d(u, x_{i+1}) \leq 2d(u, x_i).$$

Thus,

$$p(x_i, x_{i+1}) \leq 2^\alpha p(x_i, u)$$

and

$$p(x_{i+1}, x_i) \leq (1+r)^\alpha p(x_{i+1}, u).$$

Therefore,

$$w(x_i, x_{i+1}) \leq (1+r)^\alpha p(x_i, u) + 2^\alpha p(x_{i+1}, u). \quad (1)$$

Let $(u, x_{i_1}), (u, x_{i_2}), \dots, (u, x_{i_h})$ be those edges of $T(u)$, which remain in $T_r(u)$. Then, it has the following that

$$d(u, x_{i_1}) \geq rd(u, x_{i_2}) \geq r^2 d(u, x_{i_3}) \geq \dots \geq r^{h-1} d(u, x_{i_h}).$$

Therefore,

$$\begin{aligned}
& p(u, x_{i_1}) + p(u, x_{i_2}) + \cdots + p(u, x_{i_h}) \\
& \leq p(u, x_{i_1})(1 + r^{-\alpha} + \cdots + r^{-(h-1)\alpha}) \\
& \leq p(u, x_{i_1}) \frac{1}{1 - r^{-\alpha}} \\
& \leq p(u, x_1) \frac{r^\alpha}{r^\alpha - 1}.
\end{aligned}$$

Combining with (1), it can be obtained

$$\begin{aligned}
w(T_r) &= \sum_{(u, x_i) \in E(T_r(u))} w(u, x_i) \\
&+ \sum_{(x_i, x_{i+1}) \in E(T_r(u))} w(x_i, x_{i+1}) \\
&\leq p(u, x_1) \frac{r^\alpha}{r^\alpha - 1} + \sum_{(u, x_i) \in E(T_r(u))} p(x_i, u) \\
&+ (1+r)^\alpha \sum_{(x_i, x_{i+1}) \in E(T_r(u))} (p(x_i, u) + p(x_{i+1}, u)) \\
&\leq P(T(u)) \max \left(\frac{r^\alpha}{r^\alpha - 1}, 2^\alpha + (1+r)^\alpha \right).
\end{aligned}$$

Now, let $T_r = \cup_{u \in V^i(T)} T_r(u)$. Then

$$\begin{aligned}
w(T_r) &\leq \max \left(\frac{r^\alpha}{r^\alpha - 1}, 2^\alpha + (1+r)^\alpha \right) \sum_{u \in V^i(T)} P(T(u)) \\
&\leq \max \left(\frac{r^\alpha}{r^\alpha - 1}, 2^\alpha + (1+r)^\alpha \right) \cdot 2P(T). \quad \square
\end{aligned}$$

2.5 Unicast

Calinescu et al. [15] studied a unicast problem as follows:

MIN-POWER UNICAST: Given a set V of points, a source $s \in V$, and a destination $t \in V$, find a minimum power-cost path between s and t .

First, they note that the minimum power-cost path is different from the minimum cost path. For example, consider three points s , x , and t which are three vertices of an isosceles triangle with a right angle at x . Suppose $\alpha = 2$ and $c = 1$. Then, $\|(s, t)\|^2 = \|(s, x)\|^2 + \|(x, t)\|^2$. However,

$$P((s, t)) = 2\|(s, t)\|^2,$$

and

$$P(s, x, t) = p(s) + p(x) + p(t) = \frac{3}{2}\|(s, t)\|.$$

Indeed, the calculation of power-cost of a path is not a simple sum of edge cost. This fact results in that the algorithm for computing the shortest path does not work on the geometric network on node set V .

Calinescu et al. [15] gave the following solution. First, construct an edge-weighted graph G with node set $V \times V$ and following edges:

- For every three nodes $u, v, w \in V$, construct an arc $((u, v), (u, w))$ with weight $\max(0, \|(u, w)\|^\alpha - \|(u, v)\|^\alpha)$.
- For every two nodes $u, v \in V$, construct two arcs $((u, v), (v, u))$ and $((v, u), (u, v))$ each with weight $\|(u, v)\|^\alpha$.

For example, the graph G on above three points s , x , and t contains nine nodes, and the path (s, x, t) corresponds to the path $((s, x), (x, s), (x, t), (t, x))$ with total weight equal to the power-cost $P(s, x, t)$ of path (s, x, t) .

Now, MIN-POWER UNICAST is reduced to the shortest path problem in constructed graph G . Therefore, *it has the following that*

Theorem 10 MIN-POWER UNICAST can be solved in polynomial-time.

3 Minimum Energy with Unadjustable Power

In real systems of wireless ad hoc networks, after network is configured, each node is assigned with a transmission power level which would not be changed for any request such as broadcast and unicast. In wireless sensor networks, the communication range of each sensor is often fixed and hence also in the same situation that the minimization of total energy consumption is under given transmission power level at each node. When power level at every node is the same, the total energy consumption can be measured through the total node-weight at transmission nodes. In this section, several optimization problems of this type is presented.

3.1 Operations in Multiradio Multichannel Wireless Networks

In works of Li et al. [7], Cagalj et al. [6], and Liang [5], the total energy consumption of broadcast in static wireless ad hoc networks is minimized under the same given power level at every node. The following is a general formulation.

Min Node-Weight Arborescence: Given a node-weighted digraph $G = (V, E)$ with a source node s , construct an out-arborescence rooted at s with the minimum total weight of internal nodes.

Liang [5] gave an efficient algorithm evaluated through simulations. Cagalj et al. [6] presented a polynomial-time $O(\log^3 n)$ -approximation. Li et al. designed a polynomial-time approximation algorithm with performance ratio $(1 + 2 \ln(n - 1))$. Those algorithms are presented for *Min Node-Weight Arborescence* in non-weighted case. However, it is easy to extend them to weighted case, corresponding to that power levels at different nodes may be different.

Li et al. [60] and Ma et al. [61] study the broadcast in multiradio multichannel multihop wireless networks. In a multiradio multichannel multihop wireless network (MR-MC network), there are totally C non-overlapping orthogonal frequency channels, $1, 2, \dots, c$. Each node v is equipped with some omni-directional radio interfaces. Suppose the following are done after configuration:

- (a) Each node v is assigned with a channel subset $B(v)$. This means that each node v can receive messages through any channel in subset $B(v)$ and transmit messages using any channel in subset $B(v)$.
- (b) The transmission power is fixed at a certain level $p(v)$ at each node v .

Assume that compared with transmission power, energy spending for receiving data at each node can be ignored. Then, energy consumption at each node v is $p(v)$ multiplying the number of forward channels, that is, channels used for sending messages.

The problem studied in [60, 61] is to find a forward scheme, that is, for each node v , find a channel subset $F(v) \subseteq B(v)$ such that data can be broadcasted from a given source node to all wireless nodes and the total energy consumption is minimized. For any broadcasting tree T , let $NL(T)$ be the set of its internal nodes. The following is the formulation.

BROADCAST IN MR-MC NETWORK: Consider a digraph $G = (V, E)$ with a source node s and a set of radio channels $C = \{1, 2, \dots, c\}$. Given each node v a set $B(v)$ of radio channels and a power $p(v)$, find an assignment $F : V \rightarrow 2^C$ to minimize

$$W(T) = \sum_{v \in NL(T)} |F(v)| \cdot p(v)$$

under the following conditions:

- (1) $F(v) \subseteq B(v)$ for every $v \in V$
- (2) There exists a broadcast tree T from source s satisfying condition that for each arc $(u, v) \in T$, $F(u) \cap B(v) \neq \emptyset$.

While Li et al. [60] assumed that transmission power level at all nodes is the same, Ma et al. [61] did not. Actually, *Min Node-Weight Arborescence* and **BROADCAST IN MR-MC NETWORK** are equivalent in terms of approximability.

Theorem 11 *There is a polynomial-time ρ -approximation for **BROADCAST IN MR-MC NETWORK** if and only if there is a polynomial-time ρ -approximation for **MIN NODE-WEIGHT ARBORESCENCE**.*

Proof **MIN NODE-WEIGHT ARBORESCENCE** can be seen as a special case of **BROADCAST IN MR-MC NETWORK**; in such a case, $B(v)$ contains only one channel which is the same for all $v \in V$. Thus, “only if” part is trivial.

To show “if” part, BROADCAST IN MR-MC NETWORK is transformed to a special case of MIN NODE-WEIGHT ARBORESCENCE.

In this transformation, first construct an auxiliary digraph $G_{\text{aux}} = (V_{\text{aux}}, E_{\text{aux}})$ based on the input digraph $G = (V, E)$ of BROADCAST IN MR-MC NETWORK as follows.

- (1) Create a source node s^* with weight $p(s^*) = 0$.
- (2) For each node v , create $|B(v)|$ nodes v_i with weight $p(v_i) = p(v)$ for $i \in B(v)$.
- (3) Connect s^* to every s_i for the input source node s of BROADCAST IN MR-MC NETWORK with arc (s^*, s_i) .
- (4) For each arc $(u, v) \in E$, add arcs (u_i, v_j) for $i \in B(u)$, $j \in B(v)$, and $i \in B(v)$.

Thus, one has

$$V_{\text{aux}} = \{s^*\} \cup \bigcup_{v \in V} \{v_j \mid j \in B(v)\}$$

with $p(s^*) = 0$, and $p(v_j) = p(v)$ for $j \in B(v)$, and

$$E_{\text{aux}} = \bigcup_{(u,v) \in E} \{(u_i, v_j) \mid (u, v) \in E, i \in B(u) \cap B(v), j \in B(v)\}.$$

This transformation has the following property: There exists a forward scheme F with cost at most W containing a broadcast tree from node s if and only if G_{aux} contains a broadcast tree with weight at most W from node s^* .

To show “only if” part of this property, suppose the existence of forward scheme F with cost at most W containing a broadcast tree T . Construct a broadcast tree T_{aux} for G_{aux} as follows:

Initially, set $T_{\text{aux}} = \emptyset$.

- (1) For each $i \in B(s)$, add arc (s^*, s_i) to T_{aux} .
- (2) For each arc (u, v) in T , choose a channel i from $F(u) \cap B(v)$ and add arcs (u_i, v_j) to T_{aux} for every $j \in B(v)$.

From the above construction, it is easy to see that for any path from s to a node v , T_{aux} contains a path from s^* to node v_j for any $j \in B(v)$. Therefore, T_{aux} being a broadcast tree follows from T being a broadcast tree. Moreover, only in case that arc (u, v) exists (i.e., u is an internal node of T) and $i \in F(u)$, u_i can be an internal node of T_{aux} . Therefore, the total weight of internal nodes other than s^* in T_{aux} is at most $\sum_{u \in NL(T)} |F(u)| \cdot p(u) \leq W$.

To show the “if” part of the property, suppose G_{aux} contains a broadcast tree T_{aux} with weight at most W . For each $u \in V$, define

$$F(u) = \{i \mid (u_i, v_j) \text{ in } T_{\text{aux}}\}.$$

Denote by T the subgraph induced by the arc set

$$\{(u, v) \mid (u_i, v_j) \text{ in } T_{\text{aux}}\}.$$

It follows from the definition of G_{aux} that for any arc (u, v) in the arc set, $i \in F(u) \cap B(v)$, and hence, $F(u) \cap B(v) \neq \emptyset$. Now, T is claimed to be a broadcast tree.

In fact, for each node $v \in V$, T_{aux} contains a path from s^* to v_j for any $j \in B(v)$ since T_{aux} is a broadcast tree. This path would induce a path from s to v . Finally, it is noticed that $i \in F(u)$ if and only if u_i is an internal node of T_{aux} . Therefore, $W(F) \leq \sum_{(u,i) \in NL(T_{\text{aux}})} p(u) \leq W$.

Now, the theorem can be proved easily from the property. First, it follows immediately from the property that the minimum weight for a forward scheme F to contain a broadcast tree is opt if and only if the minimum cost of an arborescence in G^{opt} is opt .

Next, suppose an out-arborescence T_{aux} with cost at most $\rho \cdot opt$ for G_{aux} can be computed in polynomial-time. Then, from the proof of the property, one may see that a forward scheme F can be constructed in polynomial time to contain a broadcast tree and to have cost at most $\rho \cdot opt$. This means that if there is a polynomial-time ρ -approximation for MIN NODE-WEIGHT ARBORESCENCE on input G_{aux} with weight $p(u_i) = p(u)$, then there is a polynomial-time ρ -approximation for BROADCAST IN MR-MC NETWORK. \square

The above theorem indicates that the study on broadcast in multiradio multi-channel wireless networks can be reduced to the study on broadcast in single-radio single-channel wireless networks. Du et al. [62] found that this is true for all network operations, such as gossiping, convergecast, multicast, and unicast.

For example, gossiping is another one of most fundamental communication primitives in wireless network. The energy-efficient gossiping in multiradio multichannel wireless networks can be formulated as follows.

GOSSIPING IN MR-MC NETWORK: Consider a graph $G = (V, E)$. Each node v is associated with a set $B(v)$ of radio channels and a weight $p(v)$. The problem is to assign each node v with a subset $F(v)$ of $B(v)$ such that the directed graph with node set V and arc set $\{(u, v) \in E \mid F(u) \cap B(v) \neq \emptyset\}$ is strongly connected.

Its corresponding problem in single-radio single-channel wireless networks can be described in the following way.

MIN-WEIGHT SCDS: Given a directed graph $G = (V, E)$ with nonnegative node weight $c : V \rightarrow R^+$, find the minimum-weight strongly connected dominating set where a subset C of nodes is called a *strongly connected dominating set* if every node $v \in V - C$ has an arc (v, u) ending at $u \in C$ and also an arc (w, v) coming from $w \in C$.

Du et al. [62] showed their equivalence as follows.

Theorem 12 *If min-weight SCDS has a polynomial-time ρ -approximation if and only if gossiping in MR-MC networks has a polynomial-time ρ -approximation.*

3.2 Energy-Efficient Virtual Backbone

There are several works on energy-efficient virtual backbone, that is, energy-efficient connected dominating sets in the literature [63–66]. Since they assume that the communication range at every station has the same radius, the minimization on

total power is the same as the minimization on the size of connected dominating set, which has been studied extensively. For a current research status, the reader may see [67].

3.3 Connected Sensor Cover

Motivated from study on coverage problem [68, 69] and connected dominating set problem, Gupta, Das, and Gu [70] proposed the connected sensor cover problem as follows.

CONNECTED SENSOR COVER (AREA): Consider a sensor network $G = (V, E)$ of n sensors in the Euclidean plane and a region A . Each sensor $s_i \in V$ is associated with a sensing region S_i . The problem is to select the minimum number of sensors such that A is covered by sensing regions of selected sensors and the subgraph induced by selected sensors is connected.

A subregion of A is called a *subelement* if the maximal region cannot be cut by any sensor's sensing region. Put a target in each subelement. Then, a set of sensors can cover A if and only if it can cover all targets. This means that the area coverage problem can be reduced to a target coverage problem.

CONNECTED SENSOR COVER (TARGET): Consider a sensor network $G = (V, E)$ of n sensors and a set of m targets. Each sensor $s_i \in V$ is associated with a sensing set S_i of targets. The problem is to select the minimum number of sensors such that every target appears in the sensing set of at least one selected sensor and the subgraph induced by selected sensors is connected.

If the sensor set and the target set is identical, then this problem is exactly the minimum connected dominating set problem. Thus, CONNECTED SENSOR COVER is NP-hard because the minimum connected dominating set problem is NP-hard. Gupta, Das, and Gu [70] designed a greedy approximation with the following performance.

Theorem 13 *There is a polynomial-time approximation for CONNECTED SENSOR COVER with performance ratio at most $(r - 1)(1 + \log m)$ where r is the link radius of the sensor network, that is, the maximum communication distance between two sensors with overlapping sensing sets.*

Wang et al. [71] and Zhang and Hou [72] study CONNECTED SENSOR COVER (AREA) in the case that each sensor s is associated with two disks with center s , sensing region and communication region. They found an interesting property specially for area coverage as follows.

Theorem 14 *Suppose the radius of communication region is at least twice the radius of sensing region. If a connected region is covered by a subset S of sensors, then S induced a connected subgraph.*

Zhou, Das, and Gupta [73] extended this property to k -coverage.

Theorem 15 Suppose the radius of communication region is at least twice the radius of sensing region. If a subset of sensors has k -coverage to a connected region, that is, every point in the region receives sensing from at least k sensors, then it induced a k -connected subgraph, that is, for any two sensors there are at least k node-disjoint paths between them.

Proof Suppose S is a subset of sensors with k -coverage. Then, for any $k-1$ sensors s_1, \dots, s_{k-1} , $S - \{s_1, \dots, s_{k-1}\}$ is still able to cover the target connected region. Therefore, the subgraph induced by $S - \{s_1, \dots, s_{k-1}\}$ is connected. \square

By above theorem, one need only to pay attention to coverage when design algorithm to construct connected sensor coverage. While many efforts [70, 72, 73] were made on design of greedy approximation with performance ratio $O(\log n)$, Funke et al. [74] showed that greedy approximation cannot have performance ratio better than $\Omega(\log n)$. They also proposed a fine grid algorithm with the following performance.

Theorem 16 Suppose in a uniform wireless sensor network, the communication radius R_c is at least twice of the sensing radius R_s . Also, suppose with reduced sensing radius $R'_s = (1 - \epsilon/\sqrt{2})R_s$, the target connected region can still be fully covered. Then, the fine grid algorithm can produce an approximation solution for CONNECTED SENSOR COVER with size within a factor of 12 from the size of optimal solution for sensing radius R'_s .

Zhou, Das, and Gupta [75] study CONNECTED SENSOR COVER in sensor networks with variable sensing radius and communication radius. Alam and Hass [76] and Bai et al. [77] study the problem in three-dimensional networks. Yu et al. [78] consider the problem in networks with directional antennas. Related to CONNECTED SENSOR COVER, there is also a sensor placement problem [79–82]. For a nice and complete survey about the problem, the reader may refer to [83].

4 Maximum Lifetime

With a certain resource, adjust usage of resource to maximize the lifetime of the system. This is a classic type of resource management problems. In wireless networks, there are also many optimization problems of this type on energy efficiency. Some examples will be discussed in this section.

4.1 Sensor Coverage

A result of randomly deploying a very large number of sensors into a certain region, possibly by an aircraft, is the existence of redundant sensors. Usually, such a result is utilized to increase the lifetime of network system by scheduling

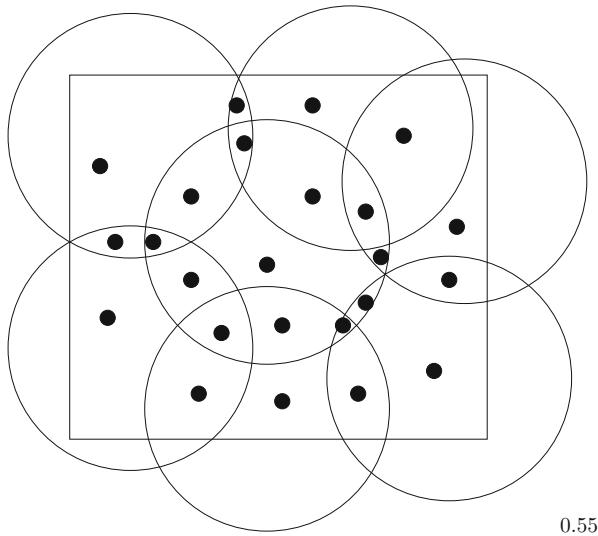

Fig. 5 Target subareas are represented by target points

active/sleep time of sensors such that sensor can be organized to work in different period so that the target area (or target points) can be covered in every period. This sensor activation scheduling with coverage of targets is called the *sensor coverage* problem. According to target type, there are two types problems: area coverage [71, 72, 84–86] and target coverage [8–10, 79, 87]. By target coverage, one usually means that targets are points.

AREA-COVERAGE. Given an area and a set of sensors each with a sensing area, find a sensor activation scheduling to maximize the lifetime of the sensor network where the sensor network is alive if and only if the given area is fully covered by active sensors.

TARGET-COVERAGE. Given a set of (point) targets and a set of sensors each with a sensing area, find a sensor activation scheduling to maximize the lifetime of the sensor network where the sensor network is alive if and only if the given targets are fully covered by active sensors.

AREA-COVERAGE can be reduced to TARGET-COVERAGE as follows: For every sensor, draw the boundary of its sensing area to divide the target area into small subareas; each subarea is a maximal area such that no boundary point of sensor's sensing area lies in its interior. Place a point-target in the interior of each subarea ([Fig. 5](#)). Then, a subarea is covered if and only if placed point-target is covered. Therefore, the given area is fully covered if and only if all point-targets are fully targets.

In the following, studying will be focused on TARGET-COVERAGE.

A simple scheduling is to divide sensors into disjoint subsets each of which fully covers all targets, called a *sensor cover*. For this type of scheduling, the sensor is activated only once, that is, once the sensor is activated, it keeps active until it dies. The specific formulation corresponding this scheduling is as follows.

DISJOINT SENSOR COVER: Given n targets r_1, \dots, r_n and m sensors s_1, \dots, s_m each with a sensing subset of targets, find the maximum number of disjoint sensor covers.

This problem is NP-hard. Various heuristics and approximation algorithms have been given in [85, 87, 88].

Cardei et al. [8] found that it is possible to increase the lifetime if each sensor is allowed to make more changes between active and sleeping. For example, suppose that sensor s_1 covers targets r_1 and r_2 , sensor s_2 covers targets r_2 and r_3 , and sensor s_3 covers targets r_1 and r_3 . Using disjoint-set strategy, the lifetime of this system is 1 unit, which is the lifetime of each sensor, because there do not exist two disjoint sensor covers. However, the following scheduling can obtain lifetime 1.5 unit time: In the first period of 0.5 unit time, sensors s_1 and s_2 are activated and sensor s_3 is put in sleeping; in the second period of 0.5 unit time, sensors s_2 keeps being active and s_3 is activated and sensor s_1 is put in sleeping; in the third period of 0.5 unit time, sensors s_1 is activated again and s_3 is still active.

The specific formulation on scheduling of nondisjoint sensor covers is as follows [8].

SENSOR-COVER-SCHEDULING: Given m sensors s_1, \dots, s_m each with a sensing subset of target set $\{r_1, \dots, r_n\}$, find a family of sensor cover S_1, \dots, S_p with time lengths t_1, \dots, t_p in $[0, 1]$, respectively, to maximize $t_1 + \dots + t_p$ subject to every sensor appears in cover sets with total time length at most 1.

This is still an NP-hard problem, which can be easily written as an 0-1 integer programming.

$$\begin{aligned} & \text{Maximize } t_1 + \dots + t_p \\ & \text{subject to } \sum_{j=1}^p x_{ij} t_j \leq 1 \text{ for } i = 1, \dots, m \\ & \quad \sum_{i \in C_k} x_{ij} \geq 1 \text{ for } k = 1, \dots, n \text{ and } j = 1, \dots, p, \\ & \quad x_{ij} = 0, 1, \text{ and } t_j \geq 0, \end{aligned}$$

where for each target r_k , C_k is the set of sensors whose sensing subset contains r_k . x_{ij} is the indicator that sensor s_i is in sensor cover S_j . The first inequality constraint means that for each sensor s_i , the total active time length does not exceed 1. The second inequality constraint means that at any time period, active sensors should form a sensor cover. Note that the first inequality constraint together with $t_j \geq 0$ implies $t_j \leq 1$. Therefore, $t_j \leq 1$ does not need to put in constraints explicitly.

Above integer programming is not linear since $x_{ij} t_j$ is not a linear term. However, it can be easily linearized by setting $y_{ij} = x_{ij} t_j$ as follows:

$$\text{Maximize } t_1 + \dots + t_p$$

$$\begin{aligned}
& \text{subject to } \sum_{j=1}^p y_{ij} \leq 1 \text{ for } i = 1, \dots, m \\
& \quad \sum_{i \in C_k} y_{ij} \geq t_j \text{ for } k = 1, \dots, n \text{ and } j = 1, \dots, p, \\
& \quad y_{ij} = 0, \text{ or } t_j, \text{ and } t_j \geq 0.
\end{aligned}$$

Cardei et al. [8] designed a heuristic using LP relaxation as follows.

By relaxing the condition $y_{ij} = 0, t_j$ to $0 \leq y_{ij} \leq t_j$, the following linear programming can be obtained from the above integer linear programming.

$$\begin{aligned}
& \text{Maximize } t_1 + \dots + t_p \\
& \text{subject to } \sum_{j=1}^p y_{ij} \leq 1 \text{ for } i = 1, \dots, m \\
& \quad \sum_{i \in C_k} y_{ij} \geq t_j \text{ for } k = 1, \dots, n \text{ and } j = 1, \dots, p, \\
& \quad 0 \leq y_{ij} \leq t_j.
\end{aligned}$$

The solution (y_{ij}^*, t^*) of this linear programming may not satisfy condition $y_{ij} = 0$ or t_j and even not necessarily satisfies $t_j \leq 1$. Therefore, the following rounding technique is employed: Set $t_j = \min_{k=1, \dots, m} \max_{i \in C_k} y_{ij}^*$. For each k , choose a i_k from C_k such that $y_{ij}^* \geq t_j$ and set $y_{ikj} = t_j$. For remaining i , set $y_{ij} = 0$.

This algorithm is employed iteratedly to utilize the remaining sensor lifetime. To do so, Cardei et al. [8] replace inequality $\sum_{j=1}^p x_{ij} t_j \leq 1$ by $\sum_{j=1}^p x_{ij} t_j \leq e_i$ where e_i is the remaining lifetime of sensor s_i .

No theoretical bound has been established for this heuristic. However, computational experiments show that the heuristic produces good solutions.

The nondisjoint model is better than the disjoint model also due to an interesting fact discovered in [89] that putting a sensor alternatively in active and sleeping states in a proper way may double its lifetime since the battery could be recovered in certain level during sleeping.

Berman et al. [90, 91] first designed an approximation algorithm for SENSOR-COVER-SCHEDULING with theoretical bound.

Theorem 17 *There exists a polynomial-time approximation for SENSOR-COVER-SCHEDULING with performance ratio $O(\log n)$ where n is the number of sensors.*

Ding et al. [92] found constant approximation for geometric version.

Theorem 18 Suppose all sensors and targets lie in the Euclidean plane and the sensing area of every sensor is a disk with the same radius. Then, there exists a polynomial-time $(4 + \epsilon)$ -approximation for SENSOR-COVER-SCHEDULING.

Both result of Berman et al. [90, 91] and Ding et al. [92] employ an algorithm of Garg and Könemann [93] and their theorem, which will be introduced in next subsection.

4.2 Garg–Könemann Algorithm

The first one who found the application of Garg–Könemann Algorithm in the study of lifetime maximization type of problems is Calnescu et al. [59].

Consider a graph $G = (V, E)$. A function $c : V \times V \rightarrow R^+$ is called a power requirement if edge (u, v) is established if and only if both the power at u and the power at v are not less than $c(u, v)$. With a power requirement c , $G = (V, E, c)$ is called a power requirement graph.

Calnescu et al. [59] consider the following general form of the minimum power problem and the maximum lifetime problem.

POWER ASSIGNMENT: Given a power requirement graph $G = (V, E, c)$, and a connectivity constraint Q , find a power assignment $p : V \rightarrow R^+$ to minimize the total power $\sum_{u \in V} p(u)$ under condition that supported subgraph H satisfies the connectivity constraint Q .

NETWORK LIFETIME: Given a power requirement graph $G = (V, E, c)$, a battery supply $b : V \rightarrow R^+$ and a connectivity constraint Q , find a feasible power schedule $PT = \{(p_1, t_1), (p_2, t_2), \dots, (p_m, t_m)\}$ to maximize $\sum_{i=1}^m t_i$, where schedule PT is feasible if $\sum_{i=1}^m p_i(u) \leq b(u)$ for every $u \in V$.

Suppose \mathcal{S} is the set of all subgraphs satisfying constraint Q . For each $H \in \mathcal{S}$, let $p_H : V \rightarrow R^+$ be the power assignment required by establishing subgraph H . Then, NETWORK LIFETIME can be formulated a linear integer programming as follows:

$$\begin{aligned} & \max \sum_{H \in \mathcal{S}} t_H \\ & \text{subject to } \sum_{H \in \mathcal{S}} p_H(u)t_H \leq b(u) \\ & \quad t_H \geq 0, \forall H \in \mathcal{S}. \end{aligned}$$

Now, the sum of coefficients for each column is exactly the total power for establishing H , which is called the *length* of the column. Computing the minimum column length is exactly the POWER ASSIGNMENT problem. Consider the following weighted version of POWER ASSIGNMENT.

WEIGHTED POWER ASSIGNMENT: Given a power requirement graph $G = (V, E, c)$, a connectivity constraint Q , and a node weight $y : E \rightarrow R^+$, find a power assignment $p : V \rightarrow R^+$ to minimize the total power $\sum_{u \in V} p(u)y(u)$ under condition that supported subgraph H satisfies the connectivity constraint Q .

Suppose WEIGHTED POWER ASSIGNMENT has an f -approximation. Then, a $(1 + \varepsilon)f$ -approximation can be computed for NETWORK LIFETIME. Indeed, the linear programming formulation of NETWORK LIFETIME falls in a general form of linear programming studied by Garg and Könemann [93] as follows:

$$\max\{c^T x \mid Ax \leq b, x \geq 0\}$$

where A is an $m \times n$ positive matrix and b and c are m -dimensional and n -dimensional positive vectors, respectively. n can be exponentially larger than m . However, The following Garg and Könemann Algorithm [93] assumes that the linear programming is actually implicitly given by vector b .

Garg–Könemann Algorithm

input: A vector $b \in R^m$, $\varepsilon > 0$, an algorithm F

for computing f -approximation of $\min_j \sum_{i=1}^m A(i, j) \frac{y(i)}{c(j)}$.
 Initially, $\delta = (1 + \varepsilon)((1 + \varepsilon)m)^{-1/\varepsilon}$.
 for $i = 1, \dots, m$, $y(i) \leftarrow \frac{\delta}{b(i)}$,
 $D \leftarrow m\delta$,
 $j = 0$;

while $D < 1$ **do**

find a column A_q using f -approximation F
 choose index p to minimize $\frac{b(p)}{A_q(p)}$
 $j \leftarrow j + 1$
 $x^j \leftarrow \frac{b(p)}{A_q(p)}$
 $A^j \leftarrow A_q$
 for $i = 1, \dots, m$, $y(i) \leftarrow y(i)(1 + \varepsilon \cdot \frac{b(p)}{A_q(p)} / \frac{b(i)}{A_q(i)})$
 $D \leftarrow b^T y$

output $\{(A^j, \frac{x^j}{\log_{1+\varepsilon} \frac{1+\varepsilon}{\delta}})\}_{j=1}^k$.

This algorithm would give a $(1 + \varepsilon)f$ -approximation for NETWORK LIFETIME. It is also proved in [93] that $k \leq m$.

Theorem 19 Consider a connectivity constraint Q and a power requirement graph $G = (V, E, c)$. For any f -approximation algorithm F for WEIGHTED POWER ASSIGNMENT, there exists a $(1 + \varepsilon)f$ -approximation algorithm for the corresponding NETWORK LIFETIME.

Garg–Könemann Algorithm successfully reduces the lifetime maximization problem to the minimum weighted power assignment problem. This gives a quite useful technique to study approximation of the lifetime maximization. With this technique, several approximation with good performance have been found in the literature [90–92, 94]. This approach may also be used in the problem studied in [95–97] to obtain some new results.

4.3 Coverage Breach

In above sensor coverage problems, the complete coverage is required during the system lifetime period. However, the number of randomly deployed sensors is often very large and the core network may not be able to provide a bandwidth large enough for receiving data from all sensors or from all sensors in a sensor cover. In this situation, a complete coverage is sometimes not available. Therefore, the partial coverage becomes an interesting subject in the study of sensor networks.

A target is in *breach* if it is not monitored by any sensor. There are three coverage breach optimization formulations studied in the literature [9, 10, 85, 90, 91]. For each formulation, there are two models, disjoint model and nondisjoint model. The following are formulations in disjoint model:

Max-lifetime coverage with breach (disjoint model): Given a set of sensors, $\{s_1, \dots, s_m\}$, a set of targets, $\{r_1, \dots, r_n\}$, and a nonnegative integer b , the problem is to partition the sensor set into maximum number of subsets such that for each sensor subset, there are at most b breaches.

Min coverage breach (disjoint model): Given a set of sensors, $\{s_1, \dots, s_m\}$, a set of targets, $\{r_1, \dots, r_n\}$, and a positive integer k , the problem is to partition the sensor set into k subsets to minimize the total number of breaches.

Min-max coverage breach (disjoint model): Given a set of sensors, $\{s_1, \dots, s_m\}$, a set of targets, $\{r_1, \dots, r_n\}$, and a positive integer k , the problem is to partition the sensor set into k subsets such that the maximum number of breaches for each sensor subset is minimized.

Corresponding formulations in disjoint model are as follows.

Max-lifetime coverage with breach (nondisjoint model): Given a set of sensors, $\{s_1, \dots, s_m\}$, a set of targets, $\{r_1, \dots, r_n\}$, and a nonnegative integer b , the problem is to find a family of sensor subsets S_1, \dots, S_p with time lengths t_1, \dots, t_p in $[0, 1]$, respectively, to maximize $t_1 + \dots + t_p$ subject to that every sensor appears in those sensor subsets with total time length at most 1 and for each of those sensor subsets, there are at most b breaches.

Min coverage breach (nondisjoint model): Given a set of sensors, $\{s_1, \dots, s_m\}$, a set of targets, $\{r_1, \dots, r_n\}$, and a positive integer k , the problem is to find a family of sensor subsets S_1, \dots, S_p with time lengths t_1, \dots, t_p in $[0, 1]$, respectively, to minimize $t_1 b_1 + \dots + t_p b_p$ where b_i is the number of breaches for sensor subset S_i , subject to that every sensor appears in those sensor subsets with total time length at most 1 and $t_1 + \dots + t_p = k$.

Min-max coverage breach (nondisjoint model): Given a set of sensors, $\{s_1, \dots, s_m\}$, a set of targets, $\{r_1, \dots, r_n\}$, and a positive integer k , the problem is to find a family of sensor subsets S_1, \dots, S_p with time lengths t_1, \dots, t_p in $[0, 1]$, respectively, to minimize $\max(b_1, \dots, b_p)$ where b_i is the number of breaches for sensor subset S_i , subject to that every sensor appears in those sensor subsets with total time length at most 1 and $t_1 + \dots + t_p = k$.

For min–max type of problem, there is a variation that the minimization is on the maximum breach interval, where a breach interval is a time period during which there exists a target not covered by any sensor at any time.

All above problems are NP-hard. However, not many efforts have been made on design of approximation algorithms [9, 10].

4.4 Maximum Lifetime Routing

The shortest path routing is very popular and a good routing strategy in many cases. However, it may not be good for energy efficiency in wireless networks. In fact, the wireless equipment has limited energy supply, often with batteries. Every message transmission would have energy consumption. If a routing strategy allows repeatedly using some stations, then network lifetime would be shorten. Thus, a maximum lifetime routing problem appeared [98–111].

Let (s, t) represent a routing request that a message is required to send from sensor s to sensor t . For simplicity of discussion, it is often assumed that all messages have the same length, which require the same amount of time to transmit.

Max-lifetime routing: Given a wireless sensor network and a sequence of routing requests $(s_1, t_1), (s_2, t_2), \dots, (s_k, t_k)$, find a routing strategy to maximize j such that routing requests $(s_1, t_1), (s_2, t_2), \dots, (s_k, t_k)$ are successfully routed.

The problem has an online version [110] as follows.

Max-lifetime online routing: Given a wireless sensor network and a sequence of routing requests coming online, find an online routing strategy to maximize j such that first j routing requests can be successfully routed.

More information about the above problems can be found in [112, 119].

5 Conclusion

In this chapter, we have argued many combinatorial optimization problems in the study of power issues in wireless networks. The issues have been discussed into three categories: (1) minimum total power with adjustable-power nodes, (2) minimum total power with unadjustable-power nodes, and (3) maximum lifetime with unadjustable-power nodes. Latest results have been shown in the introduction of these problems.

Abstract

If the vertices of a graph G are colored with k colors such that no adjacent vertices receive the same color and the sizes of any two color classes differ by at most one, then G is said to be equitably k -colorable. The equitable chromatic number $\chi_=(G)$ is the smallest integer k such that G is equitably k -colorable. In the first introduction section, results obtained about the equitable chromatic number before 1990 are surveyed. The research on equitable coloring has attracted enough attention only since the early 1990s. In the subsequent sections, positive evidence for the important equitable Δ -coloring conjecture is supplied from graph classes such as forests, split graphs, outerplanar graphs, series-parallel graphs, planar graphs, graphs with low degeneracy, graphs with bounded treewidth, Kneser graphs, and interval graphs. Then three kinds of graph products are investigated. A list version of equitable coloring is introduced. The equitable coloring is further examined in the wider context of graph packing. Appropriate conjectures for equitable Δ -coloring of disconnected graphs are then studied. Variants of the well-known and significant Hajnal and Szemerédi Theorem are discussed. A brief summary of applications of equitable coloring is given. Related notions, such as equitable edge coloring, equitable total coloring, equitable defective coloring, and equitable coloring of uniform hypergraphs, are touched upon. This chapter ends with a short conclusion section. This survey is an updated version of Lih [102].

1 Introduction

A graph G consists of a vertex set $V(G)$ and an edge set $E(G)$. All graphs considered in this chapter are finite, loopless, and without multiple edges. Let $|G|$ and $\|G\|$ denote the number of vertices, also known as the *order*, and the number of edges of the graph G , respectively. If the vertices of a graph G can be partitioned into k sets V_1, V_2, \dots, V_k such that each V_i is an *independent set* (none of its vertices are adjacent), then G is said to be *k -colorable* and the k sets are called its *color classes*. Equivalently, a coloring can be viewed as a function $\pi : V(G) \rightarrow \{1, 2, \dots, k\}$ such that adjacent vertices are mapped to distinct numbers. The mapping π is said to be a (proper) *k -coloring*. All pre-images of a fixed i , $1 \leq i \leq k$, form a color class. The smallest number k , denoted by $\chi(G)$, such that G is k -colorable is called the *chromatic number* of G . The graph G is said to be equitably colored with k colors, or *equitably k -colorable*, if there is a k -coloring whose color classes satisfy the condition $\|V_i\| - \|V_j\| \leq 1$ for every pair V_i and V_j . The smallest integer k for which G is equitably k -colorable, denoted by $\chi_=(G)$, is called the *equitable chromatic number* of G . Suppose that the graph G of order n is equitably colored with k colors. If $n = qk + r$, where $0 \leq r < k$, then there are exactly r color classes of size $q + 1$ and exactly $k - r$ color classes of size q . The sizes of the color classes can be enumerated as $\lfloor n/k \rfloor, \lfloor (n+1)/k \rfloor, \dots, \lfloor (n+k-1)/k \rfloor$ in a nondecreasing order. Note that $\lfloor (n+t-1)/k \rfloor = \lceil (n+t-k)/k \rceil$ for $1 \leq t \leq k$.

The notion of an equitable coloring was first introduced in [115] by W. Meyer. His motivation came from Tucker's paper [138], in which vertices represent garbage collection routes and two such vertices are adjacent when the corresponding routes should not be run on the same day. Meyer thought that it would be desirable to have an approximately equal number of routes run on each of the 6 days in a week.

Let $\deg_G(v)$, or $\deg(v)$ for short, denote the degree of the vertex v in the graph G and $\Delta(G) = \max\{\deg(v) \mid v \in V(G)\}$. Let $\lceil x \rceil$ and $\lfloor x \rfloor$ denote, respectively, the smallest integer not less than x and the largest integer not greater than x . The main result obtained by Meyer was that a tree T can be equitably colored with $\lceil \Delta(T)/2 \rceil + 1$ colors. However, there were gaps in his proof. According to Guy's report [63], Egginton could extend Meyer's result to show that a tree T can be equitably colored with k colors, provided $k \geq \lceil \Delta(T)/2 \rceil + 1$. A finer result about trees is the following theorem by Bollobás and Guy [16].

Theorem 1 *A tree T is equitably 3-colorable if $|T| \geq 3\Delta(T) - 8$ or $|T| = 3\Delta(T) - 10$.*

The most interesting contribution made in Meyer's paper is to propose the following conjecture. It is also called the *Equitable Coloring Conjecture (ECC)*. Let K_n and C_n denote, respectively, a complete graph and a cycle on n vertices.

Conjecture 1 *Let G be a connected graph. If G is neither a complete graph K_n nor an odd cycle C_{2n+1} , then $\chi_=(G) \leq \Delta(G)$.*

Meyer was successful in verifying the *ECC* only for graphs with six or fewer vertices. Apparently the motivation of the *ECC* came from the following fundamental Brooks' Theorem [19].

Theorem 2 *Let G be a connected graph. If G is neither a complete graph K_n nor an odd cycle C_{2n+1} , then $\chi(G) \leq \Delta(G)$.*

The well-known Hajnal and Szemerédi Theorem [64], when rephrased in terms of equitable colorings, had already shown the following before Meyer's paper.

Theorem 3 *A graph G (not necessarily connected) is equitably k -colorable if $k \geq \Delta(G) + 1$.*

Let $\chi_=(G)$ denote the smallest integer n such that G is equitably k -colorable for all $k \geq n$. Then an equivalent formulation of **Theorem 3** is that $\chi_=(G) \leq \Delta(G) + 1$ holds for any graph G . There is a notable contrast between the equitable colorability and the ordinary colorability: $\chi_=(G)$ may in fact be greater than $\chi_-(G)$. This will be demonstrated later. Therefore, it makes sense to introduce the notion $\chi_*(G)$, and it shall be called the *equitable chromatic threshold* of G .

In an entirely different context, de Werra [39] treated color sequences and the majorization order among them. His results have consequences in equitable colorability. A sequence of nonnegative integers $h = (h_1, h_2, \dots, h_k)$ is called a *color sequence* for a given graph G if the following conditions hold:

1. $h_1 \geq h_2 \geq \dots \geq h_k \geq 0$.
2. There is a k -coloring of G such that the color classes V_1, V_2, \dots, V_k satisfy $|V_i| = h_i$ for $1 \leq i \leq k$.

The *majorization order*, also known as the *dominance order*, is a widely used notion in measuring the evenness of distributions. Marshall and Olkin [110] offer a comprehensive treatment of majorization. Let $\alpha : a_1 \geq a_2 \geq \dots \geq a_k \geq 0$ and $\beta : b_1 \geq b_2 \geq \dots \geq b_k \geq 0$ be two sequences of nonnegative integers. The sequence α is said to be *majorized* by the sequence β if the following two conditions hold:

1. $\sum_{i=1}^j a_i \leq \sum_{i=1}^j b_i$ for any j , $1 \leq j < k$.
2. $\sum_{i=1}^k a_i = \sum_{i=1}^k b_i$.

Let $K_{m,n}$ denote the complete bipartite graph whose parts are of size m and size n , respectively. A *claw-free* graph is a graph containing no $K_{1,3}$ as an induced subgraph. One of de Werra's results is the following:

Theorem 4 *Let G be a claw-free graph and $h = (h_1, h_2, \dots, h_k)$ be a color sequence of G . Then any sequence of nonnegative integers $h' = (h'_1, h'_2, \dots, h'_k)$ is also a color sequence if h' is majorized by h .*

Combining Theorems 2 and 4, it follows that, for a claw-free graph G , G is equitably k -colorable for all $k \geq \chi(G)$, or equivalently $\chi^*(G) = \chi_-(G) = \chi(G)$. Although this fact can be shown directly, it was first implicitly implied in de Werra's paper. It follows immediately that the *ECC* holds for claw-free graphs. Since every line graph is claw-free, the *ECC* holds for line graphs in particular. This was also obtained in Wang and Zhang [149].

This ends the history of pre-1990 activities on the equitable coloring of graphs.

2 Bipartite Graphs

A graph is called *r-partite* if its vertex set can be partitioned into r -independent sets V_1, V_2, \dots, V_r and *complete r-partite*, denoted by K_{n_1, n_2, \dots, n_r} , if every vertex in V_i is adjacent to every vertex in V_j whenever $i \neq j$ and $|V_i| = n_i \geq 1$ for every $1 \leq i \leq r$. By convention it is always assumed that $r \geq 2$ and $1 \leq n_1 \leq n_2 \leq \dots \leq n_r$. A graph is said to be *complete multipartite* if it is complete r -partite for some r . A bipartite graph is synonymous with a 2-partite graph. Let I_n denote the graph consisting of n isolated vertices. Then I_n is equitably k -colorable with color classes of size $\lfloor x \rfloor$ or $\lceil x \rceil$ if and only if $\lfloor x \rfloor \leq \lfloor n/k \rfloor \leq \lceil n/k \rceil \leq \lceil x \rceil$ or, equivalently, if and only if $\lceil n/\lceil x \rceil \rceil \leq k \leq \lfloor n/\lfloor x \rfloor \rfloor$.

Lih and Wu [102] first settled the *ECC* for bipartite graphs.

Theorem 5 *If a connected bipartite graph G is different from any complete bipartite graph $K_{n,n}$, then G can be equitably colored with $\Delta(G)$ colors.*

Theorem 6 *The complete bipartite graph $K_{n,n}$ can be equitably colored with k colors if and only if $\lceil n/\lfloor k/2 \rfloor \rceil - \lfloor n/\lceil k/2 \rceil \rfloor \leq 1$.*

The proof for the complete bipartite case is straightforward by considering the appropriate sizes of the color classes. One interesting point to note is that, for $k = n = \Delta(K_{n,n})$, the difference involved in [Theorem 6](#) is 0 when n is even and is 2 when n is odd. In view of [Theorem 5](#), one can conclude that, except the complete bipartite graphs $K_{2m+1,2m+1}$, every connected bipartite graph G can be equitably colored with $\Delta(G)$ colors. Clearly, $\chi(K_{2m+1,2m+1}) = \chi_-(K_{2m+1,2m+1}) = 2$, yet $\chi_-^*(K_{2m+1,2m+1}) = 2m+2$. There is a gap between the equitable chromatic number and the equitable chromatic threshold. Nevertheless, *ECC* holds for connected bipartite graphs.

In many cases, the equitable chromatic number is below the maximum degree. If additional constraints are imposed upon the graph, a better bound for the equitable chromatic number could be obtained. The following is a result of this type:

Theorem 7 *Let $G = G(X, Y)$ be a connected bipartite graph with two parts X and Y such that $\|G\| = e$. Suppose $|X| = m \geq n = |Y|$ and $e < \lfloor m/(n+1) \rfloor (m-n) + 2m$. Then $\chi_-(G) \leq \lceil m/(n+1) \rceil + 1$.*

The bound for the equitable chromatic number in the above theorem is indeed better than $\Delta(G)$ when there are at least two edges. The following conjecture was made by B.-L. Chen in a personal communication:

Conjecture 2 *Let G be a connected bipartite graph. Then $\chi_-(G) \leq \lceil \Delta(G)/2 \rceil + 1$.*

Chen proved its validity when the maximum degree is at least 53. It is also trivial to see that the conjecture holds for complete bipartite graphs. The Meyer-Egginton result about trees gives another positive evidence.

Wang and Zhang [[149](#)] established the validity of *ECC* for complete multipartite graphs. The exact value of the equitable chromatic number of a complete multipartite graph K_{n_1, n_2, \dots, n_r} was determined by Lam et al. [[99](#)].

Theorem 8 *Let M be the largest natural number such that $n_i \pmod M < \lceil n_i/M \rceil$ for $1 \leq i \leq r$. Then $\chi_-(K_{n_1, n_2, \dots, n_r}) = \sum_{i=1}^r \lceil n_i/(M+1) \rceil$.*

Blum et al. [[12](#)] also obtained a formula for $\chi_-(K_{n_1, n_2, \dots, n_r})$. For $r \geq 2$, let $K_{r(n)}$ denote the complete multipartite graph $K_{\underbrace{n, n, \dots, n}_r}$. [Theorem 6](#) has been generalized to $K_{r(n)}$ in [[104](#)].

Theorem 9 Let integers $n \geq 1$ and $k \geq r \geq 2$. Then $K_{r(n)}$ is equitably k -colorable if and only if $\left\lceil \frac{n}{\lfloor k/r \rfloor} \right\rceil - \left\lfloor \frac{n}{\lceil k/r \rceil} \right\rfloor \leq 1$.

Complete multipartite graphs also furnish us with examples to show that the inequalities $\chi(G) \leq \chi_=(G) \leq \chi^*(G)$ can be strict. For instance [103], let $G_1 = K_{\underbrace{1,1,\dots,1}_m, 2n+1}$, $G_2 = K_{\underbrace{2n+1,2n+1,\dots,2n+1}_m}$, and $G_3 = K_{\underbrace{2n+1,2n+1,4n+2,4n+2,\dots,4n+2}_m}$. Then

1. $\chi(G_1) = m + 1 < \chi_=(G_1) = \chi^*(G_1) = m + n + 1$.
2. $\chi(G_2) = \chi_=(G_2) = m < \chi^*(G_2) = m(n + 1)$.
3. $\chi(G_3) = m + 2 < \chi_=(G_3) = 2(m + 1) < \chi^*(G_3) = (m + 1)(2n + 1) + 1$.

As to the gap between the chromatic number and the equitable chromatic number, Wang and Zhang [149] proposed the following:

Conjecture 3 For any graph G , $\chi_-(G) - \chi(G) \leq \lfloor \Delta(G)/2 \rfloor$.

The upper bound is sharp in the sense that it can be attained by a star $K_{1,2n+1}$.

3 Trees

A graph is said to be *nontrivial* if it contains at least one edge. There is a natural way to regard a nontrivial tree T as a bipartite graph $T(X, Y)$. The technique used to prove the *ECC* for connected bipartite graphs can be applied to find the equitable chromatic number of a nontrivial tree when the sizes of the two parts differ by at most one. First try to cut the parts into classes of nearly equal size. If there are vertices remaining, then one can manage to find nonadjacent vertices in the opposite part to form a class of the right size. The following was established in Chen and Lih [26].

Theorem 10 Let $T = T(X, Y)$ be a nontrivial tree satisfying $|X| - |Y| \leq 1$. Then $\chi_-(T) = \chi^*(T) = 2$.

When the sizes of the two parts differ by more than one, the determination in [26] for the equitable chromatic number of a tree needs extra notation. For any vertex u of a graph G , an independent set containing u is called a *u-independent set*. Let $\alpha_u(G)$ denote the maximum size of a u -independent set in G .

Now suppose that G is partitioned into $\chi_-(G)$ parts of independent sets. Let v be an arbitrary vertex of G . Then the part containing v has size at most $\alpha_v(G)$, and other parts have size at most $\alpha_v(G) + 1$. It follows that $|G| \leq \alpha_v(G) + (\chi_-(G) - 1)$ ($\alpha_v(G) + 1$) = $\chi_-(G)(\alpha_v(G) + 1) - 1$.

Lemma 1 Let v be an arbitrary vertex of G , then $\chi_-(G) \geq \lceil (|G| + 1) / (\alpha_v(G) + 1) \rceil$.

An induction based on [Theorem 1](#) leads to the following:

Theorem 11 *Let $T = T(X, Y)$ be a tree satisfying $|X| - |Y| > 1$. Then $\chi_-(T) = \chi_-^*(T) = \max\{3, \lceil(|T| + 1)/(\alpha_u(T) + 1)\rceil\}$, where u is an arbitrary vertex of maximum degree in T .*

The following result was proved by Miyata et al. in an unpublished manuscript [116] without using [Theorem 1](#):

Theorem 12 *Let T be a tree and $k \geq 3$ be an integer. Then T is equitably k -colorable if and only if $k \geq \max_{v \in V(T)} \lceil(|T| + 1)/(\alpha_v(T) + 1)\rceil$.*

The inequality in the above theorem can be equivalently described as $\alpha_v(T) \geq \lfloor |T|/k \rfloor$ for any vertex v of T . This can be seen from the following equivalences which hold for any integer k and graph G :

$$\begin{aligned} k \geq \left\lceil \frac{|G| + 1}{\alpha_v(G) + 1} \right\rceil &\Leftrightarrow k \geq \frac{|G| + 1}{\alpha_v(G) + 1} \Leftrightarrow \alpha_v(G) \geq \frac{|G| - k + 1}{k} \Leftrightarrow \alpha_v(G) \\ &\geq \left\lfloor \frac{|G|}{k} \right\rfloor. \end{aligned}$$

Actually, the difference between characterizations in [26] and [116] is only apparent. In view of the following lemma, Chang [22] gave a simplified and unified proof for the more general case of a forest:

Lemma 2 *Let u be a vertex of a forest F . If $\lceil(|F| + 1)/(\alpha_u(F) + 1)\rceil > 3$, then u is the unique vertex of maximum degree in F .*

Theorem 13 *Let F be a forest and $k \geq 3$ be an integer. Then F is equitably k -colorable if and only if $\alpha_v(F) \geq \lfloor |F|/k \rfloor$ for any vertex v of F .*

To determine when a forest F is equitably 2-colorable needs a bit more work than that of a tree. Without loss of generality, suppose that F has r components such that each component tree T_i consists of two parts X_i and Y_i . The objective is to look for a partition of $\{1, 2, \dots, r\}$ into two parts A and B such that $\sum_{i \in A} |X_i| + \sum_{j \in B} |Y_j| = \lfloor |F|/2 \rfloor$.

Hansen et al. [66] introduced the notion of an *m-bounded coloring* of a graph G , i.e., a proper coloring of G such that each color class is of size at most m . The *m-bounded chromatic number* of G , denoted by $\chi_m(G)$, is the smallest number of colors required for an m -bounded coloring of G . This notion of colorability is closely related to equitable colorability via the following observation:

Observation. The graph G has an m -bounded coloring using k colors if and only if the graph G' obtained from G by adding $mk - |G|$ isolated vertices is equitably k -colorable.

The problem of determining the m -bounded chromatic number of a tree was left open in [66]. By modifying the techniques used in [26], Chen and Lih [25] were able to determine the m -bounded chromatic number of a tree.

Theorem 14 Let $T = T(X, Y)$ be a nontrivial tree and let u be a vertex of maximum degree. Then one of the following holds:

1. $\chi_m(T) = 2$ when $m \geq \max\{|X|, |Y|\}$.
2. $\chi_m(T) = \max\{3, \lceil |T|/m \rceil, \lceil (|T| - \alpha_u(T))/m \rceil + 1 \}$ when $m < \max\{|X|, |Y|\}$.

For a nontrivial tree $T = T(X, Y)$, suppose that $|X| = q_1m + r_1$ and $|Y| = q_2m + r_2$, where $0 \leq r_1, r_2 < m$. One can color the part X with $q_1 + 1$ colors and the part Y with $q_2 + 1$ colors. Hence, $\chi_m(T) \leq q_1 + q_2 + 2 \leq \lceil |T|/m \rceil + 1$ colors. On the other hand, it is obvious that $\lceil |T|/m \rceil \leq \chi_m(T)$. A tree T is said to be *class A* if $\chi_m(T) = \lceil |T|/m \rceil$ and *class B* if $\chi_m(T) = \lceil |T|/m \rceil + 1$. Jarvis and Zhou [73] gave an explicit characterization when a tree belongs to class B. Their proof can be used to determine $\chi_m(T)$ in $O(|T|^3)$ time and produce an optimal coloring even if m is part of the input. To make a comparison, it is known [14] that the problem of determining whether a bipartite graph can be m -bounded colored with three colors is NP-complete when m is part of the input. Bentz and Picouleau [10] studied a variation of m -bounded coloring of trees.

4 The Equitable Δ -Coloring Conjecture

Unlike the ordinary colorability of a graph, the equitable colorability does not satisfy monotonicity, namely, a graph can be equitably k -colorable without being equitably $(k + 1)$ -colorable. Therefore, the *ECC* does not fully reveal the true nature of the equitable colorability. It seems that the maximum degree plays a crucial role here. For instance, by Theorems 5 and 6 the following conjecture proposed by Chen et al. [28] holds for bipartite graphs. This conjecture is called the *equitable Δ -coloring conjecture (E Δ CC).*

Conjecture 4 Let G be a connected graph. If G is not a complete graph K_n , or an odd cycle C_{2n+1} , or a complete bipartite graph $K_{2n+1, 2n+1}$, then G is equitably $\Delta(G)$ -colorable.

The conclusion of the E Δ CC can be equivalently stated as $\chi_{=}^*(G) \leq \Delta(G)$. It is also immediate to see that the E Δ CC implies the *ECC*. In Chen, Lih, and Wu [28], E Δ CC was settled for graphs whose maximum degree is at least one-half of the order. The following two lemmas supplied the basic tools for the solution. Let G^c denote the complement graph of G . Let $\delta(G)$ and $\alpha'(G)$ denote the minimum degree and the edge-independence number of G , respectively.

Lemma 3 Let G be a disconnected graph. If G is different from K_n^c and $K_{2n+1,2n+1}^c$ for all $n \geq 1$, then $\alpha'(G) > \delta(G)$.

Lemma 4 Let G be a connected graph such that $|G| > 2\delta(G) + 1$. Suppose the vertex set of G cannot be partitioned into a set H of size $\delta(G)$ and an independent set I of size $|G| - \delta(G)$ such that each vertex of I is adjacent to all vertices of H . Then $\alpha'(G) > \delta(G)$.

Theorem 15 Let G be a connected graph with $\Delta(G) \geq |G|/2$. If G is different from K_n and $K_{2n+1,2n+1}$ for all $n \geq 1$, then G is equitably $\Delta(G)$ -colorable.

As pointed out by Yap, a close examination of the proof of [Theorem 15](#) in [28] reveals that a stronger result was obtained, namely, $\chi_=(G) \leq |G| - \alpha'(G^c) \leq \Delta(G)$. In a similar vein, Yap and Zhang [155] made an analysis of the complement graph and succeeded in verifying the *ECC* for connected graphs G such that $|G|/3 + 1 \leq \Delta(G) < |G|/2$. By combining [Theorem 15](#), their proof can be modified to establish the following stronger result:

Theorem 16 The *EΔCC* holds for all connected graphs G such that $\Delta(G) \geq (|G| + 1)/3$.

Along a different direction, one may try to tackle the *EΔCC* for special classes of graphs. By attaching appropriately chosen auxiliary graphs to a nonregular graph, attention may be restricted to regular graphs due to the following lemma [28]:

Lemma 5 The *EΔCC* holds if it does so for all regular graphs.

If the chromatic number of a connected cubic graph G is 2, then the *EΔCC* has already been established. It only needs to handle cubic graphs having chromatic number 3 to obtain the following [28]:

Theorem 17 The *EΔCC* holds for all connected graphs G such that $\Delta(G) \leq 3$.

In [85], Kierstead and Kostochka extended the above to $\Delta(G) \leq 4$.

5 Split Graphs

There are interesting results dealing with special families of graphs that provide positive evidence for the *EΔCC*. A connected graph G is called a *split* graph if its vertex set can be partitioned into two nonempty subsets $U = \{u_1, u_2, \dots, u_n\}$ and $V = \{v_1, v_2, \dots, v_r\}$ such that U induces a complete graph and V induces an independent set. Denote the split graph G as $G[U; V]$, and always assume that no vertex in V is adjacent to all vertices in U . A family of bipartite graphs $BG(k)$, $k \geq 1$, can be assigned to the given split graph $G[U; V]$ in the following way.

The vertex set of $BG(k)$ is $\{u_{ij} \mid 1 \leq i \leq n \text{ and } 1 \leq j \leq k\} \cup V$, and $\{u_{ij}, v_t\}$ is defined to be an edge of $BG(k)$ if and only if u_i and v_t are nonadjacent in G . Note that $BG(k)$ is a subgraph of $BG(k+1)$. The coloring of a split graph $G[U; V]$ is closely related to independent edges of the graphs $BG(k)$. For instance, any given set of independent edges in $BG(k)$ induces a partial coloring of G in the following standard way. The i -th color is used to color u_i and all those vertices in V that are matched by the edges to some u_{ij} , $1 \leq j \leq k$. Chen, Ko, and Lih [29] proved the following:

Theorem 18 *Let $G[U; V]$ be a split graph such that $|U| = n$ and $|V| = r$. Let $m = \max\{k \mid \alpha'(BG(k)) = kn\}$ if the set in question is nonempty; otherwise let m be zero. Then $\chi^*(G[U; V]) = n + \lceil(r - \alpha'(BG(m+1)))/(m+2)\rceil$.*

Once $\chi^*(G[U; V])$ is known, it is straightforward to verify that split graphs satisfy the $E\Delta CC$.

In [29], the m -bounded chromatic number of a split graph was obtained in addition to its equitable chromatic number.

Theorem 19 *Let $G = G[U; V]$ be a split graph such that $|U| = n$ and $|V| = r$. Let $m \geq 1$ be a given integer. Then $\chi_m(G[U; V]) = n + \lceil(r - \alpha'(BG(m-1)))/m\rceil$.*

6 Outerplanar Graphs

A graph is *planar* if it can be drawn on the Euclidean plane such that edges only meet each other at points representing the vertices of the graph. An *outerplanar* graph is a planar graph that has a drawing on the plane such that every vertex lies on the unbounded face. An *edge subdivision* is the operation of replacing an edge uv by a path uvw of length 2 in which w is a newly added vertex. A *subdivision* of a graph G is a graph obtained from G by a sequence of edge subdivisions. It is well known [18] that a graph is an outerplanar graph if and only if it has no subgraph that is a subdivision of K_4 or $K_{2,3}$. Yap and Zhang [156] settled the $E\Delta CC$ for outerplanar graphs.

Theorem 20 *If G is an outerplanar graph with $\Delta(G) \geq 3$, then G is equitably $\Delta(G)$ -colorable.*

Kostochka [91] proved the following result which answers a question posed at the end of [156]:

Theorem 21 *If G is an outerplanar graph with $\Delta(G) \geq 3$, then $\chi^*(G) \leq \Delta(G)/2 + 1$.*

Note that the bound cannot be weakened even for trees because the star $K_{1,2k-1}$ has no equitable k -coloring. An efficient algorithm for equitable k -coloring of

outerplanar graphs G with maximum degree at least 3 can be extracted from Kostochka's proof whenever $k \geq \Delta(G)/2 + 1$.

A fundamental phenomenon in equitable colorings can be noticed when one examines the equitable chromatic numbers of trees. Apart from $K_{1,n}$, "most" trees admit equitable colorings with few colors. This phenomenon happens for outerplanar graphs, too. Pemmaraju [125] showed the following:

Theorem 22 *An outerplanar graph G is equitably 6-colorable if $\Delta(G) \leq |G|/6$.*

The main stepping stone to Pemmaraju's result involves a special partition of a graph. A partition $V(G) = V_1 \cup V_2$ is called an *equitable 2-forest partition* if $||V_1| - |V_2|| \leq 1$ and each induced subgraph $G[V_i]$ is a forest. The following theorem and conjecture in [125] may have independent interest:

Theorem 23 *Any outerplanar graph has an equitable 2-forest partition.*

Conjecture 5 *The vertex set of any planar graph can be partitioned into two parts V_1 and V_2 such that $||V_1| - |V_2|| \leq 1$ and each part induces an outerplanar subgraph.*

Note that Chartrand et al. [23] have proved that the vertex set of a planar graph can be partitioned into two parts such that each part induces an outerplanar subgraph. They also conjectured that the edge set of a planar graph can be partitioned into two sets such that the subgraph induced by each of the sets is outerplanar. Recently, Gonçalves [60] has proved the validity of this conjecture.

A graph is called *series-parallel* if it contains no subgraph that is a subdivision of K_4 . This class of graphs can be characterized in a number of equivalent ways [18]. Clearly, outerplanar graphs are series-parallel graphs. Zhang and Wu [159] established the $E\Delta CC$ for series-parallel graphs.

Theorem 24 *If G is a series-parallel graph with $\Delta(G) \geq 3$, then G is equitably $\Delta(G)$ -colorable.*

Zhang and Wu also conjectured the following which generalizes Theorem 21:

Conjecture 6 *If G is a series-parallel graph with $\Delta(G) \geq 3$, then $\chi^*(G) \leq \Delta(G)/2 + 1$.*

7 Planar Graphs

To determine whether a planar graph with maximum degree 4 is 3-colorable is NP-complete [58]. For a given planar graph G with maximum degree 4, let G' be obtained from G by adding $2|G|$ isolated vertices. Then G is 3-colorable if and only if G' is equitably 3-colorable. Therefore, it is NP-complete to determine if a given

planar graph with maximum vertex degree 4 has an equitable coloring using at most 3 colors.

Zhang and Yap [160] proved the following:

Theorem 25 *A planar graph G is equitably $\Delta(G)$ -colorable if $\Delta(G) \geq 13$.*

Nakprasit [117] extended the above result to planar graphs with maximum degree at least 9. Thus, the $E\Delta CC$ holds for planar graphs with maximum degree at least 9. One can go further if extra conditions are imposed on the graph.

Theorem 26 ([118, 137]) *Let G be a C_4 -free planar graph. If $\Delta(G) \geq 7$, then the $E\Delta CC$ holds for G .*

Zhu and Bu [162] established the following results. Consequently, the $E\Delta CC$ holds for planar graphs G that are (i) C_3 -free and $\Delta(G) \geq 8$ or (ii) C_4 -free, C_5 -free, and $\Delta(G) \geq 7$.

Theorem 27 *Let G be a C_3 -free planar graph. Then $\chi^*(G) \leq \max\{\Delta(G), 8\}$.*

Theorem 28 *Let G be a C_4 -free and C_5 -free planar graph. Then $\chi^*(G) \leq \max\{\Delta(G), 7\}$.*

The *girth* of a graph G , denoted by $g(G)$, is defined to be the length of a shortest cycle in G . The girth of a forest is ∞ by convention. One may impose conditions on the girth of a planar graph to get tight bound for the equitable chromatic threshold. Wu and Wang [153] first established the following:

Theorem 29 *Let G be a planar graph with $\delta(G) \geq 2$.*

1. *If $g(G) \geq 14$, then $\chi^*(G) \leq 4$.*
2. *If $g(G) \geq 26$, then $\chi^*(G) \leq 3$.*

Luo et al. [108] improved these results further.

Theorem 30 *Let G be a planar graph with $\delta(G) \geq 2$.*

1. *If $g(G) \geq 10$, then $\chi^*(G) \leq 4$.*
2. *If $g(G) \geq 14$, then $\chi^*(G) \leq 3$.*

It remains an open problem to find the best possible girth conditions for 3- or 4-equitable colorability when the planar graph G satisfies $\delta(G) \geq 2$.

A well-known theorem of Grötzsch [61] states that the chromatic number of any planar graph of girth at least 4 is at most 3. Hence, the above theorem has an immediate consequence.

Corollary 1 *Let G be a non-bipartite planar graph with $\delta(G) \geq 2$. Then $\chi(G) = \chi^*(G)$ if $g(G) \geq 14$.*

8 Graphs with Low Degeneracy

A graph with small degeneracy can be regarded as “sparse.” A graph G is said to be d -degenerate if every subgraph H of G has a vertex of degree at most d in H . It is well known that graphs without edges are 0-degenerate, forests are exactly the 1-degenerate graphs, outerplanar graphs are 2-degenerate, and planar graphs are 5-degenerate. It follows from the definition that the vertices of every d -degenerate graph can be ordered as v_1, v_2, \dots, v_n so that for every $i < n$, vertex v_i has at most d neighbors v_j with $j > i$.

The following results were obtained by Zhu and Bu [163]:

Theorem 31 *Let G be a 2-degenerate graph. Then G is equitably 3-colorable if $\|G\| \leq \frac{2}{3}|G|$.*

Theorem 32 *Let G be a 2-degenerate graph. Then G is equitably 4-colorable if $\|G\| \leq \frac{3}{4}|G|$.*

Kostochka and Nakprasit [92] tried to find bounds on the equitable chromatic thresholds for d -degenerate graphs with a given maximum degree. However, the bound in [Theorem 21](#) on outerplanar graphs does not extend to all 2-degenerate graphs. To see this, consider the graph $G(d, \Delta) = K_d \vee I_{\Delta-d+1}$, where the join operation \vee connects each vertex in one graph to all vertices of the other graph. This graph is d -degenerate and of maximum degree Δ . In every proper coloring of $G(d, \Delta)$, each vertex in K_d forms a single color class. Hence, every equitable coloring of $G(d, \Delta)$ uses at least $d + \lceil(\Delta - d + 1)/2\rceil = \lceil(\Delta + d + 1)/2\rceil$ colors. In particular, $G(2, \Delta)$ uses at least $\lceil(\Delta + 3)/2\rceil$ colors for an equitable coloring, which is greater than $\lceil\Delta/2\rceil + 1$ for even Δ . Kostochka and Nakprasit showed that $\lceil(\Delta + d + 1)/2\rceil$ colors is enough to equitably color a d -degenerate graph G with maximum degree Δ provided Δ/d is large.

Theorem 33 *Let $2 \leq d \leq \Delta/27$ and G be a d -degenerate graph with maximum degree at most Δ . Then G is equitably k -colorable if $k \geq (\Delta + d + 1)/2$.*

The example $G(d, \Delta)$ shows that the bound on k cannot be decreased. The next corollary follows from this theorem since every planar graph is 5-degenerate.

Corollary 2 *Let $\Delta \geq 135$ and the maximum degree of the planar graph G be at most Δ . Then G is equitably k -colorable if $k \geq \Delta/2 + 3$.*

Let $k \geq 14d + 1$ and the d -degenerate graph G have maximum degree at most k . Then, for $\Delta = 2k - 1 - d$, G satisfies the condition of [Theorem 33](#).

Corollary 3 *Let $d \geq 2$. Then every d -degenerate graph with maximum degree at most k is equitably k -colorable if $k \geq 14d + 1$.*

In view of [Theorem 33](#), which is also true if $d = \Delta$ by the Hajnal and Szemerédi Theorem, the following was proposed in [92]:

Conjecture 7 *Let $2 \leq d \leq \Delta$ and G be a d -degenerate graph with maximum degree at most Δ . Then G is equitably k -colorable if $k \geq (\Delta + d + 1)/2$.*

A graph with “low degeneracy” is intuitively rather similar to a graph whose every subgraph has a “small average degree.” Kostochka and Nakprasit [93] proved the $E\Delta CC$ for graphs that have “small average degree” without restrictions on their subgraphs. The *average degree* of a graph G is defined to be $Ad(G) = 2\|G\|/|G|$.

Theorem 34 *Let $\Delta \geq 46$ and G be a graph of order at least 46 and maximum degree at most Δ . If $Ad(G) \leq \Delta/5$ and $K_{\Delta+1}$ is not a subgraph of G , then G is equitably Δ -colorable.*

An immediate consequence of this result is that the $E\Delta CC$ holds for d -degenerate graphs with maximum degree Δ if $d \leq \Delta/10$.

In Kostochka et al. [95], a result similar to [Theorem 22](#) was established for d -degenerate graphs.

Theorem 35 *Every d -degenerate graph G with maximum degree at most Δ is equitably k -colorable when $k \geq 16d$ and $\Delta \leq |G|/15$.*

If the restriction on Δ is removed, they proved the following:

Theorem 36 *Every d -degenerate graph G with maximum degree at most Δ is equitably k -colorable for any k , $k \geq \max\{62d, 31d|G|/(|G| - \Delta + 1)\}$.*

Corollary 4 *Every d -degenerate graph G with maximum degree at most $|G|/2 + 1$ is equitably k -colorable for any $k \geq 62d$.*

The proof of [Theorem 36](#) is constructive, and by extending their proof method, the following result of algorithmic nature was obtained:

Theorem 37 *There exists a polynomial time algorithm that produces an equitable k -coloring of G for every equitably m -colorable d -degenerate graph G if $k \geq 31dm$.*

A concept generalizing Pemmaraju’s “equitable 2-forest partition” was also introduced in [95]. An *equitable k -partition* of a graph G is a collection of subgraphs $\{G[V_1], G[V_2], \dots, G[V_k]\}$ of G induced by the vertex partition $\{V_1, V_2, \dots, V_k\}$ of $V(G)$ such that $||V_i| - |V_j|| \leq 1$ for every pair V_i and V_j . The following provides a tool for obtaining equitable colorings with few colors:

Theorem 38 Let $k \geq 3$ and $d \geq 2$. Then every d -degenerate graph has an equitable k -partition into $(d - 1)$ -degenerate graphs.

This is an extension of [Theorem 1](#) proved by Bollobás and Guy, which can be restated as follows: Any 1-degenerate graph G with $\Delta(G) \leq |G|/3$ can be equitably 3-partitioned into 0-degenerate graphs. Pemmaraju et al. [126] gave a direct generalization.

Theorem 39 For $d \geq 1$, every d -degenerate graph G with $\Delta(G) \leq |G|/3$ can be equitably 3-partitioned into $(d - 1)$ -degenerate graphs.

Repeated applications of this theorem can get the following:

Theorem 40 For $d \geq 1$, every d -degenerate graph G with $\Delta(G) \leq |G|/3^d$ can be equitably 3^d -colored.

In the same paper, the following conjecture was proposed:

Conjecture 8 There are functions $f(d) = O(d)$ and $g(d) = O(d)$ such that if G is a d -degenerate graph with $\Delta(G) \leq |G|/f(d)$, then G can be equitably $g(d)$ -colored.

9 Graphs of Bounded Treewidth

A *tree decomposition* of a graph G is a pair (T, \mathcal{F}) , with T a tree and $\mathcal{F} = \{X_i \subseteq V(G) \mid i \in V(T)\}$, that satisfies the following conditions:

1. $\bigcup_{i \in V(T)} X_i = V(G)$.
2. For every edge uv of G , there exists an $i \in V(T)$ such that X_i contains both u and v .
3. For all $i_1, i_2, i_3 \in V(T)$, $X_{i_1} \cap X_{i_3} \subseteq X_{i_2}$ if i_2 is on the path from i_1 to i_3 in T .

The *width* of the tree decomposition (T, \mathcal{F}) is defined to be $\max_{i \in V(T)} |X_i| - 1$; the *treewidth* of a graph G denoted by $\text{tw}(G)$ is the minimum width among all tree decompositions of G . It is a folklore result that every graph G of treewidth at most k has a vertex of degree at most k and has at most $k|G|$ edges. Hence, every graph of treewidth at most k is k -degenerate.

The class of graphs with treewidth at most k can be characterized in terms of partial k -trees. The class of k -trees is defined recursively as follows:

1. The complete graph K_k is a k -tree.
2. A k -tree G with $n + 1$ vertices ($n \geq k$) is constructed from a k -tree H with n vertices by adding a new vertex adjacent to and only to all vertices of a subgraph of H that is a K_k .

There are a number of alternative characterizations of k -trees [129]. A graph is called a *partial k -tree* if it is a subgraph of a k -tree. Forests are partial 1-trees and series-parallel graphs are partial 2-trees.

Theorem 41 ([139]) *A graph G is a partial k -tree if and only if G has treewidth at most k .*

A corollary of [Theorem 36](#) is the following:

Corollary 5 *Every graph G with treewidth w and maximum degree at most Δ is equitably k -colorable for any k , $k \geq \max\{62w, 31w|G|/(|G| - \Delta + 1)\}$.*

The equitable k -coloring problem can be stated as follows. A graph G and an integer k are given, and one asks whether G has an equitable k -coloring. For graphs of bounded treewidth, Bodlaender and Fomin [13] used the above result to establish the threshold for telling when the EQUITABLE k -COLORING problem is trivially solved and when it becomes to be solvable in polynomial time by their dynamic programming approach. It amounts to the following.

Theorem 42 *The equitable k -coloring problem can be solved in polynomial time on graphs of bounded treewidth.*

They also showed that such an approach cannot be extended to the equitable k -coloring with precoloring problem: A graph G , an integer k , and a precoloring π of G are given, and one asks whether there exists an equitable k -coloring of G extending π . For a graph G , a *precoloring* π of a subset U of vertices of G in k colors is a mapping $\pi : U \rightarrow \{1, 2, \dots, k\}$. A coloring of G with color classes V_1, V_2, \dots, V_k is said to extend the precoloring π if $u \in V_{\pi(u)}$ for every $u \in U$. The following was proved in [13]:

Theorem 43 *The equitable k -coloring with precoloring problem is NP-complete on trees.*

In the framework of parameterized complexity, e.g., [41, 51], and [119], a parameterized problem with the input size n and a parameter k is called *fixed parameter tractable* (FPT) if it can be solved in time $f(k) \cdot n^c$, where f is a function only depending on k and c is a constant. The basic complexity class for fixed parameter intractability is $\mathcal{W}[1]$. The equitable coloring problem was shown by Fellow et al. [47] to be $\mathcal{W}[1]$ -hard, parameterized by the treewidth plus the number of colors. However, the equitable coloring problem is FPT when parameterized by the vertex cover number as shown by Fiala et al. [48]. The vertex cover number of a graph G is the minimum size of a set $X \subseteq V(G)$ such that $V(G) \setminus X$ is an independent set.

10 Kneser Graphs

For integers $i \leq j$, let $[i, j] = \{i, i+1, \dots, j\}$ and $[n] = [1, n]$. If X is a set, then the collection of all k -subsets of X is denoted by $\binom{X}{k}$. The *Kneser graph* $\text{KG}(n, k)$ has $\binom{[n]}{k}$ as its vertex set. Two distinct vertices are adjacent in $\text{KG}(n, k)$ if they

have empty intersection as subsets. To exclude trivialities, it is always assumed that $n > 2k$ in $\text{KG}(n, k)$. The order of $\text{KG}(n, k)$ is clearly $\binom{n}{k}$. The *odd graph* O_k is the Kneser graph $\text{KG}(2k+1, k)$. Since it is easy to see that $\text{KG}(n, 1) = K_n$ and $\chi(\text{KG}(n, 1)) = \chi_-(\text{KG}(n, 1)) = \chi_-^*(\text{KG}(n, 1)) = n$, it is assumed that $k \geq 2$ throughout this section.

The following is a much celebrated result of Lovász [107] proved by topological method:

Theorem 44 *The chromatic number of $\text{KG}(n, k)$ is equal to $n - 2k + 2$.*

For $i \in [n]$, an i -flower \mathcal{F} of $\binom{[n]}{k}$ is a subcollection of $\binom{[n]}{k}$ such that all k -subsets in \mathcal{F} have i as a common element. It is clear that every i -flower is an independent set of $\text{KG}(n, k)$. Any independent set \mathcal{F} of $\text{KG}(n, k)$, also called an *intersecting family* of $\binom{[n]}{k}$, satisfies $A \cap B \neq \emptyset$ for all A and B in \mathcal{F} . The independence number $\alpha(\text{KG}(n, k))$ of $\text{KG}(n, k)$ was obtained by Erdős et al. [44].

Theorem 45 *Suppose \mathcal{F} is an intersecting family of $\binom{[n]}{k}$. Then*

$$|\mathcal{F}| \leq \binom{n-1}{k-1}.$$

Moreover, the equality holds if and only if \mathcal{F} is an i -flower for some $i \in [n]$. Hence, $\alpha(\text{KG}(n, k)) = \binom{n-1}{k-1}$.

There are independent sets of $\text{KG}(n, k)$ which are not flowers. Denote by $\alpha_2(\text{KG}(n, k))$, or simply $\alpha_2(n, k)$, the maximum size of independent sets \mathcal{H} of $\text{KG}(n, k)$ satisfying $\bigcap_{A \in \mathcal{H}} A = \emptyset$ and $\alpha_2(n, k)$ was obtained by Hilton and Milner [69].

Theorem 46 *Suppose \mathcal{H} is an intersecting family of $\binom{[n]}{k}$ with $\bigcap_{A \in \mathcal{H}} A = \emptyset$. Then*

$$|\mathcal{H}| \leq \binom{n-1}{k-1} - \binom{n-k-1}{k-1} + 1.$$

Moreover, the equality holds if \mathcal{H} is the family $\{A \in \binom{[n]}{3} \mid |A \cap [1, 3]| \geq 2\}$ when $k=3$ or \mathcal{H} is the family $\{A \in \binom{[n]}{k} \mid 1 \in A, |A \cap [2, k+1]| \geq 1\} \cup \{[2, k+1]\}$. Hence, $\alpha_2(n, k) = \binom{n-1}{k-1} - \binom{n-k-1}{k-1} + 1$.

Since every flower of $\binom{[n]}{k}$ is an independent set of $\text{KG}(n, k)$, it is natural to partition flowers to form an equitable coloring of $\text{KG}(n, k)$. If this is successful, then every k -subset of $[n]$ is in some flower. Hence, if f is an equitable m -coloring of $\text{KG}(n, k)$ such that every color class of f is contained in some flower, then $m \geq n - k + 1$. Otherwise, suppose $m \leq n - k$ and each color class $f^{-1}(i)$ is contained in some t_i -flower for $1 \leq i \leq m$. Since $|[n] \setminus \{t_1, t_2, \dots, t_m\}| \geq n - m \geq k$, one may

choose a k -subset $A \subseteq [n] \setminus \{t_1, t_2, \dots, t_m\}$. Since f is an equitable m -coloring, $A \in f^{-1}(i)$ for some i , i.e., $t_i \in A$. Thus, a contradiction is obtained.

In [24], Chen and Huang tried to show that $\text{KG}(n, k)$ is equitably m -colorable for all $m \geq n - k + 1$ by partitioning flowers of $\binom{[n]}{k}$ into m -independent sets whose sizes are as even as possible. They succeeded in establishing the following:

Theorem 47 Suppose that $m \geq n - k + 1$. Then $\text{KG}(n, k)$ is equitably m -colorable, i.e., $\chi_{=}(\text{KG}(n, k)) \leq \chi_{=}^*(\text{KG}(n, k)) \leq n - k + 1$.

Lemma 6 Suppose that $m \leq n - k$ and $\lfloor \binom{n}{k}/m \rfloor > \alpha_2(n, k)$. Then $\text{KG}(n, k)$ is not equitably r -colorable for all $r \leq m$, i.e., $\chi_{=}^*(\text{KG}(n, k)) \geq \chi_{=}(\text{KG}(n, k)) \geq m + 1$.

Theorem 48 If $\lfloor \binom{n}{k}/(n - k) \rfloor > \alpha_2(n, k)$, then $\chi_{=}(\text{KG}(n, k)) = \chi_{=}^*(\text{KG}(n, k)) = n - k + 1$.

Observe that $\binom{n}{k}/(n - k) = O(n^{k-1})$ and $\alpha_2(n, k) = O(n^{k-2})$. Hence, the following is true.

Corollary 6 Let k be fixed. Then $\chi_{=}(\text{KG}(n, k)) = \chi_{=}^*(\text{KG}(n, k)) = n - k + 1$ when n is sufficiently large.

Finally, $\chi_{=}(\text{KG}(n, 2))$, $\chi_{=}(\text{KG}(n, 3))$, and $\chi(O_k)$ were completely determined in [24].

Theorem 49 Assume $n \geq 5$. Then

$$\chi_{=}(\text{KG}(n, 2)) = \chi_{=}^*(\text{KG}(n, 2)) = \begin{cases} n - 2 & \text{if } n = 5 \text{ or } 6, \\ n - 1 & \text{if } n \geq 7. \end{cases}$$

Theorem 50 Assume $n \geq 7$. Then

$$\chi_{=}(\text{KG}(n, 3)) = \chi_{=}^*(\text{KG}(n, 3)) = \begin{cases} n - 4 & \text{if } 7 \leq n \leq 13, \\ n - 3 & \text{if } 14 \leq n \leq 15, \\ n - 2 & \text{if } n \geq 16. \end{cases}$$

Theorem 51 For $k \geq 1$, the odd graph O_k satisfies $\chi(O_k) = \chi_{=}(\text{KG}(n, k)) = \chi_{=}^*(\text{KG}(n, k)) = 3$.

Chen and Huang concluded their paper [24] by proposing the following:

Conjecture 9 If $n > 2k \geq 4$, then $\chi_{=}(\text{KG}(n, k)) = \chi_{=}^*(\text{KG}(n, k))$.

All results about Kneser graphs in this section were also independently obtained by Fidytek et al. [49].

11 Interval Graphs and Others

A graph G is called an *interval* graph if there exists a family $\mathcal{I} = \{I_v \mid v \in V(G)\}$ of intervals on the real line such that u and v are adjacent vertices if and only if $I_u \cap I_v \neq \emptyset$. Such a family \mathcal{I} is commonly referred to as an *interval representation* of G . Instead of intervals of real numbers, these intervals may be replaced by finite intervals on a linearly ordered set.

A *clique* of a graph G is a complete subgraph Q of G . A clique is called *maximal* if it is maximal in the set-inclusion order. For an interval graph G , Gillmore and Hoffman [59] showed that its maximal cliques can be linearly ordered as $Q_0 < Q_1 < \dots < Q_m$ so that for every vertex v of G , the maximal cliques containing v occur consecutively. The finite interval $I_v = [Q_i, Q_j]$ in this linear order is assigned to the vertex v if all the maximal cliques containing v are precisely Q_i, Q_{i+1}, \dots, Q_j . Again u and v are adjacent if and only if $I_u \cap I_v \neq \emptyset$. This representation of G is called a *clique path* representation of G . Conversely, the existence of a clique path representation implies that the graph is an interval graph.

Once a clique path representation is given, let $\text{left}(v)$ and $\text{right}(v)$ stand for the left and right endpoint, respectively, of the interval I_v . Then the following linear order on the vertices of G can be defined. Let $u < v$ if ($\text{left}(u) < \text{left}(v)$) or ($\text{left}(u) = \text{left}(v)$ and $\text{right}(u) < \text{right}(v)$). If u and v have the same left and right endpoints, choose $u < v$ arbitrarily. For any three vertices u , v , and w of G , this linear order satisfies the following condition. If $u < v < w$ and $uw \in E(G)$, then $uv \in E(G)$. The existence of a linear order satisfying this condition characterizes interval graphs [120]. Chen et al. [31] utilized this linear order to obtain the following:

Theorem 52 *Let G be a connected interval graph. If G is not a complete graph, then G is equitably $\Delta(G)$ -colorable.*

And they proceeded further to show the following:

Theorem 53 *Let G be an interval graph. Then $\chi_=(G) = \chi^*_=(G)$.*

A few other classes of special graphs have been investigated for their equitable colorability. For instance, central graphs and total graphs were studied in [2, 140]. Thorny graphs were studied in [56]. Additional examples can be found in [57, 76–78].

For a given graph G , the so-called *central graph* $C(G)$ of G is obtained from G by inserting a new vertex to each edge of G and then joining each pair of vertices of G which were nonadjacent in G . The total graph $T(G)$ of G has vertex set $V(G) \cup E(G)$ and edges joining all elements of this vertex set which are adjacent or incident in G . The notation P_n represents a path on n vertices.

Results obtained in [2, 140] are listed as follows:

1. $\chi_=(C(K_{1,n})) = n$.
2. $\chi_=(C(K_{n,n})) \geq n$ if $n \geq 3$.
3. $\chi_=(C(K_n)) = 3$.

$$4. \chi_=(C(P_n)) = \begin{cases} 1 & \text{if } n = 1, \\ 2 & \text{if } n = 2, \\ 3 & \text{if } n = 3, \\ 3 & \text{if } n = 4, \\ n/2 & \text{if } n \geq 5 \text{ is even,} \\ (n+1)/2 & \text{if } n \geq 5 \text{ is odd.} \end{cases}$$

$$5. \chi_=(C(C_n)) = \begin{cases} 2 & \text{if } n = 3, \\ 3 & \text{if } n = 4, \\ n/2 & \text{if } n \geq 5 \text{ is even,} \\ (n+1)/2 & \text{if } n \geq 5 \text{ is odd.} \end{cases}$$

$$6. \chi_=(T(K_{m,n})) = \begin{cases} n+1 & \text{if } m < n, \\ n+2 & \text{if } m = n, \end{cases}$$

$$7. \chi_=(T(P_n)) = 3.$$

$$8. \chi_=(T(C_n)) = 3 \text{ if } n \text{ is a multiple of 3.}$$

An edge in a graph is called an *pendant edge* if it is incident with a *leaf*, i.e., a vertex of degree 1. Trees are the smallest set of graphs that contains single vertex and is closed under the operation of attaching a pendant edge to a vertex. By analogy to this recursive definition of trees, graphs called edge-cacti, cacti, and thorny graphs can be defined as follows.

Edge-cacti constitute the smallest set of graphs that includes all cycles and is closed under the operation of attaching a cycle to a single edge, i.e., identifying this edge with some edge of the attached cycle. *Cacti* constitute the smallest set of graphs that contains single vertex and is closed under the operation of attaching a pendant edge or cycle to a vertex. *Thorny graphs* constitute the smallest set of graphs that includes single vertex and is closed under the following operations:

1. Attaching a pendant edge to a vertex
2. Attaching a cycle to a vertex
3. Attaching a cycle to an edge

Every thorny graph is connected, planar, and tripartite. All cacti, edge-cacti, and connected outerplanar graphs are thorny graphs. The following results were established in [56]:

Theorem 54 Any thorny graph without leaves and C_3 or C_5 is equitably 3-colorable.

Theorem 55 Any thorny graph without leaves and C_3 is equitably k -colorable for all $k \geq 4$.

Corollary 7 The following statements are true:

1. Any edge-cactus without C_3 is equitably k -colorable for all $k \geq 3$. Furthermore, if an edge-cactus G is bipartite, then $\chi_=(G) = 2$.
2. Any cactus without leaves and C_3 or C_5 is equitably k -colorable for all $k \geq 3$.
3. Any bipartite cactus without leaves is equitably k -colorable for all $k \geq 3$.
4. Any cactus without leaves and C_3 is equitably k -colorable for all $k \geq 4$.

12 Random Graphs

Let $G(n, p)$ denote the probability space of all labeled graphs of order n such that every edge appears randomly and independently with probability $p = p(n)$. The space $G(n, p)$ is said to possess a property \mathcal{P} *almost surely* if the probability that $G(n, p)$ satisfies \mathcal{P} tends to 1 as n tends to infinity. In [98], Krivelevich and Patkó conjectured the following:

Conjecture 10 *There exists a constant C such that if $C/n < p < 0.99$, then almost surely $\chi_-(G(n, p)) = (1 + o(1))\chi(G(n, p))$ holds.*

Partial results proved by them included the following:

1. If $n^{-1/5+\epsilon} < p < 0.99$ for some positive ϵ , then almost surely $\chi_-(G(n, p)) \leq (1 + o(1))\chi(G(n, p))$ holds.
2. There exists a constant C such that if $C/n < p < 0.99$, then almost surely $\chi_-(G(n, p)) \leq (2 + o(1))\chi(G(n, p))$ holds.
3. If $n^{-(1-\epsilon)} < p < 0.99$ for some positive ϵ , then almost surely $\chi_-(G(n, p)) \leq (2 + o(1))\chi(G(n, p))$ holds.
4. If $(\log^{1+\epsilon} n)/n < p < 0.99$ for some positive ϵ , then almost surely $\chi_-(G(n, p)) = O_\epsilon(\chi(G(n, p)))$ holds.

13 Graph Products

Given two graphs G_1 and G_2 , it is natural to use the Cartesian product $V(G_1) \times V(G_2)$ of the two vertex sets to be the vertex set of a new graph. There are several ways to define the edge set of such a product graph. Results on three different products will be surveyed. Their edge sets are defined as follows:

1. The *square* product $G_1 \square G_2$, also known as the Cartesian product:

$$E(G_1 \square G_2) = \{(u, x)(v, y) \mid (u = v \text{ and } xy \in E(G_2)) \text{ or } (x = y \text{ and } uv \in E(G_1))\}.$$
2. The *cross* product $G_1 \times G_2$, also known as the Kronecker, direct, tensor, weak tensor, or categorical product:

$$E(G_1 \times G_2) = \{(u, x)(v, y) \mid uv \in E(G_1) \text{ and } xy \in E(G_2)\}.$$
3. The *strong* product $G_1 \boxtimes G_2$, also known as the strong tensor product:

$$E(G_1 \boxtimes G_2) = \{(u, x)(v, y) \mid (u = v \text{ and } xy \in E(G_2)) \text{ or } (uv \in E(G_1) \text{ and } x = y) \text{ or } (uv \in E(G_1) \text{ and } xy \in E(G_2))\}.$$

Note that square and cross products are so named because the products of two single edges are a square and a cross, respectively, and $G_1 \boxtimes G_2 = (G_1 \square G_2) \cup (G_1 \times G_2)$.

13.1 Square Product

For the ordinary chromatic number, Sabidussi [130] proved a product theorem.

Theorem 56 For graphs G_1 and G_2 , $\chi(G_1 \square G_2) = \max\{\chi(G_1), \chi(G_2)\}$.

In Chen et al. [31], the following results were obtained:

Theorem 57 If G_1 and G_2 are equitably k -colorable, so is $G_1 \square G_2$.

Corollary 8 For graphs G_1 and G_2 , $\chi_{=}^*(G_1 \square G_2) \leq \max\{\chi_{=}^*(G_1), \chi_{=}^*(G_2)\}$.

Corollary 9 If $\chi(G_1) = \chi_{=}^*(G_1)$ and $\chi(G_2) = \chi_{=}^*(G_2)$, then $\chi(G_1 \square G_2) = \chi_{=}^*(G_1 \square G_2) = \max\{\chi(G_1), \chi(G_2)\}$.

Corollary 10 Let $G = G_1 \square G_2 \square \cdots \square G_n$, where each G_i is a path, a cycle, or a complete graph. Then $\chi(G) = \chi_{=}^*(G) = \max\{\chi(G_i) \mid 1 \leq i \leq n\}$.

Corollary 11 Suppose that G_1 and G_2 are nontrivial graphs. Then $G_1 \square G_2$ is equitably $\Delta(G_1 \square G_2)$ -colorable, i.e., the EΔCC holds for the square product of two graphs.

Even if $\chi(G_1) = \chi_{=}^*(G_1) = k$, the product $G_1 \square G_2$ may not be equitably k -colorable. An example is the product $K_{1,5} \square P_3$. If it is assumed that $\chi_{=}^*(G_1) = \chi_{=}^*(G_2) = k$, it may not lead to the conclusion $\chi_{=}^*(G_1 \square G_2) = k$. An example is $K_{1,2n} \square K_{1,2n}$. If $G_1 = K_{3,3}$ and $G_2 = K_{1,1,2}$, then $\chi_{=}^*(G_1 \square G_2) \leq \max\{\chi_{=}^*(G_1), \chi_{=}^*(G_2)\}$ is false.

Exact values for paths, cycles, and complete graphs are also determined in [31].

Theorem 58 The following hold for positive integers m and n :

$$\chi(P_m \square P_n) = \chi_{=}^*(P_m \square P_n) = \chi_{=}^*(P_m \square P_n) = 2.$$

$$\chi(C_m \square C_n) = \chi_{=}^*(C_m \square C_n) = \begin{cases} 2 & \text{if } m \text{ and } n \text{ are even,} \\ 3 & \text{otherwise.} \end{cases}$$

$$\chi(K_m \square K_n) = \chi_{=}^*(K_m \square K_n) = \chi_{=}^*(K_m \square K_n) = \max\{m, n\}.$$

Furmańczyk [54] also obtained a number of exact values of square products between cycles, paths, and hypercubes $Q_n = \underbrace{K_2 \square K_2 \cdots \square K_2}_n$.

Theorem 59 Let k, m, n , and r be positive integers. Then the following graphs have their equitable chromatic numbers all equal 2: $Q_r \square P_{2n}$, $Q_r \square C_{2n}$, and $Q_r \square Q_r$.

Besides $\chi_{=}^*(K_{m_1,n_1} \square K_{m_2,n_2}) \leq 4$, Lin in his Ph.D. dissertation [103] (also in [105]) determined more exact values. They are listed as follows, in which m, n , and r are assumed to be positive integers.

1. $\chi_{=}^*(P_{2r} \square K_{m,n}) = \chi_{=}^*(P_{2r+1} \square K_{m,n}) = 2$ except $\chi_{=}^*(P_2 \square K_{m,n}) = 4$ when $m + n + 2 < 3 \min\{m, n\}$.

2. $\chi_{=}^*(P_{2r+1} \square K_{m,n}) = \chi_{=}^*(P_{2r+1} \square K_{m,n}) = \begin{cases} 2 & \text{if } |m - n| \leq 1, \\ 3 & \text{otherwise.} \end{cases}$

3. $\chi_=(C_{2r} \square K_{m,n}) = \chi^*_=(C_{2r} \square K_{m,n}) = 2$ except $\chi^*_=(C_4 \square K_{m,n}) = 4$ when $m + n + 2 < 3 \min\{m, n\}$.
4. $\chi_=(C_{2r+1} \square K_{m,n}) = \chi^*_=(C_{2r+1} \square K_{m,n}) = 3$.
5. $\chi_=(K_{1,m} \square K_{1,n}) = \chi^*_=(K_{1,m} \square K_{1,n}) = \begin{cases} 4 & \text{if } (m-2)(n-2) > 5, \\ 3 & \text{otherwise.} \end{cases}$

Lin also proposed some interesting conjectures:

Conjecture 11 *If G_1 and G_2 are bipartite graphs, then $\chi^*_=(G_1 \square G_2) \leq 4$.*

Conjecture 12 *If G_1 and G_2 are connected graphs, then $\chi_=(G_1 \square G_2) \leq \chi(G_1)\chi(G_2)$.*

The connectedness is essential in the above conjecture because $\chi_=(K_{1,3} \square 3K_1) = \chi^*(K_{1,3} \square 3K_1) = 3 > 2 = \chi(K_{1,3})\chi(3K_1)$.

13.2 Cross Product

The most well-known conjecture for cross product is the one proposed by Hedetniemi [67].

Conjecture 13 *For graphs G_1 and G_2 , $\chi(G_1 \times G_2) = \min\{|G_1|, |G_2|\}$.*

This has been established for complete graphs in [42]. For two recent surveys on Hedetniemi's conjecture, the reader is referred to Sauer [131] and Zhu [161]. Furmańczyk [54] showed that $\chi_=(P_3 \times P_3) = 3 > 2 = \chi_=(P_3)$. Thus, $\chi_=(G_1 \times G_2) \leq \min\{\chi_=(G_1), \chi_=(G_2)\}$ does not hold in general. However, Chen et al. [31] gave the following upper bound.

Theorem 60 *For graphs G_1 and G_2 , $\chi_=(G_1 \times G_2) \leq \min\{|G_1|, |G_2|\}$.*

The upper bound is sharp in the case $\chi_=(K_m \times K_n) = \min\{m, n\}$. In general, $\min\{|G_1|, |G_2|\}$ is not an upper bound for $\chi^*(G_1 \times G_2)$. An example was given in [31] to show that $K_2 \times K_n$ is not equitably $(n+1)/2$ -colorable when $n > 1$ and $n \equiv 1 \pmod{4}$. Even $\chi^*(G_1 \times G_2) \leq \max\{\chi^*(G_1), \chi^*(G_2)\}$ fails in general. Examples are $\chi^*(K_{2,3} \times K_{2,3}) = 3 > 2 = \chi^*(K_{2,3})$ [31] and $\chi^*(P_3 \times P_3) = 3 > 2 = \chi^*(P_3)$ [54]. The following result was conjectured in [31] and later proved to be true in [103]:

Theorem 61 *For graphs G_1 and G_2 , $\chi^*(G_1 \times G_2) \leq \max\{|G_1|, |G_2|\}$.*

It suffices to prove the above theorem for the case $K_m \times K_n$. A slightly better upper bound was actually established in [103].

Theorem 62 For positive integers m and n ,

$$\chi_{=}^*(K_m \times K_n) \leq \left\lceil \frac{mn}{\min\{m, n\} + 1} \right\rceil.$$

As to exact values, the following were established in [31] and [54], respectively:

1. $\chi_{=}^*(C_m \times C_n) = \chi_{=}^*(C_m \times C_n) = \begin{cases} 2 & \text{if } mn \text{ is even,} \\ 3 & \text{otherwise.} \end{cases}$
2. $\chi_{=}^*(P_m \times K_{1,n}) = \begin{cases} 2 & \text{if } m \text{ is even or } n = 1, \\ 3 & \text{otherwise.} \end{cases}$

Lin in his Ph.D. dissertation [103] determined more exact values. They are listed as follows. Also see [104].

1. $\chi(P_m \times K_2) = \chi_{=}^*(P_m \times K_2) = \chi_{=}^*(P_m \times K_2) = 2$, where $m \geq 2$.
2. $\chi(P_{2m+1} \times K_n) = 2 < \chi_{=}^*(P_{2m+1} \times K_n) = \chi_{=}^*(P_{2m+1} \times K_n) = 3$, where $n \geq 3$, except $\chi_{=}^*(P_3 \times K_n) = \max\{\lceil \frac{3}{2} \lceil \frac{2n}{s} \rceil \rceil \mid s \nmid 2n \text{ and } \lceil \frac{3}{2} \lceil \frac{2n}{s} \rceil \rceil \leq \lceil \frac{3n}{4} \rceil\}$.
3. $\chi(P_{2m} \times K_n) = \chi_{=}^*(P_{2m} \times K_n) = \chi_{=}^*(P_{2m} \times K_n) = 2$, where $m > 1$ and $n \geq 3$.
4. $\chi_{=}^*(P_2 \times K_n) = \max\{2 \lceil \frac{n}{s} \rceil \mid s \nmid n \text{ and } 2 \lceil \frac{n}{2} \rceil \leq \lceil \frac{2n}{3} \rceil\}$, where $n \geq 3$.
5. $\chi(C_m \times K_2) = \chi_{=}^*(C_m \times K_2) = \chi_{=}^*(C_m \times K_2) = 2$, where $m \geq 3$.
6. $\chi(C_{2m+1} \times K_n) = \chi_{=}^*(C_{2m+1} \times K_n) = \chi_{=}^*(C_{2m+1} \times K_n) = 3$, where $m > 1$ and $n \geq 3$, except $\chi_{=}^*(C_5 \times K_n) = \chi_{=}^*(C_5 \times K_n) = 4$, when $n \geq 5$.
7. $\chi_{=}^*(C_3 \times K_n) = \begin{cases} \lceil \frac{3n}{4} \rceil & \text{if } n \equiv 2 \pmod{4}, \\ \max\{3 \lceil \frac{n}{s} \rceil \mid s \nmid n \text{ and } 3 \lceil \frac{n}{s} \rceil \leq \lceil \frac{3n}{4} \rceil\} & \text{otherwise,} \end{cases}$ where $n \geq 3$.
8. $\chi(C_{2m} \times K_n) = \chi_{=}^*(C_{2m} \times K_n) = \chi_{=}^*(C_{2m} \times K_n) = 2$, where $m > 1$ and $n \geq 3$.
9. $\chi_{=}^*(C_4 \times K_n) = \max\{2 \lceil \frac{2n}{s} \rceil \mid s \nmid 2n \text{ and } 2 \lceil \frac{2n}{s} \rceil \leq \lceil \frac{4n}{5} \rceil\}$, where $n \geq 3$.
10. $\chi_{=}^*(K_{m_1, n_1}, K_{m_2, n_2}) = \chi_{=}^*(K_{m_1, n_1}, K_{m_2, n_2}) = \min\left\{\left\lceil \frac{n_1}{m_1} \right\rceil, \left\lceil \frac{n_2}{m_2} \right\rceil\right\} + 1$, where $m_1 \leq n_1$ and $m_2 \leq n_2$.

13.3 Strong Product

The upper bound for the inequality $\chi(G_1 \boxtimes G_2) \leq \chi(G_1)\chi(G_2)$ is exact when both factors are complete graphs. As to lower bounds, there are those established by Vesztergombi [141] and Jha [74], respectively.

Theorem 63 For nontrivial graphs G_1 and G_2 , $\chi(G_1 \boxtimes G_2) \geq \max\{\chi(G_1), \chi(G_2)\} + 2$.

Theorem 64 For nontrivial graphs G_1 and G_2 , $\chi(G_1 \boxtimes G_2) \geq \chi(G_1) + \omega(G_2)$, where $\omega(G)$ denotes the clique number of the graph G , i.e., the largest order of a complete subgraph in G .

Furmańczyk [54] first investigated the equitable chromatic number of a strong product. Her results have been subsumed by those in [103]. Again, Lin's results are listed as follows:

1. $\chi(C_m \boxtimes K_n) = \chi_=(C_m \boxtimes K_n) = \chi^*_=(C_m \boxtimes K_n) = \left\lceil \frac{mn}{\lceil m/2 \rceil} \right\rceil$, where $m \geq 3$ and $n \geq 2$.
2. $\chi(P_m \boxtimes K_n) = \chi_=(P_m \boxtimes K_n) = \chi^*_=(P_m \boxtimes K_n) = 2n$, where $m \geq 2$ and $n \geq 2$.
3. $\chi(C_m \boxtimes C_n) = \chi_=(C_m \boxtimes C_n) = \chi^*_=(C_m \boxtimes C_n) = \begin{cases} 4 & \text{if } m \text{ and } n \text{ are even,} \\ 5 & \text{otherwise,} \end{cases}$ where $m, n \geq 4$.
4. $\chi(C_m \boxtimes P_n) = \chi_=(C_m \boxtimes P_n) = \chi^*_=(C_m \boxtimes P_n) = \begin{cases} 4 & \text{if } m \text{ is even,} \\ 5 & \text{otherwise,} \end{cases}$ where $m \geq 4$ and $n \geq 3$.
5. $\chi(P_m \boxtimes P_n) = \chi_=(P_m \boxtimes P_n) = \chi^*_=(P_m \boxtimes P_n) = \begin{cases} 4 & \text{if } mn \text{ is even,} \\ 5 & \text{otherwise,} \end{cases}$ where $m \geq 3$ and $n \geq 3$.

Conjecture 14 Suppose that G_1 has at least one edge. Then $\chi_=(G_1 \boxtimes G_2) \geq \chi_=(G_1) + 2\omega(G_2) - 2$ and $\chi^*_=(G_1 \boxtimes G_2) \geq \chi^*_=(G_1) + 2\omega(G_2) - 2$.

The conclusions of the above conjecture hold if the equitable chromatic number of threshold is replaced by the ordinary chromatic number [103].

14 List Equitable Coloring

A mapping L is said to be a *list assignment* for the graph G if it assigns a finite list $L(v)$ of possible colors, usually regarded as positive integers, to each vertex v of G . A list assignment L for G is *k-uniform* if $|L(v)| = k$ for all $v \in V(G)$. If G has a proper coloring π such that $\pi(v) \in L(v)$ for all vertices v , then G is said to be *L-colorable* or π is an *L-coloring* of G . The graph G is said to be *k-choosable* if it is *L-colorable* for every *k-uniform* list assignment L , *equitably L-colorable* if it has a $\lceil |G|/k \rceil$ -bounded *L-coloring* for a *k-uniform* list assignment L , and *equitably list k-colorable* or *equitably k-choosable* if it is equitably *L-colorable* for every *k-uniform* list assignment L .

The concept of list-coloring was introduced by Vizing [144] and independently by Erdős et al. [45]. However, it is not appropriate to generalize the ordinary equitable coloring to this list context. To see this, let every vertex except one of a graph G be assigned the list $[k]$ and the remaining vertex v be assigned the list $[k+1, 2k]$. Unless $|G| \leq k+1$, in every proper coloring, some colors are not used, the color on v appears once, and some other color appears at least $\lceil (|G|-1)/k \rceil$ times.

This explains why the list version of an equitable coloring is defined in terms of boundedness of color classes. This notion was first introduced by Kostochka et al. [94], and they proposed two conjectures that are analogue to the Hajnál-Szemerédi Theorem and the $E\Delta CC$.

Conjecture 15 *Every graph G is equitably k -choosable whenever $k > \Delta(G)$.*

Conjecture 16 *If G is a connected graph with maximum degree at least 3, then G is equitably $\Delta(G)$ -choosable, unless G is a complete graph or is $K_{r,r}$ for some odd r .*

When $\Delta(G) = 2$, it is easy to see the validity of Conjecture 16. Conjecture 15 has been proved for $\Delta(G) \leq 3$ independently by Pelsmajer [122] and Wang and Lih [146]. In [122], a graph G was shown to be equitably k -choosable when $k \geq 2 + \Delta(G)(\Delta(G) - 1)/2$. In [94], Kostochka et al. gave the following partial results to Conjecture 15 and 16:

Theorem 65 *If $k \geq \max\{\Delta(G), |G|/2\}$, then G is equitably k -choosable unless G contains K_{k+1} or $K_{k,k}$ (with k odd in the latter case).*

Theorem 66 *If G is a forest and $k \geq \Delta(G)/2 + 1$, then G is equitably k -choosable. Moreover, for all m there is a tree with maximum degree at most m that is not equitable $\lceil m/2 \rceil$ -choosable.*

Theorem 67 *If G is a connected interval graph and $k \geq \Delta(G)$, then G is equitably k -choosable unless $G = K_{k+1}$.*

Theorem 68 *If G is a 2-degenerate graph and $k \geq \max\{\Delta(G), 5\}$, then G is equitably k -choosable.*

Pelsmajer [123] provided more partial results.

Theorem 69 *Let G be a graph with treewidth w and $k \geq 3w - 1$. Then G is equitably k -choosable if:*

1. $w \leq 5$ and $k \geq \Delta(G) + 1$, or
2. $w \geq 5$ and $k \geq \Delta(G) + w - 4$.

A graph is said to be *chordal* if it has no induced cycle of length greater than three.

Corollary 12 *Let G be a chordal graph with maximum degree at most Δ . Then G is equitably k -choosable for $k \geq \max\{3\Delta - 4, \Delta + 1\}$.*

If vertices of degree 1 are removed recursively from a graph G , then the final graph has no vertices of degree 1 and is called the *core* of G . A graph is called a $\theta_{2,2,p}$ -graph if it consists of two vertices x and y and three internally disjoint paths

of lengths 2, 2, and p joining x and y . Erdős et al. [45] characterized 2-choosable graphs in terms of these concepts. Analogous to their result, Wang and Lih [146] gave the following characterization:

Theorem 70 *A connected graph G is equitably 2-choosable if and only if G is a bipartite graph satisfying the following two conditions:*

1. *The core of G is either a K_1 , an even cycle, or a $\theta_{2,2,2r}$ -graph, where $r \geq 1$.*
2. *G has two parts X and Y such that $|X| - |Y| \leq 1$.*

Bu and his collaborators have established a series of partial results for [Conjecture 15](#) and [16](#) in the class of planar graphs as follows [100, 162, 163]:

Theorem 71 *Let G be a C_4 -free and C_6 -free planar graph. Then G is equitably k -choosable when $k \geq \max\{\Delta(G), 6\}$.*

Theorem 72 *Let G be a C_3 -free planar graph. Then G is equitably k -choosable when $k \geq \max\{\Delta(G), 8\}$.*

Theorem 73 *Let G be a C_4 -free and C_5 -free planar graph. Then G is equitably k -choosable when $k \geq \max\{\Delta(G), 7\}$.*

Theorem 74 *Let G be an outerplanar graph. Then G is equitably k -choosable when $k \geq \max\{\Delta(G), 4\}$.*

Theorem 75 *Let G be an outerplanar graph of maximum degree 3. Then G is equitably 3-choosable.*

Recently, [Theorems 74](#) and [75](#) have been generalized to series-parallel graphs by Zhang and Wu [159]. The following result confirms [Conjecture 15](#) and [16](#) for series-parallel graphs:

Theorem 76 *If G is a series-parallel graph with $\Delta(G) \geq 3$, then G is equitably k -choosable if $k \geq \Delta(G)$.*

In the framework of parameterized complexity, the list equitable coloring problem was shown by Fellow et al. [47] to be $\mathcal{W}[1]$ -hard even for forests, parameterized by the number of colors on the lists.

15 Graph Packing

The equitable coloring problem can be stated in the language of graph packing; hence it can be studied in a wider context. Two graphs G_1 and G_2 of the same order are said to *pack* if G_1 is isomorphic to a subgraph of the complement G_2^c of G_2 , or, equivalently, G_2 is isomorphic to a subgraph of the complement G_1^c of G_1 .

This definition may be extended to n graphs G_1, G_2, \dots, G_n of the same order so that they pack if every pair of them pack:

Because the problem of whether G^c packs with the cycle $C_{|G|}$ is equivalent to the existence of a Hamiltonian cycle in G , two well-known sufficient conditions for the existence of a Hamiltonian cycle, due to Dirac [40] and Ore [121], can be cast in terms of graph packings.

Theorem 77 *If $\Delta(G) \leq |G|/2 - 1$, then G packs with $C_{|G|}$.*

Theorem 78 *If $\deg(u) + \deg(v) \leq |G| - 2$ for every edge uv in G , then G packs with $C_{|G|}$.*

A graph G is k -colorable if and only if G packs with a graph of the same order that is the union of k -cliques. Let $H(n, k)$ denote the graph of order n such that it has k components each of which is a clique of order $\lfloor n/k \rfloor$ or $\lceil n/k \rceil$. This graph is the complement of the well-known Turán graph in extremal graph theory. A graph G is equitably k -colorable if and only if G packs with $H(|G|, k)$. The Brooks' Theorem and the Hajnal and Szemerédi Theorem can now be stated as follows:

Theorem 79 *If $r \geq 3$, G is a connected graph with $\Delta(G) \leq r$ and G does not pack with the complement of any r -partite graph, then $G = K_{r+1}$.*

Theorem 80 *Let G satisfy $\Delta(G) \leq r$. Then G packs with $H(|G|, r + 1)$.*

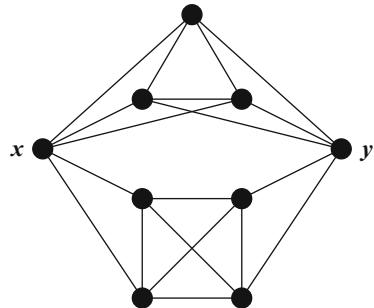

In view of Ore's theorem, the *Ore degree* of an edge uv , denoted by $\theta(uv)$, is defined to be $\deg(u) + \deg(v)$, and the *Ore degree of a graph* G is $\theta(G) = \max\{\theta(uv) \mid uv \in E(G)\}$. Following [81], those upper bounds in terms of Ore degree giving sufficient conditions for packing graphs are called *Ore-type* bounds. Those in terms of maximum degree are called *Dirac type*.

An obvious Dirac-type bound on the chromatic number of a graph G is $\chi(G) \leq \Delta(G) + 1$. The Brooks' Theorem characterizes the conditions for equality to hold: either G contains $K_{\Delta(G)+1}$ or $\Delta(G) = 2$ and G contains an odd cycle. An Ore-type bound on $\chi(G)$ can be obtained easily such that $\chi(G) \leq \lfloor \theta(G)/2 \rfloor + 1$. The bound is also attained at complete graphs. However, for small odd $\theta(G)$, there are more connected extremal graphs.

Theorem 81 *If $6 \leq k = \chi(G) = \lfloor \theta(G)/2 \rfloor + 1$, then G contains K_k .*

Kierstead and Kostochka [83] proposed the above as a conjecture and proved the statement when the lower bound 6 was replaced by 7. The theorem has been established recently by Rabern [127]. See [96] for further generalizations. The above theorem can be equivalently stated as follows: for $k \geq 6$, K_k is the only k -critical graph with maximum degree at most k whose vertices of degree k form an independent set. A k -critical graph is one that has chromatic number k , and any of its proper subgraphs has chromatic number less than k .

Fig. 1 The graph G with $\theta(G) = 9$ and $\chi(G) = 5$

The bound 6 is sharp as Fig. 1 gives a graph G with $\theta(G) = 9$ and $\chi(G) = 5$. This graph is adapted from [83]. Note that every 4-coloring of the subgraph induced by x and y and the upper three vertices assigns x and y the same color since the upper three vertices form a K_3 . On the other hand, every 4-coloring of the subgraph induced by x and y and the lower four vertices assigns x and y different colors since the lower four vertices form a K_4 . It follows that $\chi(G) > 4$.

Kierstead and Kostochka also constructed infinite families of connected graphs H with $\theta(H) \leq 7$ and $\chi(H) = 4$. Let G be a graph with $\theta(G) \leq 7$ and $\chi(G) = 4$. An example for such a graph G is illustrated in Fig. 2a. A graph G' with $\theta(G') \leq 7$ and $\chi(G') = 4$ can be constructed as follows. Choose a vertex v of G that has no neighbor of degree 4. Split v into two vertices v_1 and v_2 of degree at most two. Add two new adjacent vertices x_v and y_v , each of which is joined to both v_1 and v_2 . In this example, G' is depicted in Fig. 2b. By construction, $\theta(G') = 7$. Since v_1 and v_2 are adjacent to x_v and y_v , any 3-coloring of G' will assign the same color to v_1 and v_2 . But then a 3-coloring of G can be produced, contrary to the assumption $\chi(G) = 4$.

Kierstead and Kostochka [81] proved a generalization of the Hajnal and Szemerédi Theorem involving the Ore degree.

Theorem 82 *For every $r \geq 3$, each graph G with $\theta(G) \leq 2r + 1$ has an equitable $(r + 1)$ -coloring.*

This implies that the $E\Delta CC$ holds for graphs in which vertices of maximum degree form an independent set. In addition to K_{r+1} , the extremal graphs for the above theorem are $K_{m,2r-m}$ for every odd $0 < m \leq r$. The following Ore-type analogue of the $E\Delta CC$ was also proposed in [81] and, its truth for $r = 3$ was established.

Conjecture 17 *Let $r \geq 3$ and G be a connected graph with $\theta(G) \leq 2r$. If G differs from K_{r+1} and $K_{m,2r-m}$ for all odd m , then G is equitably r -colorable.*

A conjecture in the flavor of Conjecture 15 was proposed in [86], and positive evidence was provided for small θ .

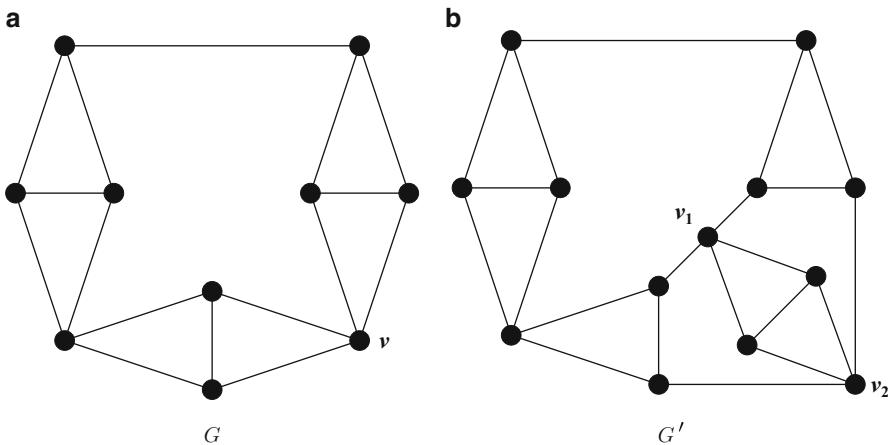

Fig. 2 A transformation from G to G'

Conjecture 18 *Every graph G is equitably $(\lceil \theta(G)/2 \rceil + 1)$ -choosable.*

Theorem 83 *If $\theta(G) \leq 6$, then G is equitably 4-choosable.*

In the graph packing area, a major outstanding conjecture was made independently by Bollobás and Eldridge [15] and Catlin [20, 21].

Conjecture 19 *Let G_1 and G_2 be two graphs of the same order n . If $(\Delta(G_1) + 1)(\Delta(G_2) + 1) \leq n + 1$, then G_1 and G_2 pack.*

The Hajnal-Szemerédi Theorem verifies the conjecture in the case when G_2 is the disjoint union of copies of a clique. Aigner and Brandt [1] and independently (for huge n) Alon and Fischer [4] settled the case $\Delta(G_1) \leq 2$. Csaba et al. [36] proved the case for $\Delta(G_1) = 3$ and huge n . Bollobás et al. [17] proved it in case that for $d \geq 2$, G_1 is d -degenerate, $\Delta(G_1) \geq 40d$, and $\Delta(G_2) \geq 215$. Kaul et al. [86] showed that for $\Delta(G_1), \Delta(G_2) \geq 300$, if $(\Delta(G_1) + 1)(\Delta(G_2) + 1) < 3n/5$, then G_1 and G_2 pack. Recently, Kun has announced a proof of the conjecture for graphs with at least 10^8 vertices.

The reader is referred to Wozniak [151] for a general survey on the graph packing area and to Kierstead et al. [79] for recent progress in Ore-type and Dirac-type bounds for graph packing problems.

16 Equitable Δ -Colorability of Disconnected Graphs

If a disconnected graph G is $\Delta(G)$ -colorable, then the conditions for G to be equitably $\Delta(G)$ -colorable are quite different. For an odd integer $r \geq 3$, G is equitably $\Delta(G)$ -colorable if $G = K_{r,r} \cup K_{r,r}$. However, G is not equitably

$\Delta(G)$ -colorable if $G = K_{r,r} \cup K_r$. The latter example can be generalized. A graph H is said to be r -equitable if r divides $|H|$, H is r -colorable, and every r -coloring of H is equitable. For an odd integer $r \geq 3$, if $H = K_{r,r}$ is a subgraph of G and $G - H$ is r -equitable, then G is not equitably r -colorable. Kierstead and Kostochka [84] gave a good description of the family of all r -equitable graphs so that all of them can be built up from simple examples in a straightforward way. Their approach to deal with disconnected graphs led them to propose the following conjecture.

Conjecture 20 Suppose that $\Delta(G) = r \geq 3$ and G is an r -colorable graph. Then G is not equitably r -colorable if and only if the following conditions hold:

1. r is odd.
2. G has a subgraph $H = K_{r,r}$.
3. $G - H$ is r -equitable.

Chen and Yen [27] have also found sufficient conditions for the nonexistence of equitable Δ -colorings for graphs that are not necessarily connected.

Theorem 84 Suppose that $\Delta(G) = r \geq 3$ and G is an r -colorable graph. Then G is not equitably r -colorable if the following conditions hold:

1. r is odd.
2. G has exactly one component $H = K_{r,r}$.
3. $\alpha(G - H) \leq |G - H|/r$.

Suppose that $\Delta(G) = r$ and G is an r -colorable graph such that G has exactly one $K_{r,r}$ component. If $G = K_{r,r}$, then $\alpha(G - K_{r,r}) = 0 = |G - K_{r,r}|/r$. Otherwise, $\alpha(G - K_{r,r}) \geq |G - K_{r,r}|/\chi(G - K_{r,r}) \geq |G - K_{r,r}|/\chi(G) \geq |G - K_{r,r}|/r$. Hence, Condition 3 can be replaced by an equality. Chen and Yen conjectured that those sufficient conditions are also necessary and established some positive evidence.

Conjecture 21 Suppose that $\Delta(G) = r \geq 3$ and G is an r -colorable graph. Then G is not equitably r -colorable if and only if the following conditions hold:

1. r is odd.
2. G has exactly one component $H = K_{r,r}$.
3. $\alpha(G - H) = |G - H|/r$.

Theorem 85 A bipartite graph G satisfying $\Delta(G) \geq 2$ is equitably $\Delta(G)$ -colorable if and only if G is different from $K_{r,r}$ for all odd $r \geq 3$.

Theorem 86 A graph G that is $\Delta(G)$ -colorable and satisfies $\Delta(G) \geq 1 + |G|/3$ is equitably $\Delta(G)$ -colorable if and only if G is different from $K_{r,r}$ for all odd $r \geq 3$.

Theorem 87 Conjecture 21 holds for $\Delta(G) = 3$.

It was shown in Chen et al. [32] that Conjecture 20 and 21 are in fact equivalent. The proof utilizes the following result that was established in Chen et al. [30].

Theorem 88 Let $r \geq \chi(G) \geq \Delta(G)$. Then there exists a proper coloring of G using r colors such that some color class has size $\alpha(G)$.

Further lemmas are needed in the equivalence proof.

Lemma 7 If G is r -colorable and $\alpha(G) = |G|/r$, then G is r -equitable.

Lemma 8 If G is r -equitable, then $r = \chi(G)$.

Lemma 9 Let $r \geq \Delta(G)$. If G is r -equitable, then $\alpha(G) = |G|/r$.

By Lemma 8, $\chi(G) = r \geq \Delta(G)$. By Theorem 88, there exists an r -coloring ϕ of G such that a color class of ϕ is of size $\alpha(G)$. Since G is r -equitable, ϕ is an equitable r -coloring and r divides $|G|$. Hence $\alpha(G) = |G|/r$.

Lemma 10 Let a graph G satisfy $\Delta(G) = r \geq 3$. If G is r -equitable, then G does not have $K_{r,r}$ as a subgraph.

Suppose on the contrary that G has a subgraph $H = K_{r,r}$. The subgraph H is a component of G since $r = \Delta(G)$. Hence, $|G| = |G - H| + |H| = |G - H| + 2r$ and $\alpha(G) = \alpha(G - H) + \alpha(H) = \alpha(G - H) + r$. By Lemma 9, $\alpha(G) = |G|/r = |G - H|/r + 2$. Therefore, $\alpha(G - H) = |G - H|/r + 2 - r \leq |G - H|/r - 1$. On the other hand, Lemma 8 implies $r = \chi(G) \geq \chi(G - H)$. Then $\alpha(G - H) \geq \lceil |G - H|/\chi(G - H) \rceil \geq \lceil |G - H|/r \rceil \geq |G - H|/r$. A contradiction is obtained.

Lemma 11 Let a graph G satisfy $\Delta(G) = r \geq \chi(G)$. If $r \geq 3$, G has a subgraph $H = K_{r,r}$, and $G - H$ is r -equitable, then G has exactly one $K_{r,r}$ component.

If $G = K_{r,r}$ or $\Delta(G - H) < r$, then G has exactly one $K_{r,r}$ component H . Now, suppose that $G \neq K_{r,r}$ and $\Delta(G - H) = r$. Since $r \geq 3$ and $G - H$ is r -equitable, $G - H$ does not have $K_{r,r}$ as a subgraph by Lemma 10. Therefore, G has exactly one $K_{r,r}$ component H .

Using Lemmas 7, 9, and 11, the equivalence of two conjectures follows.

Theorem 89 Conjecture 20 and 21 are equivalent.

In [84], Kierstead and Kostochka described their conjecture in terms of other equivalent conditions. An r -equitable graph G is said to be r -reducible if $V(G)$ has a partition $\{V_1, \dots, V_t\}$ into at least two parts such that all induced subgraphs $G[V_i]$ are r -equitable. If such a partition fails to exist, then G is called r -irreducible. Obviously, K_r is r -irreducible. It can be identified that there is one other 5-irreducible graph F_1 (Fig. 3), three other 4-irreducible graphs F_2, F_3, F_4 (Fig. 4), and six other 3-irreducible graphs F_5, \dots, F_{10} (Figs. 5 and 6). Together with K_r , the r -irreducible graphs in the list F_1, \dots, F_{10} are called r -basic graphs.

Fig. 3 The 5-irreducible graph F_1

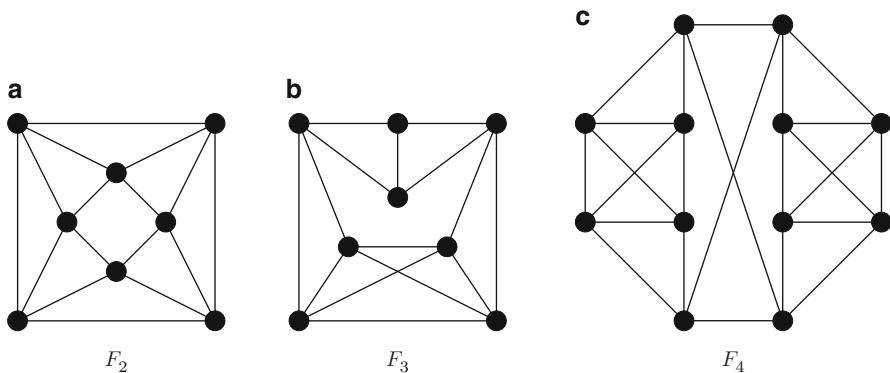

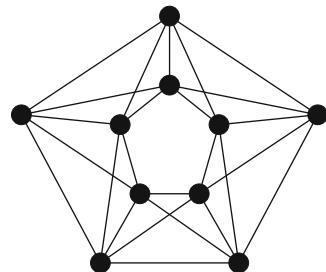

Fig. 4 The 4-irreducible graphs F_2 , F_3 , and F_4

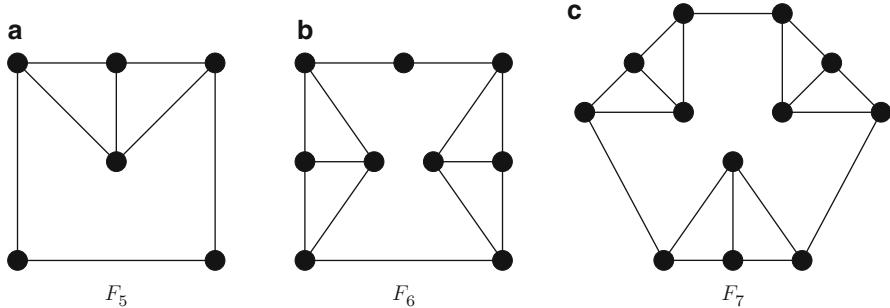

Fig. 5 The 3-irreducible graphs F_5 , F_6 , and F_7

An r -decomposition of G is a partition $\{V_1, \dots, V_t\}$ of $V(G)$ such that every induced subgraph $G[V_i]$ is r -basic. The graph G is called r -decomposable if it has an r -decomposition. A nearly equitable r -coloring of a graph G is an r -coloring of G such that exactly one color class has size $s - 1$, exactly one color class has size $s + 1$, and all other color classes have size s .

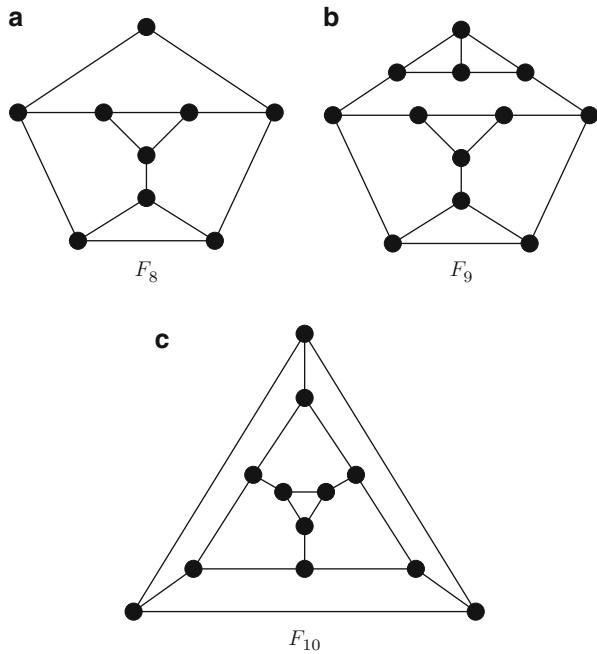

Fig. 6 The 3-irreducible graphs F_8 , F_9 , and F_{10}

Let $\mathcal{G}(r)$ be the class of all graphs whose maximum degree and chromatic number are less than or equal to r . Let $\mathcal{G}(r, n)$ denote the subclass of $\mathcal{G}(r)$ consisting of all graphs of order at most n .

Theorem 90 ([84]) *Let $G \in \mathcal{G}(r)$ and r divide $|G|$. Then the following are equivalent.*

1. *G is r -equitable.*
2. *G is r -decomposable.*
3. *G has an equitable r -coloring, but does not have a nearly equitable r -coloring.*

Conjecture 20 can now be re-stated as follows.

Conjecture 22 *Suppose that $\Delta(G) = r \geq 3$ and G is an r -colorable graph. Then G is not equitably r -colorable if and only if the following conditions hold.*

1. *r is odd.*
2. *G has a subgraph $H = K_{r,r}$.*
3. *$G - H$ is r -decomposable.*

For $r \geq 6$, this conjecture means that, if an r -colorable graph G with $\Delta(G) = r$ has no equitable r -coloring, then r is odd and there exists a partition $V(G) = V_0 \cup$

$V_1 \cup \dots \cup V_t$ such that $G[V_0] = K_{r,r}$ and $G[V_i] = K_r$ for $1 \leq i \leq t$. [Theorem 90](#) can be used to derive the corollaries below.

Corollary 13 *For all positive integers r and $n > r$, the EΔCC holds for all graphs in $\mathcal{G}(r, n)$ if and only if [Conjecture 22](#) holds for all graphs in $\mathcal{G}(r, n)$.*

Corollary 14 *Let $G \in \mathcal{G}(r)$ be r -equitable. Then G has a unique r -decomposition.*

Corollary 15 *There exists a polynomial time algorithm for deciding whether a graph $G \in \mathcal{G}(r)$ is r -equitable.*

The following conjecture proposed in [83] is a common extension of [Conjecture 17](#) and [22](#).

Conjecture 23 *Let $r \geq 3$. An r -colorable graph G with $\theta(G) \leq 2r$ has no equitable r -coloring if and only if r divides $|G|$, G has a subgraph $H = K_{m,2r-m}$ for some odd m , and $G - H$ is r -decomposable.*

This conjecture is proved to be equivalent to [Conjecture 17](#) for graphs with restricted order and Ore-degree.

Theorem 91 *Let $r \geq 3$. Assume that [Conjecture 17](#) holds for all graphs of order at most n and Ore-degree at most $2r$. Let G be an r -colorable graph of order n with $\theta(G) \leq 2r$. Then G has no equitable r -coloring if and only if r divides n , G has a subgraph $H = K_{m,2r-m}$ for some odd m , and $G - H$ is r -decomposable.*

It follows that [Conjecture 23](#) holds for $r = 3$.

17 More on the Hajnal-Szemerédi Theorem

The Hajnal-Szemerédi Theorem settled a conjecture raised by Erdős in 1964. The complete proof given in [64] was long and complicate, and did not produce a polynomial time algorithm. A simplification came when Kierstead and Kostochka [82] used a discharging argument in an approach similar to the original one. An analysis of their proof leads to a complexity results.

Theorem 92 *There is an algorithm of time complexity $O(n^5)$ that constructs an equitable $(r + 1)$ -coloring of any graph G with $|G| = n$ and $\Delta(G) \leq r$.*

An even shorter proof of the Hajnal-Szemerédi Theorem was included in the survey paper [86]. Independent of Kierstead and Kostochka, Mydlarz and Szemerédi also found polynomial time algorithm proof for the Hajnal-Szemerédi Theorem. These two groups finally worked together to refine their old methods and arrived at a faster algorithm [87].

Theorem 93 *There is an algorithm of time complexity $O(rn^2)$ that constructs an equitable $(r + 1)$ -coloring of any graph G with $|G| = n$ and $\Delta(G) \leq r$.*

However, the existence of an algorithmic version of [Theorem 82](#) is still open.

Conjecture 24 *There is a polynomial time algorithm that constructs an equitable $(r + 1)$ -coloring of any graph G with $\theta(G) \leq 2r + 1$.*

When one pays attention to the complement of the graph given in the Hajnal-Szemerédi Theorem, the theorem can be stated in the following form of which the first non-trivial case $r = 3$ had previously been solved by Corrádi and Hajnal [\[34\]](#).

Theorem 94 *Let G be a graph of order n with the minimum degree $\delta(G) \geq \frac{r-1}{r}n$. If r divides n , then G contains n/r vertex-disjoint cliques of size r .*

In order to extend the above to a multipartite version, the next conjecture was proposed in Csaba and Mydlarz [\[35\]](#). If all parts of an r -partite graph G have the same size, then G is called a *balanced r -partite graph*. Let V_1, V_2, \dots, V_r be the parts of such a graph G . The *proportional minimum degree* of G is defined as follows.

$$\tilde{\delta}(G) = \min_{1 \leq i \leq r} \min_{v \in V_i} \left\{ \frac{\deg(v, V_j)}{|V_j|} \mid j \neq i \right\}.$$

Conjecture 25 *Let G be a balanced r -partite graph of order rn . There exists a constant $M \geq 0$ such that, if $\tilde{\delta}(G)n \geq \frac{r-1}{r}n + M$, then G contains n vertex-disjoint cliques of size r .*

The extra additive constant M is necessary for the case of odd r . Partial results have been obtained by Fischer [\[50\]](#) and Johansson [\[75\]](#). The conjecture has been confirmed for $r = 3$ [\[109\]](#) and $r = 4$ [\[111\]](#). In [\[35\]](#), Csaba and Mydlarz proved a relaxed version of this conjecture. The proofs commonly used Szemerédi's Regularity Lemma [\[136\]](#) and the Blow-up Lemma [\[88\]](#) and are complicate. The cases for $r = 3$ and $r = 4$ have been reproved by Han and Zhao [\[65\]](#) using their absorbing method. The paper [\[80\]](#) by Keevash and Mycroft contains results about multipartite graphs with sufficiently large girth. Recently, [Conjecture 25](#) has been verified asymptotically by Lo and Markström [\[106\]](#). Balogh et al. [\[8\]](#) extended the result of Corrádi and Hajnal into the setting of sparse random graphs.

In order to find a understandable proof of the Hajnal-Szemerédi Theorem, Seymour [\[132\]](#) was motivated to pose the following conjecture. The *r -th power* of a graph is obtained by adding new edges joining vertices with distance at most r .

Conjecture 26 *Let G be a graph of order n with $\delta(G) \geq \frac{r}{r+1}n$. Then G contains the r -th power of C_n .*

[Theorem 77](#) is the case $r = 1$. The well-known Posa's conjecture (cf. [\[43\]](#)) is the case $r = 2$. Seymour's conjecture implies the Hajnal-Szemerédi Theorem since

any $r + 1$ consecutive vertices of the r -th power of a cycle induce K_{r+1} . Seymour's conjecture has been proved by Komolós et al. [89, 90] when the order of the graph is extremely large using Szemerédi's Regularity Lemma and the Blow-up Lemma.

Theorem 95 *For every positive integer r , there exists an integer N such that for every $n > N$ every graph G of order n with $\delta(G) \geq \frac{r}{r+1}n$ contains the r -th power of a hamiltonian cycle.*

18 Applications

Graph coloring can be regarded as a partition of resources problem. It is convenient in some situations to require color classes be of approximately the same size. Graph coloring is also a natural model for scheduling problems. Suppose that a number of jobs are given to be completed. A *conflict graph* can be constructed so that vertices represent jobs and two vertices are adjacent if there is a scheduling conflict between the jobs associated with these vertices. A proper coloring of the conflict graph corresponds to a conflict-free schedule. Some other examples are listed below.

1. The mutual exclusion scheduling problem [7, 134].
2. Scheduling in communication systems [70].
3. Round-the-clock scheduling [138].
4. Parallel memory systems [11, 37].
5. Load balancing in task scheduling [11, 97].
6. Constructing university timetables [55].

In applications, only algorithms with low time complexity could be utilized. Although checking $\chi_-(G) \leq 2$ can be achieved in polynomial time, the problem of deciding if $\chi_-(G) \leq 3$ is NP-complete even for line graphs of cubic graphs. The majority of known polynomial time results about equitable coloring are listed in [53] and [55]. Two competitive algorithms for approximate equitable coloring were also supplied. In [112, 113], and [114], Méndez-Díaz et al. gave a linear integer programming formulation for the equitable coloring problem. They studied its polyhedral structure and developed a cutting plane algorithm. Experiments on randomly generated graphs have been performed to make behavior comparisons with other algorithms of similar nature. Bahiense et al. [6] also gave two integer programming formulations based on representatives for the equitable coloring problem. They proposed a primal constructive heuristic, branching strategies, and branch-and-cut algorithms based on these formulations. Computational experiments were carried out on randomly generated graphs.

Applications of equitable colorings to other mathematical problems include the following.

Alon and Füredi [5] used equitable colorings to the determination of the threshold function for the edge probability that guarantees, almost surely, the existence of various sparse spanning subgraphs in random graphs.

Rödl and Ruciński [128] used equitable colorings to give a new proof of the Blow-Up Lemma.

Let $\mathcal{X} = \{X_1, X_2, \dots, X_n\}$ be a collection of random variables with $S = \sum_{i \in [n]} X_i$ and $\mu = E[S]$. The upper tail probability $\text{Prob}[S \geq (1 + \epsilon)\mu]$ and the lower tail probability $\text{Prob}[S \leq (1 - \epsilon)\mu]$ for $0 < \epsilon \leq 1$ are subjects of interest. A *dependency graph* for \mathcal{X} has vertex set $[n]$ and an edge set such that for each $i \in [n]$, X_i is mutually independent of all other X_j with j non-adjacent to i . In Pemmaraju [124], it is shown that a small equitable chromatic number for a dependency graph leads to sharp tail probability bounds that are roughly as good as those would have been obtained had the random variables been mutually independent. An example is an outerplanar dependency graph and [Theorem 23](#) plays an important role in the proof.

Pemmaraju also introduced an interesting notion of proportional coloring. For non-negative integer c and integer $\alpha \geq 1$, a proper coloring of G is said to be a (c, α) -coloring if all except at most c vertices are colored and $|V_i| \leq \alpha|V_j|$ for any pair of color classes V_i and V_j . [Theorem 1](#) can be extended to show that every tree has a $(1, 5)$ -coloring with two colors and every outerplanar graph has a $(2, 5)$ -coloring with four colors. Sharp tail probability bounds can be established if the dependency graph can be (c, α) -colored [124].

Pemmaraju believed that $\chi_-(G)$ should depend on the average degree rather than on the maximum degree and he proposed the conjecture below.

Conjecture 27 *There is a positive constant c such that, if a graph G has maximum degree at most $|G|/c$ and average degree d , then $\chi_-(G) = O(\chi(G) + d)$.*

The truth of this conjecture will immediately imply an $O(1)$ equitable chromatic number for most planar graphs and that will translate into extremely sharp tail probability bounds for the sum of random variables that have a planar dependency graph.

Janson et al. [71] and Janson and Ruciński [72] also used equitable colorings to get new bounds on tails of distributions of sums of random variables.

19 Related Notions of Coloring

In this section, some coloring notions related to equitable coloring will be discussed.

19.1 Equitable Edge-Coloring

An *edge-coloring* of a graph G is simply an assignment of colors to the edges of G . An edge- k -coloring of G assigns the k colors $\{1, 2, \dots, k\}$ to the edges of G . For a vertex v of G , let $c_i(v)$ denote the number of edges incident with v colored i . This edge- k -coloring is said to be *equitable* if, for each vertex v ,

$$|c_i(v) - c_j(v)| \leq 1 \quad (1 \leq i < j \leq k)$$

and *nearly equitable* if, for each vertex v ,

$$|c_i(v) - c_j(v)| \leq 2 \quad (1 \leq i < j \leq k).$$

The following was proved in [68].

Theorem 96 *If $k \geq 2$ does not divide the degree of any vertex, then the graph has an equitable edge- k -coloring.*

Hilton and de Werra made the observation at the end of their paper that the colorings can be so constructed that all color classes have equitable sizes.

An edge-coloring is said to be *proper* if any two edges are colored differently whenever they are incident to a common vertex. The smallest number of colors needed in a proper edge-coloring of G is called the *chromatic index* of G and denoted by $\chi'(G)$. Obviously, $\Delta(G) \leq \chi'(G)$. The above theorem reduces to the following well-known theorem of Vizing [142] when $k = \Delta(G) + 1$.

Theorem 97 *For any graph G , $\chi'(G) \leq \Delta(G) + 1$.*

An *edge cover coloring* of a graph G is a coloring of the edges of G so that, for every vertex v , each color appears at least once on some edge incident to v . The maximum number of colors needed for such a coloring is called the *edge cover chromatic index* of G and denoted by $\chi'_c(G)$. Let $k = \delta(G) + 1$. Applying Theorem 96 to the graph obtained from G by adjoining a pendant edge to each vertex v whose degree is a multiple of k , the following result of Gupta [62] is deduced.

Theorem 98 *For any graph G , $\delta(G) - 1 \leq \chi'_c(G) \leq \delta(G)$.*

Given $k \geq 2$, the k -core of a graph G is the subgraph of G induced by all vertices v whose degree is a multiple of k . A stronger form for Theorem 96 also appeared in [68].

Theorem 99 *Given $k \geq 2$, if the k -core of G contains no edges, then G has an equitable edge- k -coloring.*

The following recent result of Zhang and Liu [158] was first conjectured by Hilton and de Werra [68].

Theorem 100 *Given $k \geq 2$, if the k -core of G is a forest, then G has an equitable edge- k -coloring.*

A graph G is called *edge-equitable* if G has an equitable edge- k -coloring for any integer $k \geq 2$. If a graph is edge-equitable, then its chromatic index is equal to its maximum degree and its edge cover chromatic index is equal to its minimum degree. All bipartite graphs were shown to be edge-equitable in de Werra [38].

A *circuit* is a connected graph without any vertex of odd degree. A circuit is said to be odd, or even, according to its number of edges is odd, or even. It was stated in [38] that a connected graph has an equitable edge-2-coloring if and only if it is not an odd circuit. Wu [152] showed that a connected outerplanar graph is edge-equitable if and only if it is not an odd circuit. This can be generalized to series-parallel graphs. The following result was established by Song et al. [135].

Theorem 101 *Any connected series-parallel graph is edge-equitable if and only if it is not an odd circuit.*

Theorem 96 also has the following corollary.

Corollary 16 *Let $k \geq 2$. Then, for any graph G , there exists an edge- k -coloring of G such that, for each vertex v ,*

1. $|c_i(v) - c_j(v)| = 2$ for at most one pair $\{i, j\}$ of colors, and
2. $|c_s(v) - c_t(v)| \leq 1$ for all pairs $\{s, t\} \neq \{i, j\}$ of colors.

This can be proved by adjoining a pendant edge to each vertex of G whose degree is a multiple of k . Then apply Theorem 96 to this extended graph. The corresponding edge-coloring of G satisfies the above conditions. Thus, every graph has a nearly equitable edge- k -coloring for any given $k \geq 2$. In fact, Corollary 16 is equivalent to Theorem 96. To see this, suppose that k does not divide the degree of any vertex of G and the conditions of Corollary 16 are satisfied. For each vertex v of G , since $\deg(v)$ is not a multiple of k , it is not possible to have $|c_i(v) - c_j(v)| = 2$ for one pair $\{i, j\}$ of colors unless some second pair $\{s, t\} \neq \{i, j\}$ of colors satisfies $|c_s(v) - c_t(v)| = 2$ also. Thereby, an equitable edge-coloring with k colors can be produced.

For efficient algorithms for nearly equitable edge-coloring problem, the reader is referred to Shioura and Yagiura [133], Xie et al. [154], and references therein. These algorithms can produce color classes that have equitable sizes.

19.2 Equitable Total-Coloring

A *total- k -coloring* of a graph $G = (V, E)$ is a mapping $f : V(G) \cup E(G) \rightarrow \{1, 2, \dots, k\}$ such that any two adjacent or incident elements have distinct images. The *total chromatic number* $\chi''(G)$ is the smallest integer k such that G has a total- k -coloring. A total- k -coloring is said to be *equitable* if $||f^{-1}(i)| - |f^{-1}(j)|| \leq 1$ when $1 \leq i < j \leq k$. Fu [52] first studied equitable total-coloring under the name *equalized total coloring* and put forward the following tentative conjecture.

Conjecture 28 *For each $k \geq \chi''(G)$, there exists an equitable total- k -coloring of G .*

Fu proved this conjecture for complete graphs, complete bipartite graphs, trees, and complete split graph $K_m \vee I_n$. However, the tentative conjecture does not hold in general. Fu gave a family of counterexamples.

Theorem 102 *For any $n \geq 3$, let $G = nK_2 \vee I_{2n-1}$. Then $\chi''(G) = 2n + 1$, yet G has no equitable total- $(2n + 1)$ -coloring. However, G has an equitable total- k -coloring for any $k \geq 2n + 2 = \Delta(G) + 2$.*

This theorem prompted Fu to make the following refined conjecture.

Conjecture 29 *For each $k \geq \max\{\chi''(G), \Delta(G) + 2\}$, G has an equitable total- k -coloring.*

Fu also proved that G satisfies the above conjecture if $\Delta(G) = |G| - 2$, or G is a complete multipartite graph of odd order. When G is a multipartite graph of even order, the best Fu could prove was that G has an equitable total- k -coloring for any $k \geq \Delta(G) + 3$. Wang [145] proposed the following weaker conjecture in which the *equitable total chromatic index* $\chi''_=(G)$ of a graph G is defined to be the least integer k such that G has an equitable total- k -coloring. Wang proved the conjecture holds for graphs G with $\Delta(G) \leq 3$.

Conjecture 30 *For any graph G , $\chi''_=(G) \leq \Delta(G) + 2$.*

This weaker conjecture is powerful enough to imply the outstanding Total Coloring Conjecture, proposed independently by Behzad [9] and Vizing [143], which asserts $\chi''(G) \leq \Delta(G) + 2$ for any graph G .

For some classes of graphs, the upper bound in the above conjecture can be lowered to $\Delta(G) + 1$. Chungling et al. [33] proved the following for the square product of cycles.

Theorem 103 *Let $G = C_m \square C_n$. Then, for $m \geq 3$ and $n \geq 3$, $\chi''_=(G) = \Delta(G) + 1 = 5$.*

The *wheel* W_n is defined to be the join of a cycle C_n with a center vertex u . The *Mycielskian* $\mathbf{M}(W_n)$ of W_n is constructed as follows. For each vertex x of W_n , a new vertex x' is added. Join x_i and x'_j with an edge whenever x_i and x_j are adjacent in W_n . Finally, add one more new vertex w and make it adjacent to every new vertices x' . The *hypo-Mycielskian* $\mathbf{HM}(W_n)$ of W_n has the same vertex set as $\mathbf{M}(W_n)$ and all edges of $\mathbf{M}(W_n)$ except those of the form ux' , $x \neq u$. Note that $\Delta(\mathbf{HM}(W_n))$ is equal to 6 when $n = 3$ or 4 and is equal to $n + 1$ when $n \geq 5$.

Theorem 104 ([147]) *For $n \geq 3$, $\chi''_=(\mathbf{M}(W_n)) = \Delta(G) + 1$.*

Theorem 105 ([148]) *For $n \geq 3$, $\chi''_=(\mathbf{HM}(W_n)) = \Delta(G) + 1$.*

One question left open in [52] asks whether the existence of an equitable total- k -coloring implies that of an equitable total- $(k + 1)$ -coloring.

19.3 Equitable Defective Coloring

A reasonable relaxation of scheduling problem allows conflicts to happen to a certain level. The graph coloring model corresponds to this type of relaxation can be formulated as follows. A *d-defective coloring* is a coloring of the vertices of a graph in which monochromatic subgraphs have maximum degree at most d . An ordinary proper coloring is precisely a 0-defective coloring. A *defective coloring* simply means a 1-defective coloring, in which a vertex may share a color with at most one neighbor. The smallest number k such that the graph G has a 1-defective coloring is denoted by $\text{df}_1(G)$.

A graph G has an *equitable defective k -coloring*, or an *ED- k -coloring*, if G has a coloring using k colors that is both equitable and defective. This notion of coloring was introduced by Williams et al. [150]. Let $\chi_{\text{ED}}(G)$ denote the smallest integer k such that G has an ED- k -coloring, and $\chi_{\text{ED}}^*(G)$ the smallest integer k such that G has an ED- m -coloring for all $m \geq k$. It is clear that $\text{df}_1(G) \leq \chi_{\text{ED}}^*(G) \leq \chi_{\text{ED}}(G)$. These parameters may differ from each other by an arbitrarily large amount. The following example was provided in [150]. Consider $X = K_{\lceil n/2 \rceil}$ and $Y = I_{\lfloor n/2 \rfloor}$. Let G be the graph obtained from $X \vee Y$ by removing a matching between X and Y of size $\lfloor n/2 \rfloor$. Note that $\chi(G) = \chi_{\text{ED}}^*(G) = \lceil n/2 \rceil$. If X is colored with $|X|/2 = \lceil n/4 \rceil$ colors and Y is colored with one extra color, then $\text{df}_1(G) \leq \lceil n/4 \rceil + 1$. If a color class in an ED-coloring contains two vertices of X , then it cannot contain any other vertices. This forces every color class has at most three vertices. However, color classes of size three must contain at least two vertices of Y . Therefore, there are at most $|Y|/2$ color classes of size three. It follows that $\chi_{\text{ED}}(G) \geq \lceil 3n/8 \rceil$. It is easy to see that an ED-coloring with k colors exists for any $k \geq \lceil 3n/8 \rceil$, and hence $\chi_{\text{ED}}^*(G) = \lceil 3n/8 \rceil$.

Extending results in [108], Williams et al. proved the following.

Theorem 106 *If G is a planar graph with minimum degree $\delta(G) \geq 2$ and girth $g(G) \geq 10$, then $\chi_{\text{ED}}^*(G) \leq 3$.*

The condition $\delta(G) \geq 2$ is indispensable since $K_{1,n}$ has no ED- k -coloring when n is sufficiently large for any fixed k . The girth condition cannot be lower than 5 since $K_{2,n}$ has girth 4 but $\chi_{\text{ED}}^*(K_{2,n})$ is not bounded by any constant. Whether 5 is the smallest girth that a planar graph G can have so that $\chi_{\text{ED}}^*(G)$ can be bounded by a constant is an open question.

Recently, Fan et al. [46] have shown that a graph with maximum degree at most r admits an equitable ED- r -coloring and provided a polynomial-time algorithm for constructing such a coloring.

19.4 Equitable Coloring of Hypergraphs

A *hypergraph* \mathcal{H} , is an ordered pair (V, \mathcal{F}) , where \mathcal{F} is a family of subsets of the finite set V . Elements of V and \mathcal{F} are called *vertices* and *hyperedges* of \mathcal{H} , respectively. The number of hyperedges incident with a vertex of \mathcal{H} is called its *degree*. A hypergraph is said to be k -uniform if each hyperedge has precisely k -elements.

Let \mathcal{H} be a k -uniform hypergraph on n vertices. A *strong r -coloring* of \mathcal{H} is a partition of the vertices into r parts, called *color classes*, such that each hyperedge intersects each part. A strong r -coloring is called *equitable* if the size of each color class is either $\lceil n/r \rceil$ or $\lfloor n/r \rfloor$. Let $c(\mathcal{H})$ and $ec(\mathcal{H})$ denote the maximum possible number of color classes in a strong coloring and an equitable coloring of \mathcal{H} , respectively. Clearly, $1 \leq ec(\mathcal{H}) \leq c(\mathcal{H}) \leq k$. If no upper bounds are imposed on the maximum degree, then $ec(\mathcal{H}) = c(\mathcal{H}) = 1$ could happen even k is large. An example is the complete k -uniform hypergraph on $2k$ vertices that satisfies $c(\mathcal{H}) = 1$ and maximum degree less than 4^k .

Let $a \geq 1$ be any real number, and let $\epsilon > 0$ be small. Let k be sufficiently large such that there exists an integer in the interval $[k/(1 + \epsilon^2/4)a \ln k, k/(1 + \epsilon^2/8)a \ln k]$. For some γ in the interval $[\epsilon^2/8, \epsilon^2/4]$, the number $k/(1 + \gamma)a \ln k$ is an integer. Let \mathcal{H} be a k -uniform hypergraph with maximum degree at most k^a . Yuster [157] proved that there exists an equitable coloring of \mathcal{H} with $k/(1 + \gamma)a \ln k - \lceil k\sqrt{\gamma}/a \ln k \rceil > (1 - \epsilon)k/a \ln k$ colors and the following was established.

Theorem 107 *If $a \geq 1$ and \mathcal{H} is a k -uniform hypergraph with maximum degree at most k^a , then $ec(\mathcal{H}) \geq \frac{k}{a \ln k} (1 - o_k(1))$. The lower bound is asymptotically tight. For all $a \geq 1$, there exists k -uniform hypergraphs \mathcal{H} with maximum degree at most k^a and $c(\mathcal{H}) \leq \frac{k}{a \ln k} (1 + o_k(1))$.*

Note that results in Alon [3] have already implied that no equitable coloring of a k -uniform hypergraph could have more than $(k/\ln k)(1 + o_k(1))$ color classes. Yuster made the following remarks at the end of his paper [157].

Using more involved computations, Theorem 107 can be proved when a is not a constant but satisfies $a = a(k) = o(k/\ln k)$, i.e., the degree of \mathcal{H} is allowed to be any subexponential function of k .

It is possible to convert the proof of Theorem 107 into an algorithmic one. In terms of the number of vertices of the hypergraph, but not in its uniformity, a polynomial time algorithm can be found to produce an equitable partition with $(1 - o_k(1))ck/(a \ln k)$ color classes, where c is a fixed small constant depending only on a .

A special case of Theorem 107 gives the following interesting result about graphs. Let G be a k -regular graph. If k is sufficiently large, then G has an equitable

coloring with $(1 - o_k(1))(k / \ln k)$ colors such that each color class is a so-called *total dominating set*, that is a subset of the vertices such that each vertex of G has a neighbor in that subset.

20 Conclusion

The subject of graph coloring occupies a central position in graph theory. Historically speaking, much of the early development of graph theory was motivated by the attempts at solving the four-color conjecture. Later on, a large number of variants or generalizations of graph coloring problem have emerged. Graph coloring involves deep mathematical and computational issues. The possibilities for applications are also wide. When resources are allocated, a certain kind of graph coloring model may be lurking around. The requirement for even distribution is rather natural. The equitable coloring goes to the extreme to make color classes differ in size by at most one. This may be too stringent for applications in the real world. Yet it brings up hard questions to be addressed.

Although the concept of an equitable coloring of a graph was introduced in early 1970s, substantial research results have only been accumulated in the last 20 years. The importance of the equitable Δ -coloring conjecture has gradually been recognized. Positive evidence has been collected in this chapter.

Another fundamental phenomenon in equitable graph coloring is that in many graph classes “most” members admit equitable colorings with colors not extremely larger than their ordinary chromatic numbers. This phenomenon needs further investigated.

Equitable coloring of graphs can be formulated in terms of graph packings. This places equitable coloring in a wider context and gives it some previously unexpected connections and it may provide motivations to generate graph packing problems.

Abstract

Exponential algorithms, whose time complexity is $O(c^n)$ for some constant $c > 1$, are inevitable when exactly solving NP-complete problems unless $\mathbf{P} = \mathbf{NP}$. This chapter presents recently emerged combinatorial and algebraic techniques for designing exact exponential time algorithms. The discussed

techniques can be used either to derive faster exact exponential algorithms or to significantly reduce the space requirements while without increasing the running time. For illustration, exact algorithms arising from the use of these techniques for some optimization and counting problems are given.

1 Introduction

It is a folklore that any NP-complete problem can be exactly solved in exponential time via exhaustive search. Whether there is a faster way than this kind of brute-force approach to solve any such problem is still unclear. Nonetheless, many researchers have found exact exponential time algorithms that are faster than trivial exhaustive search for quite many NP-hard optimization problems such as the traveling salesman problem (TSP) [39]. The study of exact exponential algorithms for NP-hard problems has received increasing attention since the seminal survey by Woeginger [55] in 2001. As a result, some classical techniques such as inclusion-exclusion (e.g., [19, 20, 32]) have been resurrected, and some new techniques, such as fast subset convolution [12] and the algebraic methods (e.g., [9]), have been developed. Unfortunately, for some optimization problems, although it is possible to obtain faster exponential algorithms, exponential space is required, which renders these algorithms not practical for real-life use. This chapter presents some important recently resurrected or emerged combinatorial and algebraic approaches for designing faster exact exponential time algorithms and discusses how these techniques may be used to reduce the space complexity while not sacrificing the time complexity.

Notation. Throughout this chapter, a modified big-O notation is used to hide a polylogarithmic factor: for a positive real constant d and a function τ , $O^*(\tau)$ denotes a time complexity of the form $O(\tau \log^d \tau)$.

Structure of the chapter. The main theme of this chapter is to introduce two classes of methods for designing either faster or space-efficient exact exponential time algorithms. Section 2 discusses the combinatorial methods, which covers fast subset convolution and inclusion-exclusion based algorithms. Section 3 presents the recently emerged algebraic methods, which covers the algebraic sieving method and the polynomial circuit-based algebraic method. Each of these two sections will first explain how to use these techniques to design faster exact exponential time algorithms and then discuss how they may be used to reduce the space complexity while not increasing the running time. Various examples to illustrate the techniques will also be given. Section 4 concludes the chapter and Sect. 5 highlights the related work on these two classes of methods.

2 Combinatorial Methods

There are two well-developed and commonly used combinatorial techniques – fast subset convolution and inclusion-exclusion. The fast subset convolution can compute the convolution of any two given functions over some subset lattice in

$O^*(2^n)$ time, whereas a direct evaluation needs $\Omega(3^n)$ time. This fast algorithm is based on fast algorithms for the zeta transform and other related transforms which are actually accelerated dynamic programming algorithms. Thus, it needs exponential space since dynamic programming approaches have to store all the useful auxiliary information. Surprisingly, for certain special type of input functions called singletons, this exponential space could be circumvented. Furthermore, several variants of subset convolution, such as the covering product and the packing product [12], also play an important role in the design of faster exponential time exact algorithms.

The inclusion-exclusion principle is a classical sieving method: to determine the size of a set, the set is first overcounted, then subtract from this count, add again, subtract again, until finally arriving at the exact number of elements. This allows to count combinatorial objects indirectly, which is better than direct counting which could be inefficient or even impossible. Furthermore, although it needs to go through all subsets, the inclusion-exclusion technique is powerful in providing polynomial space exact algorithms. Combining it with some dynamic programming-based algorithms, such as the fast zeta transform, gives more surprising results. In fact, the inclusion-exclusion technique solves optimization problems via solving the corresponding counting problems, and hence, it is an important alternative for designing exact algorithms for counting problems.

Before the detailed descriptions of these two techniques, some essential tools needs to be introduced – the fast zeta transform and the fast Möbius transform.

2.1 Zeta Transform and Möbius Transform

Denote by R an arbitrary (possibly noncommutative) ring and by N a set of n elements, $n \geq 0$. Let f be a function that associates with every subset $S \subseteq N$ an element $f(S)$ of the ring R .

The zeta transform of f is the function $f\zeta$ that associates every $S \subseteq N$ with an element in R :

$$f\zeta(S) = \sum_{X \subseteq S} f(X). \quad (1)$$

The Möbius transform $f\mu$ of f is defined as

$$f\mu(S) = \sum_{X \subseteq S} (-1)^{|S \setminus X|} f(X). \quad (2)$$

Given the zeta transform $f\zeta$, the original function f can be obtained by the following formula which is often called Möbius inversion:

$$f(X) = \sum_{S \subseteq X} (-1)^{|X \setminus S|} f\zeta(S). \quad (3)$$

For more details of these two transforms, please refer to [27].

2.1.1 Fast Zeta Transform and Fast Möbius Transform

The straightforward way to compute the zeta transform evaluates $f\zeta(S)$ at every $S \subseteq N$, using $O(3^n)$ ring additions in total. This can be improved to use only $O(n2^n)$ ring operations by applying the Yates's method [37, 58], and the resulting algorithm is commonly called the fast zeta transform. Without loss of generality, assume that $N = \{1, 2, \dots, n\}$. To compute $f\zeta$, let initially $f\zeta_0(S) = f(S)$ for every $S \subseteq N$. Then iterate for $j = 1, 2, \dots, n$ and $S \subseteq N$ with the following recurrence:

$$f\zeta_j(S) = \begin{cases} f\zeta_{j-1}(S), & \text{if } j \notin X \\ f\zeta_{j-1}(S \setminus \{j\}) + f\zeta_{j-1}(S), & \text{otherwise.} \end{cases} \quad (4)$$

It can be verified by induction on j that the above recurrence gives $f\zeta_n(S) = f\zeta(S)$ for any $S \subseteq N$ in $O(n2^n)$ ring operations. The Möbius transform can be computed in a similar manner. Initially, let $f\mu_0(S) = f(S)$ for every $S \subseteq N$. Then iterate for $j = 1, 2, \dots, n$ and $S \subseteq N$ as follows:

$$f\mu_j(S) = \begin{cases} f\mu_{j-1}(S), & \text{if } j \notin X \\ -f\mu_{j-1}(S \setminus \{j\}) + f\mu_{j-1}(S), & \text{otherwise.} \end{cases} \quad (5)$$

Similarly, it can be proved that $f\mu_n(S) = f\mu(S)$ for any $S \subseteq N$.

Theorem 1 *Let N be a set of n elements. Then the zeta transform and the Möbius transform on the subset lattice of N can be computed in $O(n2^n)$ ring operations.*

2.2 Subset Convolution

Definition 1 (Subset convolution) Given a universe set N of n elements, f and g are functions defined on subsets of N , which associate every $S \subseteq N$ with an element of a ring R , respectively. The convolution $f * g$ for all $S \subseteq N$ is defined as follows:

$$f * g(S) = \sum_{X \subseteq S} f(X)g(S \setminus X). \quad (6)$$

The subset convolution can yield solutions to many hard computational problems. In particular, by embedding the integer max-sum or min-sum semiring into the sum-product ring, the technique can be used to implement many dynamic programming-based algorithms.

2.2.1 Fast Subset Convolution

In principle, the fast subset convolution consists of several efficient dynamic programming instances. In the fast subset convolution, the evaluation of (6) can

be achieved via the product of “ranked” extensions of the classical zeta transforms of f and g on the subset lattice, followed by a “ranked” Möbius transform. The fast subset convolution is summarized in [Algorithm 1](#).

For every $k = 0, 1, \dots, n$ and $S \subseteq N$, the ranked zeta transform of f is defined as

$$f\zeta(k, S) = \sum_{X \subseteq S, |X|=k} f(X). \quad (7)$$

Based on the above defined ranked zeta transform, the inversion can be achieved by

$$f(X) = \sum_{S \subseteq X} (-1)^{|S \setminus X|} f\zeta(|X|, S). \quad (8)$$

Although the above formula seems redundant, it will provide a key for fast evaluation of the subset convolution. Note that the ranked zeta transform can be computed in $O(n^2 2^n)$ ring operations by carrying out the fast zeta transform (4) independently for every $k = 0, 1, \dots, n$. Similarly, the ranked inversion (8) can be computed in $O(n^2 2^n)$ ring operations by carrying out the fast Möbius transform (5) independently for each $k = 0, 1, \dots, n$.

For the two ranked zeta transforms, $f\zeta$ and $g\zeta$, define a new convolution $f\zeta \otimes g\zeta$ for all $k = 0, 1, \dots, n$ and $S \subseteq N$ by

$$f\zeta \otimes g\zeta(k, S) = \sum_{j=0}^k f\zeta(j, S)g\zeta(k-j, S). \quad (9)$$

Lemma 1 $f * g(S) = \sum_{X \subseteq S} (-1)^{|S \setminus X|} f\zeta \otimes g\zeta(|S|, S)$

Proof

$$\begin{aligned} \sum_{X \subseteq S} (-1)^{|S \setminus X|} f\zeta \otimes g\zeta(|S|, S) &= \sum_{X \subseteq S} (-1)^{|S \setminus X|} \sum_{j=0}^{|S|} f\zeta(j, S)g\zeta(|S| - j, S) \\ &= \sum_{X \subseteq S} (-1)^{|S \setminus X|} \sum_{j=0}^{|S|} \sum_{\substack{U, V \subseteq X \\ |U|=j, |V|=|S|-j}} f(U)g(V). \end{aligned} \quad (10)$$

Because X ranges over all subsets of S , for any ordered pair (U, V) of subsets of S satisfying the condition that $|U| + |V| = |S|$, the term $f(U)g(V)$ occurs exactly once in the sum with sign $(-1)^{|S \setminus X|}$ for subsets X of S iff $U \cup V \subseteq X$. Then putting the terms associated with each pair (U, V) together, by the Binomial Theorem, the coefficient of $f(U)g(V)$ is

$$\sum_{x=|U \cup V|}^{|S|} \binom{|S| - |U \cup V|}{x - |U \cup V|} (-1)^{|S|-x} = \begin{cases} 1, & \text{if } |U \cup V| = |S| \\ 0, & \text{otherwise.} \end{cases} \quad (11)$$

The conditions that $|U| + |V| = |S|$ and $|U \cup V| = |S|$ imply that $U \cup V = S$ and $U \cap V = \emptyset$; and it follows that

$$\begin{aligned} \sum_{X \subseteq S} (-1)^{|S \setminus X|} f\zeta \circledast g\zeta(|S|, S) &= \sum_{U \cup V = S, U \cap V = \emptyset} f(U)g(V) \\ &= f * g(S). \end{aligned} \quad (12)$$

□

Theorem 2 *The subset convolution over an arbitrary ring can be evaluated in $O(n^2 2^n)$ ring operations using the fast subset convolution as shown in [Algorithm 1](#).*

Proof The correctness is established by [Lemma 1](#). In [Algorithm 1](#), the time is mainly consumed in lines 2, 6, and 9. By [Theorem 1](#), the time consumed in lines 2 and 9 is $O(n^2 2^n)$, and the time needed in line 6 is $O(n^2 2^n)$ according to Formula (9). Thus, the time complexity of [Algorithm 1](#) is $O(n^2 2^n)$. □

The following theorem is implied by [Theorem 2](#).

Theorem 3 *The subset convolution over the integer sum-product ring can be computed in $O^*(2^n \log M)$ time, provided that the range of the input functions is $\{-M, -M + 1, \dots, M\}$.*

Proof By [Theorem 2](#), the subset convolution can be computed in $O(n^2 2^n)$ ring operations. Thus, it suffices to note that any intermediate results, for which ring operations are performed, are $O(n \log M)$ -bit integers. This is the case because the ranked zeta transform of an input function can be computed with integers between $-M 2^n$ and $M 2^n$, and it follows that the convolution of ranked transforms

Algorithm 1 Fast subset convolution

Input: A universe set N of n elements and functions f, g defined on 2^U

Output: The subset convolution $f * g$ for every set $S \subseteq N$

- 1: **For** $i = 0$ to n **do**
 - 2: Compute the ranked zeta transforms $f\zeta(k, X), g\zeta(k, X)$ for every $X \subseteq N$ using the fast zeta transform.
 - 3: **End For**
 - 4: **For** $k = 0$ to n **do**
 - 5: **For** every $X \subseteq N$ **do**
 - 6: Compute the convolution $f\zeta \circledast g\zeta(k, X)$
 - 7: **End For**
 - 8: **End For**
 - 9: Compute the subset convolution $f * g$ for every set $S \subseteq N$ based on Formula (12) using the fast Möbius transform.
-

can be computed with $O(n \log M)$ -bit integers. Furthermore, the ranked Möbius transform is computed by adding and subtracting $O(n \log M)$ -bit integers for $O(2^n)$ times. \square

An obvious disadvantage of the fast subset convolution algorithm is its inapplicability to semirings where additive inverses need not exist. For some special semirings usually appearing in combinatorial optimization problems, for example, the integer max-sum and integer min-sum semirings, one can embed these semirings into the integer sum-product ring.

Theorem 4 *The subset convolution over the integer max-sum (min-sum) semiring can be computed in $O^*(2^n M)$ time, provided that the range of the input functions is $\{-M, -M + 1, \dots, M\}$.*

Proof Here, we only provide the proof for the max-sum semiring, as that for the min-sum semiring is similar. Without loss of generality, assume that the range of the input functions is $\{0, 1, \dots, M\}$; otherwise, the correct output can be obtained by first adding M to each value of both input functions, then computing the convolution, and finally subtracting $2M$ from the computed values.

Let f, g be the two input functions. Let $\beta = 2^n + 1$ and $M' = \beta^M$. Define new functions $f' = \beta^f$ and $g' = \beta^g$ which map the subsets of N to $\{0, 1, \dots, M'\}$. By Theorem 3, the subset convolution $f' * g'$ over the integer sum-product ring can be computed in $O^*(2^n \log M') = O^*(2^n M)$ time. It remains to show that for all $S \subseteq N$, the value for $\max_{T \subseteq S} \{f(T) + g(S \setminus T)\}$ can be efficiently deduced given the value of $f' * g'(S)$. Observe that $f' * g'(S)$ can be expressed as

$$\begin{aligned} f' * g'(S) &= \sum_{T \subseteq S} \beta^{f(T)+g(S \setminus T)} \\ &= \alpha_0(S) + \alpha_1(S)\beta + \cdots + \alpha_{2M}(S)\beta^{2M}. \end{aligned} \tag{13}$$

Due to the choice of β , each coefficient $\alpha_r(S)$ is uniquely determined and equals the number of subsets T of S for which $f(T) + g(S \setminus T) = r$. Thus, for each $S \subseteq N$, the largest r for which $\alpha_r(S) > 0$ corresponds to the value of $f * g(S)$. Clearly, this can be found in $O(M)$ time. \square

Example 1 (Partitioning Problem) The generic problem of partitioning is to divide an n -element set N into k disjoint subsets such that each of which satisfies some desired property specified by an indicator function f on the subsets of N . Given N , k , and f as input, the task is to decide whether there exists a partition $\{S_1, S_2, \dots, S_k\}$ of N such that $f(S_c) = 1$ for each $c = 1, 2, \dots, k$. Many classical graph partitioning problems are of this form. For example, in graph coloring, $f(S) = 1$ iff S is an independent set in the input graph with the vertices N . Likewise, in domatic partitioning, f is the indicator of dominating sets. Note that the number of valid partitions of N is given by $f^{*k}(N)$, where f^{*k} is defined as

$$f^{*k} = \underbrace{f * \dots * f}_{k \text{ times}}.$$

Thus, the valid partitions can be counted by $O(\log k)$ subset convolutions using the doubling trick – computing only convolutions f^{*2^i} . \square

Example 2 (Steiner Tree Problem) Given an undirected graph $G = (V, E)$, a weight $w(e) > 0$ for each edge $e \in E$, and a set of vertices $K \subseteq V$, the Steiner tree problem is to find a subgraph H of G that connects the vertices in K and has the minimum total weight $\sum_{e \in E(H)} w(e)$ among all such subgraphs of G . Here, we only consider the case where the weight of each edge is bounded by a constant. Obviously, H is necessarily a tree. A Steiner tree always refers to such an optimal subgraph. The fast subset convolution can be used to accelerate the famous Dreyfus-Wagner algorithm [25].

For a vertex subset $Y \subseteq V$, denote the total weight of a Steiner tree connecting Y in G by $W(Y)$. The Dreyfus-Wagner algorithm is based on the following dynamic programming called Dreyfus-Wagner recurrence: for $|Y| \geq 3$, and all $q \in Y$, $X = Y \setminus \{q\}$.

$$W(\{q\} \cup X) = \min\{W(\{p\}) + g_p(X) : p \in V\}, \quad (14)$$

$$g_p(X) = \min\{W(\{p\} \cup D) + W(\{p\} \cup (X \setminus D)) : \emptyset \subset D \subset X\}. \quad (15)$$

The Steiner tree problem can be solved by computing the weight $W(K)$ via the above recursion. For the base case, observe that for $|Y| = 1$ the weight $W(Y) = 0$ and for $|Y| = 2$ the weight $W(Y)$ can be determined by a shortest-path computation based on the edge weight $w(e)$, for example, Johnson's algorithm [35]. A bottom-up evaluation of $W(K)$ takes $O^*(3^k n + 2^k n^2 + nm)$ time, where $n = |V|$, $m = |E|$ and $k = |K|$. Once the values $W(\{p\} \cup Y)$ and $g_p(Y)$ for all $Y \subset K$ and $p \in V$ are computed and stored, an actual Steiner tree is easy to construct by tracing backward a path of optimal choices in (14) and (15).

The fast subset convolution over the min-sum semiring can expedite the evaluation of the Dreyfus-Wagner recursion in (15). Here the fast subset convolution needs to be implemented in a level-wise manner. For each level $l = 2, 3, \dots, k-1$, assume the value $W(\{q\} \cup X)$ has been computed and stored for all $X \subset K$ and $q \in V \setminus X$. Define the function f_p for all $X \subseteq K$ and $p \in V$ as

$$f_p(X) = \begin{cases} W(\{p\} \cup X), & \text{if } 1 \leq |X| \leq l-1 \\ \infty, & \text{otherwise.} \end{cases} \quad (16)$$

Obviously, $g_p(X) = f_p * f_p(X)$ for all $X \subseteq K$ and $|X| = l$. Then applying the fast subset convolution over the min-sum semiring, by Theorem 4, the Steiner tree problem can be solved in $O^*(2^k n^2 + nm)$ time. \square

2.3 Variants of Subset Convolution

2.3.1 Covering Product and Intersecting Covering Product

Definition 2 Given two functions f, g defined on 2^N which associate each subset of N to an element of a ring R , the covering product $f *_c g(S)$ for each $S \subseteq N$ is defined as

$$f *_c g(S) = \sum_{U, V \subseteq S, U \cup V = S} f(U)g(V). \quad (17)$$

Theorem 5 *The covering product over an arbitrary ring can be evaluated in $O(n^2 2^n)$ ring operations.*

Proof The proof is mainly based on the following Lemma.

Lemma 2 *For any $S \subseteq N$, the following holds:*

$$(f *_c g)\zeta(S) = f\zeta(S) \cdot g\zeta(S). \quad (18)$$

Proof

$$\begin{aligned} (f *_c g)\zeta(S) &= \sum_{X \subseteq S} (f *_c g)(S) \\ &= \sum_{X \subseteq S} \sum_{U \cup V = X} f(U)g(V) \\ &= \sum_{U \subseteq S} f(U) \sum_{V \subseteq U} g(V) \\ &= f\zeta(S) \cdot g\zeta(S). \end{aligned} \quad (19)$$

The third equality comes from the fact that for each $U, V \subseteq X$, there exists exactly one $X \subseteq S$ such that $U \cup V = X$. \square

By Lemma 2, $f *_c g$ can be obtained by computing the Möbius transform of $f\zeta(S) \cdot g\zeta(S)$. Then an $O^*(2^n)$ time algorithm for the covering product is as follows: first, compute $f\zeta$ and $g\zeta$ using the fast zeta transform (4), then multiply $f\zeta$ by $g\zeta$ for all $S \subseteq N$, and finally, compute $f *_c g$ using the fast Möbius transform (5). \square

Definition 3 Given two functions f, g defined on 2^N which associate each subset of N to an element of a ring R , the intersecting covering product $f *_c g(S)$ for each $S \subseteq N$ is defined as

$$f *_c g(S) = \sum_{\substack{U, V \subseteq S \\ U \cup V = S, U \cap V \neq \emptyset}} f(U)g(V). \quad (20)$$

An $O^*(2^n)$ time algorithm can be immediately derived from the fact that $f *_{ic} g = f *_c g - f * g$.

Theorem 6 *The intersecting covering product over an arbitrary ring can be evaluated in $O(n^2 2^n)$ ring operations.*

Furthermore, more precise control over the allowed intersection cardinalities $|U \cap V| = l$ besides the $l = 0$ ($f * g$) and $l > 0$ ($f *_{ic} g$) cases can be obtained by modifying (9).

Example 3 (Minimum Connected Spanning SubHypergraph (MCSH)) A hypergraph is a pair $H = (V, \mathcal{E})$, where V is a finite set and \mathcal{E} is a set consisting of subsets of V . A hypergraph $J = (W, F)$ is a subhypergraph of H if $W \subseteq V$ and $F \subseteq \mathcal{E}$. A subhypergraph is spanning if $V = W$. A path in a hypergraph H is a sequence $(x_1, E_1, x_2, E_2, \dots, E_l, x_{l+1})$ such that (a) $x_1, x_2, \dots, x_{l+1} \in V$ are all distinct, (b) $E_1, E_2, \dots, E_l \in \mathcal{E}$ are all distinct, and (c) $x_i, x_{i+1} \in E_i$ for all $i = 1, 2, \dots, l$. Such a path joins x_1 to x_{l+1} . A hypergraph is connected if for all distinct $x, y \in V$ there exists a path joining x to y .

Given a hypergraph $H = (V, \mathcal{E})$ and a weight $w(E) > 0$ for each hyperedge $E \in \mathcal{E}$, the minimum connected spanning subhypergraph problem is to find a connected spanning subhypergraph of H that has the minimum total weight or to assert that none exists. Here, the weight of every edge is assumed to be bounded by a constant. The MCSH problem can be solved in $O^*(2^n)$ time using the intersecting covering product over the min-sum semiring, where $n = |V|$.

First, define the k -th power of the intersecting covering product for all $k = 2, 3, \dots$ by

$$f *_{ic}^k = f *_{ic} (f *_{ic}^{k-1}). \quad (21)$$

Here, the order in which the products are evaluated matters because the intersecting covering product is not associative. Define the function f for all $E \subseteq V$ by

$$f(E) = \begin{cases} w(E), & \text{if } E \in \mathcal{E} \\ \infty, & \text{otherwise.} \end{cases} \quad (22)$$

Now, observe that (a) an MCSH can be constructed by augmenting a connected subhypergraph of H one hyperedge at a time, and (b) at most $n-1$ hyperedges occur in an MCSH of H . Thus, $f *_{ic}^k(V) < \infty$ is the minimum weight of a connected spanning subhypergraph of H consisting of k hyperedges. By storing the function values $f *_{ic}^k$ for each $k = 1, 2, \dots, n-1$, the actual MCSH can be determined by tracing back the computation one edge at a time.

2.3.2 Other Variants

Another important variant of the subset convolution is the packing product which is defined for all $S \subseteq N$ as

$$f *_p g(S) = \sum_{U,V \subseteq S, U \cap V = \emptyset} f(U)g(V). \quad (23)$$

Given f and g , the packing product can be evaluated in $O(n^2 2^n)$ ring operations by first computing the subset convolution $f * g$ and then convolving the result with vector $\vec{1}$ with all entries being equal to 1 based on the following fact:

$$f *_p g = f * g * \vec{1}. \quad (24)$$

Some further variations are possible by restricting the domain, for example, to any hereditary family of subsets of N . For more details, please refer to [12].

2.4 Inclusion-Exclusion

The inclusion-exclusion technique is based on a fundamental counting principle – the inclusion-exclusion principle. Clearly, it is a natural approach for solving counting problems. Here, we mainly focus on demonstrating its power in solving decision versions of optimization problems when direct computation is inefficient or even impossible. Another important feature of the inclusion-exclusion technique is that it does not need exponential space in principle. Hence, this technique is also a good choice for deriving polynomial space algorithms.

Lemma 3 (Inclusion-exclusion principle) *Let B be a finite set with subsets $A_1, \dots, A_n \subseteq B$. With the convention that $\cap_{i \in \emptyset} A_i = B$, the following holds:*

1. *The number of elements of B which lie in none of the A_i is*

$$|\bigcap_{i=1}^n \overline{A_i}| = \sum_{X \subseteq \{1, \dots, n\}} (-1)^{|X|} |\bigcap_{i \in X} A_i|. \quad (25)$$

2. *Let $w : B \rightarrow R$ be a real-valued weight function extended to the domain 2^B by setting $w(A) = \sum_{e \in A} w(e)$. Then*

$$w(|\bigcap_{i=1}^n \overline{A_i}|) = \sum_{X \subseteq \{1, \dots, n\}} (-1)^{|X|} w(|\bigcap_{i \in X} A_i|). \quad (26)$$

Proof The Lemma is proved by analyzing the contribution of every element $e \in B$ to both sides of the expression. If e is not contained by any A_i , it contributes $w(e)$ to the left hand side. To the right hand side it contributes $w(e)$ exactly once, namely, in the term corresponding to $X = \emptyset$. Conversely, assume that e lies in A_i for all $i \in I \neq \emptyset$. Its contribution to the left hand side is 0. On the right hand side, since e lies in the intersection $\cap_{i \in X} A_i$ for every $X \subseteq I$, by the Binomial Theorem, its total contribution is

$$\sum_{X \subseteq I} (-1)^{|X|} w(e) = w(e) \sum_{i=0}^{|I|} (-1)^i \binom{|I|}{i} = 0. \quad (27)$$

□

Example 4 (Set Partition) Given a set system (N, \mathcal{F}) and an integer k , where $\mathcal{F} \subseteq 2^N$, a k -partition of the given set system is a tuple (S_1, \dots, S_k) over \mathcal{F} such that $\cup_{i=1}^k S_i = N$ and $S_i \cap S_j = \emptyset$ for any $1 \leq i \neq j \leq k$. Denote $P_k(\mathcal{F})$ as the number of such k -partitions. The set partition problem is to determine the minimum k such that there is a k -partition of (N, \mathcal{F}) , that is, the minimum k such that $P_k(\mathcal{F}) > 0$. Clearly, this problem can be solved by computing $P_k(\mathcal{F})$ for at most n different k values. The following lemma shows how to compute $P_k(\mathcal{F})$ by making use of the inclusion-exclusion principle.

Lemma 4 Let $a_k(X)$ denote the number of k -tuples (S_1, \dots, S_k) over \mathcal{F} for which $S_i \cap X = \emptyset$ ($1 \leq i \leq k$) and $\sum_{i=1}^k |S_i| = n$. Then

$$p_k(\mathcal{F}) = \sum_{X \subseteq N} (-1)^{|X|} a_k(X). \quad (28)$$

Proof This is a direct application of Lemma 3, where B is the set of k -tuples (S_1, \dots, S_k) over \mathcal{F} satisfying $\sum_{i=1}^k |S_i| = n$, and $A_i \subseteq B$ are those k -tuples that avoid $\{i\}$. Then $p_k(\mathcal{F})$ is exactly the number of k -tuples that lie in none of the A_i , and $|\cap_{i \in X} A_i| = a_k(X)$. □

Write $f\zeta^{(l)}(Y)$ for the number of sets $S \in \mathcal{F}$ with $|S| = l$ and $S \subseteq Y$, and recall that it is the zeta transform of the indicator function

$$f^{(l)}(S) = \begin{cases} 1, & \text{if } S \in \mathcal{F}, |S| = l \\ 0, & \text{otherwise.} \end{cases} \quad (29)$$

Thus, the fast zeta transform (4) computes a table containing $f\zeta^{(l)}(Y)$ for all l and Y in $O^*(2^n)$ time.

Once these values have been computed, $a_k(X)$ can be obtained for any fixed $X \subseteq N$ by dynamic programming in time polynomial in k and n as follows. Define $g(j, m)$ to be the number of j -tuples (S_1, \dots, S_j) for which $S_c \cap X = \emptyset$ ($1 \leq c \leq j$) and $\sum_{c=1}^j |S_j| = m$, formally

$$g(j, m) = \sum_{l_1 + \dots + l_j = m} \prod_{c=1}^j f\zeta^{(l_c)}(N \setminus X). \quad (30)$$

Then $a_k(X) = g(k, n)$, and it can be computed by the following recursion:

$$g(j, m) = \sum_{l=0}^m g(j-1, m-l) f\zeta^{(l)}(N \setminus X), \quad (31)$$

observing that $g(1, m) = f\zeta^{(m)}(N \setminus X)$. Finally, summing up $a_k(X)$ according to (28) gives an $O^*(2^n)$ time algorithm for computing $P_k(\mathcal{F})$. \square

Example 5 (Cover Polynomial) Denote $x^i = \frac{x!}{(x-i)!}$. A Hamiltonian path of a graph is a walk that contains all the nodes exactly once. If the walk is cyclic, it is called a Hamiltonian cycle. The cover polynomial of a directed graph $D = (V, A)$ is defined as (cf. [13, 22])

$$\sum_{i,j} C_V(i, j) x^i y^j, \quad (32)$$

where $C_V(i, j)$ can be interpreted as the number of ways to partition V into i -directed paths and j -directed cycles of D . The so-called computing cover polynomial is to compute the coefficient $C_V(i, j)$.

For $X \subseteq V$, denote by $h(X)$ the number of Hamiltonian paths in $D[X]$, and denote by $c(X)$ the number of Hamiltonian cycles in $D[X]$. Define $h(\emptyset) = c(\emptyset) = 0$. Note that for all $x \in V$, $h(\{x\}) = 1$ and $c(\{x\})$ is the number of loops incident on x . Then $C_V(i, j)$ can be expressed as:

$$C_V(i, j) = \frac{1}{i!j!} \sum_{X_1, \dots, X_i, Y_1, \dots, Y_j} h(X_1) \cdots h(X_i) c(Y_1) \cdots c(Y_j), \quad (33)$$

where the sum is over all $(i + j)$ -tuples $(X_1, \dots, X_i, Y_1, \dots, Y_j)$ such that it is a partition of V .

The expression for $C_V(i, j)$ can be reformulated using the principle of inclusion-exclusion. Let z be a polynomial indeterminate. Define for every $U \subseteq V$ the polynomials

$$H_U(z) = \sum_{X \subseteq U} h(X) z^{|X|}, \quad C_U(z) = \sum_{Y \subseteq U} c(Y) z^{|Y|}. \quad (34)$$

Viewed as set functions, $H_U(z)$ and $C_U(z)$ are zeta transforms of the set functions $h(X)z^{|X|}$ and $c(Y)z^{|Y|}$, respectively. By inclusion-exclusion,

$$C_V(i, j) = \frac{1}{i!j!} \sum_{U \subseteq V} (-1)^{|V \setminus U|} \{z^n\} H_U(z)^i C_U(z)^j. \quad (35)$$

Based on the above formula, an $O^*(2^n)$ time algorithm can be obtained. For $S \subseteq V$, let $w_S(s, t, l)$ denote the number of directed walks of length l from vertex s to vertex t in $D[S]$. Define $w_S(s, t, l) = 0$ if $s \notin S$ or $t \notin S$. By inclusion-exclusion again,

$$\begin{aligned} h(X) &= \sum_{s,t \in V} \sum_{S \subseteq X} (-1)^{|X \setminus S|} w_S(s, t, |X| - 1), \\ c(Y) &= \frac{1}{|Y|} \sum_{s \in V} \sum_{S \subseteq Y} (-1)^{|Y \setminus S|} w_S(s, s, |X|). \end{aligned} \quad (36)$$

Observing $w_S(s, t, l)$ can be computed in polynomial time, the fast Möbius transform (5) can compute $h(X)$ and $c(Y)$ for every $X, Y \subseteq V$ in $O^*(2^n)$ time. Then H and C can be evaluated using the fast zeta transform according to (34). Finally, given H and C , (35) can be evaluated in $O^*(2^n)$ time. \square

2.5 Space Efficient Exact Algorithms

2.5.1 Polynomial Space Algorithm Based on Subset Convolution

For some special input functions whose zeta transforms can be determined easily, polynomial space algorithms for some combinatorial optimization problems can be derived via the subset convolution and the covering product. A particular type of input functions called singletons is used here to demonstrate how to efficiently compute the subset convolution and the covering product values for the element set N using only polynomial space. A function $f : U \rightarrow R$ is called a singleton if there exists an element $e \in U$ such that $f(x) = 0$ unless $x = e$.

Theorem 7 *Given two functions f, g defined on 2^N which associate each subset of N to an element of a ring R , if f, g , then (1) $f *_c g(N)$ can be computed in $O^*(2^n)$ time and polynomial space, and (2) $f * g(N)$ can be computed in $O^*(2^n)$ time and polynomial space.*

Proof (1) Assume that $f(X_f) = e_f$ and $g(X_g) = e_g$, where $X_f, X_g \subseteq N$ and $e_f, e_g \in R$. Since, f, g are singletons, $f(X) = 0$ for any $X \subseteq N$ other than X_f . The same result is also true for g and any subsets other than X_g . The following Lemma is proved in Sect. 2.3.1.

Lemma 5 *For any $S \subseteq N$, the following holds:*

$$(f *_c g)\zeta(S) = f\zeta(S) \cdot g\zeta(S). \quad (37)$$

Note that for singletons f, g , the zeta transforms for every $Y \subseteq N$ can be easily given as

$$f\zeta(Y) = \begin{cases} e_f, & \text{if } X_f \subseteq Y \\ 0, & \text{if otherwise.} \end{cases} \quad (38)$$

$$g\zeta(Y) = \begin{cases} e_g, & \text{if } X_g \subseteq Y \\ 0, & \text{if otherwise.} \end{cases} \quad (39)$$

Thus, the zeta transform of $f *_c g$ for every subset $Y \subseteq N$ can be computed in polynomial time after getting the zeta transforms $f\zeta$ and $g\zeta$. Then $f *_c g(N)$ can be obtained in $O^*(2^n)$ time by computing the Möbius inversion (3). The space used is polynomial since it is not necessary to store $(f *_c g)\zeta$ values for every $Y \subseteq N$.

(2) Denote $h = f * g$. Define a relaxation of a function $f : 2^N \rightarrow R$ as a sequence of functions $f_i : 2^N \rightarrow R$, for $0 \leq i \leq |N|$, such that for every $0 \leq i \leq |N|$, $Y \subseteq N$:

$$f_i(Y) = \begin{cases} f(Y), & \text{if } i = |Y| \\ 0, & \text{if } i < |Y|. \end{cases} \quad (40)$$

Observe that a function f can have many different relaxations, since there are no restrictions on what $f_i(X)$ should be when $i > |X|$. The basic idea of the proof is that for the input functions f and g , there exists a relaxation $\{h_i\}$ of h such that the zeta transform of $h_{|N|}$ can be computed efficiently. Since $h(N) = h_{|N|}(N)$, $h(N)$ can be obtained by computing the Möbius inversion (3) of $h\zeta_{|N|}$.

For input functions f and g , define $f_i = f$ and $g_i = g$ for all i . It is easy to verify that $\{f_i\}$ and $\{g_i\}$ are relaxations of f and g , respectively. Then define for all i , $h_i = \sum_{j=0}^i f_j *_c g_{i-j}$.

Lemma 6 *As defined above, $\{h_i\}$ is a relaxation of h .*

Proof By the definition of the covering product, for every $X \subseteq N$

$$h_i(X) = \sum_{j=0}^i \sum_{Y \cup Z=X} f_j(Y)g_{i-j}(Z). \quad (41)$$

Consider an arbitrary summand $f_j(Y)g_{i-j}(Z)$. There are two cases:

Case 1 ($|X| > i$) Since $Y \cup Z = X$, $|Y| + |Z| \geq |X| > i$. It concludes that either $|Y| > j$ and $f_j(Y) = 0$ or $|Z| > i - j$ and $g_{i-j}(Z) = 0$, because $\{f_i\}$ and $\{g_i\}$ both are relaxations of f and g respectively. Thus, $f_j(Y)g_{i-j}(Z) = 0$. Since $f_j(Y)g_{i-j}(Z)$ is an arbitrary term in the summation for $h_i(X)$, it follows that $h_i(X) = 0$.

Case 2 ($|X| = i$) If $|Y| + |Z| > i$, either $|Y| > j$ or $|Z| > i - j$ and $f_j(Y)g_{i-j}(Z) = 0$ which is analogous to the first case. If $|Y| + |Z| = i$, then Y and Z are disjoint. Since $\{f_i\}$ and $\{g_{i-j}\}$ are relaxations of f and g respectively, only $f_{|Y|}(Y)g_{|Z|}(Z)$ will contribute to the sum. Thus,

$$\begin{aligned} h_i(X) &= \sum_{j=0}^i \sum_{Y \cup Z=X} f_j(Y)g_{i-j}(Z) \\ &= \sum_{Y \cup Z=X, Y \cap Z=\emptyset} f_{|Y|}(Y)g_{|Z|}(Z) \end{aligned} \quad (42)$$

$$\begin{aligned}
&= \sum_{Y \cup Z = X, Y \cap Z = \emptyset} f(Y)g(Z) \\
&= h(X).
\end{aligned}$$

□

By [Lemma 5](#) and the definition of h_i in (41), it follows that $h\xi_i = \sum_{j=0}^i f\xi_j g\xi_{i-j}$. Thus, the zeta transform of $h_{|N|}(X)$ for every $X \subseteq N$ can be computed in polynomial time given the zeta transforms for $\{f_i\}$ and $\{g_i\}$. From (1), the zeta transforms of $\{f_i\}$ and $\{g_i\}$ can be obtained efficiently. Similar to what is done in (1), $h(N) = h_{|N|}(N)$ can be obtained in $O^*(2^n)$ time and polynomial space by computing the Möbius inversion

$$h_{|N|}(N) = \sum_{X \subseteq N} (-1)^{|N \setminus X|} h\xi_{|N|}(X). \quad (43)$$

□

Example 6 (Cover Polynomial Revisited) Define

$$C_Y(i, j) = \frac{1}{i!j!} \sum_{l_1 + \dots + l_{i+j} = n-i} h_{l_1} *_c \dots *_{l_i} h_{l_i} *_c c_{l_{i+1}} \dots c_{l_{i+j}}(Y), \quad (44)$$

where $h_l(Y)$ and $c_l(Y)$ are the number of Hamiltonian paths and Hamiltonian cycles of length l in $D[Y]$, respectively (here, the parameter l is introduced in order to obtain efficient computable zeta transforms). Note that paths and cycles with l edges contain $l+1$ and l nodes, respectively, which follows that the sum of the lengths of the paths and cycles in such a partition will be $n-i$. Moreover, if V is covered, the paths and cycles are disjoint because of the size restriction. The above definition for $C_V(i, j)$ is equivalent to that in [Example 5](#). Note that $h_l(Y)$ can be replaced by $h'_l(Y)$ which denotes the number of walks of length l in $D[Y]$. Similarly, $c_l(Y)$ can be replaced by $c'_l(Y)$ which is the number of cyclic walks of length l . Using the technique introduced in [Theorem 7](#), $C\xi_Y(i, j)$ can be computed using the following formula given $h\xi'_l(Y)$ and $c\xi'_l(Y)$:

$$C\xi_Y(i, j) = \frac{1}{i!j!} \sum_{l_1 + \dots + l_{i+j} = n-i} \prod_{t=1}^i h\xi'_{l_t}(Y) \prod_{p=1}^j c\xi'_{l_{i+p}}(Y). \quad (45)$$

Finally, $h\xi'_l(Y)$ and $c\xi'_l(Y)$ can be computed in polynomial time using standard dynamic programming (cf. [44]). Then $C_V(i, j)$ can be obtained by computing the Möbius inversion as described in [Theorem 7](#) (by a similar argument as used in proving [Lemma 1](#), it can be proved that all extra items introduced in the process of relaxing h_l and c_l are canceled through computing the Möbius inversion). Putting everything together will provide an $O^*(2^n)$ time and polynomial space algorithm for counting cover polynomial. □

Combining with the algebraic method to be introduced in Sect. 3.2, the technique introduced in Theorem 7 can be used to give polynomial space algorithms for the traveling salesman problem, the Steiner tree problem, the weighted set cover problem, etc., without increasing the running times as have been derived in the fastest solutions to these problems [12, 20, 28, 36].

2.5.2 Polynomial Space Exact Algorithms Based on Inclusion-Exclusion

By the inclusion-exclusion principle (25), if $|\bigcap_{i \in X} A_i|$ can be computed in polynomial time for each $X \subseteq \{1, \dots, n\}$, there exists a polynomial space algorithm evaluating Eq. (25) in $O^*(2^n)$ time.

Example 7 (Counting Hamiltonian Paths) Given a graph $G = (V, E)$, a Hamiltonian path is a walk that contains each node exactly once. The Counting Hamiltonian Path problem is to count the number of Hamiltonian paths. The following inclusion-exclusion based algorithm is due to Karp [36]: define the universe B as all walks of length $n - 1$ in G , and define A_v as all walks of length $n - 1$ containing v for each $v \in V$. By the inclusion-exclusion principle, the number of Hamiltonian paths is

$$h = \sum_{X \subseteq V} (-1)^{|X|} |\bigcap_{v \in X} \overline{A_v}|. \quad (46)$$

For $X \subseteq V$ and $s \in X$, let $w_k(s, X)$ be the number of walks from s of length k in $G[X]$. Then

$$|\bigcap_{v \in X} \overline{A_v}| = \sum_{s \in V \setminus X} w_{n-1}(s, V \setminus X). \quad (47)$$

For fixed $X \subseteq V$, $w_k(s, X)$ can be computed in polynomial time using the following recurrence:

$$w_k(s, X) = \begin{cases} 1, & \text{if } k = 0 \\ \sum_{t \in N(s) \cap X} w_{k-1}(t, X), & \text{otherwise.} \end{cases} \quad (48)$$

Notice that $w_k(s, X)$ is at most $O(n^n)$ which needs polynomial bits to represent. Thus, $|\bigcap_{v \in X} \overline{A_v}|$ can be computed in polynomial space and time, which provides an $O^*(2^n)$ time and polynomial space algorithm to evaluate Eq. (46).

Example 8 (Counting Perfect Matchings) Given two undirected graphs F and G , let $\text{sub}(F, G)$ denote the number of distinct copies of a graph F contained in a graph G . Clearly, if F is a matching of $n/2$ edges, where n is the vertex number of G , then $\text{sub}(F, G)$ is the number of perfect matchings in G .

A homomorphism from F to G is a mapping from the vertex set of F to that of G such that the image of every edge of F is an edge of G . Let $\text{hom}(F, G)$ and $\text{inj}(F, G)$ be the numbers of homomorphisms and injective homomorphisms from F to G , respectively. Furthermore, let $\text{aut}(F, F)$ denote the number of automorphisms, that

is, bijective homomorphisms, from F to itself. The following equation switches the focus to computing $\text{inj}(F, G)$, since $\text{aut}(F, F)$ for a graph F on n_F vertices can be computed in subexponential time [2]

$$\text{sub}(F, G) = \frac{\text{inj}(F, G)}{\text{aut}(F, F)}. \quad (49)$$

Let S be a given subset of $V(G)$, then a homomorphism f from F to G is called S -saturating if (a) $S \subseteq f(V(F))$ and (b) for all $v \in S$, $|f^{-1}(v)| = 1$. Let $S - \text{hom}(F, G)$ denote the number of S -saturating homomorphisms. By the inclusion-exclusion principle,

$$\text{inj}(F, G) = \sum_{W \in V(G) \setminus S} (-1)^{|W|} S - \text{hom}(F, G[V(G) \setminus W]). \quad (50)$$

Note that if F is a matching of $n/2$ edges, $S - \text{hom}(F, G[V(G) \setminus W])$ can be computed in polynomial time and polynomial space using the following equation, which gives rise to an $O^*(2^n)$ time polynomial space algorithm for counting the number of perfect matchings in G . Let $S = \{v_1, \dots, v_a\}$, then

$$\begin{aligned} S - \text{hom}(F, G[V(G) \setminus W]) &= \binom{\frac{n}{2}}{a} a! \left(\prod_{i=1}^a (2 \deg_{V(G) \setminus W}(v_i)) \right. \\ &\quad \left. |2E(G[V(G) \setminus (W \cup S)])|^{\frac{n}{2}-a}, \right) \end{aligned} \quad (51)$$

where $\deg_{V(G) \setminus W}(v_i)$ is the number of vertices adjacent to v_i in $V(G) \setminus W$.

2.5.3 Linear Space Exact Algorithms Based on Linear Space Fast Zeta Transform

As shown before, inclusion-exclusion together with the fast zeta transform can provide efficient exact algorithms for many hard problems, for example, the covering problem, the partitioning problem, and the packing problem (also cf. [19, 20, 40]). However, all these algorithms need $O^*(2^n)$ space to carry out the fast zeta transform. The following linear space fast zeta transform ([Algorithm 2](#)) can help these algorithms achieve a linear space bound without increasing the running time.

Theorem 8 (Linear Space Zeta Transform) *Suppose f vanishes outside a family \mathcal{F} of subsets of N and the member of \mathcal{F} can be listed in time $O^*(2^n)$ and space $O^*(|\mathcal{F}|)$. Then the values $f \zeta(X)$, for every $X \subseteq U$, can be listed in time $O^*(2^n)$ and space $O^*(|\mathcal{F}|)$ using [Algorithm 2](#).*

Proof Partition U into U_1 and U_2 such that $|U_1| = n_1$, $|U_2| = n_2$, where $n_2 = \lceil \log |\mathcal{F}| \rceil$ and $n_1 = n - n_2$. The correctness of [Algorithm 2](#) is established by the following Lemma.

Algorithm 2 Linear space algorithm for zeta transform

Input: A universe set N of n elements and a functions f defined on a family \mathcal{F} of subsets of N

Output: The zeta transform $f\zeta$ for all sets in 2^N

```

1: For each  $X_1 \subseteq U_1$  do
2:   For each  $Y_2 \subseteq U_2$  do
3:     set  $g(Y_2) \leftarrow 0$ 
4:   End For
5:   For each  $Y \in \mathcal{F}$  do
6:     If  $Y \cap U_1 \subseteq X_1$ , then
7:       set  $g(Y \cap U_2) \leftarrow g(Y \cap U_2) + f(Y)$ 
8:     End For
9:   Compute  $h \leftarrow g\zeta$  using the fast zeta transform on  $2^{U_2}$ 
10:  For each  $X_2 \subseteq U_2$  do
11:    output the value  $h(X_2)$  as the value  $f\zeta(X_1 \cup X_2)$ 
12:  End For
13: End For

```

Lemma 7

$$f\zeta(X_1 \cup X_2) = h(X_2) \quad (52)$$

Proof

$$\begin{aligned}
h(X_2) &= \sum_{Y_2 \subseteq X_2} g(Y_2) \\
&= \sum_{Y_2 \subseteq X_2} \sum_{Y \in \mathcal{F}} [Y \cap U_1 \subseteq X_1][Y \cap U_2 = Y_2] f(Y) \\
&= \sum_{Y \in \mathcal{F}} [Y \cap U_1 \subseteq X_1][Y \cap U_2 \subseteq X_2] f(Y) \\
&= \sum_{Y \in \mathcal{F}, Y \subseteq X_1 \cup X_2} f(Y) \\
&= \sum_{Y \subseteq X_1 \cup X_2} f(Y) \\
&= f\zeta(X_1 \cup X_2).
\end{aligned} \tag{53}$$

□

Observe that the algorithm runs in $O^*(2^{n_1}(2^{n_2} + |\mathcal{F}|))$ time and $O^*(2^{n_2})$ space. By the assigned values of n_1 and n_2 , the algorithm thus runs in $O^*(2^n)$ time and $O^*(|\mathcal{F}|)$ space. □

In [Algorithm 2](#), because the computations are independent for each $X_1 \subseteq U_1$, they can be executed in parallel on $O^*(2^n/|\mathcal{F}|)$ processors.

Example 9 (Counting k -Partitions) The problem and the notations are defined in [Example 4](#). It is convenient to express the k -partitions in terms of generating polynomials. Based on the principle of inclusion-exclusion, (28) can be reformulated as follows in which $a_k(X)$ is replaced by a polynomial over an intermediate z :

$$d_k(\mathcal{F}) = \sum_{X \subseteq N} (-1)^{|N \setminus X|} \left(\sum_{i=0}^n a_i(X) z^i \right)^k, \quad (54)$$

where the coefficient $a_j(X)$ is the number of subsets $Y \subseteq X$ that belong to \mathcal{F} and are of size j . Now, $d_k(\mathcal{F})$ is a polynomial whose coefficient of the monomial z^n is the number of k -partitions. To evaluate this expression, note that the polynomial $a(X) = \sum_{i=0}^n a_i(X) z^i$ is equal to the zeta transform $g\zeta(X)$, where $g(Y) = [Y \in \mathcal{F}] z^{|Y|}$. Now the linear space fast zeta transform operating in a ring of polynomials lists the polynomials $a(X)$ for all $X \subseteq N$ in $O^*(2^n)$ time and $O^*(|\mathcal{F}|)$ space. \square

Similar ideas to that used in the linear space fast zeta transform can give space efficient algorithms for other elementary transforms and problems, for example, the intersection transform, the disjoint sum, and the chromatic polynomial. An important feature of this type of algorithms is that they admit efficient parallelization as discussed before. In particular, some algorithms [\[17\]](#) of this type can achieve a trade-off between time and space complexities by adjusting the number of processors executing the algorithm in parallel.

2.6 Faster Exact Algorithms in Bounded-Degree Graphs

For bounded-degree graphs, faster exact algorithms can be derived for certain hard problems. The basic idea is to exploit some special properties so that only a special set of subsets of the vertex set, but not all subsets, need to be considered; then, based on a projection theorem presented by Chung et al. [\[23\]](#), which can be used to bound the size of the special set, the running time can be reduced for bounded-degree graphs. In this section, an inclusion-exclusion based algorithm will exemplify how to derive faster exact algorithms for bounded-degree graphs. This method is not only applicable to inclusion-exclusion based algorithms but also to some other types of algorithms. The following lemma is the key to employ this method.

Lemma 8 ([23]) *Let V be a finite set with subsets A_1, A_2, \dots, A_r such that every $v \in V$ is contained in at least δ subsets. Let \mathcal{F} be a family of subsets of V . For each $1 \leq i \leq r$ define the projections $\mathcal{F}_i = \{F \cap A_i : F \in \mathcal{F}\}$. Then,*

$$|\mathcal{F}|^\delta \leq \prod_{i=1}^r |\mathcal{F}_i|. \quad (55)$$

Example 10 (TSP in bounded-degree graphs) Given a graph G with nodes V and distant function $d : V \times V \rightarrow N$, the traveling salesman problem (TSP) is to find a minimum-weighted Hamiltonian cycle based on the distance function that

minimizes the total distance. Assume that the maximum degree of G is $\Delta = O(1)$. A set W of vertices is a connected dominating set if every vertex $v \in V$ is either in W or adjacent to a vertex in W and the induced subgraph $G[W]$ is connected. Denote by \mathcal{CD} the family of connected dominating sets of G .

The starting point is the algorithm by Karp [36], and, independently, by Kohn et al. [39]. Assume that the distance function is bounded by a constant, that is, $d(u, v) \in \{0, 1, \dots, B\} \cup \{\infty\}$ for any pair of vertices u, v , where $B = O(1)$.

The algorithm can be conveniently described in terms of generating polynomials. Select an arbitrary reference vertex $s \in V$, and let $U = V \setminus \{s\}$. For each $X \subseteq U$, denote by $q(X)$ the polynomial over the indeterminate z for which the coefficient of each monomial z^w counts the directed closed walks (in the complete directed graph with vertex set V and edge weights given by d) through s that (i) avoid the vertices in X , (ii) have length n , and (iii) have finite weight w . Then $q(X)$ can be computed in time polynomial in n by the following recurrence and setting $q(X) = p(n, s)$ for a fixed $X \subseteq U$. Initialize the recurrence for each vertex $u \in V \setminus X$ with

$$p(0, u) = \begin{cases} 1, & \text{if } u = s \\ 0, & \text{otherwise.} \end{cases} \quad (56)$$

For convenience, define $z^\infty = 0$. For each length $l = 1, 2, \dots, n$ and each vertex $u \in V \setminus X$, let

$$p(l, u) = \sum_{v \in V \setminus X} p(l-1, v) z^{d(v,u)}. \quad (57)$$

Here, note that due to the assumption on bounded weights, each $p(l, u)$ has at most a polynomial number of monomials with nonzero coefficients.

By the principle of inclusion-exclusion, the coefficients of the monomials in the polynomial

$$Q = \sum_{X \subseteq U} (-1)^{|X|} q(X) \quad (58)$$

count, by weight, the number of directed Hamiltonian cycles. It follows immediately that the traveling salesman problem can be solved in time $O^*(2^n)$.

For bounded-degree graphs, faster algorithms can be derived by analyzing (58) in more details. It will be convenient to work with a complemented form of (58). For each $S \subseteq U$, let $r(S) = q(U \setminus S)$. Then (58) can be rewritten as

$$Q = (-1)^n \sum_{S \subseteq U} (-1)^{|S|} r(S). \quad (59)$$

Observe that the induced subgraph $G[\{s\} \cup S]$ need not be connected. Associate with each $S \subseteq U$ the unique $f(S) \subseteq U$ such that $G[\{s\} \cup f(S)]$ is the connected component of $G[\{s\} \cup S]$ that contains s . It follows that $r(S) = r(f(S))$ for all $S \subseteq U$. This observation enables the following partition of the subsets of U into 9 f -preimages of constant r -value. For each $T \subseteq U$, let $f^{-1}(T) = \{S \subseteq U : f(S) = T\}$. Then rewrite (59) in the partition form

$$Q = (-1)^n \sum_{T \subseteq U} r(T) \sum_{S \in f^{-1}(T)} (-1)^{|S|}. \quad (60)$$

Lemma 9

$$\sum_{S \in f^{-1}(T)} (-1)^{|S|} = \begin{cases} (-1)^{|T|}, & \text{if } \{s\} \cup T \in \mathcal{CD} \\ 0, & \text{otherwise.} \end{cases} \quad (61)$$

Proof Consider an arbitrary $T \subseteq U$. The preimage $f^{-1}(T)$ is clearly empty if $G[\{s\} \cup T]$ is not connected. Thus, in the following assume that $G[\{s\} \cup T]$ is connected. For a set $W \subseteq V$, denote $\bar{N}(W)$ the set of vertices in W or adjacent to at least one vertex in W . Observe that $f(S) = T$ holds for an $S \subseteq U$ iff $T \subseteq S$ and $S \cap \bar{N}(\{s\} \cup T) = T$. In particular, if $V \setminus \bar{N}(\{s\} \cup T)$ is nonempty, then $f^{-1}(T)$ contains equally many even- and odd-sized subsets. Conversely, if $V \setminus \bar{N}(\{s\} \cup T)$ is empty (which means that $\{s\} \cup T$ is a dominating set of G), then $f^{-1}(T) = \{T\}$. \square

Using the above lemma to simplify (60), we have

$$Q = (-1)^n \sum_{T \subseteq U, \{s\} \cup T \in \mathcal{CD}} (-1)^{|T|} r(T). \quad (62)$$

To arrive at an algorithm with running time $|\mathcal{CD}|n^{O(1)}$, it suffices to list the elements of \mathcal{CD} with delay bounded by $n^{O(1)}$. Observe that \mathcal{CD} is an upclosed family of subsets of V , that is, if a set is in the family, then so are all of its supersets. Furthermore, whether a given $W \subseteq V$ is in \mathcal{CD} can be decided in polynomial time. These observations enable listing the sets in \mathcal{CD} in a top-down, depth-first manner. Thus, the only remaining task is to bound the size of \mathcal{CD} .

Lemma 10 *Let V be a finite set with r elements and with subsets A_1, A_2, \dots, A_r such that every $v \in V$ is contained in exactly δ subsets. Let \mathcal{F} be a family of subsets of V and assume that there is a log-concave function $f \geq 1$ and $0 \leq s \leq r$ such that the projections $\mathcal{F}_i = \{F \cap A_i : F \in \mathcal{F}\}$ satisfy $|\mathcal{F}_i| \leq f(|A_i|)$ for each $s+1 \leq i \leq r$. Then,*

$$|\mathcal{F}| \leq f(\delta)^{r/\delta} \prod_{i=1}^s 2^{|A_i|/\delta}. \quad (63)$$

Proof Let $a_i = |A_i|$ and note that $\sum_{i=1}^r a_i = \delta r$. By Lemma 8,

$$|\mathcal{F}|^\delta \leq \prod_{i=1}^s 2^{a_i} \prod_{i=s+1}^r f(a_i) \leq \prod_{i=1}^s 2^{a_i} \prod_{i=1}^r f(a_i). \quad (64)$$

Since f is log-concave, Jensen's inequality gives

$$\frac{1}{r} \sum_{i=1}^r \log f(a_i) \leq \log f \left(\left(\sum_{i=1}^r a_i \right) / r \right) = \log f(\delta). \quad (65)$$

Taking exponential and combining with (64) gives $|\mathcal{F}|^\delta \leq f(\delta)^r \prod_{i=1}^s 2^{|A_i|}$, which yields the claimed bound. \square

In order to bound the size of \mathcal{CD} , we need only to consider the special case where A_i are defined in terms of neighborhoods of the vertices of G . For each $v \in V$, define the closed neighborhood $N(v)$ by $N(v) = \{v\} \cup \{u \in V : u \text{ and } v \text{ are adjacent in } G\}$. Begin by defining the subsets A_v for $v \in V$ as $A_v = N(v)$. Then, for each $u \in V$ with degree $d(u) < \Delta$, add u to $\Delta - d(u)$ of the sets A_v not already containing it (it does not matter which ones). This ensures that every $u \in V$ is contained in exactly $\Delta + 1$ sets A_v . Combining with the following given bound on the size of \mathcal{CD} , an $O^*(\beta_\Delta^n)$ time algorithm can be obtained as described above, where $\beta_\Delta = (2^{\Delta+1} - 2)^{1/(\Delta+1)}$.

Lemma 11 *An n -vertex graphs with maximum vertex degree Δ has at most $\beta_\Delta^n + n$ connected dominating sets, where $\beta_\Delta = (2^{\Delta+1} - 2)^{1/(\Delta+1)}$.*

Proof Let $\mathcal{CD}' = \mathcal{CD} \setminus \{\{v\} : v \in V\}$. Then for every $C' \in \mathcal{CD}'$ and every A_v , $C' \cap A_v \neq \{v\}$. Thus, the number of sets in the projection $\mathcal{CD}'_v = \{F \cap A_v : F \in \mathcal{CD}'\}$ is at most $2^{|A_v|} - 2$, since $F \cap A_v \neq \emptyset$ for any $F \in \mathcal{CD}'$. To obtain the bound, apply Lemma 10 with the log-concave function $f(x) = 2^x - 1$ and $s = 0$. \square

3 Algebraic Methods

The application of algebraic methods in designing exact algorithms can be dated back to the famous paper by Kohn et al. [39] on solving the traveling salesman problem using the generating polynomials (for details, please refer to Example 10), in which by involving an intermediate x , a polynomial $G(x) = \sum a_i x^{e_i}$ is produced, where e_i denotes the cost of a possible tour and a_i denotes the number of tours having this cost. Then the minimal tour cost, that is, the smallest exponent, can be extracted by evaluating $G(x)$ at a specific value close to 0 and using a logarithmic technique. In this section, two recently developed algebraic methods are introduced – algebraic sieving method and polynomial circuit-based algebraic method.

3.1 Algebraic Sieving

Sieving methods are commonly used in designing exact and parameterized algorithms and have a long history. For example, the inclusion-exclusion principle is a typical sieving method by which all possibilities are first counted, and then, false contributions are canceled out. Here, a new algebraic sieving method which makes use of determinants over a field of characteristic two to achieve sieving is introduced.

The basic idea is to construct a polynomial in the underlying variables over a finite field in which at least one unique monomial exists for each required structure (e.g., Hamiltonian cycle) and no monomials results from unwanted structures (e.g., non-Hamiltonian cycle covers). The existence of structures being looked for ultimately emerges as a polynomial testing problem. Then the old fingerprint idea, often attributed to Freivalds (cf. [43]), is applied in which the polynomial is evaluated in a randomly chosen point in a finite field. The fingerprint result is used to judge whether the constructed polynomial is zero polynomial or not. The Schwartz-Zippel Lemma (cf. [43]) ensures that such judgment will be correct with high probability. The key point of this method is how to sieve the unwanted monomials to obtain the final required polynomial. So far only determinants over a finite field are taken advantage of to achieve sieving. Whether there exists some other more powerful tools that can be used for sieving under the algebraic framework needs further studying. Before going into the details, some notations need to be defined.

The determinant of an $n \times n$ matrix \mathbf{A} over an arbitrary ring R can be defined by the Leibniz formula:

$$\det(\mathbf{A}) = \sum_{\sigma:[n] \rightarrow [n]} \operatorname{sgn}(\sigma) \prod_{i=1}^n A_{i,\sigma(i)}, \quad (66)$$

where the summation is over all permutations of n elements, and sgn is a function called the sign of the permutation which assigns either 1 or -1 to a permutation. The permanent of \mathbf{A} is defined by

$$\operatorname{per}(\mathbf{A}) = \sum_{\sigma:[n] \rightarrow [n]} \prod_{i=1}^n A_{i,\sigma(i)}. \quad (67)$$

Denote $GF(2^k)$ as a finite field of characteristic two. It is well known that the determinant of \mathbf{A} over $GF(2^k)$ coincides with the permanent, since in such a field every element serves as its own additive inverse, in particular the element 1; the sgn function identically maps 1 to every permutation. Moreover, although the determinant is a sum of an exponential number of terms, it can be computed in polynomial time using for instance LU factorization of the matrix which can be found in any textbook on linear algebra. In fact, to compute the determinant is not harder than square matrix multiplication (cf. [21]). Hence, the determinant can be computed in $O(n^\omega)$ field operations where ω is the Coppersmith-Winograd exponent [24]. The following properties and lemma will be used in deriving algebraic sieving algorithms.

Property 1 \mathbf{A} is a matrix over $GF(2^k)$, then $\operatorname{per}(\mathbf{A}) = \det(\mathbf{A})$.

Property 2 For a given $n \times n$ matrix \mathbf{A} , $\det(\mathbf{A})$ can be computed in $O(n^\omega)$ time.

Lemma 12 (Schwartz-Zippel) Let $P(x_1, \dots, x_n)$ be a non zero n -variate polynomial of total degree d over a field F . Pick $r_1, \dots, r_n \in F$ uniformly at random, then

$$\Pr_r(P(r_1, \dots, r_n) = 0) \leq \frac{d}{|F|}. \quad (68)$$

3.1.1 k -Dimensional Matching

A hypergraph $H = (V, E)$ consists of a set V of n vertices and a multiset E of hyperedges which are subsets of V . In particular, hyperedges may include only one (or even no) vertex and may appear more than once. In a k -uniform hypergraph each edge $e \in E$ has size $|e| = k$. Given a vertex subset U of V , the projected hypergraph of H on U , denoted as $H[U] = (U, E[U])$, is a hypergraph on U where there is one edge $e_U \in E[U]$ for every $e \in E$, defined by $e_U = e \cap U$.

Definition 4 (k -Dimensional Matching) Given a k -uniform hypergraph $H = (V_1 \cup V_2 \cup \dots \cup V_k, E)$, with $E \subseteq V_1 \times V_2 \times \dots \times V_k$, where $|V_i| = n$ for $1 \leq i \leq k$, the k -dimensional matching problem asks whether there exists a k -dimensional matching $S \subseteq E$ such that $\bigcup_{e \in S} e = V_1 \cup V_2 \cup \dots \cup V_k$ and $\forall e_1 \neq e_2 \in S: e_1 \cap e_2 = \emptyset$.

In the following, each hyperedge e is associated with a variable x_e over $GF(2^m)$ for some $m \geq \log n + 1$. The next lemma shows how to construct a polynomial only consisting of monomials representing k -dimensional matchings by sieving unwanted monomials.

Lemma 13 Denote \mathcal{M} as the family of all k -dimensional matchings. Let $V = \bigcup_{i=1}^k V_i$ and $U = V_1 \cup V_2$, then

$$\sum_{X \subseteq V \setminus U} P(H, U, X) = \sum_{M \in \mathcal{M}} \prod_{e \in M} x_e, \quad (69)$$

where the computation is over a multivariate polynomial ring over $GF(2^m)$, and

$$P(H, U, X) = \sum_{M' \in \mathcal{M}'} \prod_{e \in M'} x_e, \quad (70)$$

where \mathcal{M}' is the family of all perfect matchings in $H[U]$ avoiding X , that is, for every $e \in M'$, $e \cap X = \emptyset$.

Proof For every $M \in \mathcal{M}$, M only avoids \emptyset . Thus, the monomial $\prod_{e \in M} x_e$ for every k -dimensional matching M emerges in the constructed polynomial precisely once. For a non- k -dimensional matching M' , it avoids all subsets of $V \setminus (\bigcup_{e \in M'} e)$. Then the monomial $\prod_{e \in M'} x_e$ for M' will be considered in $P(H, U, X')$ for every $X' \subseteq V \setminus (\bigcup_{e \in M'} e)$. It is well known that a nonempty set has even number of subsets. Hence, all of these $\prod_{e \in M'} x_e$ cancel each other since the operations are in a field of characteristic two. \square

From [Lemma 13](#), $\sum_{X \subseteq V \setminus U} P(H, U, X)$ consists of monomials representing k -dimensional matchings of H . Thus, by evaluating $\sum_{X \subseteq V \setminus U} P(H, U, X)$ on a randomly chosen point $r_1, \dots, r_{|E|} \in GF(2^m)$, the result is nonzero with probability at least $\frac{1}{2}$ if there exists at least one k -dimensional matching in H by [Lemma 12](#). If repeating the evaluation for polynomial times, the error probability can be exponentially small. The remaining work is how to efficiently compute $P(H, U, X)$ on a randomly chosen point $r_1, \dots, r_{|E|} \in GF(2^m)$ for every $X \subseteq V \setminus U$.

Clearly, $H[U]$ is a bipartite multigraph. Define its Edmonds matrix $\mathbf{A}(H, V_1, V_2)$ as

$$\mathbf{A}(H, V_1, V_2)_{ij} = \sum_{e=(i,j) \in E[U], i \in V_1, j \in V_2} x_e. \quad (71)$$

Denote \mathcal{M} as the family of all perfect matchings in $H[U]$. Then the following lemma generalizes Edmonds' work [26] for the case of bipartite multigraphs.

Lemma 14 $\det(\mathbf{A}(H, V_1, V_2)) = \sum_{M \in \hat{\mathcal{M}}} \prod_{e \in M} x_e$, where the computation is over a multivariate polynomial ring over $GF(2^m)$ and the summation is over all perfect matchings $\hat{\mathcal{M}}$ in $H[V_1 \cup V_2]$.

Proof By the definition of determinant, the summation is over all products of n of the matrix elements in which every row or column is used exactly once. In terms of the bipartite graph, this corresponds to a perfect matching in the graph since rows and columns represent the two vertex sets, respectively. Furthermore, the converse is also true. For every perfect matching there is a permutation describing it. Hence, the mapping is one-to-one. The inner product counts all choices of edges producing a matching described by a permutation σ since

$$\prod_{i=1}^n A_{i,\sigma(i)} = \prod_{i=1}^n \sum_{e=(i,\sigma(i))} x_e = \sum_{M \in \mathcal{M}(\sigma)} \prod_{e \in M} x_e, \quad (72)$$

where $\mathcal{M}(\sigma)$ is the set of all perfect matchings $\{e_1, \dots, e_n\}$ such that $e_i = (i, \sigma(i))$.

Let $H_X[U]$ denote the projected hypergraph of H on U by only projecting edges disjoint to X in H on U . Based on the above Lemma, $P(H, U, X)$ on a randomly chosen point $r_1, \dots, r_{|E|} \in GF(2^m)$ for every $X \subseteq V \setminus U$ can be computed by first constructing the Edmonds matrix of $H_X[U]$, with the variables replaced by the random sample points $r_1, \dots, r_{|E|}$, and then computing its determinant. Putting everything together generates a Monte Carlo algorithm with exponentially small error probability for the k -dimensional matching problem. The runtime bound is easily seen to be $O^*(2^{(k-2)n})$ since $|U| = |V_1| + |V_2| = 2n$ and $P(H, U, X)$ for every $X \subseteq V \setminus U$ can be evaluated in $O(n^\omega)$ time by [Lemma 14](#) and [Property 2](#).

Theorem 9 The k -dimensional matching problem on kn vertices can be solved by a Monte Carlo algorithm with an exponentially small failure probability in n and $O^*(2^{(k-2)n})$ runtime.

3.1.2 Hamiltonicity

An undirected graph $G = (V, E)$ on n vertices is said to be Hamiltonian if it has a Hamiltonian cycle, a vertex order $(v_0, v_1, \dots, v_{n-1})$ such that $v_i v_{i+1} \in E$ for all i . The indices are enumerated modulo n , that is, $v_{n-1} v_0$ is also an edge. The problem of detecting if a graph is Hamiltonian is called the Hamiltonicity problem. Clearly, this problem is a special case of the traveling salesman problem.

Before the algebraic sieving algorithm for the Hamiltonicity problem was derived, the dynamic programming recurrence that solves the general TSP in $O(n^2 2^n)$ time introduced by Bellman [6, 7] and independently by Held and Karp [30] in the early 1960s was the strongest result for this special problem. The algebraic sieving for the Hamiltonicity problem is obtained by reducing the problem to a variant of the cycle cover counting problem called labeled cycle cover sum, and then making use of the sieving algorithm to solve this variant. The algorithm will be described after introducing some useful notations.

In a directed graph $D = (V, A)$, a cycle cover is a subset $C \subseteq A$ such that for every vertex $v \in V$, there is exactly one arc $a_{v1} \in C$ starting from v and exactly one arc $a_{v2} \in C$ ending in v . The graphs considered have no loops. Denote $cc(D)$ as the family of all cycle covers of D , and $hc(D) \subseteq cc(D)$ as the set of Hamiltonian cycle covers. A Hamiltonian cycle cover consists of one big cycle passing through all vertices. The remaining cycle covers (which have more than one cycle in $cc(D) \setminus hc(D)$) are called non-Hamiltonian cycle covers. For undirected graphs, $hc(G)$ includes the Hamiltonian cycles with orientation, that is, traversed in both directions. For a Hamiltonian cycle $H \in hc(G)$ for an undirected graph G , an arc $uv \in G$ infers that the cycle is oriented from u to v along the edge uv . Denote $g : A \rightarrow B$ as a surjective function from the domain A to the codomain B and denote the preimage of every $b \in B$ as $g^{-1}(b)$, that is, $g^{-1}(b) = \{a \in A : g(a) = b\}$. For a matrix A , denote by $A_{i,j}$ the element at row i and column j . The labeled cycle cover sum problem is defined as follows:

Definition 5 Given a directed graph $D = (V, A)$, a finite set L of labels, and a function $f : A \times 2^L \rightarrow R$ on some codomain ring R , the labeled cycle cover sum problem is to compute the following defined term over R .

$$\Lambda(D, L, f) = \sum_{C \in cc(D)} \sum_{g: L \rightarrow C} \prod_{a \in C} f(a, g^{-1}(a)), \quad (73)$$

where the inner sum is over all surjective functions g .

In the above definition, f is introduced to make all non-Hamiltonian cycle covers cancel out in the sum. To do this, as before, the computations will be done over $GF(2^k)$ denoting a finite field of characteristic two. In what follows, a directed graph is bidirected if for every arc uv it has an arc in the opposite direction, that is, vu . In order to make sure that the Hamiltonian cycle cover will not be canceled as well, an asymmetry around an arbitrarily chosen special vertex s is defined. A function $f : A \times 2^L \rightarrow GF(2^k)$ is an s -oriented mirror function if

$f(uv, Z) = f(vu, Z)$ for all Z and all $u \neq s, v \neq s$. The following lemma captures how the non-Hamiltonian cycle covers vanish, which also implies the nonexistence of false positives in the resulting algorithms.

Lemma 15 *Given a bidirected graph $D = (V, A)$, a finite set L , and a special vertex $s \in V$, let f be an s -oriented mirror function with codomain $GF(2^k)$. Then*

$$\Lambda(D, L, f) = \sum_{H \in hc(D)} \sum_{g: L \rightarrow H} \prod_{a \in H} f(a, g^{-1}(a)). \quad (74)$$

Proof By the definition of the labeled cycle cover sum, a labeled cycle cover is a tuple (C, g) with $C \in cc(D)$ and $g : L \rightarrow C$. The labeled non-Hamiltonian cycle covers can be partitioned into dual pairs as follows such that both cycle covers in every pair contribute the same term to the sum. For a labeled non-Hamiltonian cycle cover (C, g) , let \mathbf{C} be the first cycle of C not passing through s (note that such cycle must exist since the cycle cover consists of at least two cycles and all cycles are vertex disjoint). Here, “first” is w.r.t. any fixed order of the cycles. Then the dual cycle cover of (C, g) is defined as $R(C, g) = (C', g')$, where $C' = C$ except for the cycle \mathbf{C} which is reversed in C' , that is, every arc $uv \in \mathbf{C}$ is replaced by the arc in the opposite direction vu in C' , and g'^{-1} is identical to g^{-1} on $C \setminus \mathbf{C}$, and is defined by $g'^{-1}(uv) = g^{-1}(vu)$ for all arcs $uv \in \mathbf{C}$. In other words, the reversed arcs preserve their original labeling. Note that such a dual cycle cover always exists since D is bidirected and $(C, g) \neq R(C, g), (C, g) = R(R(C, g))$. Hence, the mapping uniquely pairs up the labeled non-Hamiltonian cycle covers.

Since f is an s -oriented mirror function and has $f(uv, Z) = f(vu, Z)$ for all arcs uv not incident on s , (C, g) and $R(C, g)$ contribute the same product term to the sum for computing $\Lambda(D, L, f)$. Finally, since the computations are done in a field of characteristic two, all these terms will be canceled. \square

When limiting the computations over $GF(2^k)$, the labeled cycle cover sum can be computed efficiently via determinant. Permanent has a natural interpretation as the sum of weighted cycle covers in a directed graph. Formally, let $D = (V, A)$ be a directed graph with weights $w : A \rightarrow GF(2^k)$, and define a $|V| \times |V|$ matrix with rows and columns representing the vertices V

$$A_{i,j} = \begin{cases} w(ij), & \text{if } ij \in A \\ 0, & \text{otherwise.} \end{cases} \quad (75)$$

Then,

$$per(A) = \sum_{C \in cc(D)} \prod_{a \in C} w(a). \quad (76)$$

By [Property 1](#) and [2](#), $per(A)$ is identical with $det(A)$ and can be computed in $O(n^\omega)$ time. Define a polynomial in an indeterminate r as follows, with r aiming at controlling the total rank of the subsets used as labels in the labeled cycle covers:

$$p(f, r) = \sum_{Y \subseteq L} det \left(\sum_{Z \subseteq Y} r^{|Z|} M_f(Z) \right), \quad (77)$$

where

$$M_f(Z)_{i,j} = \begin{cases} f(ij, Z), & \text{if } ij \in A \\ 0, & \text{otherwise.} \end{cases} \quad (78)$$

Lemma 16 *For a directed graph D , a set L of labels, and any function $f : A \times L \rightarrow GF(2^k)$,*

$$[r^{|L|}]p(f, r) = \Lambda(D, L, f), \quad (79)$$

where $[r^{|L|}]p(f, r)$ denotes the coefficient of $r^{|L|}$ in $p(f, r)$.

Proof $p(f, r)$ can be rewritten as

$$\begin{aligned} p(f, r) &= \sum_{Y \subseteq L} \sum_{C \in cc(D)} \sum_{q:C \rightarrow 2^Y \setminus \{\emptyset\}} \prod_{a \in C} r^{|q(a)|} f(a, q(a)) \\ &= \sum_{C \in cc(D)} \sum_{q:C \rightarrow 2^L \setminus \{\emptyset\}} \sum_{\substack{\cup_{a \in C} q(a) \subseteq Y \subseteq L \\ \cup_{a \in C} q(a) = L}} \prod_{a \in C} r^{|q(a)|} f(a, q(a)). \end{aligned} \quad (80)$$

For functions $q : C \rightarrow 2^L \setminus \{\emptyset\}$ such that $\cup_{a \in C} q(a) \subset L$, that is, whose union over the elements do not cover all of L , the innermost summation is executed an even number of times with the same term (there are $2^{|L - \cup_{a \in C} q(a)|}$ equal terms). Since the computations are over $GF(2^k)$, these cancel. Then,

$$p(f, r) = \sum_{C \in cc(D)} \sum_{\substack{q:C \rightarrow 2^L \setminus \{\emptyset\} \\ \cup_{a \in C} q(a) = L}} r^{\sum_{a \in C} |q(a)|} \prod_{a \in C} f(a, q(a)), \quad (81)$$

in which the coefficient of $r^{|L|}$

$$[r^{|L|}]p(f, r) = \sum_{C \in cc(D)} \sum_{\substack{q:C \rightarrow 2^L \setminus \{\emptyset\} \\ \cup_{a \in C} q(a) = L \\ \forall a \neq b : q(a) \cap q(b) = \emptyset}} \prod_{a \in C} f(a, q(a)), \quad (82)$$

since $\cup_{a \in C} q(a) = L$, $\cup_{a \in C} |q(a)| = |L|$ implies $\forall a \neq b : q(a) \cap q(b) = \emptyset$. Inverting the function q will give the labeled cycle cover sum as defined in [Definition 5](#). \square

The above lemma is the base identity that enables a relatively efficient algorithm for computing the labeled cycle cover sum.

Lemma 17 *The labeled cycle cover sum $\Lambda(D, L, f)$ over a field $GF(2^k)$ on a directed graph D on n vertices, and with $2^k > |L|n$, can be computed in $O((|L|^2n + |L|n^{1+\omega})2^{|L|})$ arithmetic operations over $GF(2^k)$, where ω is the Coppersmith-Winograd matrix multiplication coefficient.*

Proof The labeled cycle cover sum is evaluated via the identity in Lemma 16. Observing that $p(f, r)$ as a polynomial in r has maximum degree $|L|n$, to recover one of its coefficients (the one for $r^{|L|}$), one needs to evaluate the polynomial for $|L|n$ choices of r and to use interpolation to solve for the coefficient being sought. This can be done for instance by using a generator g of the multiplicative group in $GF(2^k)$ and evaluating the polynomial in the points $r = g^0, g^1, \dots, g^{|L|n-1}$. The requirement $2^k > |L|n$ assures the distinctness of these points, and hence, the interpolation is possible. For every fixed r , the algorithm begins by tabulating $T(Y) = \sum_{Z \subseteq Y} r^{|Z|} M_f(Z)$ for all $Y \subseteq L$ through the fast zeta transform (4) in $O(|L|2^{|L|})$ field operations. Then $p(f, r) = \sum_{Y \subseteq L} \det(T(Y))$ can be evaluated in $O(n^\omega 2^{|L|})$ operations by Property 2. Once all values are computed, the polynomial time Lagrange interpolation can be used to compute the coefficient. Summing up the number of field operations required over all $|L|n$ values of r , the lemma follows. \square

Next, f will be defined to associate the argument arc, and label set with a nonconstant multivariate polynomial such that $f(su, X)$ and $f(us, X)$ will not share variables for any $su, us \in A$ to ensure that the Hamiltonian cycles oriented in opposite directions will contribute different terms to the sum. Based on the definition of f , the labeled cycle cover sum is represented by a polynomial in the underlying variables with one unique monomial per oriented Hamiltonian cycle and without monomials resulting from non-Hamiltonian cycle covers, which is a consequence of Lemma 15. Then, the fingerprint idea is employed to evaluate the polynomial in a randomly chosen point, and the Schwarz-Zippel Lemma ensures that with high probability, it can be detected whether the polynomial resulting from the labeled cycle cover sum is identically zero (i.e., no Hamiltonian cycles) or not (there is at least one Hamiltonian cycle) by identifying the evaluating result with the polynomial. For simplicity of analysis, assume that n is even.

For a uniformly randomly chosen partition $V = V_1 \cup V_2$ with $|V_1| = |V_2| = n/2$ and a fixed Hamiltonian cycle $H = (v_0, \dots, v_{n-1})$ in G . An arc $v_i v_{i+1}$ is called unlabeled by V_2 if both v_i and v_{i+1} belong to V_1 , and the set of all unlabeled arcs is denoted as $U(H)$. The remaining arcs are referred to as labeled by V_2 and denote the set of all labeled arcs as $L(H)$. Define $hc(G, V_2, m)$ as the subset of $hc(G)$ of Hamiltonian cycles which have precisely m unlabeled arcs by V_2 . Assign every edge $uv \in E$ two variables x_{uv} and x_{vu} , and x_{uv} and x_{vu} are identified except when $u = s$ or $v = s$.

Consider a complete bidirected graph $D = (V_1, F)$ and use V_2 as some of the labels. In addition to V_2 , a set L_m of size m of extra labels aiming at handling arcs unlabeled by V_2 . For each edge uv in $G[V_1]$ and every element $d \in L_m$, new variables $x_{uv,d}$ and $x_{vu,d}$ are introduced. And $x_{uv,d}$ coincides with $x_{vu,d}$ except when $u = s$ or $v = s$. For two vertices $u, v \in V$, and a subset $X \subseteq V$, define $\mathcal{P}_{u,v}(X)$ as the family of all simple paths in G from u to v passing through exactly the vertices in X . For $uv \in F$ and $X \subseteq V_2$, define

$$f(uv, X) = \sum_{P \in \mathcal{P}_{u,v}(X)} \prod_{wz \in P} x_{wz}. \quad (83)$$

For every arc $uv \in F$ such that uv is an edge in $G[V_1]$, and $d \in L_m$, define $f(uv, \{d\}) = x_{uv,d}$. In other points f is set to zero.

Lemma 18 *With $G, D, V_2, U(\cdot), L(\cdot), m, L_m$ and f defined as above,*

- (i) $\Lambda(D, V_2 \cup L_m, f) = \sum_{H \in hc(G, V_2, m)} \left(\prod_{uv \in L(H)} x_{uv} \right) \left(\sum_{\sigma: U(H) \rightarrow L_m} \prod_{uv \in U(H)} x_{uv, \sigma(uv)} \right);$
- (ii) $\Lambda(D, V_2 \cup L_m, f)$ is a zero polynomial iff $hc(G, V_2, m) = \emptyset$.

Proof (i) Since D is bidirected and f is s -oriented mirror function, by Lemma 15,

$$\Lambda(D, V_2 \cup L_m, f) = \sum_{H \in hc(D)} \sum_{g: V_2 \cup L_m \rightarrow H} \prod_{a \in H} f(a, g^{-1}(a)), \quad (84)$$

where the inner sum is over all surjective functions g . In order to prove the claim, it needs to expand the Hamiltonian cycles in D into Hamiltonian cycles of G . Note that the arcs of a Hamiltonian cycle in D in the sum above are labeled either by an element of L_m or by a nonempty subset of V_2 , since only in such cases f is nonzero. Next, the definition of labeled and unlabeled arcs are extended (which were defined previously for Hamiltonian cycles in G only). For a Hamiltonian cycle $H \in hc(D)$ labeled by the surjective function $g : V_2 \cup L_m \rightarrow H$, an arc $uv \in H$ is called labeled by V_2 if $g^{-1}(uv) \subseteq V_2$ and unlabeled by V_2 if $g^{-1}(uv) \in L_m$.

Since every arc uv unlabeled by V_2 , $g^{-1}(uv)$ is an element of L_m , only the Hamiltonian cycles in D with exactly m arcs unlabeled by V_2 leave a nonzero contribution. Then,

$$\begin{aligned} \Lambda(D, V_2 \cup L_m, f) &= \sum_{H \in hc(D)} \sum_{\substack{H_L \cup H_U = H \\ H_L \cap H_U = \emptyset \\ |H_U| = m}} \left(\sum_{g: V_2 \rightarrow H_L} \prod_{a \in H_L} f(a, g^{-1}(a)) \right) \cdot \\ &\quad \left(\sum_{\sigma: H_U \rightarrow L_m} \prod_{a \in H_U} f(a, \sigma(a)) \right), \end{aligned} \quad (85)$$

where the summation is over all surjective functions g and one-to-one functions σ . Replace f in the above expression, then

$$\begin{aligned} \Lambda(D, V_2 \cup L_m, f) = & \sum_{H \in hc(D)} \sum_{\substack{H_L \cup H_U = H \\ H_L \cap H_U = \emptyset \\ |H_U| = m \\ \forall a \in H_U : a \in E}} \left(\sum_{g: V_2 \rightarrow H_L} \prod_{a \in H_L} \sum_{P \in \mathcal{P}_{u,v}(g^{-1}(uv))} \prod_{w \in P} x_{wz} \right) \cdot \\ & \left(\sum_{\sigma: H_U \rightarrow L_m} \prod_{uv \in H_U} x_{uv, \sigma(uv)} \right), \end{aligned} \quad (86)$$

Every vertex in V_2 is mapped to precisely one arc in F on a Hamiltonian cycle H in D by g . Moreover, such a cycle H leaves a nonzero result iff there are precisely m arcs in the cycle not being mapped to by g (i.e., unlabeled by V_2) and they are also edges in G . Rewriting the expression as a sum of Hamiltonian cycles in G ,

$$\Lambda(D, V_2 \cup L_m, f) = \sum_{H \in hc(G, V_2, m)} \left(\prod_{uv \in L(H)} x_{uv} \right) \left(\sum_{\sigma: U(H) \rightarrow L_m} \prod_{uv \in U(H)} x_{uv, \sigma(uv)} \right). \quad (87)$$

(ii) If the graph G has no Hamiltonian cycles, the sum is clearly zero. For the other direction, each Hamiltonian cycle contributes a set of $m!$ different monomials per orientation of the cycle (one for each permutation σ), in which there is one variable per edge along the cycle. Monomials resulting from different Hamiltonian cycles are different since for each of two different Hamiltonian cycles, one has an edge that the other does not have. Every pair of opposite directed Hamiltonian cycles along the same undirected Hamiltonian cycle also traverse s through opposite directed arcs. Since the variables tied to the opposite directed arcs incident on s are different, these are also unique monomials in the sum. \square

The above Lemma describes how to transform the input graph G given m , V_1 , V_2 into a symbolic labeled cycle cover sum $\Lambda(D, V_2 \cup L_m, f)$ on a bidirected graph D on $n/2$ vertices and $n/2 + m$ labels $V_2 \cup L_m$. The next lemma shows that only the cases $m \leq n/4$ need to be considered.

Lemma 19 *Let $G = (V, E)$ be a Hamiltonian undirected graph. For a uniformly randomly chosen equal partition $V_1 \cup V_2 = V$, $|V_1| = |V_2| = n/2$,*

$$Pr \left(\sum_{i=0}^{n/4} |hc(G, V_2, i)| > 0 \right) \geq \frac{1}{n+1}. \quad (88)$$

Proof Consider one Hamiltonian cycle (v_0, \dots, v_{n-1}) in G . Let X denote the random variable representing the number of unlabeled arcs by V_2 . Clearly, $\Pr(v_i) = \frac{1}{2}$ for any i , and $\Pr(v_i, v_{i+1} \in V_1) < \frac{1}{4}$ since the events $v_i \in V_1$ and $v_{i+1} \in V_1$ are almost independent. Hence, the expected number of arcs unlabeled by V_2 , $E(X) < n/4$. By Markov's inequality, $\Pr(X > (1 + 1/n)E(X)) < \frac{1}{1+1/n}$, and the lemma follows. \square

Before discussing the algorithm, the only remaining problem is how to calculate f for all subsets of V_2 . This can be achieved by running a variant of the Bellman-Held-Karp recursion. Formally, let $\hat{f} : (V \times V) \times 2^V \rightarrow GF(2^k)$ be defined by

$$\hat{f}(uv, X) = \sum_{P \in \mathcal{P}_{u,v}(X)} \prod_{w \in P} x_{wz}. \quad (89)$$

Then $f(uv, X) = \hat{f}(uv, X)$ for $u, v \in V_1, X \subseteq V_2$, and the recursion

$$\hat{f}(uv, X) = \begin{cases} x_{uv}, & \text{if } |X| = 0 \\ \sum_{w \in X, uw \in E} x_{uw} \hat{f}(wv, X \setminus \{w\}), & \text{otherwise.} \end{cases} \quad (90)$$

can be used to tabulate $f(\cdot, X)$ on $X \subseteq V_2$. The running time is $O^*(2^{|V_2|})$.

Next, the algorithm is described in detail. First, pick a partition $V_1 \cup V_2 = V$ uniformly at random with $|V_1| = |V_2| = n/2$. Then, the algorithm loops over m , the number of edges unlabeled by V_2 along a Hamiltonian cycle from 0 to $n/4$. For each value of m , by Lemma 18, the problem is transformed to determine whether the symbolic labeled cycle cover sum $\Lambda(D, V_2 \cup L_m, f)$ is a nonzero polynomial. As described in Lemma 17, $\Lambda(D, V_2 \cup L_m, f)$ will be evaluated in a randomly chosen point over the field $GF(2^k)$ with $2^k > cn$ for some $c > 1$. By Lemma 12, with probability at least $1 - 1/c$ it will result in a nonzero answer iff $\Lambda(D, V_2 \cup L_m, f)$ was a nonzero polynomial (i.e., G has a Hamiltonian cycle with m edges unlabeled by V_2). Then repeat the algorithm for every $m \leq n/4$, and by Lemma 19, with probability at least $(1 - 1/c)/(n + 1)$, the presence of a Hamiltonian cycle can be detected if it exists. Running the algorithm a polynomial number of times in n , the probability of failure will be reduced exponentially small. The runtime is bounded by a polynomial factor in m and n of the runtime in Lemma 17. The worst case occurs for $m = 4/n$ in which case the time bound is $O^*(2^{3n/4})$.

Theorem 10 *There is a Monte Carlo algorithm detecting whether an undirected graph with n vertices is Hamiltonian or not in $O^*(2^{3n/4})$ time, with no false positives and no false negatives with probability exponentially small in n .*

3.2 Polynomial Circuit-Based Algorithms

This method only needs polynomial space. The problems to be solved will be translated into polynomials represented by polynomial circuits, where the translation is done in such a way that the instance considered is a “yes”-instance iff the coefficient of a special monomial in the polynomial is nonzero; this allows us only to compute the coefficient of the special monomial. A discrete Fourier transform-based technique provides an efficient way to achieve the goal.

3.2.1 Coefficient Interpolation

Given a set R and a set of variables X , an arithmetic circuit C over $(R, +, *)$ is a directed acyclic graph in which each source gate is labeled by a variable $x \in X$ or an element of R and other gates is either an addition gate or a product gate. The size $|C|$ of a circuit C is the number of gates in C . The depth $\Delta(C)$ of a circuit C is the length of a longest directed path in C . Denote by \mathbb{N} and \mathbb{C} the naturals and the complex numbers, respectively.

Computing the coefficient of some special monomial can be abstracted as the following coefficient interpolation problem which can be solved efficiently based on the discrete Fourier transform.

Definition 6 (Coefficient Interpolation) Given an arithmetic circuit C over $(\mathbb{N}, +, *)$ and variables x_1, x_2, \dots, x_β over \mathbb{N} that computes a polynomial $P(x_1, \dots, x_\beta)$, together with β integers t_1, t_2, \dots, t_β , the problem is to compute the coefficient of the term $x_1^{t_1} x_2^{t_2} \cdots x_\beta^{t_\beta}$.

Denote the coefficients of P as a β -dimensional array $\{c_{n_1, n_2, \dots, n_\beta}\}$. Furthermore, assume that the coefficients of any polynomial outputted by a gate of C are bounded by m and any exponent of x_i in the terms of P is bounded by $N_i - 1$ for $i \leq \beta$. Note that P can also be interpreted as a polynomial over the complex numbers. The discrete Fourier transform of the β -dimensional array $\{c_{n_1, n_2, \dots, n_\beta}\}$ is the array $\{C_{n_1, n_2, \dots, n_\beta}\}$ given by the following formula:

$$\begin{aligned} C_{k_1, k_2, \dots, k_\beta} &= \frac{1}{N_1 N_2 \cdots N_\beta} \sum_{n_1=0}^{N_1-1} \sum_{n_2=0}^{N_2-1} \cdots \sum_{n_\beta=0}^{N_\beta-1} c_{n_1, n_2, \dots, n_\beta} \prod_{i=1}^{\beta} \omega_{N_i}^{k_i n_i} \\ &= P(\omega_{N_1}^{k_1}, \omega_{N_2}^{k_2}, \dots, \omega_{N_\beta}^{k_\beta}), \end{aligned} \quad (91)$$

where ω_{N_i} is the i -th complex root of unity, given by $e^{-2\pi i / N_i}$. Then the inverse discrete Fourier transform can give the coefficient $c_{n_1, n_2, \dots, n_\beta}$, as follows:

$$\begin{aligned}
c_{t_1, t_2, \dots, t_\beta} &= \frac{1}{N_1 N_2 \cdots N_\beta} \sum_{n_1=0}^{N_1-1} \sum_{n_2=0}^{N_2-1} \cdots \sum_{n_\beta=0}^{N_\beta-1} C_{n_1, n_2, \dots, n_\beta} \prod_{i=1}^{\beta} \omega_{N_i}^{-t_i n_i} \\
&= \frac{1}{N_1 N_2 \cdots N_\beta} \sum_{n_1=0}^{N_1-1} \sum_{n_2=0}^{N_2-1} \cdots \sum_{n_\beta=0}^{N_\beta-1} P(\omega_{N_1}^{n_1}, \omega_{N_2}^{n_2}, \dots, \omega_{N_\beta}^{n_\beta}) \prod_{i=1}^{\beta} \omega_{N_i}^{(N_i - t_i) n_i}.
\end{aligned} \tag{92}$$

Thus, by evaluating the polynomial P for $N_1 N_2 \cdots N_\beta$ different arrays of values, which can be done using the arithmetic circuit C , $c_{t_1, t_2, \dots, t_\beta}$ can be computed based on the above formula. Hence, $c_{t_1, t_2, \dots, t_\beta}$ can be computed with $O(N_1 N_2 \cdots N_\beta |C|)$ real multiplications and additions, and only $O(\beta + |C|)$ real numbers need to be stored at any point of the calculation.

In order to overcome the problem that the real number cannot be exactly stored and worked with, the binary representations of the numbers with the bits after the l most significant bits truncated will be used instead during the execution of the algorithm. Here, the number l is chosen such that if rounding the resulting estimate c' of $c_{t_1, t_2, \dots, t_\beta}$ to the nearest integer, $c_{t_1, t_2, \dots, t_\beta}$ can be correctly obtained. Observe that addition of these estimates can be done in time $O(l)$, and that multiplication can be carried out in $O^*(l)$ time using a fast algorithm for integer multiplication, such as the Fürer's algorithm [29]. Hence, the total time spent by the algorithm is $O^*((N_1 N_2 \cdots N_\beta)l)$ and the total space is $O((\beta + |C|)l)$. The following lemma makes sure the existence of such a choice for l .

Lemma 20 ([42]) *Let C be an arithmetic circuit over $(\mathbb{C}, +, *)$ computing a polynomial $P(x_1, x_2, \dots, x_\beta)$ such that (a) all constants of C are positive integers, (b) all coefficients of P are at most m , and (c) P has degree d (d) C has depth α . Let $x_1, x_2, \dots, x_\beta \in \mathbb{C}$, $x'_1, x'_2, \dots, x'_{\beta'} \in \mathbb{C}$ be such that for every i , $\|x_i\| = 1$ and $\|x_i - x'_i\| \leq \epsilon$. Let p' be the result of applying the circuit C to $x'_1, x'_2, \dots, x'_{\beta'}$ using the floating point arithmetic, truncating intermediate results after l bits. Suppose $(\epsilon + 2 \cdot 2^{-l})(4md)^\alpha \leq 1$. Then $\|p' - P(x_1, \dots, x_\beta)\| \leq (\epsilon + 2 \cdot 2^{-l})(4md)^\alpha$.*

For a fixed value of l , one can compute for every $i \leq \beta$ an estimate of ω_{N_i} whose distance ϵ to ω_{N_i} is at most $2 \cdot 2^{-l}$. Now, given $n_1, \dots, n_\beta, t_1, \dots, t_\beta, N_1, \dots, N_\beta$, based on the circuit C for computing P , a circuit C' can be constructed for computing

$$P' = P(x_1^{n_1}, x_2^{n_2}, \dots, x_\beta^{n_\beta}) \prod_{i=1}^{\beta} x_i^{(N_i - t_i) n_i}. \tag{93}$$

Clearly, the depth of C' is $\alpha + \log N + \log \beta$, where $N = \max_i N_i$. Furthermore, the degree of C' is at most $d + \beta N$, and the largest coefficient is at most md . Choose l such that $10 \cdot 2^{-l} (4(d + \beta N)md)^{\alpha + \log N + \log \beta} \leq 1$. Applying Lemma 20 on C' yields an estimation error for

$$P'(\omega_{N_1}^{n_1}, \omega_{N_2}^{n_2}, \dots, \omega_{N_\beta}^{n_\beta}) = P(\omega_{N_1}^{n_1}, \omega_{N_2}^{n_2}, \dots, \omega_{N_\beta}^{n_\beta}) \prod_{i=1}^{\beta} \omega_{N_i}^{(N_i - t_i)n_i}, \quad (94)$$

which is less than $\frac{1}{2}$. The total estimation error for $c_{t_1, t_2, \dots, t_\beta}$ is less than $\frac{N_1 N_2 \cdots N_\beta}{2 N_1 N_2 \cdots N_\beta} = \frac{1}{2}$. Thus, c' rounded to the nearest integer is $c_{t_1, t_2, \dots, t_\beta}$. Finally, observe that $l = ((\alpha + \log d)(\log m + \log d))$, which yields the following concluding theorem.

Theorem 11 *The coefficient interpolation problem can be solved in $O^*(N_1 \cdots N_\beta (\Delta(C) + \log d)(\log m + \log d))$ time and $O(\beta + |C|(\Delta(C) + \log d)(\log m + \log d))$ space.*

Remark Here, it is necessary to point out that the indegree of the constructed circuit C is implicitly required to be bounded by a constant.

By transforming the problems to polynomials, the above technique can provide pseudo-polynomial time polynomial space algorithms for several hard problems, for example, the Knapsack problem.

Example 11 (Knapsack Problem) Given a set $S = \{s_1, \dots, s_n\}$ of n items each of which has positive integer weight w_i and value v_i , and two positive integers w and v , the Knapsack problem asks whether there exists a subset S' of items whose total weight is at most w and total value is at most v . It may further assume that all items have weight at most w and value less than v , since otherwise this problem is trivial. The Knapsack problem can be reduced to coefficient interpolation as follows.

Define the polynomial $P_S(x, y) = \sum_{i=0}^{nw} \sum_{j=0}^{nv} c_{ij} x^i y^j$, where c_{ij} is the number of item sets $S' \subseteq S$ whose total weight is exactly i and the total value of the items not in S' is exactly j . The Knapsack problem is equivalent to checking whether there exists a weight $w' \leq w$ and value $v' \leq (\sum_{s_i \in S} v_i) - v$ such that $c_{w'v'}$ is nonzero. Clearly, this can be done by solving coefficient interpolation for each pair of possible values for w' and v' , but this would incur an unnecessary overhead of vw in the running time. Instead, define the polynomial $P'_S(x, y) = p_S(x, y)(\sum_{i=0}^{nw} x^i)(\sum_{j=0}^{nv} y^j)$ and set c'_{ij} to be the coefficient of the term $x^i y^j$ in P'_S . Then it suffices to check whether c'_{wv^*} is nonzero, where $v^* = \sum_{s_i \in S} v_i - v$. The remaining task is to construct a polynomial circuit C' for P'_S such that faster polynomial space algorithms can be obtained by applying Theorem 11.

Note that $P_S(x, y)$ can be factorized into $P_S(x, y) = \prod_{i=1}^n (x^{w_i} + y^{v_i})$ which yields a circuit of size $O(n \log w + n \log v)$ and depth $O(\log w + \log v + \log n)$ for computing P_S . Based on the following given circuit of size and depth $O(\log n + \log w)$ for computing $\sum_{s_i \in S} x^{w_i}$ and circuit of size and depth $O(\log n + \log v)$ for computing $\sum_{s_i \in S} y^{v_i}$, a circuit C' of size $O(n \log w + n \log v)$ and depth $O(\log w + \log v + \log n)$ for computing P'_S can be constructed.

Lemma 21 *There exists a circuit of size and depth $O(\log m)$ that computes $\sum_{i=0}^m x^i$.*

Proof The following recurrence can be turned into a circuit for computing $\sum_{i=0}^m x^i$.

$$\sum_{j=0}^p x^j = \begin{cases} (x^{p/2} + 1) \sum_{j=0}^{p/2} x^j, & \text{if } p \text{ is even} \\ x(x^{\lfloor p/2 \rfloor} + 1) \sum_{j=0}^{\lfloor p/2 \rfloor} x^j + 1, & \text{otherwise.} \end{cases} \quad (95)$$

To make the circuit it needs to construct gates evaluating $x^{\lfloor p/2 \rfloor}$, $x^{\lfloor p/4 \rfloor}$, $x^{\lfloor p/8 \rfloor}$, etc. This can be done using an identical trick to the one above by observing that $x^p = (x^{p/2})^2$ if p is even and $x^p = x(x^{\lfloor p/2 \rfloor})^2$ if p is odd. \square

Finally, note that the coefficients of P_S are at most 2^n , and hence, the coefficients of P'_S are at most $2^n w v n^2$. Also note that the degree of P'_S is at most $2nv + 2nw$. Then applying [Theorem 11](#), one can get an algorithm for the Knapsack problem with time complexity $O^*(n^4 vw(\log v + \log w)^2)$ and space complexity $O^*(n^2(\log v + \log w)^2)$. \square

3.2.2 Combination with Subset Convolution

By introducing some special gates (e.g., the subset convolution gate and the covering product gate introduced in [Sect. 2.2](#)) in the constructed polynomial circuits, some polynomial space algorithms for many other problems can be derived, for example, the TSP problem, the weighted Steiner tree problem, and the weighted set cover problem. Based on the polynomial space result for the subset convolution and the covering product ([Theorem 7](#) in [Sect. 2.5.1](#)) and using the embedding technique (introduced in [Sect. 2.2](#)), the following result can be obtained by [Theorem 11](#). Whether some other operations and a wider range of input functions can be involved in the polynomial circuit framework to give polynomial space algorithms or faster exponential space algorithms for hard problems, as well as whether this approach can be applied to a wider range of problems, need further studies.

Theorem 12 ([42]) *Let C be a circuit over $\{f : 2^V \rightarrow \mathcal{M}\}$ with operation gates including subset convolution, covering product, addition, and product gates. Let \hat{C} be the circuit over $\{\hat{g} : 2^V \rightarrow \mathbb{N}\}$ obtained by interpreting C over $(\mathbb{N}, +, *)$, and let u be such that $u \geq h(Y)$ where h is the output of any gate of \hat{C} and $Y \subseteq V$. If the input function is a singleton and is bounded by W , then it can be decided whether $f_{out}(V) \leq k$ in $O^*(2^{|V|} W \log u)$ time and $O^*(\log u \log W)$ space.*

Example 12 (Weighted Set Cover) Given a set U , a family $\mathcal{F} = \{S_1, \dots, S_l\} \subseteq 2^U$, a weight function $w : \mathcal{F} \rightarrow \mathbb{N}$, and an integer t . A set cover of U is a family $\mathcal{C} \subseteq \mathcal{F}$ such that $U \subseteq \sum_{S \in \mathcal{C}} S$. The weight $w(\mathcal{C}) = \sum_{S \in \mathcal{C}} w(S)$. The weighted set cover problem is to decide whether there exists a set cover of U with weight at most t .

Define $m_i(Y)$ as the minimum weight of a set cover \mathcal{C} of Y such that $|\mathcal{C}| = i$. Then the problem is to determine whether $m_n(U) \leq t$. $m_i(Y)$ can be computed using the following recurrence:

$$m_i(Y) = \begin{cases} 0, & \text{if } i = 0, Y = \emptyset \\ \infty, & i = 0, Y \neq \emptyset \\ \min_{1 \leq j \leq l} m_{\lceil i/2 \rceil}(Y * m_{\lfloor i/2 \rfloor}(Y * [Y \subseteq S_j]), & \text{otherwise,} \end{cases} \quad (96)$$

where $*$ denotes the subset convolution operation. By replacing the min operation by max and making use of the embedding technique (in [Algorithm 1](#)) to turn the operations over the max-sum semiring to be done over the product-sum ring, it can be proved that the input function is a singleton and the above recurrence can be turned into a circuit of depth $O(\log |U|)$. Applying [Theorem 12](#), a polynomial space algorithm with running time $O^*(2^{|U|} W)$ can be obtained, where W is the maximum weight assigned to sets in \mathcal{F} .

4 Conclusion

This chapter summarizes some recently resurrected or newly developed combinatorial and algebraic techniques for designing either faster or space efficient exact exponential time algorithms for NP-hard problems. Detailed examples to illustrate these techniques have been given. Despite significant progresses in the past few years, the area is still largely unexplored with many open problems, and new techniques for solving these problems are very much in need. For example, can the graph coloring problem be exactly solved in time faster than $O^*(2^n)$? Can a deterministic $O^*(c^n)$ time exact algorithm be derived for TSP where $c < 2$? It appears that using the inclusion-exclusion technique alone cannot break the $O^*(2^n)$ barrier of the graph coloring problem since it needs to go through all the subsets. As [Example 12](#) shows, one promising avenue along which to design either faster or space efficient exact algorithms is to combine multiple techniques. For graph coloring, by combining the combinatorial methods and the algebraic methods, an $O^*(c^n)$ ($c < 2$) time exact exponential time algorithm might eventually be obtained. More specifically, it is worthwhile to try applying some efficient combinatorial computing tools such as fast zeta transform in an algebraic framework. Furthermore, as Alan Perlis once said [41], “*for every polynomial-time algorithm you have, there is an exponential algorithm that I would rather run,*” exponential time exact algorithms with a small constant base would be preferable to polynomial time algorithms for some problem instances of moderate or reasonably large sizes. For example, an $O^*(1.01^n)$ exact algorithm may run much faster than a polynomial time algorithm with running time $O(n^3)$ for relatively large values of n , such as 2000. Besides designing faster exact algorithms, designing space efficient (in particular polynomial or even linear space) exact algorithms is also very important since compared to exponential time consumption, exponential space

consumption could be more costly from the standpoint of computing resource usages. All in all, developing practical polynomial space exact algorithms for real-life use will need more devoted effort in the future. Although some of the open problems listed in Woeginger’s survey [55] have been solved, many other ones remain open, some of which can be found in [56, 57].

5 Further Reading

The fast zeta transform comes from Yates’s work [58]. The general theory of Möbius inversions on posets is developed by Rota [48]. Björklund et al. introduced the linear space fast zeta transform in [17]. A variant of fast zeta transform – trimmed zeta transform—is introduced in [16], which is used to give faster exact algorithms for the important algorithmic tool disjoint sum in the design of parameterized algorithms [15]. For details on Yates’s algorithm and Möbius inversion, please refer to Knuth’s book [38] and Fedor and Kratsch’s book [27].

The fast algorithm for subset convolution comes from Björklund et al. [12]. There is also an FFT-based implementation for the fast subset convolution [27]. The fast algorithms for covering product and intersecting covering product are introduced by Björklund et al. [12], whereas the proof of Lemma 2 comes from Nederlof’s paper [44]. The exact algorithms for Examples 1–3 are due to Björklund et al. [12]. The fast subset convolution has also been used to derive faster exact algorithms for counting spanning forests [44], computing Tutte polynomial [13], computing f -width and rank-width [46]. For more information on applications of the fast subset convolution, please refer to [27]. The polynomial space algorithms for the covering product and the subset convolution are based on Nederlof’s work [44] and Lokshtanov and Nederlof’s work [42]. The exact algorithm for computing cover polynomial in Example 6 is due to [44]. Subset convolution can also be used to derive faster parameterized algorithms. For example, van Rooij, Bodlaender, and Rossmanith [52] gave an $O(2^t n)$ time parameterized algorithm for counting perfect matchings in graphs of treewidth at most t based on a generalized fast subset convolution algorithm. Vassilevska and Williams [54] introduced a new approach for computing permanent of rectangular matrix based on the fast subset convolution.

The application of inclusion-exclusion to combinatorial optimization goes back to Ryser’s formula for the permanent [49], which remains the most effective way to count the number of matchings in a bipartite graph. The first explicit reference to combinatorial optimization is for TSP by Kohn, Gottlieb, and Kohn [39] and a concise paper by Karp [36] applying the idea to a number of hard problems. Karp’s paper is very compact and has probably gone slightly unnoticed, as it focuses on cases where the technique offers reduction in space as compared to a dynamic programming algorithm but at the expense of a possible slight increase in running time. Later, Bax and Franklin [3–5] used similar methods to count paths and cycles in general graphs. These techniques provide an $O^*(2^n)$ time algorithm for counting Hamiltonian paths [4, 36].

The proof of the inclusion-exclusion principle comes from Björklund et al.'s paper [20]. Exact algorithms for the set partition problem in [Example 4](#) and for computing cover polynomial in [Example 6](#) are due to Björklund et al. [13, 20]. In the conference versions [19, 40] of [20] and some other papers [11, 31–33], exact algorithms using inclusion-exclusion for other partitioning and covering problems are given. The inclusion-exclusion technique is also used to give a faster exact algorithm for computing the permanent of a matrix over rings and finite commutative semirings [18]. The polynomial space exact algorithm for counting Hamiltonian paths in [Example 7](#) is due to Karp [36]. The inclusion-exclusion approach for counting subgraph isomorphisms using homomorphism as demonstrated in [Example 8](#) is developed by Amini, Fomin, and Saurabh [1]. Nederlof [44] further developed inclusion-exclusion techniques to derive a number of polynomial space algorithms. Additionally, the approach based on a combination of branching and inclusion-exclusion is developed in [45, 47, 51, 53]. For the recent progress on the algorithmic uses of inclusion-exclusion, please refer to the survey by Husfeldt [34].

The technique used for deriving faster exact algorithms in bounded graphs is introduced by Björklund et al. in [14, 16]. The exact algorithm for TSP in bounded graphs in [Example 10](#) comes from [14].

The application of algebraic methods in designing exact algorithms can be traced back to the famous paper by Kohn et al. [39] on solving the traveling salesman problem using generating polynomials. Björklund introduced the algebraic sieving method in some recent papers [8, 9]. The exact algorithms for k -dimensional matching and Hamiltonicity come from [8] and [9], respectively. The polynomial circuit-based approach for deriving polynomial space exact algorithms is developed by Lokshtanov and Nederlof in [42]. Faster polynomial space exact algorithms for subset sum were also proposed in the same paper, and by combining with subset convolution, they gave polynomial space exact algorithms for the Steiner tree problem as well as the TSP problem. Very recently, by using a new algebraic method based on computing the hafnian over an arbitrary ring, Björklund [10] gave a faster polynomial space algorithm for counting the number of perfect matchings.

This chapter focuses only on the recently resurrected or newly developed combinatorial and algebraic approaches for designing either faster or space efficient exact algorithms. Many recent successes in using these approaches suggest that these approaches could play a significant role in the design of exponential exact algorithms for many other NP-hard problems. Other than these approaches, there are also other classical methods for tackling NP-hard problems, such as branching and local search methods. For detailed illustrations of these classical methods, please refer to Woeginger's survey [55]. Schöning in his concise survey [50] investigated how randomization can be used to design randomized exponential time algorithms. Most recently, perhaps in response to the rapid development of exact algorithms research, Fomin and Kratsch have written an excellent text [27] on exact exponential algorithms. Both classical methods and newly developed techniques such as measure and conquer are covered by this book. The book discusses also combinatorial methods for which our chapter tries to fill in some of missing details.

On top of that, this chapter demonstrates how to employ these techniques to design space efficient exact algorithms without increasing the running time, as well as how the newly developed algebraic approaches can be utilized to design either faster or space efficient exact algorithms.

Abstract

The problem of *Fault-Tolerant Facility Allocation (FTFA)* is a relaxation of the classical *Fault-Tolerant Facility Location (FTFL)* problem (Jain K, Vazirani VV (2000) An approximation algorithm for the fault tolerant metric facility location problem. In: APPROX '00: proceedings of the third international workshop on approximation algorithms for combinatorial optimization, London, UK. Springer, pp 177–183). Given a set of sites, each containing a set of identical facilities and associated with an operating cost for each facility, a set of clients, where each client-site pair has a (distance-based) connection cost and each client has a connection requirement *FTFA*, requires to compute a connection scheme between clients and sites such that each client is allocated a desired number of facilities and the total combined facility (operating) cost and connection cost

for all clients to access their required facilities is minimum. Compared with the *FTFL* problem which restricts that at most one facility can be opened at each site, the *FTFA* problem is less constrained and hence incurs a smaller cost. This chapter introduces our recent work on this problem (Xu S, Shen H (2009) The fault-tolerant facility allocation problem. In ISAAC, pp 689–698) and shows that the metric version of *FTFA*, i.e., the connection costs satisfy triangle inequality, is solvable in polynomial time within approximation ratio 1.861, which is better than the best approximation ratio 2.076 for metric *FTFL* (Swamy C, Shmoys DB (2008) Fault-tolerant facility location. ACM Trans Algorithms 4(4):1–27) known that time.

1 Introduction

Facility location [9] is one of the classical problems that has been widely studied in the field of operation research. In this problem, we are given a set \mathcal{F} of n_f sites, each holding one facility, and a set \mathcal{C} of n_c clients: every facility $i \in \mathcal{F}$ is associated with a nonnegative number f_i as the facility operating cost, and every facility-client pair $(i, j), i \in \mathcal{F}, j \in \mathcal{C}$ is associated with a connection cost c_{ij} to access facility i from client j . The objective is to open a subset of the facilities in \mathcal{F} and connect each client to an open facility so that the total cost is minimized.

Recently a generalization of the facility location problem, namely, *Fault-Tolerant Facility Allocation (FTFA)*, was studied in [27]. In this problem, each site allows an unlimited number of facilities to be opened, and each client requires a desired number of connections for fault-tolerance purpose, i.e., r_j connections to open facilities for client $j \in \mathcal{C}$. *FTFA* requires to allocate each site a proper number of facilities and further each client the required number of facilities so that the total combined facility cost and connection cost is minimized. The *FTFA* problem can be formulated by the following integer linear program:

$$\begin{aligned} & \text{minimize} && \sum_{i \in \mathcal{F}} f_i y_i + \sum_{i \in \mathcal{F}} \sum_{j \in \mathcal{C}} c_{ij} x_{ij} \\ & \text{subjected to} && \forall j \in \mathcal{C} : \sum_{i \in \mathcal{F}} x_{ij} \geq r_j \\ & && \forall i \in \mathcal{F}, j \in \mathcal{C} : y_i \geq x_{ij} \\ & && \forall i \in \mathcal{F}, j \in \mathcal{C} : x_{ij}, y_i \in \mathbb{Z}^+ \end{aligned} \tag{1}$$

In this formulation, nonnegative integer y_i indicates the number of facilities opened at site i , and x_{ij} indicates the number of connections established between site i and client j . The first constraint ensures QoS wrt client's connection requirement, i.e., established connections must satisfy client's required connection degree, achieving the desired fault-tolerance. The second constraint ensures there are enough opened facilities at site i to be connected from client j . In this chapter, the metric version of the problem, i.e., the connection costs satisfy triangle inequality, is considered.

The formulation of *FTFA* is similar to the well-studied *Fault-Tolerant Facility Location (FTFL)* problem [11, 12, 16, 25] which has the same objective function and

constraints as *FTFA* except the range of variants: x_{ij} and y_i are nonnegative integers (i.e., \mathbb{Z}^+) in *FTFA* but binary integers (i.e., 0 or 1) in *FTFL* for any $i \in \mathcal{F}, j \in \mathcal{C}$. Without the restriction on the maximum number of facilities that can be opened at each site, *FTFA* is less constrained and hence incurs a smaller total cost. The *FTFA* problem is applicable in surrogate server deployment in a Content Distribution Network. In such an application, multiple facilities (surrogate servers or ATMs in an ATM network) can be deployed at one site if necessary, which share the duty to serve clients together. It is noticed that the *FTFA* problem becomes the classical *Uncapacitated Facility Location (UFL)* problem when connectivity requirement $r_j = 1$ for all $j \in \mathcal{C}$. It is not hard to see that the hardness of *UFL*, *FTFA*, and *FTFL* complies with the following relation:

$$UFL \subseteq FTFA \subseteq FTFL.$$

Here, the second inclusion is implied by a special *FTFL* problem which has a set of facilities distributed by groups. Let $\mathcal{F}' = \mathcal{F} \times \{1, 2, \dots, R\}$, $R = \max_{j \in \mathcal{C}} r_j$ be the number of identical facilities in each group. Using this setting, the *FTFA* problem can be solved by *FTFL* algorithms because the number of facilities at any site is no more than R in any optimal solution of the *FTFA* problem. However, we notice that the existing algorithms for *FTFL* are not as efficient as the algorithms for *UFL*, in both approximation ratio and time complexity: most *FTFL* algorithms employ an LP routine which is rather time-consuming, and the best known approximation ratio for *FTFL* is 2.09 which is considerably worse than the best known 1.5 approximation ratio for *UFL*. Therefore, in order to achieve a better result than that from applying *FTFL* algorithms directly, we shall take the full advantage of existing methods for *UFL* in solving the *FTFA* problem. In fact, the *FTFA* problem can be regarded as a *UFL* problem with an additional constraint: for a given *FTFA*, consider a *UFL* problem with the aforementioned \mathcal{F}' and city set $\mathcal{C}' = \{(j, p), j \in \mathcal{C}, 1 \leq p \leq r_j\}$, where (j, p) is the p -th port of city j . In this setting, we need to ensure no parallel connections are made between any facility-city pair, i.e., different ports of a city must be connected with different facilities. This constraint is nontrivial and as a result, *FTFA* becomes harder to solve than *UFL*, yielding the first inclusion. In the subsequent sections, we will show how to deal with this constraint and obtain better single-factor and bi-factor approximation solutions to *FTFA* than that for *FTFL*.

2 Related Work

The facility location problem and its variants occupy a central place in operations research [9]. For the simplest problem – the maximization variant of *Uncapacitated Facility Location* – Cornuejols et al. [8] obtained a $(1 - e^{-1})$ -approximation algorithm. The first approximation algorithm for the minimization variant is a greedy algorithm due to [13], which is $O(\log n)$ -approximation in the general (nonmetric) case. The *UFL* problem has found extensive applications since this

works, and one of the most widely studied problems is *metric UFL*. In this problem, the function of connection cost forms a metric, i.e., the connection costs between facilities and cities satisfy triangle inequality. Existing algorithms for the *metric UFL* problem mainly use two types of techniques, i.e. LP rounding and primal-dual algorithms.

The first constant-factor approximation algorithm for the *metric UFL* problem was due to Shmoys et al. [23]. They gave a 3.16-approximation algorithm using the filtering technique of Lin and Vitter [19] to round the optimal solution of a linear programming relaxation. Chudak improves the approximation ratio to 1.736 [7] and 1.582 [24] also by rounding an optimal fractional solution to a linear program. These results are achieved through linear programming and rounding.

Charikar and Guha obtained 1.853- and 1.728-approximation algorithms [4] by using primal-dual theory and greedy augmentation; Jain et al. presented greedy algorithms based on dual-fitting and factor-revealing LP technique, achieving approximation guarantees 1.861 [14, 22] and 1.61 [14, 18]. Different from traditional primal-dual schema [15, 26], dual fitting relaxes the feasibility of the dual solution. Suppose the dual solution becomes feasible after being shrunk by a factor, then this factor is the approximation ratio of the algorithm. They also studied the trade-off [14] between facility and connection cost and got a series of bi-factor approximation guarantees. Mahdian et al. further improved the approximation ratio to 1.52 [20] by adding a scaling and greedy augmentation procedure to the JMS algorithm. Recently, Jaroslow [2] presented a 1.5-approximation algorithm by modifying Chudak and Shmoys's algorithm [6] and then combining it with a bi-factor result of JMS algorithm [18]. This is currently the best known result for the problem touching the approximability limit.

Fault-Tolerant Facility Location [16] is a generalization of *UFL*, where connectivities at different cities (e.g., the number of distinct facilities that serves a city) are specified to meet fault-tolerant requirements. Guha et al. obtained a 3.16-approximation algorithm by rounding the optimal fractional solution to the problem and further improve the result to 2.41 by employing a greedy local improvement step [12]. Swamy and Shmoys presented a 2.076-approximation by using LP rounding [25]. Recently, Byrka et al. [2] applied the dependent-rounding technique to FTFL and achieved the current best approximation ratio 1.725. All these results hold for both uniform connectivity case and nonuniform connectivity case (general case). Guha and Khuller proved that the best approximation ratio (lower bound) to *UFL* is 1.463 [10], assuming $\text{NP} \not\subseteq \text{DTIME}[n^{O(\log \log n)}]$; this result also holds for fault-tolerant version of the problem.

The *k-Median* problem [19] has also been studied extensively [1, 3, 5], and the best known approximation ratio for this problem is $3 + \varepsilon$ [1]. Jain et al. study a new problem called *k-Facility* which is a combination of the *k-Median* and *UFL* problems and achieve a 6-approximation algorithm [17] and further a 4-approximation [14] based on the JMS algorithm [14, 18]. The *Fault-Tolerant k-Facility* problem was also studied by Swamy and Shmoys [25], and they achieved

a 4-approximation algorithm for a special case of the problem where all cities have an identical connectivity requirement. Performance of their algorithm is unknown for the general case.

3 Problem Formulation

In order to obtain a suitable dual for formulation (1) from which a satisfactory approximation ratio can be derived, we need to first transform (1) into an equivalent formulation by applying a greedy approach of multiphase connection establishment as follows.

Without loss of generality, assume $\mathcal{R} = \{1, 2, 3, \dots, R\}$; otherwise, we may add dummy clients with the missing connectivity requirements. Further assume r_j ports at each client and R facilities at each site. All ports of a client must be connected in the order from 1 to r_j , and all facilities at a site can be opened, if necessary, in the order from 1 to R . We use multiphase algorithms to establish connections for certain cities in each phase. More specifically, we establish one connection for all cities in $\mathcal{C}^p = \{j \in \mathcal{C} : r_j \geq p\}$ in phase p . We use vector $y_i^p \in \{0, 1\}$ to denote whether the p -th facility at site i is opened in phase p and $x_{ij}^p \in \{0, 1\}$ whether the p -th port of a city is connected with a facility at site i . It is clear that $y_i = \sum_{p \in \mathcal{R}} y_i^p$, $x_{ij} = \sum_{p \in \mathcal{R}} x_{ij}^p$, and $x_{ij}^p = 0$ if $p > r_j$. With this said, formulation (1) can be rewritten as

$$\begin{aligned} \text{minimize} \quad & \sum_{i \in \mathcal{F}} \sum_{p \in \mathcal{R}} (f_i y_i^p + \sum_{j \in \mathcal{C}} c_{ij} x_{ij}^p) \\ \text{subjected to} \quad & \forall p \in \mathcal{R}, j \in \mathcal{C}^p : \sum_{i \in \mathcal{F}} x_{ij}^p \geq 1 \\ & \forall p \in \mathcal{R}, j \in \mathcal{C}^p, i \in \mathcal{F} : \sum_{p \in \mathcal{R}} y_i^p \geq \sum_{p \in \mathcal{R}} x_{ij}^p \\ & \forall p \in \mathcal{R}, j \in \mathcal{C}^p, i \in \mathcal{F} : x_{ij}^p, y_i^p \in \{0, 1\}. \end{aligned} \quad (2)$$

Note that the second constraint does not necessarily imply $y_i^p \geq x_{ij}^p$ for any $p \in \mathcal{R}$ which otherwise will make the problem a simple aggregation of the UFL problem. Now consider the situation that $y_i^p < x_{ij}^p$, i.e., $y_i^p = 0$ and $x_{ij}^p = 1$ for some p . Since $\sum_{p \in \mathcal{R}} y_i^p \geq \sum_{p \in \mathcal{R}} x_{ij}^p$, for any (i, j, p) with $y_i^p < x_{ij}^p$, there must exist a $q < p$ that satisfies $y_i^q - x_{ij}^q > 0$. This observation implies that a connection can be established with a facility opened at an earlier phase. Let f_i^p be the cost paid to open a facility at site i in phase p . That is,

$$f_i^p = \begin{cases} f_i & \text{if a new facility of site } i \text{ must be opened in phase } p; \\ 0 & \text{otherwise.} \end{cases}$$

As an open facility can be accessed for free, the cost paid to the site is equal to zero if no new facility has to be opened. We use $z_i^p \in \{0, 1\}$ to denote whether site i is involved in the new established connections in phase p , i.e., $z_i^p = 1$ if $\sum_{j \in \mathcal{C}^p} x_{ij}^p > 0$ and 0 otherwise. Apparently, $y_i^p = 1 \Rightarrow z_i^p = 1$ because for any i ,

$\max_{j \in \mathcal{C}} \sum_{q=1}^p x_{ij}^q > \sum_{q=1}^{p-1} y_i^q \geq \max_{j \in \mathcal{C}} \sum_{q=1}^{p-1} x_{ij}^q$ implies $\sum_{j \in \mathcal{C}} x_{ij}^p > 0$, i.e., $z_i^p = 1$. Therefore, we have $z_i^p \geq y_i^p$ for any i and p . This yields $f_i^p = f_i$ if $y_i^p < z_i^p$ and 0 otherwise. Since the object of formulation (2) carries a minimization function and $f_i^p z_i^p \geq f_i^p y_i^p \geq 0$, it is easy to see that with proper case reduction, we can equivalently transform the object to

$$\text{minimize} \sum_{p \in \mathcal{R}} \sum_{i \in \mathcal{F}} (f_i^p z_i^p + \sum_{j \in \mathcal{C}^p} c_{ij} x_{ij}^p),$$

and at the same time the second constraint to

$$z_i^p \geq x_{ij}^p, \forall p \in \mathcal{R}, j \in \mathcal{C}^p, i \in \mathcal{F}.$$

As a result, formulation (2) can be rewritten as

$$\begin{aligned} \text{minimize} \quad & \sum_{p \in \mathcal{R}} \sum_{i \in \mathcal{F}} (f_i^p z_i^p + \sum_{j \in \mathcal{C}^p} c_{ij} x_{ij}^p) \\ \text{subjected to} \quad & \forall p \in \mathcal{R}, j \in \mathcal{C}^p : \sum_{i \in \mathcal{F}} x_{ij}^p \geq 1 \\ & \forall p \in \mathcal{R}, j \in \mathcal{C}^p, i \in \mathcal{F} : z_i^p - x_{ij}^p \geq 0 \\ & \forall p \in \mathcal{R}, j \in \mathcal{C}^p, i \in \mathcal{F} : x_{ij}^p, z_i^p \in \{0, 1\}. \end{aligned} \tag{3}$$

Noting $\sum_{p \in \mathcal{R}} z_i^p$ is not necessarily equal to y_i , we set $y_i = \max_{j \in \mathcal{C}} \sum_{p \in \mathcal{R}} x_{ij}^q$.

The LP relaxation of this formulation can be obtained by allowing x_{ij} and y_i to be nonnegative real numbers. The dual problem of this LP relaxation can be easily derived as follows:

$$\begin{aligned} \text{maximize} \quad & \sum_{p \in \mathcal{R}} \sum_{j \in \mathcal{C}^p} \alpha_j^p \\ \text{subjected to} \quad & \forall p \in \mathcal{R}, i \in \mathcal{F} : \sum_{j \in \mathcal{C}^p} \beta_{ij}^p \leq f_i \\ & \forall p \in \mathcal{R}, i \in \mathcal{F}, j \in \mathcal{C}^p : \alpha_j^p - \beta_{ij}^p \leq c_{ij} \\ & \forall p \in \mathcal{R}, i \in \mathcal{F}, j \in \mathcal{C}^p : \alpha_j^p, \beta_{ij}^p \geq 0. \end{aligned} \tag{4}$$

We use the same interpretation for dual variables, α_j^p and β_{ij}^p , as in [14, 22], which will be explained in detail later.

Lemma 1 For any feasible solution (α, β) to dual problem (4) and feasible solution (x, y) to primal problem (2), we have $\sum_{p \in \mathcal{R}} \sum_{j \in \mathcal{C}^p} \alpha_j^p \leq \sum_{i \in \mathcal{F}} (\sum_{j \in \mathcal{C}} c_{ij} x_{ij} + f_i y_i)$.

Proof We derive the inequality by applying all conditions in the constraints of the primal and dual:

$$\sum_{p \in \mathcal{R}} \sum_{j \in \mathcal{C}^p} \alpha_j^p \leq \sum_{p \in \mathcal{R}} \sum_{j \in \mathcal{C}^p} \left(\sum_{i \in \mathcal{F}} x_{ij}^p \right) \alpha_j^p$$

$$\begin{aligned}
& (\text{because } \sum_{i \in \mathcal{F}} x_{ij}^p \geq 1 \text{ (3 [c1])}) \\
& \leq \sum_{p \in \mathcal{R}} \sum_{i \in \mathcal{F}} \sum_{j \in \mathcal{C}^p} [(\alpha_j^p - \beta_{ij}^p)x_{ij}^p + \beta_{ij}^p z_i^p] \\
& (\text{because } z_i^p \geq x_{ij}^p \text{ (3 [c2])}) \\
& \leq \sum_{p \in \mathcal{R}} \sum_{i \in \mathcal{F}} \left(\sum_{j \in \mathcal{C}^p} c_{ij} x_{ij}^p + f_i^p z_i^p \right) \\
& (\text{because } \alpha_j^p - \beta_{ij}^p \leq c_{ij} \text{ (4 [c2])}, \sum_{j \in \mathcal{C}^p} \beta_{ij}^p \leq f_i \text{ (4 [c1]) and } x_{ij}^p, \\
& \quad z_i^p \geq 0 \text{ (3 [c3])}) \\
& = \sum_{i \in \mathcal{F}} \left(\sum_{j \in \mathcal{C}} c_{ij} x_{ij} + f_i y_i \right)
\end{aligned}$$

□

According to weak duality theorem, finding a feasible solution to the primal problem (3) is transformed to that to the dual problem (4), because the latter's approximation ratio (to the optimal solution of the primal) will never exceed the former's.

4 The Algorithm

We now show how to construct an effective algorithm for solving the dual problem (4). An interesting observation is that we can extract $p \in \mathcal{R}$ in the constraints of the dual problem and this even holds for the objective function because $\alpha_j^p = 0$ when $p > r_j$. We utilize this observation to design a high-level algorithm which decomposes the problem into R subproblems and process them in the order. Specifically, all ports are categorized into groups according to their port IDs, and $\mathcal{C}^p \subset \mathcal{C} = \{j \in \mathcal{C}, r_j \geq p\}$. For the sake of simplicity, let vector $\mathbf{X}^b = \sum_{p=1}^b \mathbf{x}^p$ and $\mathbf{Y}^b = \sum_{p=1}^b \mathbf{y}^p$, $1 \leq b \leq R$, our algorithm evolves the solution from the initial stage (suppose $\mathbf{X}^0 = 0$ and $\mathbf{Y}^0 = 0$), through R phases, to \mathbf{X}^R and \mathbf{Y}^R . In each phase $p \in \mathcal{R}$, the algorithm establishes one connection for each city in \mathcal{C}^p . A facility opened in one phase at site i can be used for free by any city j in a later phase, suppose p , if this usage does not violate the constraint $X_{ij}^p \leq Y_i^p$.

The process of our algorithm is presented in [Algorithm 1](#): in the p -th phase, the solution inherited from the last phase, i.e., $(\mathbf{X}^{p-1}, \mathbf{Y}^{p-1})$, as well as \mathcal{F} and \mathcal{C}^p , is used as the input of the subroutine. Note that clients with $r_j < p$ are already fully connected and therefore not included in \mathcal{C}^p . Suppose the new opened facilities and

Algorithm 1 1.861-approximation algorithm

Input: f_i, r_j, c_{ij} for any $i \in \mathcal{F}, j \in \mathcal{C}$.

Output: x_{ij}, y_i for any $i \in \mathcal{F}, j \in \mathcal{C}$.

- (1) Initially set vector $\mathbf{X}^0 \leftarrow \mathbf{0}, \mathbf{Y}^0 \leftarrow \mathbf{0}, \mathcal{C}^1 = \mathcal{C}$ and the number of current phase $p \leftarrow 1$.
 - (2) While $p \leq R$:
 - (a) Invoke **the p -th phase algorithm** with input $(\mathbf{X}^{p-1}, \mathbf{Y}^{p-1}, \mathcal{F}, \mathcal{C}^p)$, suppose the output is $(\mathbf{X}^p, \mathbf{Y}^p)$.
 - (b) Set $p \leftarrow p + 1$.
 - (3) Set $\mathbf{x} = \mathbf{X}^R$ and $\mathbf{y} = \mathbf{Y}^R$
-

new established connections are denoted by $(\mathbf{x}^p, \mathbf{y}^p)$, then in the next phase, we have $\mathbf{X}^p = \mathbf{X}^{p-1} + \mathbf{x}^p$ and $\mathbf{Y}^p = \mathbf{Y}^{p-1} + \mathbf{y}^p$ as part of the input. The algorithm ends when all R phases are finished.

In *the p -th phase algorithm*, we use the notation of star and definition of cost efficiency. A star is composed of a facility and a group of clients that are connected with the facility. Consider the time before the new star is selected, the *cost efficiency* of a star is defined to be

$$\text{eff}(i, p, C') = \frac{f_i^p + \sum_{j \in C'} c_{i,j}}{|C'|}, \quad (5)$$

where f_i^p is the cost paid to open a facility at site i in phase p and C' the set of member clients in the star. The two items in the numerator represent the total cost of the star, and therefore, the cost efficiency of a star is actually the average payment of all member clients to establish the star. Let $U \subseteq \mathcal{C}^p$ be the set of un-fully connected clients in phase p , and $C' \subseteq U$ is a set of clients chosen by the algorithm to be connected with facility i . As an open facility can be accessed for free under certain condition, the cost paid to the facility is equal to zero if no new facility has to be opened.

Now the dual variables, i.e., α_j^p and β_{ij}^p , can be used to find the most cost-efficient star. We use the same interpretation which was first used to interpret their counterparts in *UFL* as in [14, 22]: α_j^p is the total cost (including the connection cost and the contribution to open facilities) paid by the p -th port of client j , and β_{ij}^p is the contribution received by facility i from the p -th port of client j . As such, the most cost-effective star in each iteration of the subroutine can be found in this way: if the dual variables of all unconnected clients are raised simultaneously, the most cost-effective star will be the first star (i, p, C') such that

Algorithm 2 The p -th phase algorithm

-
- (1) Let $U \subseteq \mathcal{C}^p$ be the set of not fully connected cities, initially set $U \leftarrow \mathcal{C}^p$.
 - (2) While $U \neq \emptyset$:
 - (a) Find the most cost efficient star (i, p, C') according to formulation (5).
 - (b) Open a facility at site i , if it is not already open, and establish a connection to the facility for all cities in C' .
 - (c) Set $f_i \leftarrow 0$, $U \leftarrow U \setminus C'$.
-

$$\sum_{j \in C'} \max(t - c_{ij}, 0) = f_i^p,$$

where $\alpha_j^p = t$ and $\beta_{ij}^p = \max(t - c_{ij}, 0)$.

The p -th phase algorithm opens the most cost-efficient star repeatedly until all the clients in \mathcal{C}^p are *connected* with a facility. Once a client is connected, it is removed from U ; in contrast, a facility is never removed, instead it can be reused for free under certain condition. In fact, the subroutine is very close to the MMS algorithm proposed in [14, 22] for the *UFL* problem. The difference is, here, we need to ensure the feasibility of the solution by maintaining $X_{ij}^p \leq Y_i^p$ for any $i \in \mathcal{F}$, $p \in \mathcal{R}$, $j \in \mathcal{C}^p$. For the sake of simplicity, we set $y_i^p \leftarrow 1$ when a new facility at site i is opened and $x_{ij}^p \leftarrow 1$ when a new connection between client j and facility i is established. In order to maintain the feasibility of a solution, i.e., $X_{ij}^p \leq Y_i^p$, we consider three cases for any $j \in \mathcal{C}^p$:

1. $X_{ij}^{p-1} < Y_i^{p-1}$: In this case, feasibility of the solution maintains if we set $x_{ij}^p \leftarrow 1$. There is no need to open a new facility at site i and $f_i^p = 0$. We say the facility i is eligible to be connected by client j .
2. $X_{ij}^{p-1} = Y_i^{p-1}$ and $y_i^p = 0$: In this case, we must open a new facility at site i , i.e., set $y_i^p \leftarrow 1$, in order to establish a new connection for client j and therefore, $f_i^p = f_i$. The operating cost is shared between a set of clients in C' that need to connect to facility i .
3. $X_{ij}^{p-1} = Y_i^{p-1}$ and $y_i^p = 1$: In this case, a new facility has been opened by some clients before j in C' during the p -th phase, so client j can access facility i without paying any operating cost. Feasibility of the solution maintains if we set $x_{ij}^p \leftarrow 1$ and $f_i^p = 0$.

In these three cases, only the second one involves more than one client. Suppose each facility has a list of clients that are ordered according to their connection costs to the facility. As shown in Fig. 1, the most cost efficient star will consist of a facility and a set, containing the first k cities in this order, for some k . Therefore, the algorithm can be finished efficiently in polynomial time.

Here, we use three types of events to process these cases respectively. Note that a client will contribute to opening a facility only when it has accumulated more credit (increases in time) than the connection cost to an eligible open facility, and a star

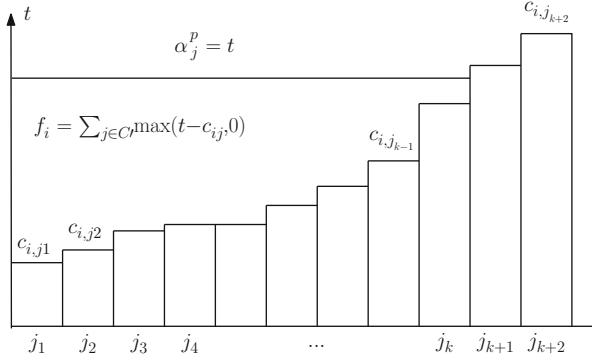

Fig. 1 Credit offers for opening a facility

Algorithm 3 Restatement of the p -th phase algorithm

- (1) At the beginning, all cities are unconnected, i.e., $t \leftarrow 0, U \leftarrow \mathcal{C}^p$. Assume city $j \in U$ has r_j ports each with some credit which increases from zero simultaneously with time before the port is connected. Set $\alpha_j^p = 0$ for any $j \notin U$.
 - (2) While $U \neq \emptyset$, increase time t until an instance of *Event-1* or *Event-2* or *Event-3* occurs. If two events occur at the same time, process them in an arbitrary order:
 - (a) *Event-1*: A city $j \in U$ has enough credit to be connected with an eligible site, suppose i , i.e., $t = c_{ij}$ and $X_{ij}^{p-1} < Y_i^{p-1}$. Set $X_{ij}^p \leftarrow X_{ij}^{p-1} + 1$ in this case.
 - (b) *Event-2*: A site $i \in \mathcal{F}$ receives enough payment from cities in U to open its p -th facility, i.e., $\sum_{j \in U} \max(t - c_{ij}, 0) = f_i$. In this case, let $C' = \{j \in U : c_{ij} \leq t\}$, set $Y_i^p \leftarrow Y_i^{p-1} + 1$ and $X_{ij}^p \leftarrow X_{ij}^{p-1} + 1$ for any $j \in C'$.
 - (c) *Event-3*: A city $j \in U$ has enough credit to be connected with a new opened facility, i.e., $t = c_{ij}$. Set $X_{ij}^p \leftarrow X_{ij}^{p-1} + 1$ in this case.
 - (d) For any city $j \in U$, set $\alpha_j^p \leftarrow t$ and remove city j from U if it is connected with a facility in phase p .
-

is formed only when a set of unconnected clients collectively make a contribution f_i to open a facility at site i . We restate the p -th phase algorithm based on these observations.

Remark 1 [Algorithm 1](#) is independent on the order of client set processed, e.g., we may also process clients in order $\mathcal{C}^R, \mathcal{C}^{R-1}, \dots, \mathcal{C}^1$.

5 Analysis

We assume the function of connection cost forms a metric. In order to show the performance of [Algorithm 1](#), we claim that the maximum cost ratio in each phase is bounded by a constant for any instance of the problem. Formally, let \mathcal{I} be an instance of the *FTFA* problem and $p \in \mathcal{R}$ a phase when solving the problem; we define

$$\lambda_{p,\mathcal{I}} = \max_{i \in \mathcal{F}, p \in \mathcal{R}, C' \subseteq \mathcal{C}^p} \frac{\sum_{j \in C'} \alpha_j^p}{f_i + \sum_{j \in C'} c_{ij}}$$

as the maximum cost ratio with respect to any possible star (i, p, C') .

Claim 1 The cost of the solution in each phase is equal to $\sum_{j \in \mathcal{C}_p} \alpha_j^p$, and the maximum cost ratio $\lambda_{p,\mathcal{I}}$ is bounded by a constant λ for any phase $p \in \mathcal{R}$ and any instance \mathcal{I} of the problem.

We use the inverse dual fitting technique here to analyze the approximation ratio of the high level algorithm. We do this by composing an extra instance of the problem which has the same size as the original problem but different value of facility cost and connection cost. We achieve this by scaling the facility cost and connection cost by constant λ : $f'_i \leftarrow \lambda f_i$ and $c'_{ij} \leftarrow \lambda c_{ij}$. Instead of shrinking the dual variable as in the dual-fitting [14, 18, 22] technique to achieve a feasible solution to the unscaled dual problem, we use the unshrunk dual solution which is feasible to the composed instance of the dual problem and achieve a λ -approximation ratio based on the claim. It is not hard to see that the same result can be achieved by using the dual fitting technique. However, we argue that our inverse dual fitting technique is more powerful in multifactor approximation analysis as shown in our another work [27].

Theorem 1 If the p -th phase algorithm fulfills the claim, the high level algorithm, i.e., [Algorithm 1](#), is a λ -approximation algorithm to the FTFA problem.

Proof First we check the feasibility of the solution. In the p -th phase algorithm, each phase we have $\forall i \in \mathcal{F}, j \in \mathcal{C}^p : X_{ij}^p \leq Y_i^p$. In fact, this is required by the subproblem (2) in each phase. It is not hard to see that X_{ij}^p stops increasing when $p > r_j$ because a client j is included in \mathcal{C}^p only when $p \leq r_j$ and not yet processed when $p > r_j$. Therefore, we have $\forall i \in \mathcal{F}, j \in \mathcal{C} : X_{ij}^R \leq Y_i^R$ because Y_i^p is increasing monotonously (we never close a facility). Feasibility of the solution is proved.

In order to show the cost ratio, we compose an extra instance of the problem and its feasible dual solution. Let $\beta_{ij}^p = \max(\alpha_j^p - \lambda c_{ij}, 0)$ for any $i \in \mathcal{F}, j \in \mathcal{C}, p \in \mathcal{R}$ and $C' = \{j \in \mathcal{C} : \alpha_j^p \geq \lambda c_{ij}\}$, we have $\sum_{j \in \mathcal{C}} \beta_{ij}^p = \sum_{j \in C'} \beta_{ij}^p = \sum_{j \in C'} (\alpha_j^p - \lambda c_{ij})$. According to the claim, we have

$$\sum_{j \in C'} (\alpha_j^p - \lambda c_{ij}) \leq \lambda f_i$$

for any $i \in \mathcal{F}, p \in \mathcal{R}$. That is, there exists dual variable $\beta_{ij}^p \geq 0$ such that

$$\forall p \in \mathcal{R}, i \in \mathcal{F} : \sum_{j \in \mathcal{C}} \beta_{ij}^p \leq \lambda f_i \quad (6)$$

$$\text{and } \forall p \in \mathcal{R}, i \in \mathcal{F}, j \in \mathcal{C} : \alpha_j^p - \beta_{ij}^p \leq \lambda c_{ij}. \quad (7)$$

From the definitions of α_i and β_{ij} , apparently $\forall p \in \mathcal{R}, i \in \mathcal{F}, j \in \mathcal{C} : \alpha_j^p, \beta_{ij}^p \geq 0$.

We note that the above inequalities are exactly the constraints of the dual problem (4) after λ -factor scaling on f_i and c_{ij} . Therefore, we can compose an instance of the dual, suppose \mathcal{I}' , with facility cost $f'_i = \lambda f_i$ and connection cost $c'_{ij} = \lambda c_{ij}$. Let OPT_2 be the optimal solution to the primal problem of \mathcal{I}' , and OPT_1 the optimal solution to the primal problem of \mathcal{I} . It is clear that

$$OPT_2 = \lambda OPT_1. \quad (8)$$

From Inequalities (6) and (7), we know that (α, β) is a feasible solution to the dual problem of \mathcal{I}' . Due to the weak duality theorem, which states that the optimum of the dual problem (in the form of maximization) is no more than the optimum of the primal problem (in the form of minimization), we have

$$\sum_{j \in \mathcal{C}^p} \sum_{p \in \mathcal{R}} \alpha_j^p \leq OPT_2. \quad (9)$$

On the other hand, let SOL be the solution derived by the algorithm; we have

$$SOL = \sum_{p \in \mathcal{R}} \sum_{j \in \mathcal{C}^p} \alpha_j^p \quad (10)$$

according to the first part of the claim. Combining (8), (9), and (10), we have

$$SOL \leq \lambda OPT_1.$$

The theorem follows. \square

Remark 2 The same result can be achieved by using dual fitting, i.e., shrinking the dual solution λ times to make it “fit” to the original problem. Another interesting observation is that the greedy algorithm for the *UFL* problem, like the MMS algorithm [14, 22] or JMS algorithm [14, 18], can also be analyzed through decomposing the optimal solution into a group of stars. This is true because any solution to *UFL* can be decomposed into stars without overlap or interference. However, in the *FTFA* problem, a client is involved in multiple stars, and how to assign their costs to achieve the balance between regarding stars is a nontrivial task. Fortunately, by using the (inverse) dual-fitting technique, it provides an alternative approach to reveal the approximation ratio.

From [Algorithm 1](#), we can see that all payments are either for the connection cost or operating cost. Therefore, the first part of the claim is complied by the algorithm, and we only need to find a proper value of $\lambda \geq 1$ such that for any instance \mathcal{I} of the *FTFA* problem

$$\max_{i \in \mathcal{F}, p \in \mathcal{R}, C' \subseteq \mathcal{C}^p} \frac{\sum_{j \in C'} \alpha_j^p}{f_i + \sum_{j \in C'} c_{ij}} \leq \lambda.$$

It is clear that we only need to consider clients in $C' = \{j \in \mathcal{C}^p : \alpha_j^p \geq \lambda c_{ij}\}$ for each p . Without loss of generality, suppose there are k such clients in \mathcal{C}^p and $\alpha_1^p \leq \alpha_2^p \leq \dots \leq \alpha_k^p$. We consider some important properties of the p -th phase algorithm in order to find a proper value of λ . First, we have the following lemma on the contribution received by a facility according to Event-2 and Event-3.

Lemma 2 For any instance \mathcal{I} and phase $p \in \mathcal{R}$, $\sum_{j=h}^k \max(\alpha_h^p - c_{ij}, 0) \leq f_i$ holds for any facility $i \in \mathcal{F}$ and any client h , $1 \leq h \leq k$.

Proof Assume $\sum_{j=h}^k \max(\alpha_h^p - c_{ij}, 0) > f_i$; then a new facility at site i must be opened at the moment $t = \alpha_h^p - \epsilon$ according to Event-2 because any j with $\alpha_j^p \geq \alpha_h^p$ is still contributing to open facilities at time t . According to the assumption, there is at least one client, suppose j' , such that

$$\alpha_{j'}^p \geq \alpha_h^p, \text{ and } \alpha_{j'}^p > c_{ij'}$$

That is, $\alpha_{j'}^p > c_{ij'}$. On the other hand, j' can be connected with facility i at least at time t according to Event-3 of the algorithm which implies $\alpha_{j'}^p \leq c_{ij'}$. The contradiction directly establishes the lemma. \square

It is natural to imitate the approach proposed by Mahdian et al. [14, 22] to obtain a property regarding the triangle inequality. However, in the fault-tolerant context, this becomes more complex. In fact, we are not able to conclude that a contribution is less than the connection cost to any open facility. As shown in Fig. 2a, neither $\alpha_j^3 \leq c_{i_1 j}$ nor $\alpha_j^3 \leq c_{i_2 j}$ can be achieved even if i_1 and i_2 are opened. This is because h is already connected with facilities i_1 and i_2 before making its third contribution. Fortunately, in our algorithm, only ports of the same rank are processed in a phase, and this makes an important difference. In fact, if there are p open facilities, the p -th contribution of a client is no more than the maximum connection cost from the client to these facilities. As shown in Fig. 2b, we have $\alpha_j^3 \leq c_{i_3 j}$. Formally, we have the following lemma.

Lemma 3 For any instance \mathcal{I} and phase $p \in \mathcal{R}$, $\alpha_j^p \leq \alpha_h^p + c_{ih} + c_{ij}$ holds for any facility $i \in \mathcal{F}$ and clients h and j , $1 \leq h, j \leq k$.

Proof Assume $\alpha_j^p > \alpha_h^p$; otherwise, the lemma is obvious. Let F_1 be the set of facilities that are connected with client h at the moment when $t = \alpha_j^p - \epsilon$, we have $|F_1| = p$ because h is already connected in the p -th phase. Hence, there must exist a facility among F_1 which is not connected with j at the moment in phase p . Suppose this is a facility at site i' , we have $X_{i'j}^{p-1} < Y_{i'j}^p$. Therefore, j can be

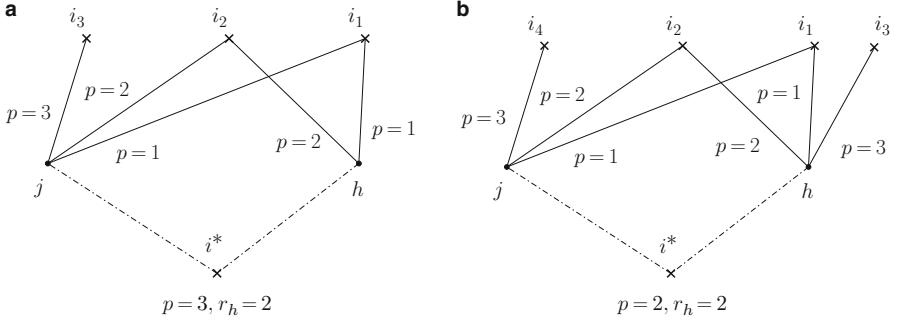

Fig. 2 Ranking of contributions. (a) $p = 3, r_h = 2$. (b) $p = 2, r_h = 2$

connected with i' without paying operating cost. Consider two cases, i.e., the facility is opened, respectively, in a previous phase and in phase p ; we have $\alpha_j^p \leq c_{i'j}$ for both cases due to Event-1 and Event-3. Further, we have $\alpha_j^p \leq c_{ij}$ if $i = i'$; otherwise, combine the triangle inequality $c_{i'j} \leq c_{i'h} + c_{ih} + c_{ih}$, and we have $\alpha_j^p \leq \alpha_h^p + c_{ij} + c_{ih}$ because $\alpha_h^p \geq c_{i'h}$ for any i' connected with client h . The lemma follows. \square

The above lemmas present some important properties of the p -th phase algorithm, and the following result turns out that they are enough to bound the ratio of the total cost of a derived solution to that of an optimal solution. Let λ_k be the maximum of the following LP:

$$\begin{aligned} & \text{maximize } \sum_{j=1}^k \alpha_j / (f + \sum_{j=1}^k d_j) \\ & \text{subjected to } \forall 1 \leq j < h \leq k : \alpha_h \leq \alpha_j + d_j + d_h \\ & \quad \forall 1 \leq h \leq k : \sum_{j=h}^k \max(\alpha_h - d_j, 0) \leq f \\ & \quad \forall 1 \leq j \leq k : \alpha_j, d_j, f \geq 0. \end{aligned} \tag{11}$$

If λ_k has an upper bound with respect to any integer k , we are able to choose this upper bound as the value of λ with respect to the claim. Formulations similar to (11) are also called factor-revealing LPs in the literature [14, 18, 21, 22].

Corollary 1 *Algorithm 1* is a 1.861-approximation algorithm for the FTFA problem.

Proof Let α_j^p be denoted by α_j , c_{ij} by d_j , and f_i by f . It is clear that Lemma 1 and 2 imply the two constraints of formulation (11). As a result,

$$\lambda \leq \sup_{k \geq 1} \{\lambda_k\}.$$

In fact, Mahdian et al. [14, 22] show that formulation (11) has an upper bound 1.861 in their analysis for the MMS algorithm. Combined with Theorem 1, the corollary follows. \square

In each phase, there are at most $n_f \cdot |\mathcal{C}^P|$ events for which the algorithm needs $n_f \cdot |\mathcal{C}^P| \log(n_f \cdot |\mathcal{C}^P|)$ time to sort these events. Considering that the algorithm runs R phases and in each phase $|\mathcal{C}^P| \leq |\mathcal{C}|$, we have the following lemma.

Lemma 4 *Time complexity of Algorithm 1 is $O(mR \log m)$, where $m = n_c n_f$.*

6 Conclusion

We have overviewed some of our recent work on the Fault-Tolerant Facility Allocation (FTFA) problem [27] which generalizes the classical facility location (FL) problem and relaxes the more challenging problem of Fault-Tolerant Facility Allocation (FTFL). For n_f sites and n_c clients with maximum number of connections R , our FTFA algorithm achieves an approximation ratio of 1.861 in time $O(mR \log m)$, where $m = n_f n_c$. Instead of restricting only one facility provided at each site as in FTFL, FTFA allows a site to hold multiple (identical) facilities for parallel access from a client. This difference makes FTFA suitable for numerous emerging applications such as content delivery networks, cloud service (virtual machine) delivery, fault-tolerant network design, and fuzzy clustering.

Suppose the downtime of facilities or links is predictable. For example, in a system where each facility needs a fraction of time to rest, the downtime ratio (percent of time to rest) is uniformly b for all facilities, and the usability required by client j is b_j (percent of time that a service is operating), and then the regarding network design problem can be modeled as an FTFA problem with r_j set as $\lceil b_j / (1 - b) \rceil$. If the downtime is unpredictable, then r_j should be set to $\lceil \log_b(1 - b_j) \rceil$. In both cases, we can apply the proposed algorithm to solve the network design problem directly. However, if facilities or links have a nonuniform downtime, the constraints on connectivity become $\sum_{i \in \mathcal{F}} (1 - b_{ij})x_{ij} \geq b_j$ for the deterministic model and $\prod_{i \in \mathcal{F}: x_{ij}=1} b_{ij} \leq 1 - b_j$ for the stochastic model. We leave these problems for future research. FTFA can also be extended into *Fault-Tolerant k-Facility Allocation* which has an extra constraint on the maximum number of open facilities as shown in our other work [27].

In our other study [27] it was shown that using factor-revealing technique we can achieve an approximation ratio of 1.61 in time $O(Rn^3)$, where $n = \max\{n_f, n_c\}$, and this ratio can be further improved to 1.52 derivable from bi-factor approximation with the help of scaling and greedy augmentation.

Abstract

This chapter considers combinatorial optimization problems with objective functions in the form of ratios of two functions. A parametric approach to such problems is described and two main general algorithmic methods—the Newton method and Megiddo's parametric search—are explained, using in both cases the same example of computing maximum-ratio paths in acyclic graphs. Some general properties of these methods are presented, including a proof of a strongly polynomial bound on the number of iterations of the Newton method and a proof of the speedup of Megiddo's parametric search obtained by using parallel algorithms. The power of these methods is further shown in detail analyses of an algorithm for the maximum mean-weight cut problem based on the Newton method and an algorithm for the maximum profit-to-time ratio cycle problem based on Megiddo's parametric search.

1 Introduction

An instance of a *fractional combinatorial optimization* problem \mathcal{F} consists of a specification of a set $\mathcal{X} \subseteq \{0, 1\}^p$ and two functions $f : \mathcal{X} \rightarrow \mathbf{R}$ and $g : \mathcal{X} \rightarrow \mathbf{R}$. The objective is to

$$\mathcal{F} : \quad \text{maximize} \frac{f(\mathbf{x})}{g(\mathbf{x})} \quad \text{for } \mathbf{x} \in \mathcal{X}. \quad (1)$$

It is assumed that $f(\mathbf{x}) > 0$ for some $\mathbf{x} \in \mathcal{X}$ and $g(\mathbf{x}) > 0$ for all $\mathbf{x} \in \mathcal{X}$. The elements of the discrete domain \mathcal{X} are often called *structures*, since in concrete fractional combinatorial optimization problems, they represent combinatorial structures such as cycles, spanning trees, or other types of subgraphs. Examples of fractional combinatorial optimization include the minimum-ratio spanning-tree problem [7], the weighted maximum-mean subtree problem [5], the maximum profit-to-time cycle problem [14, 21], the maximum-mean cycle problem [15–17, 34, 38], the maximum mean-weight cut problem [50], and the fractional 0–1 knapsack problem [31]. A problem of minimizing/maximizing a fractional objective $f(\mathbf{x})/g(\mathbf{x})$ can be often solved by considering the equivalent problem of maximizing/minimizing fractional objective $(-f(\mathbf{x}))/g(\mathbf{x})$, or $(Bg(\mathbf{x}) - f(\mathbf{x}))/g(\mathbf{x})$, for a suitably large number B , if it is important to keep the numerator positive.

Fractional combinatorial optimization is a special case of (general) fractional optimization: maximize $f(\mathbf{x})/g(\mathbf{x})$ over a subset D of \mathbf{R}^n . Fractional optimization problems have been extensively studied, and many algorithms have been designed and analyzed (see, e.g., surveys [55–58, 60]). Computational methods designed for general fractional optimization can usually be adapted to fractional combinatorial optimization, but the analysis of a method for the combinatorial case may be considerably different from the analysis of the same method for the general case. For example, when general fractional optimization is considered, it is often assumed that the domain D is a compact subset of \mathbf{R}^n and functions f and g are continuous. Such assumptions clearly do not have equivalent counterparts in fractional combinatorial optimization. Computational methods for general fractional optimization converge to the optimum objective value, but they might not guarantee that this value is actually reached. In most cases, the corresponding methods for fractional combinatorial optimization do produce optimal solutions. Note that the domain \mathcal{X} is finite, so an optimal solution can be found in finite time by simply checking all structures $\mathbf{x} \in \mathcal{X}$.

In the context of optimization problems, the term “fractional” is often used to indicate nonintegral solutions. Therefore, to avoid ambiguity, “fractional optimization” is sometimes referred to using a more elaborate phrase, for example, “optimization with rational objective functions.” In this chapter, however, “fractional” consistently refers to the form of the objective function.

This chapter focuses on two main methods for fractional combinatorial optimization, the *Newton method* and *Megiddo’s parametric search method*. Both these methods, as well as most of the existing methods for general fractional optimization, are based on a reduction from fractional optimization to non-fractional, parametric optimization. The Newton method was introduced for general fractional

optimization by Dinkelbach [18], and there are a number of results concerning the fast convergence of this method and its variants (e.g., [30, 47, 54]). The analyses of the Newton method for fractional combinatorial optimization presented in this chapter are mostly based on [48, 50]. Megiddo's parametric search method [41, 42] was designed for the case of fractional combinatorial optimization when both functions f and g are linear. This method gave, for example, the first *strongly polynomial* algorithm for the maximum profit-to-time cycle problem. A strongly polynomial bound related to problem \mathcal{F} is a bound which depends polynomially on p and does not depend on any other input parameters.

This chapter is organized in the following way. [Section 2](#) describes basic properties of fractional combinatorial optimization, the reduction from fractional optimization to parametric optimization, and the binary search method. This section also introduces the maximum-ratio path problem for acyclic graphs, which is used later in the chapter to illustrate both the Newton method and Megiddo's parametric search. [Section 3](#) introduces the Newton method for fractional combinatorial optimization and presents some general results about its convergence. [Section 4](#) shows that if both functions f and g of problem \mathcal{F} are linear, then the Newton method finds an optimal solution in a strongly polynomial number of iterations, regardless of the structure of the domain \mathcal{X} . [Section 5](#) discusses in depth Megiddo's parametric search method. [Sections 6](#) and [8](#) contain two case studies. [Section 6](#) shows how Megiddo's parametric search leads to fast algorithms for the maximum profit-to-time ratio cycle problem. [Section 8](#) presents an analysis of the Newton method for the maximum mean-weight cut problem, which gives the best-known bound on the computational complexity of this problem. Most of the fastest known algorithms for fractional combinatorial optimization problems are based on either the Newton method, or Megiddo's parametric search, or the basic binary search method. The most notable exception to this rule is Karp's algorithm for the maximum-mean cycle problem [34]. This algorithm and its analysis are presented in [Sect. 7](#). [Section 9](#) contains concluding remarks, mentions other approaches, and gives suggestions for further reading.

2 Fractional Combinatorial Optimization: The General Case

For $\mathbf{x} \in \mathcal{X}$, numbers $f(\mathbf{x})$, $g(\mathbf{x})$, and $f(\mathbf{x})/g(\mathbf{x})$ are called the *cost*, the *weight*, and the *mean-weight cost* of structure \mathbf{x} . Using this terminology, problem \mathcal{F} is to compute the maximum mean-weight cost of a structure in domain \mathcal{X} and to find a structure which achieves this maximum mean-weight cost.

Consider the following problem:

$$\mathcal{P} : \quad \text{minimize } \delta \in \mathbf{R}, \quad \text{subject to } f(\mathbf{x}) - \delta g(\mathbf{x}) \leq 0, \quad \text{for all } \mathbf{x} \in \mathcal{X}.$$

A pair $(\delta^*, \mathbf{x}^*) \in \mathbf{R} \times \mathcal{X}$ is an optimal solution of problem \mathcal{P} , if and only if,

$$f(\mathbf{x}) - \delta^* g(\mathbf{x}) \leq 0 = f(\mathbf{x}^*) - \delta^* g(\mathbf{x}^*), \quad \text{for each } \mathbf{x} \in \mathcal{X}.$$

This condition is equivalent to

$$f(\mathbf{x})/g(\mathbf{x}) \leq \delta^* = f(\mathbf{x}^*)/g(\mathbf{x}^*), \quad \text{for each } \mathbf{x} \in \mathcal{X},$$

which means that δ^* is the optimum objective value and \mathbf{x}^* is an optimal solution of problem \mathcal{F} . Thus, problems \mathcal{F} and \mathcal{P} are equivalent. Many iterative methods for solving problem \mathcal{F} generate and solve a sequence of instances of the following problem, where $\delta \in \mathbf{R}$ is an additional input parameter.

$$\mathcal{P}(\delta) : \quad \text{maximize } f(\mathbf{x}) - \delta g(\mathbf{x}), \quad \text{for } \mathbf{x} \in \mathcal{X}. \quad (2)$$

Problem $\mathcal{P}(\delta)$ is called the *parametric problem* corresponding to problem \mathcal{F} and sometimes also the *non-fractional version* of problem \mathcal{F} . Let $h(\delta)$ and \mathbf{x}_δ^* denote the optimum objective value and an optimal solution of problem $\mathcal{P}(\delta)$. Then, $h(\delta) = 0$, if and only if, $(\delta, \mathbf{x}_\delta^*)$ is an optimal solution of problem \mathcal{P} , that is, if and only if, δ and \mathbf{x}_δ^* are the optimum objective value and an optimal solution of problem \mathcal{F} . This gives another equivalent formulation \mathcal{Z} of problem \mathcal{F} .

\mathcal{Z} : find $\delta \in \mathbf{R}$ such that $h(\delta) = 0$, where

$$h(\delta) = \max\{f(\mathbf{x}) - \delta g(\mathbf{x}) \mid \mathbf{x} \in \mathcal{X}\}. \quad (3)$$

This formulation suggests that one can try to design algorithms for problem \mathcal{F} by applying classical methods for finding a root of a function. The following properties of function h can be easily obtained from the fact that h is the maximum of a finite number of decreasing linear functions:

1. Function h is continuous on $(-\infty, +\infty)$ and strictly decreasing from $+\infty$ to $-\infty$.
2. $h(0) > 0$ (this follows from the assumption that $f(\mathbf{x}) > 0$, for some $\mathbf{x} \in \mathcal{X}$).
3. Function h has exactly one root δ^* , and $\delta^* > 0$.
4. If $\delta_1 < \delta_2 < \dots < \delta_q$ denote all values of δ for which two lines in $\{f(\mathbf{x}) - \delta g(\mathbf{x}) \mid \mathbf{x} \in \mathcal{X}\}$ intersect, then function h is linear on each interval $[-\infty, \delta_1]$ and $[\delta_i, \delta_{i+1}]$, for $i = 1, 2, \dots, q-1$, and $[\delta_q, \infty]$.
5. Function h is convex.

Some methods for solving problem \mathcal{F} require a subroutine only for the following weaker version of problem $\mathcal{P}(\delta)$.

$$\begin{aligned} \mathcal{P}_0(\delta) : & \text{ find } \mathbf{y} \in \mathcal{X} \text{ such that} \\ & \text{sign}(f(\mathbf{y}) - \delta g(\mathbf{y})) = \text{sign}(\max\{f(\mathbf{x}) - \delta g(\mathbf{x}) : \mathbf{x} \in \mathcal{X}\}). \end{aligned}$$

That is, problem $\mathcal{P}_0(\delta)$ is only to find the sign of the objective value of problem $\mathcal{P}(\delta)$. Further discussion of the properties of computational methods for problem \mathcal{F} refers to the following three parameters:

$$\text{MAX}_f = \max\{f(\mathbf{x}) : \mathbf{x} \in \mathcal{X}\},$$

$$\begin{aligned}\text{MAX}_g &= \max\{g(\mathbf{x}) : \mathbf{x} \in \mathcal{X}\}, \\ \text{MIN}_g &= \min\{g(\mathbf{x}) : \mathbf{x} \in \mathcal{X}\}, \\ \text{GAP} &= \min \left\{ \left| \frac{f(\mathbf{x}')}{g(\mathbf{x}')} - \frac{f(\mathbf{x}'')}{g(\mathbf{x}'')} \right| : \mathbf{x}', \mathbf{x}'' \in \mathcal{X}, \text{ and } \frac{f(\mathbf{x}')}{g(\mathbf{x}')} \neq \frac{f(\mathbf{x}'')}{g(\mathbf{x}'')} \right\}.\end{aligned}$$

The assumptions on functions f and g imply that the optimum objective value of problem \mathcal{F} is contained in interval $(0, \text{MAX}_f/\text{MIN}_g]$. Parameter GAP is the smallest difference between two different mean-weight costs.

If the weight function g counts the number of ones, then problem \mathcal{F} is called a *uniform* fractional combinatorial optimization problem:

$$\mathcal{F}_U : \text{maximize } \frac{f(x_1, x_2, \dots, x_p)}{x_1 + x_2 + \dots + x_p}, \quad \text{for } (x_1, x_2, \dots, x_p) \in \mathcal{X}.$$

If both the cost function f and the weight function g are linear, then problem \mathcal{F} is called a *linear* fractional combinatorial optimization problem:

$$\begin{aligned}\mathcal{F}_L : \text{maximize } & \frac{a_1 x_1 + a_2 x_2 + \dots + a_p x_p}{b_1 x_1 + b_2 x_2 + \dots + b_p x_p} \\ \text{subject to } & (x_1, x_2, \dots, x_p) \in \mathcal{X}.\end{aligned}$$

An instance of problem \mathcal{F}_L consists of a specification of a set of structures $\mathcal{X} \subseteq \{0, 1\}^p$ and two real vectors $\mathbf{a} = (a_1, a_2, \dots, a_p)$ and $\mathbf{b} = (b_1, b_2, \dots, b_p)$. Throughout this chapter, the inner product $c_1 z_1 + c_2 z_2 + \dots + c_p z_p$ of two vectors $\mathbf{c} = (c_1, c_2, \dots, c_p)$ and $\mathbf{z} = (z_1, z_2, \dots, z_p)$ is denoted by $\mathbf{c}\mathbf{z}$. Thus in problem \mathcal{F}_L , the cost, the weight, and the mean-weight cost of a structure \mathbf{x} are equal to \mathbf{ax} , \mathbf{bx} , and $(\mathbf{ax})/(\mathbf{bx})$, respectively.

Maximum-Ratio Paths in Acyclic Graphs

The algorithmic methods for fractional combinatorial optimization which are considered in this chapter will be illustrated using as an example the following MaxRatioPath problem. An input instance of this problem consists of an integer $n \geq 1$, a set of edges E of an acyclic-directed graph with n vertices $1, 2, \dots, n$, an edge-cost function $\mathbf{c} : E \rightarrow \mathbf{R}$, and an edge-weight function $\mathbf{w} : E \rightarrow \mathbf{R}$. To keep this example simple, the following assumptions are made: there are no multiple edges, the vertices are numbered according to a topological sort of the graph (e.g., if $(v, u) \in E$, then $v < u$), and each vertex is reachable from vertex 1. For a path P , let $f(P) = \sum_{(v,u) \in P} \mathbf{c}(v, u)$, $g(P) = \sum_{(v,u) \in P} \mathbf{w}(v, u)$, and $f(P)/g(P)$ be the cost, the weight, and the mean-weight cost of this path. The task is to find a path from vertex 1 to vertex n which has the maximum mean-weight cost.

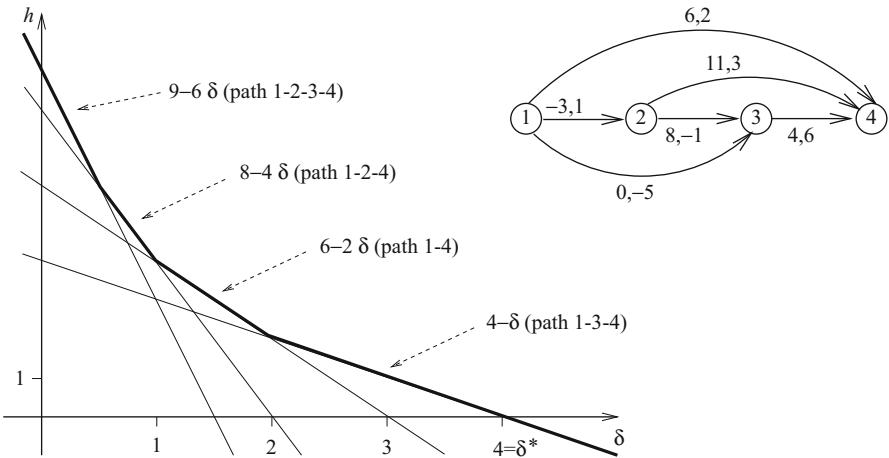

Fig. 1 An input for the MaxRatioPath problem and the corresponding function $h(\delta)$. Lines $9 - 6\delta$, $8 - 4\delta$, $6 - 2\delta$, and $4 - \delta$ correspond to the four paths from vertex 1 to vertex 4. The optimal path is 1-3-4

$$\text{MaxRatioPath} : \underset{\text{over all paths } P \subseteq E \text{ from vertex 1 to vertex } n.}{\text{maximize}} \frac{f(P)}{g(P)},$$

This is a linear fractional combinatorial optimization problem. In the terminology of the general fractional combinatorial optimization, the set of structures \mathcal{X} is here the set of characteristic vectors $\mathbf{x} \in \{0, 1\}^E$ corresponding to paths from vertex 1 to vertex n .

The parametric problem corresponding to the MaxRatioPath problem is

$$\text{MaxPath}(\delta) : \underset{\text{over all paths } P \subseteq E \text{ from vertex 1 to vertex } n.}{\text{maximize}} f(P) - \delta g(P),$$

For a fixed $\delta \in \mathbf{R}$ and a path P , $f(P) - \delta g(P) = \sum_{e \in P} (\mathbf{c}(e) - \delta \mathbf{w}(e))$, so the optimum value of problem MaxPath(δ) is the maximum cost of a path from vertex 1 to vertex n according to the edge-cost function $\mathbf{c} - \delta \mathbf{w}$. An example of an input instance of the MaxRatioPath problem and the corresponding function h are shown in Fig. 1.

In an acyclic graph, the shortest paths, as well as the longest ones, can be computed by considering the vertices according to a topological order [12, Chapter 25]. Algorithm MAXCOST described below computes the maximum cost of a path from vertex 1 to vertex n for a set of edges E and an arbitrary edge-cost function \mathbf{a} by considering the vertices from 1 to $n - 1$. While considering vertex v , the algorithm examines all edges outgoing from v . During the computation, the Boolean variable $seen[u]$ indicates whether vertex u has already been encountered.

At the end of the computation, number $d[v]$, for each $v = 1, 2, \dots, n$, is equal to the maximum cost of a path from vertex 1 to vertex v . The *predecessor* pointers form a “longest-paths” tree rooted at vertex 1.

MAXCOST(n, E, \mathbf{a})

- 1) $d[1] \leftarrow 0; seen[1] \leftarrow \text{true}$
- 2) **for** $v \leftarrow 2$ **to** n **do** $seen[v] \leftarrow \text{false}$
- 3) **for** $v \leftarrow 1$ **to** $n - 1$ **do**
- 4) **for** each u such that $(v, u) \in E$ **do**
- 5) **if** (not $seen[u]$) or $(d[v] + \mathbf{a}(v, u) - d[u] > 0)$ **then**
- 6) $d[u] \leftarrow d[v] + \mathbf{a}(v, u); predecessor[u] \leftarrow v; seen[u] \leftarrow \text{true}$
- 7) let $P = (v_1, v_2, \dots, v_k)$ where $v_1 = 1, v_k = n$, and
 $v_i = predecessor[v_{i+1}]$, for $i = 1, 2, \dots, k - 1$
- 8) **return** $d[n]$ and path P

The running time of algorithm MAXCOST is clearly $O(m)$. Thus, for each $\delta \in \mathbf{R}$, problem MaxPath(δ) can be solved in $O(m)$ time. The MaxRatioPath problem will be used later in this chapter to illustrate both the Newton method and Megiddo’s parametric search. Some details of algorithm MAXCOST may look at this point somewhat awkward, but this presentation will make it simpler to explain Megiddo’s parametric search method in Sect. 5.

The Binary Search Method

To apply the binary search method to the problem of finding the root of function h defined in (3), an algorithm \mathcal{A}_0 which for a given $\delta \in \mathbf{R}$ solves problem $\mathcal{P}_0(\delta)$ is needed. During the binary search, an interval (α, β) containing the root δ^* of function h and a structure \mathbf{x}_α such that $f(\mathbf{x}_\alpha) - \alpha g(\mathbf{x}_\alpha) > 0$ are maintained. Structure \mathbf{x}_α is a “witness” that $\delta^* > \alpha$. During one iteration of the binary search, algorithm \mathcal{A}_0 is run for the value $\delta = (\alpha + \beta)/2$. If it returns a structure \mathbf{x} such that $f(\mathbf{x}) - \delta g(\mathbf{x}) = 0$, then \mathbf{x} is an optimal solution of problem \mathcal{F} , and the computation terminates. If the returned structure \mathbf{x} is such that $f(\mathbf{x}) - \delta g(\mathbf{x}) > 0$, then δ^* must be in the interval (δ, β) , so α is set to δ and \mathbf{x}_α is set to \mathbf{x} . Otherwise δ^* is in the interval (α, δ) , so β is set to δ .

The computation proceeds until an optimal solution has been found or the desired precision has been reached. At the end of the current iteration, $\alpha < f(\mathbf{x}_\alpha)/g(\mathbf{x}_\alpha) \leq \delta^* < \beta$, so $\delta^* - f(\mathbf{x}_\alpha)/g(\mathbf{x}_\alpha) < \beta - \alpha$. Therefore, after $\lceil \log((\beta_0 - \alpha_0)/\epsilon) \rceil$ iterations, $\delta^* - f(\mathbf{x}_\alpha)/g(\mathbf{x}_\alpha) < \epsilon$, where (α_0, β_0) is the initial interval (α, β) . Throughout this chapter, the base of logarithms is 2. If the computation is continued for a sufficient number of iterations, it actually finds an optimal solution of problem \mathcal{F} . Observe that when $\delta^* - f(\mathbf{x}_\alpha)/g(\mathbf{x}_\alpha)$, which is equal to $f(\mathbf{x}^*)/g(\mathbf{x}^*) - f(\mathbf{x})/g(\mathbf{x})$ for an optimal structure \mathbf{x}^* , becomes eventually less than GAP, then $f(\mathbf{x}_\alpha)/g(\mathbf{x}_\alpha) = \delta^*$, so \mathbf{x}_α is an optimal structure. This means that the binary search finds an optimal solution of problem \mathcal{F} in at most $\lceil \log((\beta_0 - \alpha_0)/\text{GAP}) \rceil$ iterations. The initial interval (α_0, β_0) can be $(0, U/L)$, where U and L are an upper bound on MAX_f and a positive lower bound on MIN_g , respectively. For concrete fractional combinatorial optimization problems, such bounds are usually readily available. The binary search procedure

described here can be modified in a straightforward way to work with a somewhat weaker algorithm \mathcal{A}_0 , which finds only a structure \mathbf{x} with nonnegative $f(\mathbf{x}) - \delta g(\mathbf{x})$, provided that such a structure exists.

As an example, consider the special case of the MaxRatioPath problem when all edge costs and weights are integers not greater than U . For this problem, $\text{MAX}_f \leq nU$, $\text{MIN}_g \geq 1$, and $\text{GAP} \geq 1/(nU)^2$, so the binary search method gives an $O(m \log(nU))$ -time algorithm.

3 The Newton Method

The Newton method for a fractional combinatorial optimization problem \mathcal{F} , called also the Dinkelbach method [18], is an application of the classical Newton method to the problem of finding the root of function h defined in (3). To use this method, a stronger algorithm \mathcal{A}_{\max} is needed. For a given $\delta \in \mathbf{R}$, algorithm \mathcal{A}_{\max} computes $h(\delta)$ and a structure $\mathbf{x} \in \mathcal{X}$ such that $f(\mathbf{x}) - \delta g(\mathbf{x}) = h(\delta)$. That is, algorithm \mathcal{A}_{\max} solves problem $\mathcal{P}(\delta)$ for a given $\delta \in \mathbf{R}$.

The Newton method for problem \mathcal{F} is an iterative process which in each iteration generates a new, better lower estimate on the optimum objective value δ^* . During iteration i , the current estimate $\delta_i \leq \delta^*$ is considered and the following computation is performed. Algorithm \mathcal{A}_{\max} is executed for $\delta = \delta_i$ to obtain $h_i = h(\delta_i)$ and a structure $\mathbf{x}_i \in \mathcal{X}$ such that $f(\mathbf{x}_i) - \delta_i g(\mathbf{x}_i) = h_i$. If $h_i = 0$, then $\delta_i = \delta^*$ and \mathbf{x}_i is an optimal solution of problem \mathcal{F} , so the computation terminates. Otherwise a new, better estimate $\delta_{i+1} \leftarrow f(\mathbf{x}_i)/g(\mathbf{x}_i)$ is derived (observe that $\delta_i < \delta_{i+1} \leq \delta^*$, since in this case $h_i > 0$) and the algorithm proceeds to the next iteration. This process is illustrated in Fig. 2. The computation begins with $\delta_1 = 0$.

The aim is to derive bounds on the number of iterations. Let t be the index of the last iteration, or $+\infty$, if the computation does not terminate, and let $f_i = f(\mathbf{x}_i)$ and $g_i = g(\mathbf{x}_i)$, for each $1 \leq i < t + 1$. From the description of the computation,

$$h_i = f_i - \delta_i g_i, \quad \text{for each } 1 \leq i < t + 1, \quad (4)$$

$$\delta_{i+1} = \frac{f_i}{g_i}, \quad \text{for each } 1 \leq i < t. \quad (5)$$

Lemma 1 *The Newton method terminates in a finite number of iterations and*

- (a) $h_1 > h_2 > \dots > h_{t-1} > h_t = 0$,
- (b) $0 = \delta_1 < \delta_2 < \dots < \delta_{t-1} < \delta_t = \delta^*$,
- (c) $g_1 > g_2 > \dots > g_{t-1} \geq g_t$.

Proof This lemma follows immediately from the following claim. For each $1 \leq i < t + 1$,

- (a) $h_1 > h_2 > \dots > h_{i-1} > h_i \geq 0$,
- (b) $0 = \delta_1 < \delta_2 < \dots < \delta_{i-1} < \delta_i \leq \delta^*$,
- (c) $g_1 > g_2 > \dots > g_{i-1} \geq g_i$,

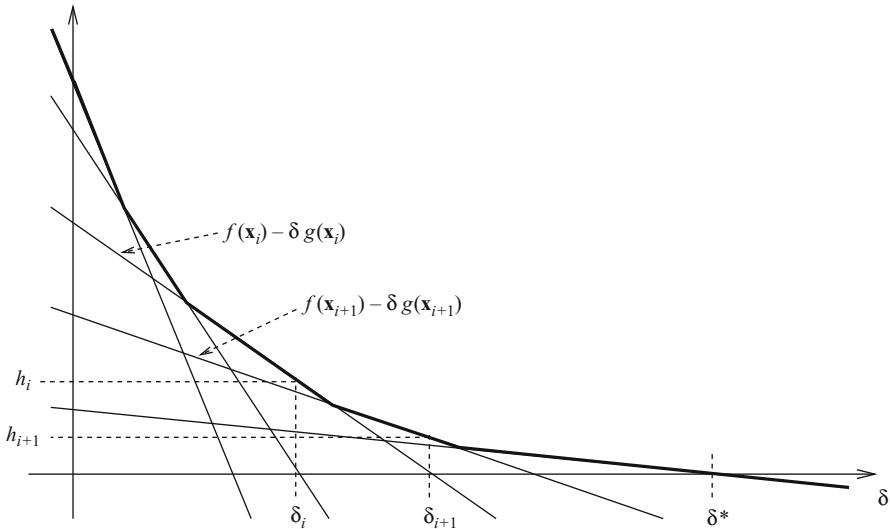

Fig. 2 The Newton method for solving $h(\delta) = 0$

and the equalities at the end of these three chains are possible only if iteration i is the last iteration in the whole computation. This claim can be proven by induction on i . For $i = 1$ the claim follows from the properties (ii) and (iii) of function h . Assume now that the claim is true for $i = j$, for some $1 \leq j < t$. Using (4) and (5),

$$\delta^* \geq \frac{f_j}{g_j} = \delta_{j+1} \quad \text{and} \quad \delta_{j+1} = \frac{f_j}{g_j} = \frac{h_j}{g_j} + \delta_j > \delta_j,$$

so (b) is true for $i = j + 1$. Since $\delta_j < \delta_{j+1} \leq \delta^*$, the monotonicity of function h implies that $h_{j+1} = h(\delta_{j+1}) < h(\delta_j) = h_j$ and $h_{j+1} = h(\delta_{j+1}) \geq h(\delta^*) = 0$, so (a) is true for $i = j + 1$. To show that also (c) is true for $i = j + 1$, the following two inequalities are used:

$$f_{j+1} - \delta_j g_{j+1} \leq \max_{\mathbf{x} \in \mathcal{X}} \{f(\mathbf{x}) - \delta_j g(\mathbf{x})\} = h_j = f_j - \delta_j g_j,$$

$$f_{j+1} - \delta_{j+1} g_{j+1} = h_{j+1} = \max_{\mathbf{x} \in \mathcal{X}} \{f(\mathbf{x}) - \delta_{j+1} g(\mathbf{x})\} \geq f_j - \delta_{j+1} g_j.$$

Subtracting these two inequalities gives $g_{j+1} \leq g_j$, and the equality is possible only if $h_{j+1} = f_j - \delta_{j+1} g_j$. Since $f_j - \delta_{j+1} g_j$ is by definition equal to 0 [see (c)], $g_{j+1} = g_j$ only if $h_{j+1} = 0$, that is, only if iteration $j + 1$ is the last iteration of the whole computation. Hence, (3) is true for $i = j + 1$. This concludes the proof of the claim.

The claim implies that all elements of sequence $(g_i)_{1 \leq i < t}$ are distinct, so t must be finite (numbers g_i are weights of structures from \mathcal{X} , so $t - 1 \leq |\mathcal{X}| < +\infty$). \square

The following lemma indicates that sequences $(h_i)_{1 \leq i \leq t}$ and $(g_i)_{1 \leq i \leq t}$ should geometrically decrease to zero. This lemma is the basic tool in all analyses of the Newton method presented in this chapter.

Lemma 2 *For each $i = 1, 2, \dots, t - 1$,*

$$\frac{h_{i+1}}{h_i} + \frac{g_{i+1}}{g_i} \leq 1. \quad (6)$$

Proof Let $1 \leq i \leq t - 1$. Structure \mathbf{x}_i maximizes $f(\mathbf{x}) - \delta_i g(\mathbf{x})$ over \mathcal{X} , so

$$\begin{aligned} h_i &= f_i - \delta_i g_i = f(\mathbf{x}_i) - \delta_i g(\mathbf{x}_i) \\ &\geq f(\mathbf{x}_{i+1}) - \delta_i g(\mathbf{x}_{i+1}) = f_{i+1} - \delta_i g_{i+1}. \end{aligned}$$

Therefore, using (4) and (5),

$$\begin{aligned} h_i &\geq f_{i+1} - \delta_i g_{i+1} \\ &= h_{i+1} + \delta_{i+1} g_{i+1} - \delta_i g_{i+1} \\ &= h_{i+1} + \frac{f_i}{g_i} g_{i+1} - \frac{h_i - f_i}{g_i} g_{i+1} \\ &= h_{i+1} + h_i \frac{g_{i+1}}{g_i}. \end{aligned}$$

This inequality immediately implies Inequality (6). \square

Lemma 2 leads to a general bound on the number of iterations of the Newton method given in [Theorem 1](#). [Theorems 2](#) and [3](#) show related bounds for special classes of fractional combinatorial optimization.

Theorem 1 *The Newton method solves problem \mathcal{F} in at most $\log(\text{MAX}_f) + \log(\text{MAX}_g) - \log(\text{MIN}_g) - \log(\text{GAP}) + 2$ iterations.*

Proof [Lemma 2](#) implies that for $i = 1, 2, \dots, t - 1$,

$$\frac{h_{i+1}g_{i+1}}{h_i g_i} \leq \frac{1}{4}. \quad (7)$$

Hence, $h_{t-1}g_{t-1} \leq (1/4^{t-2})h_1g_1$ and

$$t \leq \log_4(h_1g_1) - \log_4(h_{t-1}g_{t-1}) + 2. \quad (8)$$

Since $h_1 = \text{MAX}_f$, so

$$h_1g_1 \leq \text{MAX}_f \cdot \text{MAX}_g. \quad (9)$$

Equations (4) and (5) imply that for each $i = 1, 2, \dots, t - 1$, $\delta_{i+1} - \delta_i = h_i/g_i$. Hence,

$$h_{t-1}g_{t-1} = (\delta_t - \delta_{t-1})g_{t-1}^2 = \left(\frac{f_{t-1}}{g_{t-1}} - \frac{f_{t-2}}{g_{t-2}} \right) g_{t-1}^2 \geq \text{GAP} \cdot (\text{MIN}_g)^2. \quad (10)$$

Inequalities (8)–(10) imply the bound on the number of iterations stated in this theorem. \square

The following two theorems have been frequently rediscovered in the context of many different fractional combinatorial optimization problems.

Theorem 2 *For a linear fractional combinatorial optimization problem \mathcal{F}_L such that all input numbers a_i and b_i , $1 \leq i \leq p$, are integers not greater than U , the Newton method runs in $O(\log(pU))$ iterations.*

Proof For such a problem \mathcal{F}_L , $\text{MAX}_f \leq pU$, $\text{MAX}_g \leq pU$, $\text{MIN}_g \geq 1$, and $\text{GAP} \geq 1/(pU)^2$, so [Theorem 1](#) implies an $O(\log(pU))$ bound on the number of iterations. \square

Theorem 3 *For a uniform fractional combinatorial optimization problem \mathcal{F}_U , the Newton method runs in at most $p + 1$ iterations.*

Proof Sequence $(g_i)_{1 \leq i \leq t-1}$ is strictly decreasing. For a uniform fractional optimization problem, each number g_i is a positive integer not greater than p , so $t \leq p + 1$. \square

4 The Newton Method for the Linear Case

In this section a strongly polynomial bound on the number of iterations of the Newton method for linear fractional combinatorial optimization problem \mathcal{F}_L is derived. More precisely, it is shown that the number of iterations is $O(p^2 \log^2 p)$, using the notation introduced in [Sect. 3](#) and following the presentation in [50]. A slightly better bound of $O(p^2 \log p)$ was shown by Wang et al. [67]. Inequality (7), which is a direct consequence of [Lemma 2](#), says that the sequence $(h_i g_i)$ geometrically decreases to zero. Equations (4) and (5) imply that $h_1 g_1 = f_1 g_1$ and for $2 \leq i \leq t$,

$$h_i g_i = (f_i - \delta_i g_i) g_i = \left(f_i - \frac{f_{i-1}}{g_{i-1}} g_i \right) g_i. \quad (11)$$

For each $1 \leq i \leq t$, numbers f_i and g_i are sums of some numbers drawn from $2p$ numbers a_1, a_2, \dots, a_p and b_1, b_2, \dots, b_p . Thus, the elements of sequence $(h_i g_i)$ are created from fixed $2p$ numbers using $O(p)$ additions/subtractions and up to three multiplications/divisions. Bounds on the numbers of iterations of the Newton

method for linear fractional combinatorial optimization come from the fact that a geometric sequence whose elements are constructed in such a limited way cannot be long.

To establish intuition why such sequences cannot be long, it is useful to consider a simple special case when $b_1 \geq b_2 \geq \dots \geq b_p \geq 0$, and there exists a constant α such that for every $i = 1, 2, \dots, t-1$, $g_{i+1}/g_i \leq \alpha < 1$. That is, for this case the sequence $(g_i)_{1 \leq i \leq t}$ on its own geometrically decreases to zero. Each number g_i is equal to the sum of distinct elements drawn from the multi-set $\{b_1, b_2, \dots, b_p\}$. Obviously $g_1 \leq pb_1$. Since the sequence $(g_i)_{1 \leq i \leq t}$ decreases geometrically, then $g_k < b_1$, for some $k = O(\log p)$. This means that number b_1 is not a term in the sum g_k nor does it occur in any sum g_i , for $i \geq k$, so it can be excluded from further considerations. Since $g_k < b_1$, then $g_k \leq (p-1)b_2$, and after next $O(\log p)$ iterations, the number b_2 can be excluded, then b_3 , and so on. Therefore, the length of the sequence (g_i) is only $O(p \log p)$. (In fact, one can show that in this case the length of the sequence (g_i) is $O(p)$. See Lemma 8.)

The actual analysis of the number of iterations is more involved than what the previous paragraph may suggest, because numbers $h_i g_i$ are more “complicated” than numbers g_i (see Eq. (11)). Moreover, the sums of numbers which appear in the general case are not necessarily nonnegative. Even if all numbers a_1, a_2, \dots, a_p and b_1, b_2, \dots, b_p are positive, negative terms may appear since subtractions are used in the definition of numbers h_i . The following lemma, which gives a bound on the length of a geometrically decreasing sequence of sums of numbers, is the main tool in bounding the number of iterations of the Newton method. In the statement of this lemma, the elements of sequence $(\mathbf{y}_k \mathbf{c})_{k \geq 1}$ are constructed by adding and/or subtracting numbers drawn from the set of the components of vector \mathbf{c} .

Lemma 3 *Let $\mathbf{c} = (c_1, c_2, \dots, c_p)$ be a p -dimensional vector with nonnegative real components, and let $\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_q$ be vectors from $\{-1, 0, 1\}^p$. If for all $i = 1, 2, \dots, q-1$*

$$0 < \mathbf{y}_{i+1} \mathbf{c} \leq \frac{1}{2} \mathbf{y}_i \mathbf{c},$$

then $q = O(p \log p)$.

Proof Consider the following polyhedron

$$\begin{aligned} P = \{ \mathbf{z} = (z_1, z_2, \dots, z_p) \in \mathbb{R}^p : \\ (\mathbf{y}_i - 2\mathbf{y}_{i+1})\mathbf{z} \geq 0, \text{ for } i = 1, 2, \dots, q-1, \\ \mathbf{y}_q \mathbf{z} = 1, \\ z_i \geq 0, \text{ for } i = 1, 2, \dots, p \}. \end{aligned}$$

Let A and \mathbf{b} denote the coefficient matrix and the right-hand side vector of the system defining polyhedron P . This polyhedron is not empty because it contains vector $\mathbf{c}/(\mathbf{y}_q \mathbf{c})$. It follows from the polyhedral theory that there exists a vector

$\mathbf{c}^* = (c_1^*, c_2^*, \dots, c_p^*) \in P$ such that $A'\mathbf{c}^* = \mathbf{b}'$ for some nonsingular $p \times p$ submatrix A' of matrix A and a subvector \mathbf{b}' of vector \mathbf{b} (the vertices of the polyhedron are such vectors). Cramer's rule says that for each $i = 1, 2, \dots, p$,

$$c_i^* = \frac{\det A'_i}{\det A'},$$

where matrix A'_i is obtained from matrix A' by replacing the i th column with vector \mathbf{b}' .

The determinant of a $p \times p$ matrix $M = (m_{ij})$ is equal to

$$\det M = \sum_{\sigma} \varepsilon_{\sigma} m_{1,\sigma(1)} m_{2,\sigma(2)} \cdots m_{p,\sigma(p)},$$

where the summation is over all permutations σ of the set of indices $\{1, 2, \dots, p\}$ and each number ε_{σ} is equal to either 1 or -1 . Thus, $|\det M| \leq m^p p!$, where m is the maximum absolute value of an entry of matrix M . The entries of matrix A and vector \mathbf{b} , and consequently the entries of all matrices A'_i , are integers from interval $[-3, 3]$. Thus, $|\det A'_i| \leq 3^p p!$, for each $i = 1, 2, \dots, p$. Since also $|\det A'| \geq 1$, then $c_i^* \leq 3^p p!$, for each $i = 1, 2, \dots, p$, and

$$\mathbf{y}_j \mathbf{c}^* \leq \sum_{i=1}^p c_i^* \leq p 3^p p!,$$

for each $j = 1, 2, \dots, q$. Finally,

$$1 = \mathbf{y}_q \mathbf{c}^* \leq \frac{1}{2^{q-1}} \mathbf{y}_1 \mathbf{c}^* \leq \frac{1}{2^{q-1}} p 3^p p!,$$

so $q \leq \log(p 3^p p!) + 1 = O(p \log p)$. \square

The following rephrasing of [Lemma 3](#) will also be used in the further analysis of the Newton method.

Corollary 1 *Let $\mathbf{c} = (c_1, c_2, \dots, c_p) \in \mathbb{R}^p$, and let $\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_q$ be vectors from $\{0, 1\}^p$. If for all $i = 1, 2, \dots, q - 1$*

$$0 < \mathbf{y}_{i+1} \mathbf{c} \leq \frac{1}{2} \mathbf{y}_i \mathbf{c},$$

then $q = O(p \log p)$.

Two bounds on the number of iterations of the Newton method for linear fractional combinatorial optimization are shown below. The first $O(p^3 \log p)$ bound ([Theorem 4](#)) comes from a direct analysis of the sequence $(h_i g_i)$. This analysis uses

Inequality (7), Eq. (11), and Lemma 3. Then, by analyzing the sequences (h_i) and (g_i) separately, the $O(p^2 \log^2 p)$ bound is derived (Theorem 5).

Theorem 4 *The Newton method solves a linear fractional combinatorial optimization problem \mathcal{F}_L in $O(p^3 \log p)$ iterations.*

Proof For each $1 \leq i \leq t-1$, $h_i > 0$. This fact, Eq. (11), and Inequality (7) imply that for each $i = 2, 3, \dots, t-2$,

$$0 < \left(f_{i+1} - \frac{f_i}{g_i} g_{i+1} \right) g_{i+1} \leq \frac{1}{4} \left(f_i - \frac{f_{i-1}}{g_{i-1}} g_i \right) g_i,$$

and since $0 < g_i \leq g_{i-1}$, then

$$0 < f_{i+1}g_{i+1}g_i - f_i g_{i+1}^2 \leq \frac{1}{4} f_i g_i g_{i-1} - f_{i-1} g_i^2.$$

Hence, setting $s_i = f_i g_i g_{i-1} - f_{i-1} g_i^2$, the following inequalities hold for each $i = 2, 3, \dots, t-2$:

$$0 < s_{i+1} \leq \frac{1}{4} s_i.$$

For a p^3 -dimensional vector \mathbf{c} whose set of components is $\{|a_j b_k b_l| : 1 \leq j, k, l \leq p\}$, there exist p^3 -dimensional vectors $\mathbf{y}_2, \mathbf{y}_3, \dots, \mathbf{y}_{t-1}$ with components from $\{-1, 0, 1\}$ such that $s_i = \mathbf{y}_i \mathbf{c}$, for each $i = 2, 3, \dots, t-1$. The bound $t = O(p^3 \log p)$ follows now from Lemma 3. \square

The $O(p^2 \log^2 p)$ bound on the number of iterations is based on the following two lemmas.

Lemma 4 *There are at most $O(p \log p)$ iterations k such that $g_{k+1} \leq (2/3)g_k$.*

Proof Let $k_1 < k_2 < \dots < k_q$ be the indices k such that $g_{k+1} \leq (1/2)g_k$. Since sequence $(g_i)_{1 \leq i \leq t}$ is nonincreasing, then for each $i = 1, 2, \dots, q-1$,

$$0 < \mathbf{x}_{k_{i+1}} \mathbf{b} = g_{k_{i+1}} \leq g_{k_i+1} \leq \frac{1}{2} g_{k_i} = \frac{1}{2} \mathbf{x}_{k_i} \mathbf{b}.$$

Corollary 1, with $\mathbf{c} = \mathbf{b}$ and $\mathbf{y}_i = \mathbf{x}_{k_i}$ for $i = 1, 2, \dots, q$, implies that $q = O(p \log p)$. Monotonicity of sequence $(g_i)_{1 \leq i \leq t}$ further implies that there are at most $2q = O(p \log p)$ iterations k such that $g_{k+1} \leq (2/3)g_k$. \square

Lemma 5 *There are at most $O(p \log p)$ consecutive iterations k such that $g_{k+1} \geq (2/3)g_k$.*

Proof Consider a sequence of q consecutive iterations $j+1, j+2, \dots, j+q$ such that for each $k = j+1, j+2, \dots, j+q-1$,

$$g_{k+1} \geq \frac{2}{3} g_k. \quad (12)$$

The proof of this lemma is based on showing that [Corollary 1](#) can be applied to vector $\mathbf{c} = \delta_{j+q}\mathbf{b} - \mathbf{a}$ and the sequence of $q-2$ vectors $\mathbf{x}_k, k = j+1, \dots, j+q-2$. Inequalities (12) and (6) imply that for $k = j+1, j+2, \dots, j+q-1$,

$$h_{k+1} \leq \frac{1}{3} h_k. \quad (13)$$

Equations (4) and (5), and Inequalities (12) and (13), imply that the following relations hold for each $k = j+1, j+2, \dots, j+q-2$,

$$\delta_{k+2} - \delta_{k+1} = \frac{h_{k+1}}{g_{k+1}} \leq \frac{1}{2} \cdot \frac{h_k}{g_k} = \frac{1}{2}(\delta_{k+1} - \delta_k). \quad (14)$$

Inequality (14) implies

$$\begin{aligned} \delta_{j+q} - \delta_{k+1} &= (\delta_{j+q} - \delta_{j+q-1}) + (\delta_{j+q-1} - \delta_{j+q-2}) + \cdots + (\delta_{k+2} - \delta_{k+1}) \\ &\leq \frac{1}{2}(\delta_{j+q-1} - \delta_{j+q-2}) + \cdots + \frac{1}{2}(\delta_{k+1} - \delta_k) \\ &= \frac{1}{2}(\delta_{j+q-1} - \delta_k) \\ &< \frac{1}{2}(\delta_{j+q} - \delta_k). \end{aligned} \quad (15)$$

Using Eq. (5), it can be shown that $\mathbf{x}_k(\delta_{j+q}\mathbf{b} - \mathbf{a})$ is positive for each $k = j+1, j+2, \dots, j+q-2$:

$$\mathbf{x}_k(\delta_{j+q}\mathbf{b} - \mathbf{a}) = \delta_{j+q}\mathbf{b}\mathbf{x}_k - \mathbf{a}\mathbf{x}_k = \delta_{j+q}g_k - f_k = (\delta_{j+q} - \delta_{k+1})g_k > 0.$$

Thus, Inequalities (15) and the monotonicity of the sequence (g_i) imply that the following relations hold for each $k = j+1, j+2, \dots, j+q-3$:

$$\begin{aligned} 0 < \mathbf{x}_{k+1}(\delta_{j+q}\mathbf{b} - \mathbf{a}) &= (\delta_{j+q} - \delta_{k+2})g_{k+1} \leq (\delta_{j+q} - \delta_{k+2})g_k \\ &\leq \frac{1}{2}(\delta_{j+q} - \delta_{k+1})g_k = \frac{1}{2}\mathbf{x}_k(\delta_{j+q}\mathbf{b} - \mathbf{a}). \end{aligned}$$

Now [Corollary 1](#), applied to the vector $\mathbf{c} = \delta_{j+q}\mathbf{b} - \mathbf{a}$ and the sequence of $q-2$ vectors $\mathbf{x}_k, k = j+1, \dots, j+q-2$, implies the bound $q = O(p \log p)$. \square

[Lemmas 4](#) and [5](#) immediately imply the following bound on the number of iterations of the Newton method.

Theorem 5 *The Newton method solves a linear fractional combinatorial optimization problem \mathcal{F}_L in $O(p^2 \log^2 p)$ iterations.*

Strongly polynomial bounds on the number of iterations of the Newton method for problem \mathcal{F}_L are somewhat unexpected because, as the following example demonstrates, function $h(\delta)$ may consist of an exponential number of linear segments. Let $\mathbf{a} = (a_1, a_2, \dots, a_{3p})$ and $\mathbf{b} = (b_1, b_2, \dots, b_{3p})$ be vectors such that

$$a_i = \begin{cases} 2^{i-1}, & \text{for } i = 1, 2, \dots, p, \\ 0, & \text{for } i = p+1, \dots, 3p, \end{cases}$$

$$b_i = \begin{cases} 0, & \text{for } i = 1, 2, \dots, p, \\ 2^{i-p-1}, & \text{for } i = p+1, \dots, 3p. \end{cases}$$

Let $\mathcal{U} \subseteq \{0, 1\}^{3p}$ (respectively, $\mathcal{W} \subseteq \{0, 1\}^{3p}$) be the set such that a binary vector $\mathbf{x} = (x_1, \dots, x_{3p})$ belongs to \mathcal{U} (respectively, \mathcal{W}) if and only if $x_i = 0$ for each $p < i \leq 3p$ (respectively, for each $1 \leq i \leq p$). The 2^p numbers \mathbf{au} , for $\mathbf{u} \in \mathcal{U}$, are numbers $0, 1, \dots, 2^p - 1$, and the 2^{2p} numbers \mathbf{bw} , for $\mathbf{w} \in \mathcal{W}$, are numbers $0, 1, \dots, 2^{2p} - 1$. For $\mathbf{u} \in \mathcal{U}$, let $\mathbf{w}_\mathbf{u}$ denote the vector for which $\mathbf{bw}_\mathbf{u} = (\mathbf{au})^2$. Finally, let $\mathcal{X} = \{(\mathbf{u}, \mathbf{w}_\mathbf{u}) : \mathbf{u} \in \mathcal{U}, \mathbf{u} \neq \mathbf{0}\}$. For this instance $(\mathcal{X}, \mathbf{a}, \mathbf{b})$ of linear fractional combinatorial optimization, function h is equal to

$$h(\delta) = \max\{k - \delta k^2 : k = 1, 2, \dots, 2^p - 1\}$$

and consists of $2^p - 1$ linear segments.

The bound stated in [Theorem 5](#) is the best-known bound on the number of iterations of the Newton method for a general problem \mathcal{F}_L . However, when a concrete problem of type \mathcal{F}_L is considered, it often happens that special properties of this problem enable us to derive a better bound. For example, [Theorem 5](#) implies that the Newton method solves the MaxRatioPath problem in $O(m^2 \log^2 m)$ iterations and, consequently, in $O(m^3 \log^2 m)$ total time. It will be shown below, using the properties of the MaxRatioPath problem, that if the edge weights are nonnegative, then the Newton method requires actually only $O(m \log n)$ iterations. A more advanced example of such an analysis is presented in [Sect. 8](#). One more technical lemma about the Newton method for the general case is needed.

Lemma 6 *For each $1 \leq i \leq t-2$ and $\delta \geq \delta_{i+2}$,*

$$f_i - \delta g_i \leq -h_{i+1}. \tag{16}$$

Proof Since sequence (δ_i) monotonically increases and numbers g_i are positive, it is enough to show that Inequality (16) is true for each $1 \leq i \leq t-2$ and $\delta = \delta_{i+2}$. Equations (4) and (5) and Lemma 1(1) imply that for each $1 \leq i \leq t-2$,

$$\begin{aligned} h_{i+1} &= f_{i+1} - \delta_{i+1} g_{i+1} = (\delta_{i+2} - \delta_{i+1}) g_{i+1} \\ &\leq (\delta_{i+2} - \delta_{i+1}) g_i = \delta_{i+2} g_i - f_i. \end{aligned}$$

Thus Inequality (16) is true for each $1 \leq i \leq t-2$ and $\delta = \delta_{i+2}$. \square

Theorem 6 *The Newton method solves the MaxRatioPath problem in $O(m \log n)$ iterations and in $O(m^2 \log n)$ total time, if the weights of the edges are nonnegative.*

Proof Let $(n, E, \mathbf{c}, \mathbf{w})$ be an input instance of the MaxRatioPath problem. The proof uses the notation from the description of the MaxRatioPath problem in Sect. 2 and the following additional definitions. For $\delta \in \mathbf{R}$, a vertex v and an edge $(v, u) \in E$

$$\mathbf{c}_\delta(v, u) \stackrel{\text{def}}{=} (\mathbf{c} - \delta \mathbf{w})(v, u) = \mathbf{c}(v, u) - \delta \mathbf{w}(v, u),$$

$d_\delta(v) \stackrel{\text{def}}{=} \text{the maximum length of a path from vertex 1 to vertex } v$
according to the edge-cost function \mathbf{c}_δ ,

$$\bar{\mathbf{c}}_\delta(v, u) \stackrel{\text{def}}{=} \mathbf{c}_\delta(v, u) + d_\delta(v) - d_\delta(u).$$

For a subset of edges $Q \subseteq E$, $\mathbf{c}_\delta(Q)$ [respectively, $\bar{\mathbf{c}}_\delta(Q)$] denotes the sum of $\mathbf{c}_\delta(e)$ (respectively, $\bar{\mathbf{c}}_\delta(e)$) over all edges $e \in Q$. The introduced definitions imply that for each path $P \subseteq E$,

$$\mathbf{c}_\delta(P) = f(P) - \delta g(P).$$

It is also easy to verify that for each edge $(v, u) \in E$,

$$\bar{\mathbf{c}}_\delta(v, u) \leq 0 \tag{17}$$

and for each path P from vertex 1 to vertex n ,

$$\bar{\mathbf{c}}_\delta(P) = \mathbf{c}_\delta(P) - d_\delta(n). \tag{18}$$

Consider the computation of the Newton method on input $(n, E, \mathbf{c}, \mathbf{w})$. For $i = 1, 2, \dots, t$, let P_i be the path from vertex 1 to vertex n computed during iteration i . For each $1 \leq i \leq t$,

$$h_i = f(P_i) - \delta_i g(P_i) = \mathbf{c}_{\delta_i}(P_i) = d_{\delta_i}(n). \tag{19}$$

An edge e is said to be *essential* at the beginning of iteration i , if it belongs to at least one of the paths P_i, P_{i+1}, \dots, P_t . The proof of the theorem is based on showing that a sequence of $k = \lceil \log n \rceil + 1$ consecutive iterations decreases the number of essential edges at least by one. Consider a sequence of iterations $i, i+1, \dots, i+k$. Inequality (7) implies that

$$h_{i+k} g_{i+k} \leq \frac{1}{n^2} h_{i+1} g_{i+1}. \quad (20)$$

If $g_{i+k} \leq (1/n)g_i$, then let $e \in P_i$ be such an edge that

$$\mathbf{w}(e) \geq \frac{1}{|P_i|} \sum_{a \in P_i} \mathbf{w}(a) = \frac{1}{|P_i|} g(P_i) \geq \frac{1}{n-1} g_i > g_{i+k}.$$

Since sequence (g_j) is nonincreasing, then for each $j \geq i+k$, $\mathbf{w}(e) > g_j = \sum_{a \in P_j} \mathbf{w}(a)$, so edge e does not belong to path P_j . Thus, edge e is essential at the beginning of iteration i (since $e \in P_i$) but is not essential at the beginning of iteration $i+k$ (since $e \notin P_j$, for each $j \geq i+k$).

If $g_{i+k} > (1/n)g_i$, then also $g_{i+k} > (1/n)g_{i+1}$, and Inequality (20) implies that $h_{i+k} < (1/n)h_{i+1}$. This inequality and Lemma 6 imply that

$$\mathbf{c}_{\delta_{i+k}}(P_i) = f(P_i) - \delta_{i+k} g(P_i) = f_i - \delta_{i+k} g_i \leq -h_{i+1} < -nh_{i+k}.$$

Therefore, using (18) and (19),

$$\bar{\mathbf{c}}_{\delta_{i+k}}(P_i) = \mathbf{c}_{\delta_{i+k}}(P_i) - d_{\delta_{i+k}}(n) < -nh_{i+k} - h_{i+k} = -(n+1)h_{i+k}.$$

This means that there must be an edge $e \in P_i$ such that $\bar{\mathbf{c}}_{\delta_{i+k}}(e) < -h_{i+k}$. Let e be such an edge. Referring to (17) and (18), for any path P from vertex 1 to vertex n which contains edge e ,

$$\mathbf{c}_{\delta_{i+k}}(P) = \bar{\mathbf{c}}_{\delta_{i+k}}(P) + d_{\delta_{i+k}}(n) \leq \bar{\mathbf{c}}_{\delta_{i+k}}(e) + h_{i+k} < 0.$$

Hence, none of the paths P_j , for $j \geq i+k$, contain edge e , because $\delta_j \geq \delta_{i+k}$ and

$$\mathbf{c}_{\delta_{i+k}}(P_j) \geq \mathbf{c}_{\delta_j}(P_j) = h_j \geq 0.$$

Thus, edge e is essential at the beginning of iteration i but is not essential at the beginning of iteration $i+k$. \square

5 Megiddo's Parametric Search

This section presents the parametric search method for fractional combinatorial optimization proposed by Megiddo [41, 42]. The method is introduced using the MaxRatioPath problem as an example. Let $(n, E, \mathbf{c}, \mathbf{w})$ be an input instance of this

problem and let δ^* denote the optimum value for this input. See Sect. 2 for the notation concerning the MaxRatioPath problem. The maximum cost of a path from vertex 1 to vertex n according to the edge-cost function $\mathbf{c} - \delta^* \mathbf{w}$ is equal to 0. Thus, if δ^* is known and algorithm MAXCOST is run on input $(n, E, \mathbf{c} - \delta^* \mathbf{w})$, then it returns value 0 and a path P which is optimal for the input instance $(n, E, \mathbf{c}, \mathbf{w})$ of the MaxRatioPath problem.

The crucial idea of Megiddo's method is to run algorithm MAXCOST on input $(n, E, \mathbf{c} - \delta^* \mathbf{w})$ without knowing the value of δ^* . Inspecting the pseudocode of this algorithm, it should be clear that the problem with running algorithm MAXCOST for the cost function $\mathbf{c} - \delta^* \mathbf{w}$ with unknown δ^* is the comparisons performed in line 5. An oracle which gives correct outcomes of those comparisons is needed.

When algorithm MAXCOST is run for the cost function $\mathbf{c} - \delta^* \mathbf{w}$ with unknown δ^* , then at each point of the computation, each $d[v]$ is no longer a number but a function of δ^* . Fortunately, the way the variables $d[v]$ are updated in line 6 implies that they are always linear functions of δ^* . Therefore, the comparison

$$d[v] + (\mathbf{c}(v, u) - \delta^* \mathbf{w}(v, u)) - d[u] > 0?$$

performed in line 5 is always of the form “ $s - \delta^* t > 0$?” for some known numbers s and t . To find out the outcome of such a comparison, the relation between numbers s/t and δ^* has to be established. The three possibilities, $s/t < \delta^*$, $s/t = \delta^*$, and $s/t > \delta^*$, are equivalent to the optimum value of the problem MaxPath(s/t) being positive, equal to 0, or negative, respectively. Thus, establishing the relation between s/t and δ^* can be done by running algorithm MAXCOST for the cost function $\mathbf{c} - (s/t)\mathbf{w}$. That is, the required oracle can be implemented using algorithm MAXCOST itself. The pseudocode of the resulting algorithm for the MaxRatioPath problem is given below.

WEIGHTEDMAXCOST $(n, E, \mathbf{c}, \mathbf{w})$

- 1) $d[1] \leftarrow 0$; $seen[1] \leftarrow \text{true}$
- 2) **for** $v \leftarrow 2$ **to** n **do** $seen[v] \leftarrow \text{false}$
- 3) **for** $v \leftarrow 1$ **to** $n - 1$ **do**
- 4) **for** each u such that $(v, u) \in E$ **do**
- 5) let s and t be the numbers such that

$$s - \delta^* t = d[v] + \mathbf{c}(v, u) - \delta^* \mathbf{w}(v, u) - d[u]$$
- 6) **if** $t \neq 0$ **then**
- 7) $x \leftarrow$ the number returned by $\text{MAXCOST}(n, E, \mathbf{c} - (s/t)\mathbf{w})$
- 8) **if** (not $seen[u]$) or ($t = 0$ and $s > 0$) or ($tx < 0$) **then**
- 9) $d[u] \leftarrow d[v] + \mathbf{c}(v, u) - \delta^* \mathbf{w}(v, u)$
- 10) $predecessor[u] \leftarrow v$; $seen[u] \leftarrow \text{true}$
- 11) let $P = (v_1, v_2, \dots, v_k)$ where $v_1 = 1$, $v_k = n$, and
 $v_i = predecessor[v_{i+1}]$, for $i = 1, 2, \dots, k - 1$
- 12) **return** path P

Theorem 7 Algorithm WEIGHTEDMAXCOST solves the MaxRatioPath problem in $O(m^2)$ time.

Proof The computation $\text{MAXCOST}(n, E, \mathbf{c} - \delta^* \mathbf{w})$ returns an optimal path P for the instance $(n, E, \mathbf{c}, \mathbf{w})$ of the MaxRatioPath problem. Tracing, in parallel, the computations $\text{MAXCOST}(n, E, \mathbf{c} - \delta^* \mathbf{w})$ and $\text{WEIGHTEDMAXCOST}(n, E, \mathbf{c}, \mathbf{w})$ shows that the *predecessor* pointers change in exactly the same way in both computations, because the outcomes of the corresponding conditions checked in line 5 of the first algorithm and in line 8 of the second one are always the same. Thus, both computations return the same path, so the computation $\text{WEIGHTEDMAXCOST}(n, E, \mathbf{c}, \mathbf{w})$ returns an optimal path P for the instance $(n, E, \mathbf{c}, \mathbf{w})$ of the MaxRatioPath problem. The running time of algorithm WEIGHTEDMAXCOST is $O(m^2)$ because algorithm MAXCOST is executed at most m times. \square

To generalize the above idea, the notion of *linear algorithm* is needed. Let $\mathcal{Q}(\delta)$ denote a problem whose input includes a parameter $\delta \in \mathbf{R}$. An algorithm \mathcal{A} is a linear algorithm for problem $\mathcal{Q}(\delta)$, if it satisfies the following conditions:

1. For each fixed $\bar{\delta} \in \mathbf{R}$, algorithm \mathcal{A} computes a correct solution of problem $\mathcal{Q}(\bar{\delta})$.
2. The value of each arithmetic expression on each possible execution path of algorithm \mathcal{A} is a linear function of parameter δ .

Observe that algorithm WEIGHTEDMAXCOST does not actually need in line 7 an algorithm which computes a maximum-cost path. Everything works equally well if instead an algorithm is used which only finds a positive-cost path, if such a path exists. In general terms, this means that instead of considering problem $\mathcal{P}(\delta)$, it is enough to consider problem $\mathcal{P}_0(\delta)$. The following theorem summarizes the basic form of Megiddo's parametric search.

Theorem 8 *If there exists a linear algorithm \mathcal{A} for the parametric problem $\mathcal{P}_0(\delta)$ corresponding to a fractional combinatorial optimization problem \mathcal{F} which runs in time T , then problem \mathcal{F} can be solved in $O(T^2)$ time.*

Proof Run algorithm \mathcal{A} for problem $\mathcal{P}_0(\delta^*)$ with unknown δ^* . Since \mathcal{A} is a linear algorithm, each comparison encountered during the computation is equivalent to a comparison “ $s - \delta^* t > 0 ?$ ” for some numbers s and t and can be evaluated by solving problem $\mathcal{P}_0(s/t)$. If each such problem is solved by running algorithm \mathcal{A} with $\delta = s/t$, then the whole computation runs in $O(T^2)$ time. \square

A better bound than the bound stated in [Theorem 8](#) may be obtained, if possible independence of comparisons in algorithm \mathcal{A} is exploited. Consider, for example, iteration v , $1 \leq v \leq n - 1$, of the outer loop of the computation $\text{MAXCOST}(n, E, \mathbf{c} - \delta^* \mathbf{w})$. Each comparison in line 5 performed during this iteration would give exactly the same outcome if it were performed right at the beginning of the iteration, because it does not depend on any updates done during this iteration. (Note that this statement would not be true if the graph had multiple edges.) Let $s_k - \delta^* t_k$, for $k = 1, 2, \dots, \deg(v)$, be the expressions which have to be compared with 0 during this iteration, where $\deg(v)$ denotes the number of edges outgoing from vertex v . To know the outcome of these comparisons, the relation between unknown number δ^* and all numbers s_k/t_k has to be established. The relation between s_k/t_k and δ^* can be established for each k independently, by computing

$\text{MAXCOST}(n, E, \mathbf{c} - \delta\mathbf{w})$ for each $\delta = s_k/t_k$. Alternatively, the numbers s_k/t_k can first be sorted, and then, the position of δ^* with respect to the elements of the sorted sequence (s'_k/t'_k) can be established by binary search. The latter approach requires only $O(\log(\deg(v)))$ applications of algorithm MAXCOST, one application per one iteration of the binary search. The running time of sorting $\deg(v)$ numbers and $O(\log(\deg(v)))$ applications of algorithm MAXCOST is $O(\deg(v) \log(\deg(v))) + O(m \log(\deg(v))) = O(m \log(\deg(v)))$. Thus, the running time of the whole computation is

$$O\left(m \sum_{v=1}^{n-1} \log(\deg(v))\right) = O(m n \log(m/n)), \quad (21)$$

since $\sum_{v=1}^{n-1} \deg(v) = m$ and the logarithmic function is concave.

To generalize this idea, the notion of a *stage* of the computation is introduced. Consider a problem \mathcal{Q} whose input includes a parameter $\delta \in \mathbf{R}$. A stage of the computation of an algorithm for problem \mathcal{Q} is a (continual) part of the computation which has the following property. For each comparison performed during one stage, if this comparison is moved to the beginning of this stage, the outcome of the comparison does not change. Only the comparisons whose outcomes may depend on the value of parameter δ are considered here. An algorithm is said to consist of r stages, if the computation of this algorithm can be partitioned into r stages, independently of the actual input values. The theorem below distinguishes between the main algorithm \mathcal{A}_1 , which guides the whole computation, must be linear, and should ideally consist of a small number of stages, and the “subordinate” algorithm \mathcal{A}_2 , which is used to resolve individual comparisons performed by algorithm \mathcal{A}_1 . Algorithms \mathcal{A}_1 and \mathcal{A}_2 may of course be the same, but they are usually different, if they are to provide the best possible running time of the whole computation (see Sect. 6).

Theorem 9

If there exist

1. A linear algorithm \mathcal{A}_1 for the parametric problem $\mathcal{P}_0(\delta)$ corresponding to a fractional combinatorial optimization problem \mathcal{F} , which runs in time T_1 and consists of r stages with q_i comparisons during stage i , and
2. An algorithm \mathcal{A}_2 for problem $\mathcal{P}_0(\delta)$ which runs in time T_2 , then problem \mathcal{F} can be solved in $O(T_1 + T_2 \sum_{i=1}^r \log q_i)$ time.

Proof Run algorithm \mathcal{A}_1 for problem $\mathcal{P}_0(\delta^*)$ with unknown δ^* . Consider stage i of this computation. During this stage, q_i independent comparisons of the form $s - \delta^* t$ are to be resolved. Computing the outcomes of all these comparisons can be reduced to computing the relation between δ^* and q_i numbers x_1, x_2, \dots, x_{q_i} .

If these numbers are first sorted and then δ^* is located in the sorted sequence by binary search, as suggested earlier in the example, then the running time of this stage is $O(q_i \log q_i + T_2 \log q_i)$. This gives, however, only an $O(T_1 \max_i \{\log q_i\} + T_2 \sum_{i=1}^r \log q_i)$ bound on the running time of the whole computation.

To obtain the bound claimed in the statement of the theorem, observe that sorting numbers x_1, x_2, \dots, x_{q_i} can be avoided. Instead, the median of these numbers can be found in $O(q_i)$ time [4] and compared with δ^* by running algorithm \mathcal{A}_2 . The outcome of this comparison reveals the relation between δ^* and half of the numbers x_1, x_2, \dots, x_{q_i} . This process can be continued by finding the median of the remaining half. This way, the numbers x_1, x_2, \dots, x_{q_i} are eventually partitioned into the numbers smaller than δ^* and the numbers greater than δ^* . The running time of this computation is

$$O\left(\sum_{k=0}^{\log q_i} \left(\frac{q_i}{2^k} + T_2\right)\right) = O(q_i + T_2 \log q_i).$$

Summing this bound over all stages i gives the bound claimed in this theorem. \square

To minimize the bound of [Theorem 9](#) for a given fractional combinatorial optimization problem, algorithm \mathcal{A}_2 should obviously be the fastest known algorithm for the non-fractional version of this problem. To find good candidates for algorithm \mathcal{A}_1 , parallel algorithms should be considered, since such algorithms are specially designed to have a small number of stages. A parallel algorithm which runs in time T and uses P processors can be viewed as an algorithm which runs in sequential time TP and consists of T stages with at most P operations per stage. Thus, the following theorem is an immediate corollary of [Theorem 9](#).

Theorem 10 *If there exist*

1. *A linear parallel algorithm \mathcal{A}_1 for the parametric problem $\mathcal{P}_0(\delta)$ corresponding to a fractional combinatorial optimization problem \mathcal{F} , which runs in time T_1 and uses P processors, and*
2. *A (sequential) algorithm \mathcal{A}_2 for problem $\mathcal{P}_0(\delta)$ which runs in time T_2 , then problem \mathcal{F} can be solved in $O(T_1 P + T_2 T_1 \log P)$ time.*

Consider another example of fractional combinatorial optimization, the maximum-ratio spanning-tree problem. An input instance of this problem consists of an undirected connected graph $G = (V, E)$, an edge-cost function $\mathbf{c} : E \rightarrow \mathbf{R}$, and an edge-weight function $\mathbf{w} : E \rightarrow \mathbf{R}$. The cost and the weight of a spanning tree in graph G are equal to the sum of the costs and the sum of the weights of the edges of this tree, respectively. The problem is to find a spanning tree in graph G with the maximum cost-to-weight ratio or, using the introduced terminology, a spanning tree with the maximum mean-weight cost. The corresponding parametric problem $\mathcal{P}(\delta)$ is the problem of computing a maximum spanning tree for the edge-cost function $\mathbf{c} - \delta \mathbf{w}$. The maximum-cost spanning-tree problem, which is equivalent to the minimum-cost spanning-tree problem, can be solved in $T_{\text{MST}} = O(\min\{m \log \log n, m + n \log n\})$ time [22, 68], where m is the number of edges and n is the number of vertices in the input graph.

A maximum-ratio spanning tree is a maximum-cost spanning-tree for the edge-cost function $\mathbf{c} - \delta^* \mathbf{w}$. Maximum-cost spanning trees depend only on the order of the edges by their costs. Thus, to find a maximum-cost spanning-tree for the edge-cost function $\mathbf{c} - \delta^* \mathbf{w}$, it is enough to sort m numbers $\mathbf{c}(e) - \delta^* \mathbf{w}(e)$, $e \in E$. Sorting m numbers can be done in $O(\log m)$ parallel time using m processors [11]. Therefore, [Theorem 10](#) implies that the maximum-ratio spanning-tree problem can be solved in $O(m \log m + T_{\text{MST}} \log^2 m) = O(T_{\text{MST}} \log^2 m)$ time.

Going back to the general case, since the objective is maximization, then it could be reasonably expected that many subtasks appearing during the computation of algorithm \mathcal{A}_1 of [Theorem 9](#) may be of the form

$$u(\delta^*) \leftarrow \max\{u_1(\delta^*), u_2(\delta^*), \dots, u_q(\delta^*)\}, \quad (22)$$

where each u_i is a linear function of parameter δ . Two different approaches to computing such a maximum are discussed next. If the maximum (22) is calculated by comparing each u_i , for $i = 2, 3, \dots, q$, with the already known maximum of u_1 through u_{i-1} , then this computation has $q - 1$ stages with one comparison per stage, and the maximum can be computed in $O(T_2 q)$ time. Here T_2 denotes, as in [Theorem 9](#), the running time of an algorithm \mathcal{A}_2 , which is used to resolve the comparisons performed during the computation of algorithm \mathcal{A}_1 .

Computation of the maximum (22) can be organized in $\lceil \log q \rceil$ stages by scheduling the comparisons in a tournament tree. Each stage consists of $O(q)$ comparisons, so [Theorem 9](#) implies that the maximum (22) can be computed in $O(q + T_2 \log^2 q)$ time. The number of stages needed to compute the maximum can be further reduced to $O(\log \log q)$ in the following way. Follow the tournament for $O(\log \log \log q)$ stages to reduce the number of live elements to $k_1 \leq q / (\log \log q)$. Live elements are those which so far have won all their comparisons. Now perform a sequence of the following stages. During stage i , partition the set of k_i live elements into $k_i^2 / (2k_1)$ equal-size groups, and perform all pairwise comparisons in each group. This stage requires $2k_1 = O(q / \log \log q)$ comparisons and reduces the number of live elements to $k_{i+1} = k_i^2 / (2k_1)$. Thus, $k_i = k_1 / 2^{2^{i-1}-1}$, so there are only $O(\log \log q)$ such stages. Therefore, this algorithm for computing the maximum of q numbers consists of $O(q)$ comparisons partitioned into $O(\log \log q)$ stages. Using this algorithm as algorithm \mathcal{A}_1 , [Theorem 9](#) implies that the maximum (22) can be computed in $O(q + T_2 \log q \log \log q)$ time. The above $O(\log \log q)$ -stage algorithm for computing the maximum of q numbers is based on Valiant's parallel algorithm which runs in $O(\log \log q)$ time and uses q processors [65].

There is an alternative approach to computing the maximum (22). The maximum of q linear functions is a convex, piecewise linear function with at most q breakpoints. If two convex, piecewise linear functions π_1 and π_2 have q_1 and q_2 breakpoints, respectively, and these breakpoints are given as two sequences sorted by x -coordinates, then the sorted sequence of the breakpoints of the function $\max\{\pi_1, \pi_2\}$ can be computed in $O(q_1 + q_2)$ time by a straightforward merging

process. Therefore, by following the merging scheme of the merge–sort algorithm, all breakpoints of the maximum of q linear functions u_i can be computed in $O(q \log q)$ time. Finding the linear segment of function u which contains δ^* can then be done by binary search over the breakpoints of function u . Using this approach, the maximum (22) can be computed in $O(q \log q + T_2 \log q)$ time.

Consider an algorithm \mathcal{A} for a problem \mathcal{Q} whose input includes a parameter $\delta \in \mathbf{R}$. A *maxima-computing phase* of an algorithm \mathcal{A} is a (continual) part of the computation of \mathcal{A} such that all comparisons performed during this part of the computation are (implicitly) involved in computing maxima, and all these maxima are independent, that is, they can be performed in arbitrary order without changing the outcome of the whole computation. As in the definition of a stage of an algorithm, only comparisons whose outcomes may depend on the value of parameter δ are considered here. The following theorem is based on the two approaches to computing the maximum (22) described above. The *size* of a maximum of q elements is equal to q .

Theorem 11 *If there exist*

1. *A linear algorithm \mathcal{A}_1 for the parametric problem $\mathcal{P}_0(\delta)$ corresponding to a fractional combinatorial optimization problem \mathcal{F} , which runs in time T_1 and consists of r maxima-computing phases, and the total size of the maxima in phase i is at most q_i , and*
2. *An algorithm \mathcal{A}_2 for problem $\mathcal{P}_0(\delta)$ which runs in time T_2 , then problem \mathcal{F} can be solved in*
 - (i) $O(T_1 + T_2 \sum_{i=1}^r \log q_i \log \log q_i)$ *time and*
 - (ii) $O(T_1 + \sum_{i=1}^r (q_i + T_2) \log q_i)$ *time.*

Proof Run algorithm \mathcal{A}_1 for problem $\mathcal{P}_0(\delta^*)$ with unknown δ^* and consider phase i of this computation. During this phase, independent maxima of the total size at most q_i have to be computed. If these maxima are computed in parallel using the $O(\log \log q)$ -stage algorithm described above, then the running time of this phase is $O(q_i + T_2 \log q_i \log \log q_i)$, and the running time of the whole computation is as in part (i) of the theorem. If first all breakpoints of all maxima are computed and sorted together and then δ^* is located in the sorted list by binary search, then the running time of this phase is $O((q_i + T_2) \log q_i)$ and the running time of the whole computation is as in part (ii) of the theorem.

The best bound for the MaxRatioPath problem shown so far in this chapter is $O(mn \log(m/n))$ (see (21)). Using Theorem 11, an $O(mn)$ bound is now shown. This bound, however, is based on other algorithm for computing a maximum-cost path than algorithm MAXCOST. Algorithm MAXCOST considers vertices $1, 2, \dots, n - 1$, and while considering vertex v , it examines all edges outgoing from v . The following algorithm MAXCOST2 considers vertices $2, 3, \dots, n$, and while considering vertex v , it examines all edges incoming into v . This algorithm returns only the maximum cost of a path from vertex 1 to vertex n but can be easily modified so that it returns also a maximum-cost path.

```

MAXCOST2( $n, E, \mathbf{a}$ )
1)  $d[1] \leftarrow 0$ 
2) for  $v \leftarrow 2$  to  $n$  do  $d[v] \leftarrow -\infty$ 
3) for  $v \leftarrow 2$  to  $n$  do
4)    $d[v] \leftarrow \max\{d[u] + \mathbf{a}(u, v) : (u, v) \in E\}$ 
5) return  $d[n]$ 

```

Algorithm MAXCOST2 is still not quite what is needed. If [Theorem 11](#) is applied with algorithm MAXCOST2 as algorithm \mathcal{A}_1 , then the bound $O(mn \log(m/n) \log \log(m/n))$ is obtained from part (i) of the theorem and the bound $O(mn \log(m/n))$ from part (ii) of the theorem. These bounds do not improve bound (21).

By rearranging the computation of algorithm MAXCOST2, the recursive algorithm MAXCOSTRECURSIVE shown below is obtained. This algorithm considers first, recursively, the subgraph induced by vertices $u = 1, 2, \dots, k = \lfloor (n+1)/2 \rfloor$, then considers the edges $(u, v) \in E$ such that $1 \leq u \leq k < v \leq n$ (observe that all maxima of this part of the computation—lines 7–8 below—are independent), and finishes up by considering, again recursively, the subgraph induced by vertices $v = k, k+1, \dots, n$.

```

MAXCOSTRECURSIVE( $n, E, \mathbf{a}$ )
1)  $d[1] \leftarrow 0$ 
2) for  $v \leftarrow 2$  to  $n$  do  $d[v] \leftarrow -\infty$ 
3) COMPUTEMAXIMA(1,  $n$ )
4) return  $d[n]$ 
COMPUTEMAXIMA( $p, r$ )
5)  $k \leftarrow \lfloor (p+r)/2 \rfloor$ 
6) if  $k > p$  then COMPUTEMAXIMA( $p, k$ )
7) for  $v \leftarrow k+1$  to  $r$  do
8)    $d[v] \leftarrow \max\{d[v], d[u] + \mathbf{a}(u, v) : p \leq u \leq k, (u, v) \in E\}$ 
9) if  $k+1 < r$  then COMPUTEMAXIMA( $k+1, r$ )

```

Algorithm MAXCOSTRECURSIVE runs in $O(m)$ time (each edge is considered only once), and for each $k = 1, 2, \dots, \log n$, it has $r_k = n/2^k$ maxima-computing phases (assume for convenience that n is a power of 2). Each of these r_k phases considers only edges $(u, v) \in E$ such that $a+1 \leq u \leq a+2^{k-1} < v \leq a+2^k$, for some integer a , so the total size of the maxima in one such phase is at most $q_k = \min\{2^{2k}, m\}$. Therefore, part (11) of [Theorem 11](#) implies that the MaxRatioPath problem can be solved within the time bound:

$$O\left(m + \sum_{k=1}^{\log n} r_k(q_k + m) \log q_k\right) = O\left(m + \sum_{k=1}^{\log n} \frac{n}{2^k} \cdot m \cdot (2k)\right) = O(nm).$$

Bound (i) of [Theorem 11](#) gives here the same time bound. [Theorem 11](#) is used in the next section to show low time bounds for computing a maximum profit-to-time ratio cycle.

This section is concluded with a comment about implementation of Megiddo's parametric search. Throughout the whole computation of algorithm \mathcal{A}_1 , an interval (α, β) containing the optimum value δ^* should be maintained. Initially $(\alpha, \beta) = (0, +\infty)$. If during the computation the relation between a given number x and unknown δ^* has to be established, then it should be first checked if x belongs to (α, β) . If $x \notin (\alpha, \beta)$, then the relation between x and δ^* is known. If $x \in (\alpha, \beta)$, then algorithm \mathcal{A}_2 is run to find out whether $x = \delta^*$, $\delta^* \in (\alpha, x)$, or $\delta^* \in (x, \beta)$. If $x = \delta^*$, then the entire computation should be terminated, since the optimum objective value has just been found. In the other two cases, the interval (α, β) should be updated and the computation should proceed to the next iteration. Maintaining interval (α, β) does not improve the worst-case running times, but it should significantly improve the average running times.

6 Maximum Profit-to-Time Ratio Cycles

In this section we consider the following classical fractional combinatorial optimization problem, which we call the MaxRatioCycle problem. An input instance of this problem consists of a directed graph $G = (V, E)$, an edge-cost function $\mathbf{c} : E \rightarrow \mathbf{R}$, and an edge-weight function $\mathbf{w} : E \rightarrow \mathbf{R}$. Let n and m denote the number of vertices and the number of edges in graph G , respectively. As in the MaxRatioPath problem, if P is a path in G , then $f(P) = \sum_{(i,j) \in P} \mathbf{c}(i, j)$, $g(P) = \sum_{(i,j) \in P} \mathbf{w}(i, j)$, and $f(P)/g(P)$ are the cost, the weight, and the mean-weight cost of this path. The task is to find a cycle in graph G with the maximum mean-weight cost.

$$\text{MaxRatioCycle : } \text{maximize } \frac{f(\Gamma)}{g(\Gamma)} \text{ over all cycles } \Gamma \text{ in graph } G.$$

We assume that graph G is not acyclic, the weight of each cycle is positive, and there exists a cycle with positive cost. A cycle $\Gamma = (v_0, v_1, \dots, v_j = v_0)$ is simple if the vertices v_0, v_1, \dots, v_{j-1} are distinct. There are infinitely many cycles in G , but to find a cycle with the maximum mean-weight cost, we can limit the search only to simple cycles. If a cycle Γ is not simple, then its set of edges can be partitioned into a number of simple cycles $\Gamma_1, \Gamma_2, \dots, \Gamma_k$, and

$$\frac{f(\Gamma)}{g(\Gamma)} = \sum_{i=1}^k \frac{f(\Gamma_i)}{g(\Gamma)} = \sum_{i=1}^k \frac{g(\Gamma_i)}{g(\Gamma)} \cdot \frac{f(\Gamma_i)}{g(\Gamma_i)} \leq \max_{1 \leq i \leq k} \left\{ \frac{f(\Gamma_i)}{g(\Gamma_i)} \right\}.$$

The inequality holds because numbers $g(\Gamma_i)/g(\Gamma)$ are positive and sum up to 1. Therefore, there must be a simple cycle which has the maximum mean-weight cost

among all cycles. For convenience, however, instead of considering only simple cycles, we define the set of feasible solutions \mathcal{X}_G as the set of the cycles in graph G which contain at most n edges.

The MaxRatioCycle problem models the following *tramp-steamer* problem [14, 39]. A trip from a port v to a port u takes $\mathbf{w}(v, u)$ time and gives profit of $\mathbf{c}(v, u)$ units. To maximize the mean daily profit, the steamer should follow a cycle which maximizes the ratio of the total profit to the total time. The MaxRatioCycle problem is often called the *maximum profit-to-time ratio cycle problem*.

The parametric problem corresponding to the MaxRatioCycle problem is

$$\text{MaxCycle}(\delta) : \text{maximize } f(\Gamma) - \delta g(\Gamma), \text{ over all cycles } \Gamma \in \mathcal{X}_G.$$

An optimal solution of problem MaxCycle(δ) is a cycle from \mathcal{X}_G with the maximum cost according to the edge-cost function $\mathbf{c} - \delta\mathbf{w}$. To be able to directly apply the Newton method to the MaxRatioCycle problem, we need an algorithm which for given edge costs finds a cycle $\Gamma \in \mathcal{X}_G$ with the maximum cost. (Observe that restricting cycles to simple cycles only makes the problem NP-hard.) A weaker algorithm, which finds a positive-cost cycle, if there exists one, is sufficient for Megiddo's parametric search.

Let $\mathbf{a} : E \rightarrow \mathbf{R}$ be an arbitrary edge-cost function. Let $d_k(v, u)$ denote the maximum cost of a path from vertex v to vertex u containing at most k edges. If there is no path from v to u , then $d_k(v, u) = -\infty$. We have

$$d_1(v, u) = \begin{cases} \mathbf{a}(v, u), & \text{if } (v, u) \in E, \\ -\infty, & \text{if } (v, u) \notin E, \end{cases}$$

and

$$d_{2k}(v, u) = \max\{ d_k(v, u), \max_{x \in V} \{d_k(v, x) + d_k(x, u)\} \}. \quad (23)$$

To abstract from technical details, we assume that n is a power of 2. For n other than a power of 2, we could simply change the set of feasible solutions to the set of all cycles containing at most $2^{\lceil \log n \rceil}$ edges. The recursive relation (23) gives immediately an $O(n^3 \log n)$ algorithm for computing numbers $d_n(v, u)$, for each pair of vertices v and u . If during the computation the information about the numbers which define the maxima in Eq. (23) is stored, then a maximum-cost path from v to u can also be found, for each pair of vertices v and u . The maximum cost of a cycle $\Gamma \in \mathcal{X}_G$ is equal to $\max_{v \in V} \{d_n(v, v)\}$. Hence, we have an $O(n^3 \log n)$ algorithm which for a given δ solves problem MaxCycle(δ). Using this algorithm and the Newton method, we obtain an algorithm for the MaxRatioCycle problem which runs in $O(n^3 m^2 \log^3 n)$ time for arbitrary edge costs and weights (see [Theorem 5](#)) and in $O(n^3 \log n \log(nU))$ time, if all edge costs and weights are integers not greater than U (see [Theorem 2](#)). Using a similar analysis to the analysis presented for the MaxRatioPath problem in the proof of [Theorem 6](#), one can show that if the weights of the edges are nonnegative, then the Newton method solves the MaxRatioCycle problem in $O(m \log n)$ iterations and, consequently, in $O(n^3 m \log^2 n)$ time. This $O(m \log n)$ bound on the number of iterations for the

MaxRatioCycle problem, as well as for the MaxRatioPath problem, can be further improved to $O(m)$ (an example of analysis which can give such a bound is presented in Sect. 8). However, we do not include here a proof of this bound, since this bound anyway yields a slower algorithm than algorithms which can be obtained by using Megiddo's parametric search.

Let $\text{MaxCycle}_0(\delta)$ denote the problem of detecting a positive-cost cycle according to the edge-cost function $\mathbf{c} - \delta\mathbf{w}$, if there exists such a cycle. To apply Megiddo's parametric search to the MaxRatioCycle problem, we have to combine two algorithms for the parametric problem $\text{MaxCycle}_0(\delta)$: a linear algorithm \mathcal{A}_1 , which is to be run with unknown δ^* and should ideally have a small number of stages/phases, and a fast algorithm \mathcal{A}_2 used for resolving comparisons performed by the first algorithm (see Theorems 9 and 11). The problem of detecting a positive-cost cycle is equivalent to the problem of detecting a negative-cost cycle (simply negate the edge costs). All known algorithms for detecting a negative-cost cycle are actually based on single-source shortest-path algorithms. The best-known bound for shortest-path algorithms on graphs with arbitrary edge costs is $O(nm)$. This bound is achieved, for example, by the Bellman–Ford algorithm [2, 20]. Goldberg's shortest-path algorithm [23] runs in $O(m\sqrt{n} \log U)$, if the edge costs are integers greater than $-U$, for a positive number U . Thus, for arbitrary edge costs, the best-known bound on the running time of algorithm \mathcal{A}_2 is $O(nm)$. It turns out that the best candidate for algorithm \mathcal{A}_1 is the algorithm which is based on the computation of numbers $d_k(v, u)$ using the recursive relation (23). This algorithm runs in $O(n^3 \log n)$ time and consists of $O(\log n)$ maxima-computing phases, and the total size of all maxima in one phase is $O(n^3)$. Therefore, Theorem 11 implies that the MaxRatioCycle problem can be solved in $O(n^3 \log n + nm \log^2 \log \log n)$ time (part (i) of the theorem) and in $O(n^3 \log^2 n)$ time (part (ii) of the theorem).

7 Maximum-Mean Cycles

The maximum-mean cycle problem is the uniform MaxRatioCycle problem. An input instance of this problem consists of a directed graph $G = (V, E)$ and an edge-cost function $\mathbf{c} : E \rightarrow \mathbf{R}$. We want to find a maximum-mean cycle in G , that is, a cycle which has the maximum mean cost. The mean cost of a cycle Γ is equal to $(\sum_{e \in \Gamma} \mathbf{c}(e)) / |\Gamma|$. In this section we describe the $O(nm)$ algorithm for the maximum-mean cycle problem designed by Karp [34]. This algorithm is an example that there are specialized algorithms for some fractional combinatorial optimization problems, which are faster than algorithms yielded by general methods such as the Newton method and Megiddo's parametric search.

Let n and m denote the number of vertices and the number of edges in graph G . We assume that graph G is not acyclic. Let s be a vertex in graph G such that all other vertices are reachable from s . If such a vertex does not exist, we can add to graph G a new vertex s and edges (s, v) with arbitrary costs, for each $v \in V$. This modification does not change the cycles or their costs. For each vertex $v \in V$ and integer $k \geq 0$, let $d_k(v)$ be the maximum cost of a path of length k from vertex s to vertex v . If no such path exists, then $d_k(v) = -\infty$. For a subset of edges $A \subseteq E$,

$\mathbf{c}(A)$ denotes the sum $\sum_{e \in A} \mathbf{c}(e)$. Let δ^* denote the maximum mean cost of a cycle in graph G .

Theorem 12

$$\delta^* = \max \left\{ \min_{0 \leq k \leq n-1} \left\{ \frac{d_n(v) - d_k(v)}{n-k} \right\} : v \in V \text{ and } d_n(v) > -\infty \right\}. \quad (24)$$

Proof If we decrease the cost of each edge by the same amount α , then for each vertex $v \in V$ and each $k \geq 0$, $d_k(v)$ decreases by αk , and consequently, $(d_n(v) - d_k(v))/(n-k)$ decreases by α . Thus, both sides of Eq. (24) decrease by α . Therefore, it is enough to prove the theorem for the case when $\delta^* = 0$.

If $\delta^* = 0$, then Eq. (24) is equivalent to

$$0 = \max \left\{ \min_{0 \leq k \leq n-1} \{d_n(v) - d_k(v)\} : v \in V \text{ and } d_n(v) > -\infty \right\},$$

which is equivalent to

$$0 = \max \{ d_n(v) - \max_{0 \leq k \leq n-1} \{d_k(v)\} : v \in V \text{ and } d_n(v) > -\infty \}. \quad (25)$$

Let v be a vertex such that $d_n(v) > -\infty$, and let P be a path of length n and cost $d_n(v)$ from s to v . Path P is not simple (i.e., at least one vertex occurs on P more than once), so the edges of P can be partitioned into a cycle Γ and, possibly trivial, path R from s to v . Let $k = |R| \leq n-1$. Since $\delta^* = 0$, then $\mathbf{c}(\Gamma) \leq 0$, and we have

$$d_n(v) = \mathbf{c}(P) = \mathbf{c}(R) + \mathbf{c}(\Gamma) \leq \mathbf{c}(R) \leq d_k(v) \leq \max_{0 \leq k \leq n-1} \{d_k(v)\}.$$

Thus, the right-hand side of (25) is at most zero.

Now we show that the right-hand side of (25) is at least zero. Let Γ be a zero-cost cycle in graph G . Since $\delta^* = 0$, such a cycle must exist. Let v be an arbitrary vertex on cycle Γ , and let P_1 be a maximum-cost path from s to v . Such a path must exist because the graph does not have positive-cost cycles. Let P_2 be a path of length at least n which consists of path P_1 followed by some number of repetitions of cycle Γ . Since the cost of cycle Γ is equal to 0, the costs of paths P_1 and P_2 are the same, so path P_2 is a maximum-cost path from s to v . Let P_3 be the path which consists of the first n edges of path P_2 . Path P_3 is a maximum-cost path from vertex s to some vertex w , because any initial part of a maximum-cost path must be a maximum-cost path. Thus, we have

$$d_n(w) = \mathbf{c}(P_3) = \max_{0 \leq k \leq n-1} \{d_k(w)\}.$$

This means that the right-hand side of (25) is at least zero. □

Karp's algorithm for the maximum-mean cycle problem is based on [Theorem 12](#). Start with $d_0(s) = 0$ and $d_0(v) = -\infty$, for each $v \neq s$. Then in each phase $k = 1, 2, \dots, n$, numbers $d_k(v)$ for each $v \in V$ are computed using the following relation:

$$d_k(v) = \max\{d_{k-1}(u) + \mathbf{c}(u, v) : (u, v) \in E\}. \quad (26)$$

Knowing all numbers $d_k(v)$, for $v \in V$ and $0 \leq k \leq n$, δ^* can be computed in $O(n^2)$ time using Eq. (24). Let v be a vertex which gives the maximum in (24), and let P be a maximum-cost path from s to v of length n . Such a path can be constructed, if during the computation of numbers $d_k(x)$ the information about the edges which give the maxima in Eq. (26) is stored. Each cycle extracted from path P , and there must be at least one, is a maximum-mean cycle.

Karp's algorithm, if implemented in the straightforward way as described above, runs in $\Theta(nm)$ time: each edge is considered once in each of the n phases. Dasdan and Gupta [16] propose implementations of Karp's algorithm, which try to limit the number of edges considered in each phase, improving average running time. Hartmann and Orlin [28] extend Karp's algorithm to the maximum cost-to-time ratio cycles, for the case when the edge transit times (edge weights) are small integers. Orlin and Ahuja [45] show a scaling algorithm for the minimum (and maximum)-mean cycle problem with integral edge costs bounded by C , which runs in $O(\sqrt{nm} \log(nC))$ time.

8 Maximum Mean-Weight Cuts

In [Sect. 6](#) a problem was discussed (the MaxRatioCycle problem) for which the algorithms obtained by applying Megiddo's parametric search are considerably better than the algorithms yielded by the Newton method, at least for the worst-case inputs. In this section the MaxRatioCut problem is considered, which is an example of the reverse situation. Megiddo's parametric search method does not give fast algorithm for this problem, because there are no fast parallel algorithms for the maximum-flow problem, which is de facto the non-fractional version of the MaxRatioCut problem. The main aim of this section is to show a linear bound on the number of iterations of the Newton method for the MaxRatioCut problem with nonnegative edge weights. This linear bound gives the fastest known algorithm for this problem.

A network $G = (V, E, \mathbf{u}, \mathbf{d})$ is a directed, strongly connected graph with a set of vertices V , a set of edges E , a nonnegative edge-capacity function $\mathbf{u} : E \rightarrow \mathbf{R}$, and a demand function $\mathbf{d} : V \rightarrow \mathbf{R}$ such that $\sum_{v \in V} \mathbf{d}(v) = 0$. Without loss of generality, it is assumed that the set of edges is symmetric, that is, if $(x, y) \in E$, then also $(y, x) \in E$. If $\mathbf{d}(v)$ is negative, then v is a *source*—a node with supply. If $\mathbf{d}(v)$ is positive, then v is a *sink*—a node with demand. As before, n and m denote the number of vertices and the number of edges in network G , respectively.

For a subset of vertices $W \subseteq V$, $\mathbf{d}(W) \stackrel{\text{def}}{=} \sum_{v \in W} \mathbf{d}(v)$ is the net demand in W . If $S \subseteq V$, $T = V - S$, $S \neq \emptyset$, and $T \neq \emptyset$, then $\text{cut}(S, T)$ is the set of edges (x, y) such that $x \in S$ and $y \in T$. The *capacity* and the *surplus* of a cut (S, T) are defined as, respectively,

$$\mathbf{u}(S, T) \stackrel{\text{def}}{=} \sum_{e \in (S, T)} \mathbf{u}(e),$$

$$\text{surplus}(S, T) \stackrel{\text{def}}{=} \mathbf{d}(T) - \mathbf{u}(S, T).$$

If network G is viewed as a model for designing shipment of the commodity from the sites with supply (the sources) to the sites with demand (the sinks), then a positive $\text{surplus}(S, T)$ means that not all demand in T can be satisfied. The amount of the demand in T which cannot be satisfied without violating the edge capacities is at least $\text{surplus}(S, T)$.

If an *edge-weight function* $\mathbf{w} : E \rightarrow \mathbf{R}$ is given, then $g(S, T) \stackrel{\text{def}}{=} \sum_{e \in (S, T)} \mathbf{w}(e)$ and $\text{surplus}(S, T)/g(S, T)$ are the *weight* and the *mean-weight surplus* of cut (S, T) . The assumption that the underlying graph is strongly connected guarantees that each cut has at least one edge. It is further assumed, as in the general model of fractional combinatorial optimization, that the edge weights are such that the weight of each cut is positive. The MaxRatioCut problem is the problem of finding a cut with the maximum mean-weight surplus in a given network G and for a given edge-weight function \mathbf{w} . The corresponding parametric problem MaxSurplusCut(δ) is the problem of finding a maximum-surplus cut in network $G_\delta = (V, E, \mathbf{u} + \delta\mathbf{w}, \mathbf{d})$, that is, in network G with the edge-capacity function changed to function $\mathbf{u} + \delta\mathbf{w}$. The problem of finding a maximum-surplus cut in network G can be reduced in $O(m)$ time to the problem of computing a maximum flow in network G . All known algorithms for computing maximum-surplus cuts are based on maximum-flow algorithms. Let $T_{\text{MaxFlow}}(n, m)$ denote the worst-case time complexity of computing a maximum flow in a network with n vertices and m edges. The results from [24, 36] imply that

$$T_{\text{MaxFlow}}(n, m) = O(\min\{nm \log(n^2/m), nm + n^{2+\epsilon}\}), \quad (27)$$

where ϵ is an arbitrary positive constant.

The MaxMeanCut problem is the uniform MaxRatioCut problem, the special case of the MaxRatioCut problem when all edge weights are equal to 1. The MaxMeanCut and the MaxRatioCut problems appear, for example, in the context of the classical *minimum-cost flow problem*. Goldberg and Tarjan [25] showed a simple strongly polynomial iterative method for solving the minimum-cost flow problem, which is based on computation of minimum-mean cycles. Erolina and McCormick [19] (see also [51]) showed an analogous method for solving the dual problem of the minimum-cost flow problem, which is based on computation of maximum mean-surplus cuts. Wallacher [66] used minimum mean-weight cost cycles in a generalization of Goldberg and Tarjan's method. Analogously,

maximum mean-weight surplus cuts can be used in a generalization of Ervolina and McCormick's method.

Theorem 8 implies that Megiddo's parametric search solves the MaxRatioCut problem in $O((T_{\text{MaxFlow}}(n, m))^2) = O(n^2 m^2 \log^2 n)$ time. The first parallel algorithm for the maximum-flow problem is due to Schiloach and Vishkin [63]. This algorithm runs in $O(n^2 \log n)$ time and uses n processors. **Theorem 10** implies that Megiddo's parametric search based on Schiloach and Vishkin's algorithm solves the MaxRatioCut problem in $O(n^3 m \log^3 n)$ time. So far no parallel maximum-flow algorithm has been designed, which would lead to a better bound for Megiddo's parametric search for the MaxRatioCut problem than $O^*(n^3 m)$. Notation O^* () hides a poly-logarithmic factor.

Theorem 5 gives an $O(m^2 \log^2 n)$ bound on the number of iterations of the Newton method for the MaxRatioCut problem. In the remaining part of this section, it is shown that special properties of the MaxRatioCut problem, notably the "maximum flow-minimum cut" duality, imply that the number of iterations is actually only $O(m)$, provided that the edge weights are nonnegative. This bound implies that the Newton method solves the MaxRatioCut problem with nonnegative edge weights in $O(m T_{\text{MaxFlow}}(n, m)) = O(n m^2 \log n)$ time. Observe that in the case of the MaxMeanCut problem, an $O(m)$ bound on the number of iterations follows from **Theorem 3** (in this case a stronger $O(n)$ bound can be shown, see [50]). From now on it is assumed that the edge weights are nonnegative.

A function $\mathbf{r} : E \rightarrow \mathbf{R}$ is a *flow* in network G if for each edge $(x, y) \in E$,

$$\begin{aligned}\mathbf{r}(x, y) &\leq \mathbf{u}(x, y), \\ \mathbf{r}(x, y) &= -\mathbf{r}(y, x).\end{aligned}$$

For a flow \mathbf{r} , if $A \subseteq E$, then $\mathbf{r}(A) \stackrel{\text{def}}{=} \sum_{e \in A} \mathbf{r}(e)$, and if $v \in V$, then $\mathbf{r}^{(\text{in})}(v)$ denotes the net flow into vertex v :

$$\mathbf{r}^{(\text{in})}(v) \stackrel{\text{def}}{=} \sum_{(v, x) \in E} \mathbf{r}(v, x).$$

Define $\mathbf{u}_\mathbf{r} \stackrel{\text{def}}{=} \mathbf{u} - \mathbf{r}$, $\mathbf{d}_\mathbf{r} \stackrel{\text{def}}{=} \mathbf{d} - \mathbf{r}^{(\text{in})}$ and, for a cut (S, T) ,

$$\text{surplus}_\mathbf{r}(S, T) \stackrel{\text{def}}{=} \mathbf{d}_\mathbf{r}(T) - \mathbf{u}_\mathbf{r}(S, T).$$

Values $\mathbf{u}_\mathbf{r}(e)$ and $\mathbf{d}_\mathbf{r}(v)$ are commonly called the residual capacity of edge e and the residual demand at vertex v with respect to flow \mathbf{r} . A flow \mathbf{r} is a *maximum flow* if it minimizes $\sum_{v \in V} |\mathbf{d}_\mathbf{r}(v)|$. The following facts from the network-flows theory are needed. Let \mathbf{r} , \mathbf{r}_{\max} , and (S_{\max}, T_{\max}) be a flow, a maximum flow, and a maximum-surplus cut in network $G = (V, E, \mathbf{u}, \mathbf{d})$.

- F1. For each cut (S, T) , $\text{surplus}_\mathbf{r}(S, T) = \text{surplus}(S, T)$.
- F2. $\mathbf{u}_{\mathbf{r}_{\max}}(S_{\max}, T_{\max}) = 0$.

- F3. For each $T \subseteq V$, $\mathbf{d}_{\mathbf{r}_{\max}}(T) \leq \mathbf{d}_{\mathbf{r}_{\max}}(T_{\max})$.
- F4. Let a new edge-capacity function \mathbf{u}' be such that $\mathbf{u}'(e) \geq \mathbf{u}(e)$, for each edge $e \in E$. There exists a maximum flow \mathbf{r}'_{\max} in network $G' = (V, E, \mathbf{u}', \mathbf{d})$ such that,
1. For each vertex $v \in V$, $d_{\mathbf{r}'_{\max}}(v)$ and $d_{\mathbf{r}_{\max}}(v)$ have the same sign;
 2. For each edge $e \in E$, $|\mathbf{r}'_{\max}(e) - \mathbf{r}_{\max}(e)| \leq d_{\mathbf{r}_{\max}}(T_{\max})$; and
 3. For each cut (S, T) in G , $|\mathbf{r}'_{\max}(S, T) - \mathbf{r}_{\max}(S, T)| \leq d_{\mathbf{r}}(T_{\max})$.

These facts can be derived from the properties of network flows described in [12, 46, Chapter 27]. Fact F1 follows actually directly from the introduced definitions (for each flow \mathbf{r} and cut (S, T) , the differences $\mathbf{d}(T) - \mathbf{d}_{\mathbf{r}}(T)$ and $\mathbf{u}(S, T) - \mathbf{u}_{\mathbf{r}}(S, T)$ are the same). Facts F2 and F3 are closely related to the maximum-flow/minimum-cut theorem. Informally speaking, the conditions listed in Fact F4 are satisfied by a maximum flow \mathbf{r}'_{\max} in network G' which “extends” the maximum flow \mathbf{r}_{\max} in network G .

The analysis of the Newton method for the MaxRatioCut problem uses the same notation as in Sect. 3, where this method was introduced. Thus,

$$\begin{aligned} f_i &= \text{surplus}(S_i, T_i), \\ g_i &= g(S_i, T_i), \\ h_i = h(\delta_i) &= \text{surplus}(S_i, T_i) - \delta_i g(S_i, T_i) = \text{surplus}_{\delta_i}(S_i, T_i), \end{aligned} \quad (28)$$

where (S_i, T_i) is the maximum-surplus cut in network $G_{\delta_i} = (V, E, \mathbf{u} + \delta_i \mathbf{w}, \mathbf{d})$ computed in iteration i . Subscript δ will always indicate that the underlying network is network G_δ , that is, network G with the edge-capacity function changed to function $\mathbf{u} + \delta \mathbf{w}$. In particular,

$$\begin{aligned} \text{surplus}_\delta(S, T) &\stackrel{\text{def}}{=} \mathbf{d}(T) - (\mathbf{u} + \delta \mathbf{w})(S, T) \\ &= \text{surplus}(S, T) - \delta g(S, T), \end{aligned} \quad (29)$$

$$\text{surplus}_{\delta, \mathbf{r}}(S, T) \stackrel{\text{def}}{=} \mathbf{d}_{\mathbf{r}}(T) - \mathbf{u}_{\delta, \mathbf{r}}(S, T), \quad (30)$$

where \mathbf{r} is a flow in network G_δ . The analysis in this section is similar to the analysis of the Newton method for the MaxRatioPath problem presented in the proof of Theorem 6. An edge e is said to be *essential* at the beginning of iteration i , if it belongs to a cut (S_j, T_j) , for some $j \geq i$. As the computation proceeds, the number of essential edges decreases and the rate of this decrement is to be analyzed. As in the proofs of the other bounds on the number of iterations of the Newton method, Lemma 2 and its direct consequence expressed in Inequality (7) are used to measure the progress of the computation.

Let \mathbf{r}_i , for $i = 1, 2, \dots, t$ (t is the index of the last iteration), be maximum flows in networks G_{δ_i} such that for each i , all conditions of Fact F4 above are satisfied with $G = G_{\delta_i}$, $G' = G_{\delta_{i+1}}$, $\mathbf{r}_{\max} = \mathbf{r}_i$, and $\mathbf{r}'_{\max} = \mathbf{r}_{i+1}$. Using (30), Facts F1 and F2, and then (28),

$$\begin{aligned}
\mathbf{d}_{\mathbf{r}_i}(T_i) &= \text{surplus}_{\delta_i, \mathbf{r}_i}(S_i, T_i) - \mathbf{u}_{\delta_i, \mathbf{r}_i}(S_i, T_i) \\
&= \text{surplus}_{\delta_i}(S_i, T_i) \\
&= h_i.
\end{aligned} \tag{31}$$

The following lemma gives a simple, sufficient condition for an edge not to be essential.

Lemma 7 *If*

$$\mathbf{u}_{\delta_i, \mathbf{r}_i}(e) > h_i, \tag{32}$$

then edge e is not essential at the beginning of iteration i .

Proof Let (S, T) be a cut containing an edge e which satisfies Inequality (32). Using Facts F1 and F3 and Eq. (31),

$$\begin{aligned}
\text{surplus}_{\delta_i}(S, T) &= \text{surplus}_{\delta_i, \mathbf{r}_i}(S, T) = \mathbf{d}_{\mathbf{r}_i}(T) - \mathbf{u}_{\delta_i, \mathbf{r}_i}(S, T) \\
&\leq \mathbf{d}_{\mathbf{r}_i}(T_i) - \mathbf{u}_{\delta_i, \mathbf{r}_i}(S, T) = h_i - \mathbf{u}_{\delta_i, \mathbf{r}_i}(S, T) \\
&\leq h_i - \mathbf{u}_{\delta_i, \mathbf{r}_i}(e) < 0.
\end{aligned}$$

Therefore, none of the cuts (S_j, T_j) , for $j \geq i$, can contain edge e , because $\delta_j \geq \delta_i$ and

$$\text{surplus}_{\delta_i}(S_j, T_j) \geq \text{surplus}_{\delta_j}(S_j, T_j) = h_j \geq 0.$$

This means that edge e is not essential at the beginning of iteration i . \square

The proof of the $O(m)$ bound on the number of iterations shown below in **Theorem 14** involves quite a few technical details. Therefore, to highlight the main line of the argumentation, a simpler $O(m \log m)$ bound is first shown.

Theorem 13 *The Newton method solves the MaxRatioCut problem in $O(m \log m)$ iterations, if the edge weights are nonnegative.*

Proof The proof shows that a sequence of $k = \lfloor \log m \rfloor + 2$ consecutive iterations decreases the number of essential edges at least by 1. This claim immediately implies the $O(m \log m)$ bound on the number of iterations. Consider iterations $i, i+1, \dots, i+k$. Inequality (7) implies that

$$h_{i+k} g_{i+k} < \frac{1}{m^2} h_{i+1} g_{i+1}. \tag{33}$$

If $g_{i+k} < (1/m)g_i$, then, using the assumption that the edge weights are nonnegative, for some edge $e \in (S_i, T_i)$,

$$\mathbf{w}(e) \geq \frac{1}{|(S_i, T_i)|} \sum_{a \in (S_i, T_i)} \mathbf{w}(a) \geq \frac{1}{m} g_i > g_{i+k}.$$

Such an edge e cannot belong to cut (S_{i+k}, T_{i+k}) or to any cut (S_j, T_j) , for $j \geq i + k$ (since sequence (g_l) is nonincreasing), so e is essential at the beginning of iteration i but is not essential at the beginning of iteration $i + k$.

If $g_{i+k} \geq (1/m)g_i$, then also $g_{i+k} \geq (1/m)g_{i+1}$, and Inequality (33) implies that $h_{i+k} < (1/m)h_{i+1}$. Fact F3 implies that for each vertex $v \in T_i$, $d_{r_i}(v)$ is nonnegative. Hence, Fact F4(8) further implies that for each vertex $v \in T_i$, $d_{r_{i+k}}(v)$ is nonnegative, so $d_{r_{i+k}}(T_i)$ must be nonnegative as well. Therefore, using Lemma 6 and Fact F1,

$$\begin{aligned} -mh_{i+k} &> -h_{i+1} \geq f_i - \delta_{i+k} g_i \\ &= \text{surplus}(S_i, T_i) - \delta_{i+k} g(S_i, T_i) \\ &= \text{surplus}_{\delta_{i+k}}(S_i, T_i) \\ &= \text{surplus}_{\delta_{i+k}, r_{i+k}}(S_i, T_i) \\ &= \mathbf{d}_{r_{i+k}}(T_i) - \mathbf{u}_{\delta_{i+k}, r_{i+k}}(S_i, T_i) \\ &\geq -\mathbf{u}_{\delta_{i+k}, r_{i+k}}(S_i, T_i). \end{aligned} \quad (34)$$

The above inequality implies that there is an edge $e \in (S_i, T_i)$ such that $\mathbf{u}_{\delta_{i+k}, r_{i+k}}(e) > h_{i+k}$. Such an edge is essential at the beginning of iteration i , but Lemma 7 implies that it is not essential at the beginning of iteration $i + k$. \square

Theorem 14 *The Newton method solves the MaxRatioCut problem in $O(m)$ iterations, if the edge weights are nonnegative.*

Proof Lemma 2 implies that for each iteration i except the last one,

$$\frac{g_{i+1}}{g_i} \leq \frac{1}{2} \quad (35)$$

or

$$\frac{h_{i+1}}{h_i} \leq \frac{1}{2}. \quad (36)$$

In the proof of this theorem, separate bounds are derived for the number of iterations when Inequality (35) holds and for the number of iterations when Inequality (36) holds. Let i_1, i_2, \dots, i_q be the indices of the iterations for which Inequality (35) holds. Let $\mu_j = g_{i_j}$, for $j = 1, 2, \dots, q$, and let $(\alpha_k)_{k=1}^m$ be the sequence of the edge weights in nonincreasing order. Sequences $(\alpha_k)_{k=1}^m$ and $(\mu_j)_{j=1}^q$ satisfy the conditions of Lemma 8 below, so $q \leq m$.

Now an upper bound on the number of iterations when Inequality (36) holds is established. Here the argument is more involved, because numbers h_i are not

simply subsums of a fixed set of m numbers. From now on only iterations when Inequality (36) holds are considered. To avoid towering subscripts, these iterations are numbered from 1 to $t' \leq t$. Thus, “iteration i ” and subscripts i refer now to the i th iteration for which Inequality (36) holds. In the remaining of the proof, the same notation and definitions as in the proof of [Theorem 13](#) are used, but the new numbering of the iterations is taken into account.

Consider cut $(S_i, T_i) = \{e_1, e_2, \dots, e_p\}$ computed in iteration i . For technical reasons, it is assumed that there are at least $\log p + 5$ iterations following iteration i , that is, $t' \geq i + \log p + 5$. The proof of [Theorem 13](#) was based on showing that at least one edge from cut (S_i, T_i) becomes unessential by the beginning of iteration $i + \lfloor \log m \rfloor + 2$. Here, it is shown that there exists $l \geq 3$ such that at least $l - 2$ edges from cut (S_i, T_i) become unessential by the beginning of iteration $i + l + 2$. This claim immediately implies an $O(m)$ bound on the number of iterations.

Fact F4(2), Eq. (31), and Inequality (36) imply that for each edge $e \in E$ and index l such that $i + 3 \leq l \leq t'$,

$$\begin{aligned} |\mathbf{u}_{\delta_{i+3}, \mathbf{r}_{l+1}}(e) - \mathbf{u}_{\delta_{i+3}, \mathbf{r}_l}(e)| &= |\mathbf{r}_{l+1}(e) - \mathbf{r}_l(e)| \\ &\leq \mathbf{d}_{\mathbf{r}_l}(T_l) = h_l \\ &\leq \frac{1}{2^{l-i-2}} h_{i+2}. \end{aligned} \quad (37)$$

Analogously, using Fact F4(3), for each cut (S, T) and index l such that $i + 3 \leq l \leq t'$,

$$|\mathbf{u}_{\delta_{i+3}, \mathbf{r}_{l+1}}(S, T) - \mathbf{u}_{\delta_{i+3}, \mathbf{r}_l}(S, T)| \leq \frac{1}{2^{l-i-2}} h_{i+2}. \quad (38)$$

The derivations (34) for $k = 3$ and Inequality (36) give

$$\mathbf{u}_{\delta_{i+3}, \mathbf{r}_{i+3}}(S_i, T_i) \geq h_{i+1} \geq 2h_{i+2}. \quad (39)$$

Using this inequality and Inequality (38), for each index l such that $i + 4 \leq l \leq t'$,

$$\begin{aligned} \mathbf{u}_{\delta_{i+3}, \mathbf{r}_l}(S_i, T_i) &= \mathbf{u}_{\delta_{i+3}, \mathbf{r}_{i+3}}(S_i, T_i) \\ &\quad + (\mathbf{u}_{\delta_{i+3}, \mathbf{r}_{i+4}}(S, T) - \mathbf{u}_{\delta_{i+3}, \mathbf{r}_{i+3}}(S, T)) \\ &\quad + \cdots + (\mathbf{u}_{\delta_{i+3}, \mathbf{r}_l}(S, T) - \mathbf{u}_{\delta_{i+3}, \mathbf{r}_{l-1}}(S, T)) \\ &\geq \mathbf{u}_{\delta_{i+3}, \mathbf{r}_{i+3}}(S_i, T_i) - h_{i+2} \left(\frac{1}{2} + \frac{1}{2^2} + \cdots + \frac{1}{2^{l-i-3}} \right) \\ &\geq h_{i+2}. \end{aligned} \quad (40)$$

For each $l = 1, 2, \dots, t' - i - 2$ and $j = 1, 2, \dots, p$, let

$$\alpha_{l,j} = \frac{1}{h_{i+2}} \mathbf{u}_{\delta_{i+3}, \mathbf{r}_{i+2+l}}(e_j).$$

Inequalities (39) and (40) imply that matrix $(\alpha_{l,j})$ satisfies Condition 2 of 9 below (since $\sum_{j=1}^p \alpha_{l,j} = \mathbf{u}_{\delta_{i+3}, \mathbf{r}_{i+2+l}}(S_i, T_i) / h_{i+2}$). Inequality (37) implies that Condition 3 is satisfied as well. Condition 1 holds because it was assumed that $t' \geq i + \log p + 5$. Thus, Lemma 9 can be applied to matrix $(\alpha_{l,j})$. According to the definition of “good entries” in the statement of Lemma 9, if $\alpha_{l,j}$ is a good entry, then there exists $1 \leq l' \leq l$ such that $\alpha_{l',j} > 1/2^{l'}$. If $\alpha_{l',j} > 1/2^{l'}$, then

$$\mathbf{u}_{\delta_{i+2+l'}, \mathbf{r}_{i+2+l'}}(e_j) \geq \mathbf{u}_{\delta_{i+3}, \mathbf{r}_{i+2+l'}}(e_j) = h_{i+2}\alpha_{l',j} > \frac{1}{2^{l'}} h_{i+2} \geq h_{i+l'+2},$$

so Lemma 7 implies that edge e_j is unessential at the beginning of iteration $i+l+2$. Lemma 9 implies that there exists $l \geq 3$ such that there are at least $l-2$ good entries among entries $\alpha_{l,1}, \alpha_{l,2}, \dots, \alpha_{l,p}$. The $l-2$ edges corresponding to these $l-2$ entries are essential at the beginning of iteration i but become unessential by iteration $i+l+2$. \square

It remains to prove the following two technical lemmas.

Lemma 8 *Let $\alpha_1 \geq \alpha_2 \geq \dots \geq \alpha_m \geq 0$ and $\mu_1 > \mu_2 > \dots > \mu_q > 0$ be such that*

1. $\mu_{j+1} \leq (1/2)\mu_j$, for $j = 1, 2, \dots, q-1$, and
2. $\mu_j \leq \sum \{\alpha_k \mid \alpha_k \leq \mu_j\}$, for $j = 1, 2, \dots, q$.

Then, $q \leq m$.

Proof Let $\bar{\alpha}_k = \alpha_k + \alpha_{k+1} + \dots + \alpha_m$. Condition 2 implies that $\mu_1 \leq \bar{\alpha}_1$, and if $\mu_j < \bar{\alpha}_m = \alpha_m$, then $\mu_j \leq 0$. Thus, all numbers μ_j lie in the interval $[\bar{\alpha}_m, \bar{\alpha}_1]$. To prove that $q \leq m$, it is shown that each of the intervals $(\bar{\alpha}_m, \bar{\alpha}_{m-1}]$ and $(\bar{\alpha}_{m-1}, \bar{\alpha}_{m-2}], \dots, (\bar{\alpha}_2, \bar{\alpha}_1]$ contains at most one element from the sequence (μ_j) . Let $\mu_j \in (\bar{\alpha}_{k+1}, \bar{\alpha}_k]$, for some $1 \leq j \leq q-1$ and $1 \leq k \leq m-1$. It is shown next that $\mu_{j+1} \leq \bar{\alpha}_{k+1}$, so $\mu_{j+1} \notin (\bar{\alpha}_{k+1}, \bar{\alpha}_k]$. If $\bar{\alpha}_{k+1} \geq (1/2)\bar{\alpha}_k$, then

$$\mu_{j+1} \leq \frac{1}{2}\mu_j \leq \frac{1}{2}\bar{\alpha}_k \leq \bar{\alpha}_{k+1}.$$

If $\bar{\alpha}_{k+1} < (1/2)\bar{\alpha}_k$, then

$$\mu_{j+1} \leq \frac{1}{2}\mu_j \leq \frac{1}{2}\bar{\alpha}_k = \bar{\alpha}_k - \frac{1}{2}\bar{\alpha}_k = \alpha_k + \bar{\alpha}_{k+1} - \frac{1}{2}\bar{\alpha}_k < \alpha_k.$$

The above inequality and Condition 2 imply that the inequality $\mu_{j+1} \leq \bar{\alpha}_{k+1}$ holds also in this case. \square

Lemma 9 *Let $(\alpha_{l,j})$ be a $q \times p$ matrix such that*

1. $q \geq \log p + 3$,
2. $\sum_{j=1}^p \alpha_{l,j} \geq 1$, for each $1 \leq l \leq q$, and
3. $|\alpha_{l+1,j} - \alpha_{l,j}| \leq 1/2^l$, for each $1 \leq l \leq q-1$ and $1 \leq j \leq p$.

If $\alpha_{l,j} > 1/2^l$, then this and all subsequent entries in column j are “good entries.” There exists l such that $3 \leq l \leq q$ and row l of the matrix contains at least $l - 2$ good entries.

Proof Condition 3 implies that if $1 \leq l' < l'' \leq q$ and $1 \leq j \leq p$, then

$$\begin{aligned}\alpha_{l'',j} &\leq \alpha_{l',j} + \frac{1}{2^{l'}} + \frac{1}{2^{l'+1}} + \cdots + \frac{1}{2^{l''-1}} \\ &< \alpha_{l',j} + \frac{1}{2^{l'-1}}.\end{aligned}\tag{41}$$

If $\alpha_{l,j}$ is the first good entry in column j and $l \geq 2$, then

$$\alpha_{l,j} \leq \alpha_{l-1,j} + \frac{1}{2^{l-1}} \leq \frac{1}{2^{l-1}} + \frac{1}{2^{l-1}} = \frac{1}{2^{l-2}}.\tag{42}$$

The first inequality above follows from Condition 3, and the second one holds because entry $\alpha_{l-1,j}$ is not a good entry.

Assume that for each $3 \leq l \leq q$, row l contains at most $l - 3$ good entries. (In particular, there are no good entries in rows 1–3.) The proof proceeds by showing that this assumption implies that the sum of the entries in the last row is less than 1, which contradicts Condition 2 of the lemma. Let j_1, j_2, \dots, j_r be the indices of all columns which have at least one good entry. Let $\alpha_{l_1,j_1}, \alpha_{l_2,j_2}, \dots, \alpha_{l_r,j_r}$ be the first good entries in these columns. Let j_1, j_2, \dots, j_r be ordered in such a way that $l_1 \leq l_2 \leq \cdots \leq l_r$. Hence, for each $k = 1, 2, \dots, r$, entries $\alpha_{l_k,j_1}, \alpha_{l_k,j_2}, \dots, \alpha_{l_k,j_k}$ are good entries, so row l_k contains at least k good entries. Row l_k contains at most $l_k - 3$ good entries (from the assumption), so

$$k \leq l_k - 3.\tag{43}$$

The sum of the entries in the last row is at most

$$\begin{aligned}&\frac{p-r}{2^q} + \alpha_{q,j_1} + \alpha_{q,j_2} + \cdots + \alpha_{q,j_r} \\ &\leq \frac{p}{2^q} + \left(\alpha_{l_1,j_1} + \frac{1}{2^{l_1-1}} \right) + \cdots + \left(\alpha_{l_r,j_r} + \frac{1}{2^{l_r-1}} \right) \\ &\leq \frac{1}{8} + \left(\frac{1}{2^{l_1-2}} + \frac{1}{2^{l_1-1}} \right) + \cdots + \left(\frac{1}{2^{l_r-2}} + \frac{1}{2^{l_r-1}} \right) \\ &= \frac{1}{8} + 6 \left(\frac{1}{2^{l_1}} + \cdots + \frac{1}{2^{l_r}} \right) \\ &\leq \frac{1}{8} + 6 \left(\frac{1}{2^4} + \frac{1}{2^5} + \cdots \right) \\ &< 1.\end{aligned}$$

The first inequality follows from Inequality (41), the second one from Condition 1 and Inequality (42), and the third one from Inequality (43). \square

9 Conclusion

The binary search, the Newton method, and Megiddo's parametric search form together a powerful set of methods for solving fractional combinatorial optimization problems. All three methods reduce a fractional problem to a sequence of instances of the corresponding non-fractional problem. Implementations of the binary search and the Newton method are straightforward once a procedure for solving the non-fractional problem is provided. Implementation of Megiddo's parametric search is a bit more complicated, because this method, unlike the other two, does not treat a procedure for the underlying non-fractional problem as a black box but has to examine its structure and modify it appropriately.

Megiddo originally proposed his parametric search method in the context of fractional combinatorial optimization problems such as the minimum-ratio spanning-tree problem and the maximum profit-to-time cycle problem [41]. Since then, however, his method has been extended to far more general optimization problems; see for example [9, 10, 27, 44, 64]. If Megiddo's parametric search method is used to obtain a fast algorithm for a given fractional combinatorial optimization problem, then the main task is to find a parallel algorithm for the underlying non-fraction problem which exhibits a right trade-off between the parallel running time and the total amount of computation performed.

The Newton method for general fractional optimization has been extensively studied since Dinkelbach [18] introduced it in 1967, and a number of modifications and extensions of this method have been proposed and analyzed [30, 47, 54]. The strongly polynomial bounds on the number of iterations in the Newton method for fractional combinatorial optimization presented in Sects. 4 and 8 come from early 1990s [49, 50], but it is still not clear how tight those bounds are. The $O(p^2 \log^2 p)$ bound shown in Theorem 5 can be improved to $O(p^2 \log p)$, as shown by Wang et al. [67], but the best-known worst-case lower bound on the number of iteration is only $\Omega(p \log p)$. The main tool used in Sect. 4 in the derivation of the $O(p^2 \log^2 p)$ bound is Lemma 3, which gives an $O(p \log p)$ bound on the length of a geometric sequence of subsums of a p -element set. The same lemma is also the basis for the $O(p^2 \log p)$ bound in [67]. Goldmann (M. Goldmann, On a subset-sum problem, 1994, personal communication) shows that the $O(p \log p)$ bound in Lemma 3 is tight, but there may be a better way of using it in the analysis of the Newton method.

For problems such as MaxRatioPath, MaxRatioCycle, and MaxRatioCut, the Newton method requires only a linear number of iterations, provided that the edge weights are nonnegative, and the proofs of these three bounds are remarkably similar to each other (compare the proofs of Theorems 6 and 13). However, a unified

framework which would generalize these three examples has not been proposed yet. Such a framework would have to be based on the “primal-dual” structure of problems such as the three problems mentioned here. Another related task is to examine if the assumption that the edge weights are nonnegative is really necessary to obtain a liner bound on the number of iterations.

The Newton method for fractional combinatorial optimization is an application of the classical Newton method to compute the root of a piecewise linear, convex function h defined in (3). The number of linear segments of function h is an obvious upper bound on the number of iterations of this method. The artificial example presented in Sect. 4 shows that function h may consist of an exponential number of linear segments, even for a linear fractional combinatorial optimization problem. The results of Gusfield [26] (upper bound) and Carstensen [6] (lower bound) imply that for the MaxRatioPath and the MaxRatioCycle problems, function h consists, in the worst case, of $n^{\Theta(\log n)}$ linear segments. Such tight bounds, however, are known only for relatively few problems. For example, no tight bounds on the complexity of function h for the MaxRatioCut problem have been reported yet.

The Newton method constructs a sequence of improving lower bounds converging to the optimum objective value, but since it does not provide upper bounds, no bound on the error is available at any given iteration. There are methods for general fractional optimization, which are based on the Newton method but also construct improving upper bounds (see, e.g., [30, 47, 54]). It is not clear yet if these methods can also lead to interesting results for fractional combinatorial optimization.

The methods for solving fractional combinatorial optimization problems rely on methods for solving the corresponding non-fractional optimization problems. The underlying non-fractional problem may however be difficult itself and might not have an efficient exact algorithm. Hashizume et al. [29] analyze Megiddo’s parametric search method for maximizing $(a_0 + \mathbf{ax})/(b_0 + \mathbf{bx})$, when the algorithm for the underlying non-fractional problem of maximizing $(\mathbf{a} - \delta\mathbf{b})\mathbf{x}$ returns only approximate solutions. They show that, under appropriate assumptions, the accuracy of the approximate solution obtained for the fractional problem is at least as good as the accuracy of the solutions computed for the non-fractional problem. As an example of their analysis, they present a fully polynomial approximation scheme for the fractional 0–1 knapsack problem. Billionet [3] presents a different way of extending Megiddo’s method to approximation algorithms, which relaxes some assumptions needed in [29] and leads to improved approximation algorithms for fractional knapsack problems.

Both Hashizume et al. [29] and Billionet [3] need for their approximation scheme for fractional optimization a good approximation algorithm for the corresponding linear optimization, which may involve negative coefficients even if all coefficients in the fractional objective function are positive (the objective function of problem (2) for a fixed value of parameter δ may have negative coefficients). This is not an issue for the (linear) knapsack problem since the items with negative values can be simply discarded, but there are linear optimization problems which admit approximation schemes only for the case when all coefficients are nonnegative. Correa et al. [13]

discusses examples of such problems and proposes an extension of Megiddo's method which is based on approximation algorithms for linear optimization with nonnegative coefficients. As an application of their method, they show improved approximation algorithms for finding a minimum average weight k -connected subgraphs.

In the binary search scheme described in Sect. 2, it may be possible to use a faster approximation algorithm $\tilde{\mathcal{A}}_0$ instead of the exact algorithm \mathcal{A}_0 while still guaranteeing that the interval (α, β) with the optimal value δ^* shrinks by a constant factor in each iteration. Examples of such approximate binary search for fractional combinatorial optimization include algorithms for the maximum mean-cut problem proposed by McCormick [40] and Iwano et al. [32] and an algorithm for the fractional assignment problem proposed by Shigeno et al. [62]. Kabadi and Aneja [33] extend the Newton method to approximation algorithms and give a strongly polynomial bound on the number of iterations.

Both the Newton method and Megiddo's parametric search require a good algorithm for solving the corresponding parametric problem (2) for any fixed value of parameter δ . The parametric problem (2), however, might not have a more convenient objective function than the original fractional problem. For example, for a fractional *cost-to-reliability ratio* problem

$$\text{CostToReliability : } \begin{aligned} & \text{minimize} && \frac{c_1x_1 + c_2x_2 + \cdots + c_px_p}{r_1^{x_1}r_2^{x_2}\cdots r_p^{x_p}}, \\ & \text{for } \mathbf{x} \in \mathcal{X} \subseteq \{0, 1\}^p, \end{aligned}$$

where each cost c_i is nonnegative and each reliability factor r_i is in $(0, 1]$, the corresponding parametric problem (2) is

$$\mathcal{P}(\delta) : \text{minimize } c_1x_1 + c_2x_2 + \cdots + c_px_p - \delta r_1^{x_1}r_2^{x_2}\cdots r_p^{x_p}, \text{ for } \mathbf{x} \in \mathcal{X}.$$

If the objective function of the above parametric problem turns out to be too difficult, then the following simpler parameterization may be more helpful:

CostToReliability(δ) :

$$\begin{aligned} & \text{minimize} && c_1x_1 + c_2x_2 + \cdots + c_px_p + \delta(d_1x_1 + d_2x_2 + \cdots + d_px_p), \\ & \text{for } \mathbf{x} \in \mathcal{X}, \end{aligned}$$

where $d_i = -\ln r_i$. It can be shown that there is a value $\hat{\delta}$ such that an optimal solution of the $\text{CostToReliability}(\hat{\delta})$ problem is an optimal solution of the CostToReliability problem. Thus, the CostToReliability problem can be solved by solving $\text{CostToReliability}(\delta)$ over the whole range of δ ($\hat{\delta}$ exists, but it is not known how $\hat{\delta}$ could be pre-calculated). This approach was used by Ahuja [1] for computing the minimum cost-to-reliability path and by Chandrasekaran et al. [8]

for computing the minimum cost-to-reliability spanning tree but may be impractical for other problems, if the parametric problem $\text{CostToReliability}(\delta)$ has a large (super-polynomial) number of solutions. Katoh [35] proposed a general approximation scheme for the CostToReliability problem, which is based on the parametric problem $\text{CostToReliability}(\delta)$.

The optimal solutions of a fractional combinatorial optimization problem of maximizing $f(\mathbf{x})/g(\mathbf{x})$, for $\mathbf{x} \in \mathcal{X} \subseteq \{0, 1\}^p\}$, belong to the *Pareto-optimal frontier* $P \subseteq \mathcal{X}$ of the bi-objective optimization problem of maximizing $f(\mathbf{x})$ and minimizing $g(\mathbf{x})$, for $\mathbf{x} \in \mathcal{X}$. A solution $\mathbf{x} \in \mathcal{X}$ belongs to P if, and only if, for each $\mathbf{y} \in \mathcal{X}$, $f(\mathbf{x}) \geq f(\mathbf{y})$ or $g(\mathbf{x}) \leq g(\mathbf{y})$. Mittal and Schulz [43] propose the following nonparametric approximation framework: compute a (suitably defined) approximate Pareto-optimal frontier $\widetilde{P} \subseteq \mathcal{X}$ for this bi-objective optimization, and return a solution $\mathbf{x} \in \widetilde{P}$ which gives the largest ratio $f(\mathbf{x})/g(\mathbf{x})$. They show sufficient conditions under which this framework leads to fully polynomial approximation schemes. This general approach can be tried whenever the objective function is a combination of several functions (a fractional objective $f(\mathbf{x})/g(\mathbf{x})$ is a simple example of a function which combines two functions $f(\mathbf{x})$ and $g(\mathbf{x})$). Mittal and Schulz apply their approach to a *sum-of-ratios problem* with a knapsack-type constraint, which arises, for example, in the context of assortment optimization in retail management [52, 53]. The sum-of-ratios optimization problems are a natural generalization of fractional optimization. (The terms “fractional optimization” and “fractional programming” are actually often used as encompassing both single-ratio and multi-ratio problems.) Schaible and Shi [59] survey sum-of-ratio optimization problems with convex subsets of R^n as feasible regions. However, there are still only few theoretical and algorithmic results for sum-of-ratio *combinatorial* optimization problems.

Although the focus of this chapter is on asymptotic bounds for the worst-case running times of methods and algorithms for fractional combinatorial optimization, it should be mentioned that theoretical research on this topic has been complemented by experimental studies which aim at evaluation of practical performance of algorithms. These include experimental studies of algorithms for the maximum-mean cycle and maximum mean-weight cycle problems [15, 17], algorithms for the fractional prize-collecting Steiner tree problem on trees [37], and parametric algorithms for the maximum mean cut problem arising in the context of seat allocation to political parties within the regions after a general election [61]. The results of experimental studies do not always match the theoretical analysis. For example, Klau et al. [37] observe that an $O(n^2)$ -time algorithm based on the Newton method consistently outperforms in their experiments an $O(n \log n)$ -time algorithm based on Megiddo’s parametric search.

Abstract

Decision-making is an ongoing process for humankind. Many of these real-world decisions can be modeled using the problems contained in the generalized area of combinatorial optimization. Another area with recent advancements is fuzzy logic.

This chapter is concerned about the fuzzy solution approaches of combinatorial optimization problems. First section presents the fuzzy graph theory. Fuzzy linear programming and fuzzy integer programming are explained in second and third sections. Fuzzy spanning trees, fuzzy shortest path, fuzzy network flows, and the fuzzy minimum cost flow problems are introduced at Sects. 4–7. Fuzzy matching algorithm, fuzzy matroids, and fuzzy approximation algorithm are discussed in Sects. 8–10. Basic information on fuzzy knapsack and fuzzy bin-packing problems is given in Sects. 11 and 12. Fuzzy multicommodity flows and edge-disjoint paths are explained in Sect. 13 in detail with four subsections. Fuzzy network design problems and fuzzy traveling salesman problem are provided in Sects. 14 and 15 respectively. Finally, fuzzy facility location is presented in the last section.

1 Fuzzy Graph

A pair $G = (V, E)$ with $E \subseteq E(V)$ is called a graph (on V). The elements of V are the vertices of G , and those of E the edges of G . The vertex set of a graph G is denoted by V_G and its edge set by E_G . Therefore, $G = (V_G, E_G)$.

In the literature, graphs are also called simple graphs; vertices are called nodes or points; edges are called lines or links. More extensive information on graph theory can be found at [1, 2].

Fuzzy graph theory was introduced by Rosenfeld in 1975 [3], and some important definitions about this theory are as follows [3–10]:

Definition 1 A fuzzy graph G which is a pair of functions can be denoted by $G : (\sigma, \mu)$ where σ is a fuzzy subset of set V (a nonempty set) and μ is a symmetric fuzzy

relation on σ . The underlying crisp graph of $G : (\sigma, \mu)$ is denoted by $G^*(V, E)$ where $E \subseteq V \times V$. A fuzzy graph G is complete if $\mu(uv) = \sigma(u) \wedge \sigma(v)$ for all $u, v \in V$ where uv stands for the edge between u and v .

Definition 2 A fuzzy graph G denoted by $G : (\sigma, \mu)$. The degree of a vertex u is $d_{G(u)} = \sum_{u \neq v} \mu(uv)$. As $\mu(uv) > 0$ for $uv \in E$ and $\mu(uv) = 0$ for $uv \notin E$, this is equivalent to $d_{G(u)} = \sum_{uv \in E} \mu(uv)$. Then the minimum degree of G is $\delta(G) = \Lambda\{d(v)/v \in V\}$, and the maximum degree of G is $\Delta(G) = \vee\{d(v)/v \in V\}$.

Definition 3 The strength of connectedness between two vertices u and v is $\mu^\infty(u, v) = \sup\{\mu^k(u, v)/k = 1, 2, \dots\}$ where

$$\mu^k(u, v) = \sup\{\mu(uu_1) \wedge \mu(u_1u_2) \wedge \dots \wedge \mu(u_{k-1}v)/u_1, \dots, u_{k-1} \in V\}.$$

Definition 4 An edge uv is a fuzzy bridge of $G : (\sigma, \mu)$ if deletion of uv reduces the strength of connectedness between pair of vertices.

Definition 5 A vertex u is a fuzzy cut vertex of $G : (\sigma, \mu)$ if deletion of u reduces the strength of connectedness between some other pair of vertices.

Definition 6 Let $G : (\sigma, \mu)$ be a fuzzy graph such that $G^*(V, E)$ is a cycle. Then G is a fuzzy cycle if and only if there does not exist a unique edge xy such that $\mu(xy) = \vee\{\mu(uv)/(uv) > 0\}$.

Definition 7 The order of a fuzzy graph G is $O(G) = \sum_{u \in V} \sigma(u)$. The size of a fuzzy graph G is $S(G) = \sum_{uv \in E} \mu(uv)$.

Definition 8 Let $G : (\sigma, \mu)$ be a fuzzy graph on $G^*(V, E)$. If $d_G(v) = k$ for all $v \in V$, that is, if each vertex has some degree k , then G is said to be a regular fuzzy graph of degree k or a k -regular fuzzy graph. This is analogous to the definition of regular graphs in crisp graph theory.

Definition 9 Let $G : (\sigma, \mu)$ be a fuzzy graph on $G^*(V, E)$. The total degree of a vertex $u \in V$ is defined by $td_G(u) = \sum_{u \neq v} \mu(UV) + \sigma(u) = \sum_{uv \in E} \mu(UV) + \sigma(u) = d_G(u) + \sigma(u)$. If each vertex G has the same total degree k , then G is said to be a totally regular fuzzy graph of total degree k or a k -totally regular fuzzy graph.

The most important areas for the application of fuzzy graphs and fuzzy relations are logic, topology, pattern recognition, information theory, control theory, artificial intelligence, neural networks, operations research, planning, and systems analysis.

Bhattacharya [4] established some connectivity concepts regarding fuzzy cut nodes and fuzzy bridges. The author also introduced the notions of eccentricity and center.

Moreover, Bhattacharya and Suraweera [11] introduced an algorithm to find the connectivity of a pair of nodes in a fuzzy graph [4].

Furthermore, Tong and Zheng [12] presented an algorithm to find the connectivity matrix of a fuzzy graph. While, Xu [13] introduced connectivity parameters of fuzzy graphs to problems in chemical structures, Sunitha and Vijayakumar [7] focused on characterizing fuzzy trees using its unique maximum spanning tree. In addition, a sufficient condition for a node to be a fuzzy cut node is presented in [14]. Also, center problems in fuzzy graphs [15], blocks in fuzzy graphs [16], and properties of self-complementary fuzzy graphs [17] were introduced by the same authors. Therefore, using the concept of the strongest paths, they have obtained a characterization for blocks in fuzzy graphs [15]. Bhutani and Rosenfeld have focused on the concepts of strong arcs [18], fuzzy end nodes [19], and geodesics in fuzzy graphs [20]. In [17], the authors have defined the concepts of strong arcs and strong paths. They have pointed out the existence of a strong path between any two nodes of a fuzzy graph and have studied the strong arcs of a fuzzy tree. In [15], the concepts of fuzzy end nodes and multimin and locamin cycles are studied. The concept of strong arc in maximum spanning trees [21] and its applications in cluster analysis and neural networks were presented by Sameena and Sunitha [21, 22]. According to Mathew and Sunitha, there are different types of arcs in fuzzy graphs and they have obtained an arc identification procedure [14].

2 Fuzzy Linear Programming

Linear programming is one of the most widely used decision-making tools for solving real-world problems. Many researchers focus on the area of fuzzy linear programming because of the fact that the real-world situations are characterized by imprecision rather than exactness. In order to have a clear understanding, few of such researches are discussed/shown below.

Gupta and Mehlawat studied a pair of fuzzy primal–dual linear programming problems and calculate duality results using an aspiration level approach. They use an exponential membership function, which is in contrast to the earlier works that relied on a linear membership function. As the fuzzy environment causes a duality gap, they investigate how choosing the exponential membership function impacts the gap [23].

Amiria and Nasseria applied a linear ranking function to order trapezoidal fuzzy numbers. Then, they establish the dual problem of the linear programming problem with trapezoidal fuzzy variables and hence deduce some duality results. In particular, they prove that the auxiliary problem is indeed the dual of the linear programming problems with trapezoidal fuzzy variables (FVLP). Having established the dual problem, the results will then follow as natural extensions of duality results for linear programming problems with crisp data. Finally, using the results, they develop a new dual algorithm for solving the FVLP problem directly, making use of the primal simplex tableau [24].

In his paper, Ramik introduced a broad class of FLP problems firstly and defined the concepts of β -feasible and (α, β) -maximal and minimal solutions of FLP problems. The class of classical LP problems can be embedded into the class of

FLP ones. Furthermore, he defines the concept of duality and proves the weak and strong duality theorem generalizations of the classical ones for FLP problems [25].

On the other hand, Inuiguchi treats fuzzy linear programming problems with uncertain parameters whose ranges are specified as fuzzy polytopes in his study. The problem is formulated as a necessity measure optimization model. It is shown that the problem can be reduced to a semi-infinite programming problem and solved by a combination of a bisection method and a relaxation procedure. An algorithm in which the bisection method and the relaxation procedure converge simultaneously is proposed. A simple numerical example is given to illustrate the solution procedure [26].

Wua et al. present an efficient method to optimize such a linear fractional programming problem. First, some theoretical results are developed based on the properties of max-Archimedean t-norm composition. Then, the result is used to reduce the feasible domain. The problem can thus be simplified and converted into a traditional linear fractional programming problem and eventually optimized in a small search space. A numerical example is provided to illustrate the procedure [27].

In addition to above-mentioned studies, a new method to find the fuzzy optimal solution of same type of fuzzy linear programming problems is proposed by Kumar et al. It is easier to apply the proposed method, compared to the existing method in order to solve the fully fuzzy linear programming problems with equality constraints occurring in real-life situations. To illustrate, the proposed method numerical examples are solved, and the obtained results are discussed [28]. Additionally, Lotfi et al. discussed full fuzzy linear programming (FFLP) problems of which all parameters and variables are triangular fuzzy numbers. They use the concept of the symmetric triangular fuzzy number and introduce an approach to defuzzify a general fuzzy quantity [29].

By proposing the fuzzy multiobjective linear programming (FMOLP) model with triangular fuzzy numbers, Zenga et al., transformed the FMOLP model and its corresponding fuzzy goal programming (FGP) problem to crisp ones. These can be solved by the conventional programming methods. The FMOLP model was applied to crop area planning of Liang Zhou region, Gansu province of northwest China, and then the optimal cropping patterns were obtained under different water-saving levels and satisfaction grades for water resources availability of the decision-makers (DM) [30].

Further, Liang developed an interactive fuzzy multiobjective linear programming (i-FMOLP) method for solving the fuzzy multiobjective transportation problems with piecewise linear membership function. Proposed i-FMOLP method aims to simultaneously minimize the total distribution costs and the total delivery time. i-FMOLP method also has reference to fuzzy available supply and total budget at each source and fuzzy forecast demand with maximum warehouse space at each destination. Additionally, the above-mentioned method describes a systematic framework that facilitates the fuzzy decision-making process, enabling a decision-maker (DM) to interactively modify the fuzzy data and related parameters until a set of satisfactory solutions are obtained. An industrial case is presented to demonstrate the feasibility of applying such proposed method to real transportation problems [31].

Peidro et al. modeled supply chain (SC) uncertainties by fuzzy sets and develop a fuzzy linear programming model for tactical supply chain planning in a multi-echelon, multiproduct, multilevel, multi-period supply chain network in their study. In this approach, the demand, process, and supply uncertainties are jointly considered. The aim is to centralize multi-node decisions simultaneously to achieve the best use of the available resources along the time horizon so that customer demands are met at a minimum cost. With this intention, Peidro et al.'s proposal is tested by using data from a real automobile SC. Thus, fuzzy model provides the decision-maker (DM) with alternative decision plans with different degrees of satisfaction [32].

Other solutions are found by Buckley and Feuring to the fully fuzzified linear program where all the parameters and variables are fuzzy numbers in their study. First, they change the problem of maximizing a fuzzy number, the value of the objective function, into a multiobjective fuzzy linear programming problem. Then, they prove that fuzzy flexible programming can be used to explore the whole nondominated set to the multiobjective fuzzy linear program. Hence, an evolutionary algorithm is designed to solve the fuzzy flexible program, and they apply this program to two applications to generate good solutions [33].

Comparatively, Chanas and Zielinski analyzed the linear programming problem with fuzzy coefficients in the objective function. The set of nondominated (ND) solutions with respect to an assumed fuzzy preference relation, according to Orlovsky's concept, is supposed to be the solution of the problem. Special attention is paid to unfuzzy nondominated (UND) solutions (the solutions which are nondominated to the degree 1). The main results of their paper are sufficient conditions on a fuzzy preference relation which allows reducing the problem of determining UND solutions to that of determining optimal solutions of a classical linear programming problem. These solutions can thus be determined by means of classical linear programming methods [34].

Another major study is by Stanciulescu et al., modeling a multiobjective decision-making process by a multiobjective fuzzy linear programming problem with fuzzy coefficients for the objectives and the constraints. Moreover, the decision variables are linked together because they have to sum up to a constant. Most of the time, the solutions of a multiobjective fuzzy linear programming problem are crisp values. Thus, the fuzzy aspect of the decision is partly lost, and the decision-making process is constrained to crisp decisions. However, they propose a method that uses fuzzy decision variables with a joint membership function instead of crisp decision variables. First, they consider lower-bounded fuzzy decision variables that set up the lower bounds of the decision variables. Second, the method is generalized to lower-upper-bounded fuzzy decision variables that also set up the upper bounds of the decision variables. The results are closely related to the special type of the problem they are coping with, since they embed a sum constraint in the joint membership function of the fuzzy decision variables. Numerical examples are presented in order to illustrate their method [35].

By the same token, as a case study, Sadeghi and Hosseini tried to demonstrate the method of application of FLP for optimization of supply energy system in Iran.

They used FLP model comprises fuzzy coefficients for investment costs. Following the mentioned purpose, it is realized that FLP is an easy and flexible approach that can be a serious competitor for other confronting uncertainties approaches, that is, stochastic and minimax regret strategies [36].

On the other hand, Liu proposed a new kind of method for solving fuzzy linear programming problems based on the satisfaction (or fulfillment) degree of the constraints. Using a new ranking method of fuzzy numbers, the fulfillment of the constraints can be measured. Then the properties of the ranking index are discussed. With this ranking index, the decision-maker can make the constraints tight or loose based on his optimistic or pessimistic attitude and get the optimal solution from the fuzzy constraint space. The corresponding value of objective distribution function therefore can be obtained. A numerical example illustrates the merits of the approach [37].

Chen and Ko proposed fuzzy linear programming models to determine the fulfillment levels of PCs under the requirement to achieve the determined contribution levels of design requirements (DRs) for customer satisfaction. In addition, by considering the design risk, they incorporate failure modes and effect analysis (FMEA) into quality function deployment (QFD) processes, which are treated as the constraint in the models. In order to cope with the vague nature of product development processes, fuzzy approaches are used for both FMEA and QFD. The illustration of the suggested models is performed with a numerical example to indicate the applicability in practice [38].

Eventually, Katagiri et al. considered multiobjective linear programming problems with fuzzy random variables coefficients. A new decision-making model is proposed to maximize both possibility and probability, which is based on possibilistic programming and stochastic programming. An interactive algorithm is constructed to obtain a satisficing solution satisfying at least weak Pareto optimality [39].

3 Fuzzy Integer Programming

The linear programming models that have been discussed thus far all have been continuous, in the sense that decision variables are allowed to be fractional.

Often this is a realistic assumption. For instance, we might easily produce 102 3/4 gallons of a divisible good such as wine. It might also be reasonable to accept a solution giving an hourly production of automobiles at 58 1/2 if the models were based upon average hourly production, and the production had the interpretation of production rates.

At other times, however, fractional solutions are not realistic, and we must consider the optimization problem:

$$\text{Maximize} \quad \sum_{j=1}^n c_j x_j, \quad (1)$$

subject to

$$\sum_{j=1}^n a_{ij} = b_i, (i = 1, 2, \dots, m), \quad (2)$$

$$x_j \geq 0 (j = 1, 2, \dots, n), \quad (3)$$

$$x_j \text{ integer (for some or all } j = 1, 2, \dots, n). \quad (4)$$

This problem is called the (linear) integer programming problem. It is said to be a mixed-integer program when some, but not all, variables are restricted to be integer and is called a pure integer program when all decision variables are integers.

The implications of fuzzy set theory in optimal decision-making were first recognized by Bellman and Zadeh [40] and were later extended to linear programming problems with fuzzy constraints and multiple objectives by Zimmermann [41]. The latter formulation was subsequently extended to integer programming problems [42–45]. Fuzzy techniques have recently been applied to the analysis and optimization [46, 47]. Also, linear and integer linear programming are known to capture well optimization problems relevant to high-speed networks [48].

The fuzzy integer programming (FIP) methods provide another type of potentially useful approach for integer programming under uncertainty. Major shortcomings with the FIP methods are that, firstly, it may be difficult to obtain membership information for all system components in practical problems; secondly, FIP methods may lead to more complicated submodels that are computationally difficult for practical applications; and thirdly, most of the FIP solution algorithms are indirect approaches containing intermediate control variables or parameters, which are difficult to determine by certain criteria. They are thus unable to communicate uncertainty directly into the optimization processes and resulting specific solutions [49].

Tan et al. present integer programming optimization models for planning the retrofit of power plants at the regional or national level at their study. In addition to the base case (i.e., non-fuzzy or crisp) formulation, two fuzzy extensions are given to account for the inherent conflict between environmental and economic goals, as well as parametric uncertainties pertaining to the emerging carbon capture technologies. Case studies are shown to illustrate the modeling approach [50].

Asratian and Kuzjurin considered covering programs with 0–1 variables and cost function of the form $\sum_j x_j$ under the assumption that they know a pattern of coefficients in constraints, which are nonzero and only those coefficients can vary in some interval $[1, M]$ (zero elements do not change their value). As their main result, they found some sufficient conditions guaranteeing the variation of integral optimum in the average case (over all zero–nonzero patterns) is close to 1 as the number of variables tends to infinity. This means that for typical patterns the values of nonzero elements in A can vary without affecting significantly the value of the optimum of the integer program (i.e., the optimum value depends mostly on the pattern but not on the values of nonzero elements) [48].

Gharehgozli et al. present a new mixed-integer goal programming (MIGP) model for a parallel-machine scheduling problem with sequence-dependent setup times and release dates. Two objectives are considered in the model to minimize the total weighted flow time and the total weighted tardiness simultaneously. Due to the complexity of the above model and uncertainty involved in real-world scheduling problems, it is sometimes unrealistic or even impossible to acquire exact input data. Hence, they consider the parallel-machine scheduling problem with sequence-dependent setup times under the hypothesis of fuzzy processing time's knowledge and two fuzzy objectives as the MIGP model [51].

Li et al. developed a two-stage fuzzy robust integer programming (TFRIP) method for planning environmental management systems under uncertainty. Their approach integrates techniques of robust programming and two-stage stochastic programming within a mixed-integer linear programming framework. It can facilitate dynamic analysis of capacity-expansion planning for waste-management facilities within a multistage context. The TFRIP method is applied to a case study of long-term waste-management planning under uncertainty. Generated solutions for continuous and binary variables can provide desired waste-flow allocation, capacity-expansion plans with a minimized system cost, and maximized system feasibility [52].

Allahviranloo and Afandizadeh formulated an investment model to find the optimum investment steps by application of operational research science and fuzzy logic concept to model the available uncertainties. Fuzzy integer linear programming models are used to determine the optimum investment and development of a port [53].

Also, Emam studied a bi-level integer nonlinear programming problem [54] with linear or nonlinear constraints, where nonlinear objective function at each level is maximized. The bi-level integer nonlinear programming (BLI-NLP) problem can be thought as a static version of the Stackelberg game, which is used as a leader-follower game. A Stackelberg game is used by the leader, or the higher-level decision-maker (HLD), given the rational reaction of the follower, or the lower-level decision-maker (LLD). He proposed a two-planner integer model and a solution method for solving this problem. This method uses the concept of tolerance membership function and the branch-and-bound technique to develop a fuzzy max-min decision model for generating Pareto optimal solution for this problem; an illustrative numerical example is given to represent the obtained results [53].

4 Fuzzy Spanning Trees

In classical mathematical programming, the coefficients of objective functions or constraints in problems are assumed to be completely known. However, in real systems, they are uncertain than constant. In order to deal with such uncertainty, stochastic programming [55] and fuzzy programming [56] were considered. Both are useful tools for the decision-making under a stochastic environment or a fuzzy environment, respectively [57].

In parallel Gao and Lu formulated a fuzzy quadratic minimum spanning tree problem as expected value model, chance-constrained programming, and dependent-chance programming according to different decision criteria in their study. Then the crisp equivalents are derived when the fuzzy costs are characterized by trapezoidal fuzzy numbers. Furthermore, a simulation-based genetic algorithm using Prüfer number representation is designed for solving the proposed fuzzy programming models as well as their crisp equivalents, and a numerical example is displayed to illustrate the effectiveness of the genetic algorithm at the end of the study [57].

Katagiri et al. [58] investigated bottleneck spanning tree problems where each cost attached to the edge in a given graph is represented with a fuzzy random variable. The problem is to find the optimal spanning tree that maximizes a degree of possibility or necessity under some chance constraint. After transforming the problem into the deterministic equivalent one, they introduce the subproblem which has close relations to the deterministic problem. Utilizing fully the relations, they give a polynomial order algorithm for solving the deterministic problem.

Additionally, Katagiri et al. [59] studied minimum spanning tree problems where each edge weight is a fuzzy random variable. A fuzzy goal for the objective function is defined to capture the imprecise judgment of the decision-maker. They also proposed a decision-making model based on a possibilistic programming model and the expectation optimization model in stochastic programming.

5 Fuzzy Shortest Path

The shortest path problem (SPP) is one of the most fundamental and well-known combinatorial optimization problem that appears in many applications, including communications, transportation, routing, supply chain management, or models involving agents as a subproblem [60].

The problem of finding the shortest path from a specified source node to the other nodes is a fundamental matter in graph theory and one that is currently being greatly studied [61–68].

The classical problem seeks to select a path with minimum length from a finite set of paths. In real-world problems, arc lengths represent traveling time, cost, distance, or other variables. However, in practice, uncertainty cannot be avoided, and usually, the arc lengths cannot be determined precisely. For instance, on road networks, for several reasons, that is, traffic, accidents, or weather condition, arc lengths representing the vehicle travel time are subject to uncertainty. In such situations, a fuzzy shortest path problem (FSPP) seems to be more realistic and reliable.

According to Hernandes et al., an iterative algorithm assumes a generic ranking index for comparing the fuzzy numbers involved in the problem, in such a way that each time in which the decision-maker wants to solve a concrete problem(s) he/she can choose (or propose) the ranking index that best suits that problem. Hernandes et al.'s algorithm is based on the Ford–Moore–Bellman algorithm for classical graphs. In concrete, it can be applied in graphs with negative parameters,

and it can detect whether there are negative circuits. For the sake of illustrating the performance of the algorithm in the study, it has been developed using only certain order relations. However, it is not restricted at all to use these comparison relations exclusively. As the theoretical base of a decision support system's concern is to solve this kind of problems, the proposed iterative algorithm is easy to understand [69].

Tajdin et al. concerned with the design of a model and an algorithm for computing a shortest path in a network having various types of fuzzy arc lengths. Firstly, to obtain membership functions for the considered additions, they developed a new technique for the addition of various fuzzy numbers in a path using α -cuts by proposing a linear least squares model. Then, using a recently proposed distance function for comparison of fuzzy numbers, they present a dynamic programming method for finding a shortest path in the network [70].

Moazeni discussed the shortest path problem in his study. A positive fuzzy quantity is assigned to each arc as its arc length on a network. He defines an order relation between fuzzy quantities with finite supports. Then by applying Hansen's multiple labeling method together with Dijkstra's shortest path algorithm, he proposes a new algorithm for finding the set of nondominated paths with respect to the extension principle. Moreover, he shows that the only existing approach for this problem, Klein's algorithm, may lead to a dominated path in the sense of extension principle [60].

Keshavarz and Khorram concentrated on a shortest path problem on a network where arc lengths (costs) are not deterministic numbers, but imprecise ones in their study. Here, costs of the shortest path problem are fuzzy intervals with increasing membership functions, whereas the membership functions of the total cost of the shortest path are a fuzzy interval with a decreasing linear membership function. By the max-min criterion suggested in [71], the fuzzy shortest path problem can be treated as a mixed-integer nonlinear programming problem. They pointed out that this problem can be simplified into a bi-level programming problem that is very solvable. In order to solve the bi-level programming problem, they propose an efficient algorithm based on the parametric shortest path problem. An illustrative example is used to denote their algorithm [72].

In a network, the arc lengths may represent time or cost. In practical situations, it is reasonable to assume that each arc length is a discrete fuzzy set. It is called the discrete fuzzy shortest path problem. There are several methods reported to solve this kind of problem in the literature. In these methods, they can obtain either the fuzzy shortest length or the shortest path. In their study, Chuang and Kung claimed a new algorithm which can obtain both of them. The discrete fuzzy shortest length method is proposed to find the fuzzy shortest length, and the fuzzy similarity measure is utilized to get the shortest path. An illustrative example represents their proposed algorithm [62].

Ji et al. considers the shortest path problem with fuzzy arc lengths in their study. According to different decision criteria, the concepts of expected shortest path, α -shortest path, and the shortest path in fuzzy environment are originally introduced, and three types of models are formulated. In order to solve these models, a hybrid intelligent algorithm integrating simulation and genetic algorithm are asserted and numerous examples illustrate its effectiveness [73].

Okada deals with a shortest path problem on a network in which a fuzzy number, instead of a real number, is assigned to each arc length in his study. Such a problem is “ill-posed” because each arc cannot be identified as being either on the shortest path or not. Therefore, based on the possibility theory, he introduces the concept of “degree of possibility” that an arc is on the shortest path. Every pair of distinct paths from the source node to any other node is implicitly assumed to be noninteractive in the conventional approaches. This assumption is unrealistic and also involves inconsistencies. To overcome this drawback, he defines a new comparison index between the sums of fuzzy numbers by considering interactiveness among fuzzy numbers. An algorithm is presented to determine the degree of possibility for each arc on a network. This algorithm is evaluated by means of large-scale numerical examples. Consequently, this approach is found efficient even for real-world practical networks [66].

The fuzzy shortest path (SP) problem aims at providing decision-makers with the fuzzy shortest path length (FSPL) and the SP in a network with fuzzy arc lengths. In their study, Chuand and Kung represent each arc length a triangular fuzzy set and propose a new algorithm to deal with the fuzzy SP problem. First, they proposed a heuristic procedure to find the FSPL among all possible paths in a network. It is based on the idea that a crisp number is a minimum number if and only if any other number is larger than or equal to it. It owns a firm theoretic base in fuzzy sets theory and can be implemented effectively. Second, they propose a way to measure the similarity degree between the FSPL and each fuzzy path lengths. The path with the highest similarity degree is the SP. An illustrative example is added to display their proposed approach [61].

6 Fuzzy Network Flows

Network flow problems have a wide range of engineering and management applications such as analyses and design of computer networks, cable television networks, transportation systems, communication networks, project schedules, queuing systems, inventory systems, and manpower allocation [74].

In parallel, Liu and Kao [74] studied the network flow problems in that the arc lengths of the network and the objective value are fuzzy numbers. The illustrative example is on the problem of multimedia transmission over Internet.

Flows in networks provide very useful models in a number of practical contexts. The major techniques in the area revolve around celebrated max-flow min-cut theorem (MFMCT) and associated algorithms. In this context, Diamond develops analogues of the MFMCT and Karp–Edmonds algorithm for networks with fuzzy capacities and flows in their study. The principal difference between fuzzified and traditional crisp versions is that although the maximum fuzzy flow corresponds to a minimum fuzzy capacity, the latter may incorporate a number of network cuts. Preliminary results are for interval-valued flows and capacities which, in

themselves, provide robustness and estimates for flows in an uncertain environment. In turn, a fuzzy theorem and algorithm are obtained by regarding these intervals as level sets of fuzzy numbers [75].

Georgiadis considered a general class of optimization problems regarding spanning trees in directed graphs (arborescence). In his study, Georgiadis considered the following optimization problem. He assumed that edge costs take values in a set U endowed with a dyadic relation and a dyadic operation. He sought to find the directed spanning tree whose cost (with respect to the dyadic operation) is minimal with respect to the dyadic relation. Then, he provided an algorithm for solving the problem, which can be considered as generalization of Edmonds' special cases of this problem provide algorithms for the minimum sum, bottleneck and lexicographically optimal arborescence, as well as the widest-minimum sum spanning arborescence problem [76].

7 Fuzzy Minimum Cost Flow Problems

Minimal cost flow problem (MCFP) is an important problem in combinatorial optimization and network flows and has many applications in practical problems, such as communication, transportation, urban design, and job scheduling models [77].

The aim of the minimal cost flow problem (MCFP) in fuzzy nature, denoted with FMCFP, is to find the least cost of the shipment of a commodity through a capacitated network in order to satisfy imprecise concepts in supply or demand of network nodes and capacity or cost of network links [78].

Ghatee and Hashemi presented a model in which the supply and demand of nodes and the capacity and cost of edges are represented as fuzzy numbers. For easier reference, they refer to this group of problems as fully fuzzified MCFP. Hukuhara's difference and approximated multiplication are used to represent their model. Thereafter, they sort fuzzy numbers by an order using a ranking function and show that it is a total order, that is, a reflexive, antisymmetric, transitive, and complete binary relation. Utilizing the proposed ranking function, they transform the fully fuzzified MCFP into three crisp problems solvable in polynomial time [79].

Also, Ghatee and Hashemi deal with fuzzy quantities and relations in multi-objective minimum cost flow problem in their study. When t-conorms and t-conorms are available, the goal programming is applied to minimize the deviation among the multiple costs of fuzzy flows and the given targets. To obtain the most optimistic and the most pessimistic satisficing solutions of the problem, two different polynomial time algorithms are introduced by applying some network transformations. To verify the performance of this approach in actual substances, network design under fuzziness is considered, and an efficient scheme is proposed including genetic algorithm including fuzzy minimum cost flow problem [80].

Similarly, Ghatee et al. study the minimal cost flow problem (MCFP) with fuzzy link costs, say fuzzy MCFP, to understand the effect of uncertain factors in applied shipment problems. With respect to the most possible case, the worst case, and the

best case, the fuzzy MCFP can be converted into a three-objective MCFP. Applying a lexicographical ordering on the objective functions of derived problem, two efficient algorithms are provided to find the preemptive priority-based solution(s), namely, p-successive shortest path algorithm and p-network simplex algorithm. In both of them, lexicographical comparison is used which is a natural ordering in many real problems especially in hazardous material transportation where transporting through some links jeopardizes people's lives. Presented schemes maintain the network structure of the problem, and so, they are efficiently implementable. A sample network is added to illustrate the procedure and to compare the computational experiences with those of previously established works. Finally, the above-presented approach is applied to find an appropriate plan to transit hazardous materials in Khorasan roads network using annual data of accidents [81].

8 Fuzzy Matching Algorithm

Matching problem is one of the most important optimization problems. The model is widely used in practice such as pattern recognizing, system optimization, and job assignment problem. A matching of a graph is an independent subset M of edge set. In other words, a matching is a set of pairwise disjoint edges.

To explain this algorithm, first, we will explain fuzzy maximum matching algorithms. A maximum matching has as many edges in it as possible. Another version of this general problem is called the maximum weighted matching problem, and significantly more difficult will be captured in the second subsection of this section.

A maximum weighted matching problem is to choose a maximum matching in a given graph so that the sum of weight of the edges in it is at the maximum level. Nonbipartite weighted matching appears to be one of the “hardest” combinatorial optimization problems that can be solved in polynomial time.

Another version of weighted matching algorithms is a well-known problem called the assignment problem (AP). It can also be called as the minimum weight perfect matching problem in bipartite graphs. The fuzzy assignment problem (FAP) is also introduced at the Sect. 8.2.1.

There are several other inexact matching methods based on continuous optimization that have been proposed in the recent years. Among them we can cite the fuzzy graph matching (FGM) that is a simplified version of weighted graph matching (WGM) problem and based on fuzzy logic. In FGM, as the cost of matching two nodes does not depend on the matching of the other nodes of the graph, the objective function is considerably simpler than the objective function in WGM problem [82].

Medasani et al. [83] provided a relaxation approach to graph matching based on a fuzzy assignment matrix. Hence, the authors are able to derive that iterative FGM algorithm, which has a matching accurate than the graduated assignment algorithm.

Medasani and Krishnapuram [84] introduced a fuzzy approach to content-based retrieval of segmented images using fuzzy attributed relational graphs (FARGs) and an efficient FGM. In sum, the FGM algorithm is of the order $O(n^2m^2)$ and hence suitable for image retrieval.

8.1 Fuzzy Maximum Matching Algorithms

The maximum matching model is also called cardinality matching problem. An independent subset of the edges set is called a matching of a graph, and a matching with as many edges in it as possible is called a maximum matching.

Matching problems with fuzzy weights arise when the decision-maker has some vague information about some data of the real-world system. In other words, the parameters of a system can be characterized by fuzzy variables.

Essentially, Liu et al. initialized the concepts of expected maximum fuzzy weighted matching, the α -maximum fuzzy weighted matching, and the most maximum fuzzy weighted matching. According to various decision criteria, by using the credibility theory, with crisp equivalents are also given, the maximum fuzzy weighted matching problem is formulated as expected value model, chance-constrained programming, and dependent-chance programming. Furthermore, a hybrid genetic algorithm is designed to solve the proposed fuzzy programming models. Finally, a numerical example is given. The weights of the edges are trapezoidal fuzzy variables in the numerical example [85].

Liu and Gao [86] suggested concepts of the maximum random fuzzy weighted matching problem: (a) the expected maximum random fuzzy weighted matching, (b) the (α, β) -maximum random fuzzy weighted matching, and (c) the most maximum random fuzzy weighted matching. Later they formulated the maximum random fuzzy weighted matching problem as an expected value model, chance-constrained programming, and dependent-chance programming. To get the expected maximum random fuzzy weighted matching, the expected maximum random fuzzy weighted matching problem can be formulated as follows:

$$\begin{cases} \max \sum_{(i,j) \in E} x_{ij} \\ \max E[\sum_{(i,j) \in E} \xi_{ij} x_{ij}] \\ s.t. \sum_{j:(i,j) \in E} x_{ij} \leq 1, i = 1, 2, \dots, |V| \\ x_{ij} = 0 \text{ or } 1, (i, j) \in E. \end{cases} \quad (5)$$

Later a knowledge-based hybrid genetic algorithm is designed for solving the problem.

8.2 Fuzzy Weighted Matching Algorithm

Main goal of the algorithm is to find a matching in a given graph such that sums the weights of the edges at its maximum level. The sum of the weights of the edges in a matching is called the weight of matching. Sometimes, instead of a matching maximum weighted matching problem is used to find a maximum matching with maximum weight.

When the decision-maker has some vague information about some data of a real-life system, the matching model with fuzzy weighted is used. In other words, fuzzy variables are used for the parameters of a system.

In recent years, a lot of researches on matching have been conducted. A quite compact and flexible search-based artificial algorithm that makes use of relations based on representation of the graph is proposed by Balakrishnarajan and Venuganligam [87] to find all the perfect matching on a general graph.

An extension of the bipartite weighted matching problem is studied by Hsieh et al. [88]. A reduction algorithm reducing the matching problem to the assignment problem is proposed. Also, three examples are used to illustrate the process of the proposed method and its applications. As a result of the reduction to assignment problem on a larger graph, exact solution can be found at polynomial time.

Hsieh et al. [89] studied the weighted matching problem for on-line handwritten Chinese character recognition. The Hungarian method and a greedy algorithm based on the Hungarian method are proposed to solve the matching problem by a reduction algorithm. For each iteration of the greedy algorithm, a matched pair is deleted, and if the relation of their neighbors does not match, a new matching is then found by applying Hungarian method.

Lamb [90] studied the weighted matching with penalty and showed that bipartite weighted matching with penalty problem can be reduced to a bipartite maximum weight matching problem. The reduction to a maximum weight matching problem is not only easier than the reduction of Hsieh et al. [88, 89] to an AP, but also produces a smaller problem.

By using the appropriate data structures, Steiner and Yeomans [91] designed a linear time algorithm for maximum matching in convex, bipartite graphs and showed that the maximum matching problem can be efficiently transformed into an off-line minimum problem. This algorithm finds a maximum matching in less time complexity which is less than the graph size.

Kim and Wormald [92] studied the matching problem as an extension of matching problem, in random regular graphs, which are showing a random d -regular graph for even d asymptotically, almost surely (a.s.), has an edge decomposition into Hamilton cycles.

Zito [93] also studied bipartite and d -regular random graphs, and proved that with high probability, ratio between the sizes of any two maximal matchings approaches one in dense random graphs and random bipartite graphs. According to their findings, weaker bounds hold for sparse random graphs and random d -regular graphs.

For this model primarily, some preliminary knowledge of credibility theory and notations could be used. Let ξ be a fuzzy variable with membership function $\mu(x)$ and r a real number. Then, the possibility measure [94] and the necessity measure of fuzzy event $\leq \{\xi \leq r\}$ are defined as

$$\text{Pos}\{\xi \leq r\} = \sup_{x \leq r} \{\mu(x)\}, \text{Nec}\{\xi \leq r\} = 1 - \text{Pos}\{\xi > r\},$$

respectively.

The credibility measure of fuzzy event $\{\xi \leq r\}$ is defined by Liu and Liu [95] as

$$\text{Cr}\{\xi \leq r\} = \frac{1}{2}(\text{Pos}\{\xi \leq r\} + \text{Nec}\{\xi \leq r\}).$$

It can easily verified that $\text{Cr}\{\xi \leq r\} + \text{Cr}\{\xi > r\} = 1$ for any fuzzy event $\{\xi \leq r\}$. Liu [96] also presented two critical values, say α -optimistic value which was defined as

$$\xi_{\sup}(\alpha) = \sup\{r | \text{Cr}\{\xi \geq r\} \geq \alpha\}$$

and a pessimistic value which was defined as

$$\xi_{\inf}(\alpha) = \inf\{r | \text{Cr}\{\xi \leq r\} \geq \alpha\},$$

which serve as roles to rank fuzzy variables, where $\alpha \in (0, 1]$ and ξ is a fuzzy variable. The expected value of a fuzzy variable ξ is defined as

$$E[\xi] = \int_0^\infty \text{Cr}\{\xi \geq r\} dr - \int_{-\infty}^0 \text{Cr}\{\xi \leq r\} dr$$

provided that at least one of the two integrals is finite.

For more detailed properties of credibility measure, the interested reader may consult Liu [97].

For this model, it is thought that all the graphs are undirected and simple. Let $G(V, E, \xi)$ be a graph, where V , E , and ξ are the vertices set, edges set, and weights vector of the graph G . Sometimes, we employ $E(G)$ and $V(G)$ to denote the edges set and the vertices set of graph G , respectively. The degree and the set of incident edges of the vertex $v \in V$ are denoted by $dG(v)$ and $Ne[v]$, respectively. For a subset S of E or V , $G[S]$ denotes the subgraph induced by the subset S . The weight of edge $(i, j) \in E$ is denoted by a fuzzy variable ξ_{ij} , where

$$\xi_{ii} = 0 \text{ and } \xi_{ij} = \xi_{ji}, i, j = 1, 2, \dots, [V(G)].$$

Let $M \subseteq E$ be a matching of $G(V, E, \xi)$. Let

$$x_{ij} = \begin{cases} 1, & \text{if } (i, j) \in M, \\ 0, & \text{otherwise.} \end{cases}$$

Then the matching M can also be denoted by such a vector x , and the cost function of matching x can be defined as

$$f(x, \xi) = \sum_{(i, j) \in E} \xi_{ij} x_{ij'}$$

where x and ξ denote the vectors consist of x_{ij} and ξ_{ij} , $(i, j) \in E$, respectively.

Definition 10 The α -cost of $f(x, \xi)$ is defined as the cost value \bar{f} such that

$$\text{Cr}\{f(x, \xi) \geq \bar{f}\} \geq \alpha,$$

where α is a predetermined confidence level between 0 and 1.

It is clear that the cost function $f(x, \xi)$ is also a fuzzy variable when the vector ξ is a fuzzy vector. In order to rank $f(x, \xi)$, different ideas are employed in different situations. If the decision-maker wants to find a maximum weighted matching with maximum expected value of the cost function $f(x, \xi)$, then the following concept is induced.

Definition 11 A maximum matching x^* is called the expected maximum fuzzy weighted matching if

$$E[x^*] \geq E[f(x, \xi)]$$

for any maximum matching x .

In other situation, the decision-maker hopes to maximize the a-cost value \bar{f} with

$$\text{Cr}\{f(x, \xi) \geq \bar{f}\} \geq \alpha.$$

For this case, we propose the concept of a-maximum fuzzy weighted matching as follows:

Definition 12 A maximum matching x^* is called a-maximum fuzzy weighted matching if

$$\max\{\bar{f} | \text{Cr}\{f(x^*, \xi) \geq \bar{f}\} \geq \alpha\} \geq \max\{\bar{f} | \text{Cr}\{f(x, \xi) \geq \bar{f}\} \geq \alpha\}$$

for any maximum matching x , where a is a predetermined confidence level.

Furthermore, the most maximum weighted matching arises when the decision-maker gives a cost value \bar{f} and hopes that the credibility of the cost value exceeding \bar{f} will be as maximized as possible

Definition 13 A maximum matching x^* is called the most maximum fuzzy weighted matching if

$$\text{Cr}\{f(x^*, \xi) \geq \bar{f}\} \geq \text{Cr}\{f(x, \xi) \geq \bar{f}\}$$

for any maximum matching x , where \bar{f} is a predetermined cost value.

Based upon these, we will recast the maximum fuzzy weighted matching problem as multiobjective expected value model, chance-constrained programming, and dependent-chance programming, respectively.

Liu and Liu [95] initialized the fuzzy expected value model. Its main idea is to optimize the expected value of the objective function subjected to some expected constraints. Therefore, the expected maximum fuzzy weighted matching problem can be formulated as

$$\begin{cases} \max \sum_{(i,j) \in E} x_{ij} \\ \max E[\sum_{(i,j) \in E} \xi_{ij} x_{ij}] \\ s.t. \sum_{(i,j) \in E} x_{ij} \leq 1, i = 1, 2, \dots, |V|, \\ x_{ij} = 0 \text{ or } 1. \end{cases} \quad (6)$$

With respect to stochastic chance-constrained programming [98], Liu and Iwamura [99] offered the concept of fuzzy chance-constrained programming. When the decision-maker wants to optimize the critical value of the cost function subjected to some chance-constraints, the chance-constrained programming is employed. Therefore, the α -maximum fuzzy weighted matching problem can be formulated as follows:

$$\begin{aligned} & \max \sum_{(i,j) \in E} x_{ij} \\ & \max \bar{f} \\ & s.t. \text{Cr}\{\sum_{(i,j) \in E} \xi_{ij} x_{ij} \geq \bar{f}\} \geq \alpha \\ & \sum_{(i,j) \in E} x_{ij} \leq 1, i = 1, 2, \dots, |V| \\ & x_{ij} = 0 \text{ or } 1. \end{aligned} \quad (7)$$

Liu [100] proposed the dependent-chance programming in which the goal is to optimize a fuzzy event's chance in an uncertain environment, such as possibility, necessity, or credibility. According to this model, the problem to find a most maximum fuzzy weighted matching with given cost value \bar{f} can be formulated as follows:

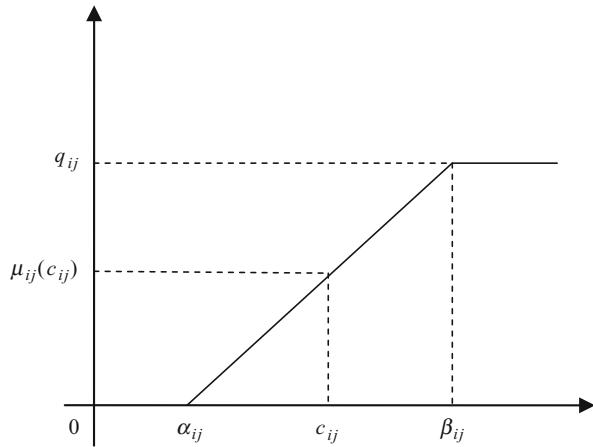

$$\begin{cases} \max \sum_{(i,j) \in E} x_{ij} \\ \max \text{Cr}\{\sum_{(i,j) \in E} \xi_{ij} x_{ij} \geq \bar{f}\} \\ s.t. \sum_{(i,j) \in E} x_{ij} \leq 1, i = 1, 2, \dots, |V|, \\ x_{ij} = 0 \text{ or } 1. \end{cases} \quad (8)$$

8.2.1 Fuzzy Assignment Problem

Assignment problem (AP) is a special type of linear programming problem and widely used in both manufacturing and service systems. AP can also be called as the minimum weight perfect matching problem in bipartite graphs.

In this model the objective is to assign n number of jobs to n number of persons at a minimum cost or time. The problem's mathematical formulation suggests that this is a 0–1 programming problem and is highly degenerate. It is applicable for transportation problems in which all the algorithms developed to find optimal solution.

Fig. 1 Membership function of c_{ij}

The AP parameters are imprecise numbers instead of fixed real numbers because time or cost for doing a job by a firm (machine or person) might vary due to a lot of reasons. Assigning men to jobs, drivers to buses, trucks to delivery routes, etc. are some examples over the past 50 years for this matter.

Here, it is aimed to find such an assignment, in which the total costs or sum of the single assignments is to become a minimum ratio [101]. The Hungarian method [102], which is the most popular algorithm for AP, carries through the algorithm directly on the $n \times n$ cost matrix $[c_{ij}]$, where c_{ij} represents the cost associated with worker i ($i = 1, 2, \dots, n$) who has performed job j ($j = 1, 2, \dots, n$) as seen in Fig. 1.

In this model, all c_{ij} 's are deterministic numbers.

The AP also could be modeled as a 0–1 integer programming problem:

$$\min \sum_{i=1}^n \sum_{j=1}^n c_{ij} x_{ij} \quad (9)$$

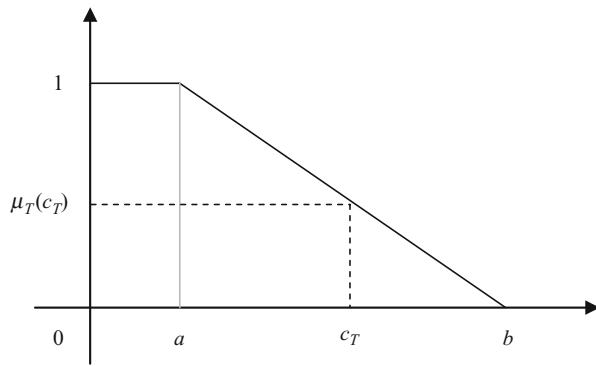

$$s.t. \sum_{j=1}^n x_{ij} = 1 \text{ for } i = 1, 2, \dots, n, \quad (10)$$

$$\sum_{i=1}^n x_{ij} = 1 \text{ for } j = 1, 2, \dots, n, \quad (11)$$

$$x_{ij} \in \{0, 1\} \text{ for } i, j = 1, 2, \dots, n. \quad (12)$$

However, many real-world application costs are not deterministic. For example, a consultant company provides different services to their customers for predetermined charges in each case. The job or case quality (may be the satisfaction of the customer or the job performance of the worker) may assume to be positively correlated to the input time or cost of the worker. Highest quality of the case is different because of the difference among individual workers. Furthermore, the manager of the company usually restricts the total labor hours or costs to a range as his fuzzy goal.

Fig. 2 Membership function of c_T

Hence, a minimum personnel cost is assumed to perform a job, and bigger spending costs to get result for higher quality until it reaches an upper bound, but it has to be thought that an increase in cost does not increase the quality. In this case, the costs are no longer deterministic numbers, and they will be denoted as c_{ij} 's, α_{ij} as the least cost associated with the worker i performing the job j and β_{ij} as the least cost associated with worker i performing the job j at the highest quality (it is assumed that $\beta_{ij} > \alpha_{ij} > 0$). Also the quality matrix $[q_{ij}]$ that represents the highest quality associated with the worker i performing the job j ($0 < q_{ij} \leq 1$) is defined. In most real cases, $0 < q_{ij} < 1$ and then c_{ij} is a subnormal fuzzy interval. The membership function of c_{ij} is defined as the linear monotone increasing function shown in Fig. 2, which suggests that any expense exceeding β_{ij} is useless since the quality (worker's job performance or customer's satisfaction) can no longer be increased at its upper limit q_{ij} condition.

$x_{ij} = 1$ is added to (13) because there is no real expense if $x_{ij} = 0$ in any feasible solution x of (12).

$$\mu_{ij}(c_{ij}) = \begin{cases} q_{ij} & \text{if } c_{ij} \geq \beta_{ij}, x_{ij} = 1, \\ \frac{q_{ij}(c_{ij} - \alpha_{ij})}{\beta_{ij} - \alpha_{ij}}, & \text{if } \alpha_{ij} \leq c_{ij} \leq \beta_{ij}, x_{ij} = 1, \\ 0 & \text{otherwise.} \end{cases} \quad (13)$$

The notation α_{ij}, β_{ij} is used to denote c_{ij} (all the α_{ij} 's form the matrix $[\alpha_{ij}]$ and β_{ij} 's form the matrix $[\beta_{ij}]$).

Matrix $[c_{ij}]$ is shown as follows:

$$[\tilde{c}_{ij}] = [\langle \alpha_{ij}, \beta_{ij} \rangle] = \begin{bmatrix} \langle \alpha_{11}, \beta_{11} \rangle & \cdots & \langle \alpha_{1n}, \beta_{1n} \rangle \\ \vdots & \ddots & \vdots \\ \langle \alpha_{n1}, \beta_{n1} \rangle & \cdots & \langle \alpha_{nn}, \beta_{nn} \rangle \end{bmatrix}. \quad (14)$$

In addition to this model, let c_T denote the total cost that is related to the job performance of the manager, and for the upper and lower bounds of the total cost,

numbers a and b are defined. The membership function of c_T is defined as the linear monotonically decreasing function in (15) and uses the notation $(a;b)$ to denote fuzzy interval c_T . The manager chooses a and b numbers as constant values. Then Werners [103] fuzzy linear programming in which taking a number less than or equal to the minimum assignment of matrix $[\alpha_{ij}]$ as a , and a number larger than or equal to the maximum assignment of matrix $[\beta_{ij}]$ as b could be used:

$$\mu_T(c_T) = \mu_T\left(\sum_{i=1}^n \sum_{j=1}^n c_{ij}x_{ij}\right) = \begin{cases} 1, & c_T \leq a \\ \frac{b - \sum_{i=1}^n \sum_{j=1}^n c_{ij}x_{ij}}{b-a}, & a \leq c_T \leq b, \\ 0, & c_T \geq b. \end{cases} \quad (15)$$

The performance of worker i , denoted as μ_i , based on the solution x will be

$$\mu_i = \mu_i(c_{ij}) \text{ for } x_{ij} = 1. \quad (16)$$

Here Bellman–Zadeh's criterion [71] was chosen that maximizes the minimum of the membership functions corresponding to which solution, to equally emphasize the performance of workers and manager, that is,

$$\max - \min_{x_{ij}} (\mu_i, \mu_T(c_T)) \quad (17)$$

or

$$\max - \min_{x_{ij}} = 1(\mu_{ij}(c_{ij}), \mu_T(c_T)), \quad (18)$$

where x_{ij} is an element of a feasible solution x of (9). Then we can represent the fuzzy AP as follows:

$$\max - \min(\mu_{ij}(c_{ij}), \mu_T(c_T))x_{ij} = 1 \quad (19)$$

$$s.t. \sum_{j=1}^n x_{ij} = 1 \text{ for } i = 1, 2, \dots, n, \quad (20)$$

$$\sum_{i=1}^n x_{ij} = 1 \text{ for } j = 1, 2, \dots, n,$$

$$x_{ij} \in \{0, 1\} \text{ for } i, j = 1, 2, \dots, n.$$

The cost of worker i performing job j is restricted to be less than or equal to β_{ij} since any expense exceeding β_{ij} is useless. By membership functions of (13) and (15), the following model (20) could be showed:

$$\max \lambda \quad (21)$$

$$s.t. \lambda x_{ij} \leq \frac{q_{ij}(c_{ij}^\lambda - \alpha_{ij})}{\beta_{ij} - \alpha_{ij}} x_{ij} \quad \text{for } i, j = 1, 2, \dots, n \quad (22)$$

$$\lambda \leq \frac{b - \sum_{i=1}^n \sum_{j=1}^n c_{ij}^\lambda x_{ij}}{b - a},$$

$$0 \leq \lambda x_{ij} \leq q_{ij} x_{ij} \quad \text{for } i = 1, 2, \dots, n, \quad (23)$$

$$0 \leq \lambda \leq 1$$

$$\sum_{j=1}^n x_{ij} = 1 \quad \text{for } i = 1, 2, \dots, n, \quad (24)$$

$$\sum_{i=1}^n x_{ij} = 1 \quad \text{for } i = 1, 2, \dots, n, \quad (25)$$

$$c_{ij}^\lambda x_{ij} \leq \beta_{ij} x_{ij} \quad \text{for } i, j = 1, 2, \dots, n \quad (26)$$

$$x_{ij} \in \{0, 1\} \quad \text{for } i, j = 1, 2, \dots, n, \quad (27)$$

where C_{ij}^λ denotes the α -cut of c_{ij} , and $\sum_{i=1}^n \sum_{j=1}^n c_{ij}^\lambda x_{ij}$ is the corresponding total cost c_T^λ . In (26), since x_{ij} , c_{ij}^λ and λ all are decision variables, it can be treated as a mixed-integer nonlinear programming model.

In recent years, both fuzzy transportation and fuzzy assignment problems have received major attention. Many have been developed to advance numerous methodologies and applications to various decision problems. To deal with imprecision, and vagueness in real-life situations, Zadeh [104] introduced the concept of fuzzy sets.

Chen [105] presented a fuzzy assignment model that did not consider the differences of individuals. Similarly, Wang [106] solved a model by graph theory.

Dubois and Fortemps [107] proposed a flexible assignment problem, which combines with fuzzy theory, multiple criteria decision-making, and constraint-directed methodology. They survey refinements of the ordering of solutions supplied by the max-min formulation, namely, the discrimin partial ordering and the leximin complete preordering. Additionally, they have given a general algorithm which computes all maximal solutions in the sense of these relations. They also demonstrated and solved an example of fuzzy assignment problem.

On the other hand, Sakawa et al. [108] dealt with actual problems on production and work force assignment in a housing material manufacturer and a subcontract firm and formulated two-level linear and linear fractional programming problems according to profit and profitability maximization respectively. By applying interactive fuzzy programming for two-level linear and linear fractional programming problems, they derived satisfactory solutions to the problems.

Chanas et al. [109] solved transportation problems with fuzzy supply and demand values. Tada and Ishii [110] and Chanas and Kuchta [111] added an integer restriction to that fuzzy transportation problem and solved it. Also they suggested a specific definition for an optimal solution to the transportation problem using fuzzy cost coefficients and proposed an algorithm [112].

Lin and Wen [113] solved the assignment problem with fuzzy interval number costs by a labeling algorithm. The algorithm begins with primal feasibility and proceeds to obtain dual feasibility while maintaining complementary slackness until the primal optimal solution is found.

Feng and Yang [114] investigated a two-objective-cardinality assignment problem. A chance-constrained goal programming model is constructed for the problem, and tabu search algorithm based on fuzzy simulation is used to solve the problem.

Majumdar and Bhunia [115] proposed an elitist genetic algorithm with interval-valued fitness function to solve generalized assignment problem with imprecise cost/time. In their study, the coefficient of the interval-valued assignment problem's objective function has been considered as interval-valued number. Also, they represented the imprecision of cost(s)/time(s) with interval-valued numbers.

Ye and Xu [116] proposed an effective method on priority-based genetic algorithm to solve fuzzy vehicle routing assignment when there is no genetic algorithm which can give clearly procedure of solving it.

Liu and Gao [117] proposed an equilibrium optimization problem using genetic algorithm. Then they extended the assignment problem to the equilibrium multi-job assignment problem and equilibrium multi-job quadratic assignment problem.

Kumar et al. [118] proposed a new method to find the fuzzy optimal solution of fuzzy assignment problems by representing all the parameters as triangular fuzzy numbers. In their method, decision-maker takes the final results as fuzzy numbers, and if there is no uncertainty about the cost, their method gives the same result as in crisp assignment problem.

Mukherjee and Basu [119] introduced a mathematical model of the assignment problem considering the restrictions on job cost and person cost based on his/her efficiency/qualification. Under these conditions, both the cost and the restriction of qualification are considered as triangular or trapezoidal fuzzy numbers. They also considered the case where a person without certain qualification/efficiency should not be assigned a particular job.

However, Nagarajan and Solairaju [120] considered the assignment costs as imprecise numbers described by fuzzy numbers. They transformed the fuzzy assignment problem to a crisp assignment problem using Robust's ranking indices.

9 Fuzzy Matroids

In combinatorial optimization, matroid means independence structure which is a structure that generalizes linear independence in vector spaces. Many real-world problems can be defined and solved using matroids theory. Matroids are precisely the structures for which the very simple and efficient greedy algorithm works.

When we take as E the set of all edges in graph G and consider a set of edges independent if and only if it does not contain a simple cycle, this edge set is called a forest in graph theory. It can also be called the cycle matroid or graphic matroid of G ; it is usually written $M(G)$. The graphic matroid of G can also be defined as the column matroid of any oriented incidence matrix of G . A base can be called a spanning tree in G , and a circuit is a subset of edges creating a simple cycle in G .

When we want to find an object A composed of the elements of a given finite set E , a real weight $w(e)$ is associated with every element e of E , and we seek an

object A for which the total weight $w(A) = \sum_{e \in A} w(e)$ is minimal or maximal. A classical example is finding the minimum spanning tree or a shortest path in a given graph, where E is the set of edges of this graph [121].

A system is called weighted if there is a nonnegative weight $w(e)$ given for every element $e \in E$ [122].

In the matroidal combinatorial optimization problem, a nonnegative weight $w(e)$ is given for every element $e \in E$, and we seek a base B , for which the cost $F(B) = \sum_{e \in E} w_e$ is maximal (or minimal) [123].

In classical problem, it is assumed that all the weights are precisely known. However, this assumption may be a serious restriction since in many practical applications, the exact values of the weights are not known in advance. A typical example is traveling time between two cities in the shortest path problems or activity durations in scheduling problems. One of the simplest methods of modeling the imprecise weights is to define them as closed intervals. It is then assumed that the value of each weight may fall within a given range, independently on the values taken by the other weights. Classical intervals can be generalized into so-called fuzzy numbers, which are actually fuzzy intervals, and are richer in information [120].

In [121, 122, 124, 125], when all values of a weight function are closed intervals or fuzzy numbers, the optimality of solutions and the optimality of elements are characterized by means of a family of interval matroids $\{(E, I_a) : a \in [0, 1]\}$. Because of the varying nature of the world, they used fuzzy intervals to model the not precisely known element weights.

Another use of fuzzy sets is in a matroid problem solved by Goetschel and Voxman where a group of independent fuzzy sets was defined as a crisp family of fuzzy subsets of a finite set satisfying certain set of axioms [126]. Their closed regular fuzzy matroid can be shown as follows: [155] if w is a weight function on E and A is a fuzzy subset of E , it could be defined as:

$$w(A) = \sum_{A(\theta) > 0} w(e)A(e). \quad (28)$$

The question asked is whether we can find an object $B \in [0, 1]^E$ for which the total weight $w(B)$ is minimal or maximal?

For Goetschel–Voxman fuzzy matroids, we can refer to studies [127–131].

Defining a fuzzy subset of a finite set E as a subset of $E_x(0, 1]$, we obtain fuzzy matroids by fuzzifying independence spaces on $E_x(0, 1]$. Instead, by defining fuzzy subsets of E as functions from E into $[0, 1]$, we can obtain fuzzy matroids from polymatroids associated with “real” rank functions [132].

The concepts of fuzzy pre-matroid and hereditary fuzzy pre-matroid are introduced and investigated. The property “to be perfect” for hereditary fuzzy pre-matroids is also considered. It is shown that Goetschel and Voxman fuzzy matroids coincide with perfect hereditary fuzzy pre-matroids. The fuzzy rank function of a Goetschel–Voxman fuzzy matroid (E, I) was defined by a map $R : [0, 1]^E \rightarrow N$.

But in general, a Goetschel–Voxman fuzzy matroid and its fuzzy rank function are not one-to-one corresponding [133].

Also in the literature, Shi [121] proposed a closed fuzzy pre-matroid as a fuzzifying matroid and generalized it to L-fuzzy set theory. They showed that an L-fuzzifying matroid can be characterized by means of its L-fuzzifying rank function which is one-to-one corresponding with the L-fuzzifying matroid.

10 Fuzzy Approximation Algorithms

In Sect. 10.1 we focus on the quite general problem called the minimum weight set cover problem. The minimum weight edge cover problem is also a special case of the minimum weight set cover problem. In Sect. 10.2 we discuss a strongly NP-hard problem, the maximum weight cut problem. The edge coloring and the vertex coloring in planar graphs will be defined in Sect. 10.3.

10.1 Fuzzy Set Covering

Hwang et al. [134] proposed the fuzzy set-covering model which uses auxiliary 0–1 variables and a system of inequalities. Model is obtained by taking logarithm of the inequalities constraints and using the nature of the Boolean variables of this fuzzy set-covering model.

Given two subsets $I = \{1, 2, \dots, m\}$ and $J = \{1, 2, \dots, n\}$ of integers, let $\tilde{p}_j = \{(i, \mu_j(i)) : i \in I\}$ be a fuzzy subset of I and $(\mu_j(i)) \in [0, 1]$ be the membership grade of $i \in I$, using the membership function μ_j of fuzzy set p_j .

The model is proposed as

$$\min \sum_{j=1}^n c_j x_j \quad (29)$$

$$s.t. 1 - \prod_{j=1}^n (1 - \mu_j(i)) \geq \alpha, \quad i = 1, 2, \dots, m, \quad (30)$$

$$x_j \in \{0, 1\}, \quad j = 1, 2, \dots, n, \quad (31)$$

$$\text{where } x_j = \begin{cases} 1, & \text{if } \tilde{p}_j \in^*, \\ 0, & \text{otherwise.} \end{cases}$$

In this model α is a given real number (level degree) that represents the desired level (each $i \in I$ and the membership grade of i is no less than the level degree α). According to Theorem 1 in [135], Problem (P_1) can be transformed to Problem (P_2) by replacing the product of 0–1 variables in constraints (30) with auxiliary variables and a system of linear inequalities. The details can be found in [135].

$$\min \sum_{j=1}^n c_j x_j \quad (32)$$

$$s.t. \sum_{t=1}^n \mu_{j_t}(i)x_{j_t} + \sum_{k=2}^n \sum_{j_1 < j_2 < \dots < j_k} (-1)^{k+1} \left(\prod_{t=1}^k \mu_{j_t}(i) \right) y_{j_1 j_2 \dots j_t} \geq \alpha, \quad (33)$$

$$i = 1, 2, \dots, m,$$

$$2y_{j_1 j_2 \dots j_t} \leq y_{j_1 j_2 \dots j_{t-1}} + x_{j_t} \leq 1 + y_{j_1 j_2 \dots j_t}, t = 1, 2, \dots, k, \quad (34)$$

$$y_{j_1 j_2 \dots j_k} = \prod_{t=1}^k x_{j_t}, \quad (35)$$

$$x_j \in \{0, 1\}, \quad j = 1, 2, \dots, n. \quad (36)$$

The mentioned formulation is mathematically appropriate and also elegant, but solutions are difficult to find because of the fact that the number of decision variables is proportion to the number of auxiliary variables and extra constraints that usually grows exponentially [135] as the number of variables increases.

10.2 Fuzzy Max-Cut Problem

The max-cut problem is a combinatorial optimization problem and is one of the first problems proved to be NP-hard [136], because it determines the maximum cut of a graph. Its goal is to find a division of a vertex set into two parts, maximizing the sum of weights over all the edges across the two vertex subsets in a given edge-weighted graph. For an unweighted graph, the weights over the edges are equal to 1. Such a division is called a maximum cut.

This problem has many applications in various fields, that is, network design, circuit layout design [137], and data clustering [138]. The weight of the cut in the max-cut problem has real and concrete implications when applied in real life due to the fact that parameters are not so deterministic owing to the effects of many factors. For example, for network design, the weight may represent the cost of some infrastructure.

There are many optimization problems that are based on this theory, and several optimization models in stochastic models [95] and also including various fuzzy programming models [139], fuzzy shortest path problems [66], and fuzzy max-flow problems [75] have been studied. Recently, Liu [140] developed a credibility theory where the expected value criterion, the optimistic value criterion, and the credibility criterion are used as fuzzy ranking methods.

10.2.1 The Max-Cut Problem with Fuzzy Coefficients

The max-cut problem is widely used in practical applications. When applied in real life, the weights of a graph have real and concrete implications. They are often not

so deterministic. The weights on edges can be formulated as fuzzy variables and are more proper to describe the quantities in the real world since decision-makers are often faced with some uncertain situations due to the vagueness or subjective nature of these parameters.

To compute this problem with fuzzy coefficients, let $G = (V, E)$ be an undirected edge-weighted graph with nonnegative weights $\xi : E \rightarrow R^+$. A cut C of G is any nontrivial subset of V , and the weight of a cut is the sum of weights of edges crossing C and \bar{C} , where

$$\bar{C} = V - C.A. \quad (37)$$

Then a max-cut is defined as a cut of G with maximum weight. The max-cut problem's goal is to find such a cut.

Assume that the vertices in V are labeled as (v_1, v_2, \dots, v_n) and the edges in E are labeled as

$$e_{ij} = (v_i, v_j), \text{ where } n = |V|, i, j = 1, 2, \dots, n. \quad (38)$$

ξ_{ij} is the weight associated with the edge e_{ij} . We define a binary variable x_i for each vertex v_i to denote whether it is in a cut

C or not:

$$x_i = \begin{cases} 1 & \text{if } v_i \in C \\ -1 & \text{if } v_i \in V - C. \end{cases} \quad (39)$$

Then any cut of the graph G can be denoted by an n -dimensional binary vector $(x_1, x_2, \dots, x_n)^T$ over $\{1, -1\}$. Similarly, any n -dimensional binary vector x_1, x_2, \dots, x_n^T over $\{1, -1\}$ corresponds to a cut of G . So the weight of a cut $(x_1, x_2, \dots, x_n)^T$ can be denoted as

$$W(x, \xi) = \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n \xi_{ij} (1 - x_i x_j). \quad (40)$$

Obviously, if and only if v_i and v_j respectively belong to two parts of the vertex set V ($x_i x_j = -1$), the weight of the edge (if any) linking them is considered. Let B be the set of all cuts of G . Then a cut x^* is called a maximum cut if and only if $W(x^*, \xi) \geq W(x, \xi)$ for any $x \in B$.

10.3 Fuzzy Coloring

A vertex coloring of graph G is defined as an assignment of colors to the vertices of G . So, no adjacent vertices get the same color. An edge coloring of graph G is an assignment of colors to the edges of G so that no adjacent edges have the same color.

A total coloring of a graph G is a coloring of the vertices and edges of G in such a way that no two adjacent elements have the same color. More information on coloring graphs can be found in [141].

The smallest possible total over all vertices that can occur among all colorings of G using natural numbers for the colors is called the chromatic sum of a graph G [142].

Munoz et al. [143] discussed two different approaches to the graph coloring problem of a fuzzy graph with crisp nodes and fuzzy edges. The traffic lights problem and a timetabling problem are studied according to these two different approaches. They also provided the concept of chromatic number of fuzzy graphs.

Chaudhuri and De [144] also introduced a timetabling problem called the university course timetable problem. Fuzzy genetic heuristic for this problem is discussed. There is a considerable amount of uncertainty involved in objectives which comprises of different aspects of real-life data. This uncertainty is handled by formulating some parameters using fuzzy membership functions.

The class of quasi-line graphs and more specifically fuzzy circular interval graphs gained a lot of attention recently. Eisenbrand and Niemeier [145] introduced a combinatorial algorithm that calculates weighted colorings and the weighted coloring number for fuzzy circular interval graphs efficiently.

11 Fuzzy Knapsack Problems

Knapsack problem (KP) has m different objects to choose from to put into the knapsack. Each object has a weight (w_i) and benefit (p_i). Aim of the problem is to choose the objects giving the maximum benefit without exceeding the total knapsack capacity. There are many real-life problems that can be modeled as the KP, such as cargo loading, capital budgeting, cutting stock, and economic, and network planning. Basic model for the crisp KP is as follows:

Indices

i : object indice(m)

Decision Variables

$$x_i \begin{cases} 1 & \text{if object } i \text{ lays in knapsack,} \\ 0 & \text{not in knapsack,} \end{cases}$$

Parameters

p_i : benefit of project i

w_i : cost of project i

c : capacity of knapsack not to be exceeded

Objective Function

$$\max \sum_{i=1}^m p_i x_i \text{ Benefit maximization} \quad (41)$$

Constraints

$$\sum_{i=1}^m w_i x_i \leq c \forall i \text{ size not to be exceeded} \quad (42)$$

$$x_i \in [0, 1]^m \quad \forall \text{ integer constraint} \quad (43)$$

Kuchta [146] discussed a fuzzy multiple choice KP where the total risk is minimized while staying in the budget. Each project has a risk and cost where each of these is represented with fuzzy numbers.

In Kasperski and Kulej [147], the concept of using fuzzy weights and fuzzy profits for the KP is used. This is different than the classical problem where it is assumed that all the item profits and weights are deterministic, because in practice many knapsack-type problems involve items whose weights or profits are not precisely known which is a useful extension. One of the methods of dealing with imprecision in real-world data is applying the fuzzy sets theory; they used the concept of a fuzzy interval to model the imprecise profits and the imprecise weights of items.

Lin and Yao [148] introduced a fuzzy KP where all weight coefficients are fuzzy numbers to model the imprecise weights in practical situations. They find it easier for the decision-maker to decide the value of the weight of an object as a range rather than a crisp value. After defuzzifying the fuzzy number, they use the same methodology to solve the problem as the crisp version.

On the other hand, Lin [149] provided a genetic algorithm methodology to solve imprecise weight coefficients in KPs.

In addition, Sakawa et al. [150] introduced an interactive fuzzy satisficing method for multiobjective multidimensional 0–1 KPs by using both the interactive fuzzy programming methods and genetic algorithms. By considering the imprecise nature of decision-maker (DM) judgments, fuzzy goals of the objective functions are quantified by using linear membership functions.

Chen [151] proposed a parametric programming approach to the continuous knapsack problem with fuzzy objective weights. The fuzzy maximum total return is analyzed. In this model, when the object weights are fuzzy, the maximal total profit also becomes fuzzy.

The mathematical model of the crisp continuous KP is as follows: Lin and Yao [152],

$$Z = \max \sum_{i=1}^n p_i x_i \quad (44)$$

$$s.t. \sum_{i=1}^1 w_i x_i \leq M \quad (45)$$

$$0 \leq x_i \leq 1, \quad i = 1, 2, \dots, n. \quad (46)$$

The continuous KP with fuzzy object weights is of the following form Chen [153]:

$$\tilde{Z} = \max \sum_{i=1}^n p_i x_i \quad (47)$$

$$s.t. \sum_{i=1}^l \tilde{W}_i x_i \leq M \quad (48)$$

$$0 \leq x_i \leq 1, \quad i = 1, 2, \dots, n. \quad (49)$$

For this model there are some example studies. One is Nezhad et al. [154], introducing a fuzzy capital budgeting model for selecting an optimum portfolio of projects. A real-world extension of all parameters of the projects was assumed to be imprecise.

Verdegay and Moreno's work [155] focused on the advantage of a fuzzy termination criterion providing results with low errors and with very short times with respect to both the exact and approximate solutions especially when the number of objects increases. The fuzzy-rule based systems and mathematical programming models and methods are used to solve the conventional KP.

Kato and Sakawa [156] provided a genetic algorithm with decomposition structures for large-scale multidimensional 0–1 KPs with block angular structures.

Lin [157] introduced a generalized fuzzy multiconstraint KP model, and extend it to another fuzzy multiobjective programming model. The multiconstraint 0–1 KPs are solved with imprecise weight coefficients.

Hasuike et al. [158] proposed a new model of random fuzzy 0–1 KPs where the objectives are represented with fuzzy goals and expected returns assumed as random fuzzy numbers.

Shih [159] focused on fuzzy multiobjective and multilevel KPs and proposed a solution procedure.

12 Fuzzy Bin Packing

Within a given rectangular area, finding an efficient packing has much relevance to operating systems, operations research, and manufacturing industries [160, 161]. For example, in a given time to operating systems or in steelworks, the problem is related with the allocation of resources. The task is cutting the roll of raw steel to make components of products. As these are mentioned, such can be formulated as *bin-packing (BP)* problems. BP is a problem that has long been studied by many researchers to better formulate and efficiently solve practical problems [162].

The problem is known to be NP-hard [163], while its description seems to be simple; it is very difficult to solve this problem precisely. In order to simplify the formulations of the problem, we have to concentrate on finding more efficient heuristics. Most formulations, therefore, assume *rigidity*, *orientation*, and *orthogonality* of the pieces [164, 165].

Suppose that there is a bin $B = (W, H)$ and a set of pieces $P = \{p_1, \dots, p_n\}$. We can represent each piece in the following manner: $p_i = (w_i, h_i)$ because the piece is rigid and oriented (we cannot change the size of a piece or its orientation). Letting (x_i, y_i) denote the center position of a piece p_i , we can also obtain the

height of the packing as $\max_i(y_i + h_i/2)$ because of the orthogonality assumption [166]. The bin-packing problem's goal is to minimize the height of the packing $\max_i(y_i + h_i/2)$ by choosing appropriate center positions (x_i, y_i) 's, which also satisfy the two following constraints: (1) all pieces should be contained within the bin and (2) no two pieces should overlap. By applying simple arithmetic, we can convert the two constraints as a set of inequalities.

However, assuming that the heights are rigid, that is, a constraint becomes too strong in many applications. When facing strong conflicting requirements, we should trade-off between the efficiency and the satisfaction. If we want to pay additional costs for decreasing the designer's satisfaction, then we could degrade the satisfaction because of the reduction.

However, in above-mentioned issue, we are not supposing the long-term cost such as deterioration of production quality or customer dissatisfactions. Long-term cost is due reducing the heights of pieces; thus, we call the cost as *reduction cost*. In fuzzy bin-packing problems, the model formulates the height of a piece as a fuzzy number. So, its goal is to minimize the *height cost* and the *reduction cost*. From these costs combining, the total cost emerges.

The *fuzzy bin packing problem* alleviates the rigidity constraint of the conventional bin-packing problem. In the conventional bin-packing problem, a piece p_i is represented as an ordered pair of two real numbers, (w_i, h_i) in which w_i stands for the width, and h stands for the height. In the fuzzy bin-packing problem, we represent the piece as an ordered pair of a real number and a fuzzy number, (w_i, \tilde{h}_i) .

We define the fuzzy bin-packing problem N as a tuple with three components, $N = (B, P, \Psi)$, where B is the *bin*, P is the *set of pieces*, and W is the *reduction cost function*. The bin B is a rectangle which has a limited width (W) and an unlimited height ($H = \infty$). The set of pieces P is a collection of rectangular pieces $p_i = (w_i, \tilde{h}_i)$, where h is a fuzzy number. Therefore, we can get a membership degree for a reduced height \tilde{h}_i . At the initial height h_i^0 , the membership degree is 1. This degree is called as the *satisfaction degree*. As a trade-off for reducing the height of a piece, the reduction cost function W is also given to evaluate the additional cost due to reduction. It is a function of the satisfaction degree and the initial height.

Yet, the conventional bin-packing problems' two constraints are not changed in the fuzzy bin-packing problem. Unlike in the conventional bin-packing problem, these constraints cannot be represented by a set of inequalities because the height is a fuzzy number. Therefore, we define the two constraints using the α -cut operation of fuzzy sets. The fuzzy set A is usually represented by a mapping $\mu_A : U \rightarrow [0, \dots, 1]$. The α -cut of a fuzzy set A at the given membership degree n produces a crisp set, $\alpha(A, \mu) = \{x | \mu_A(x) \geq \mu\}$.

In this model α -cut of a fuzzy number always becomes an interval because the fuzzy number is a convex and normal fuzzy set. If we have two α -cuts of two fuzzy numbers \tilde{a} and \tilde{b} , that is, if we have $\alpha(\tilde{a}, \mu_a)$ and $\alpha(\tilde{b}, \mu_b)$, α -cut can be defined as follows:

$$\begin{aligned} & [\alpha(\tilde{a}, \mu_a), \alpha(\tilde{b}, \mu_a)] \\ &= \{x | \forall a \in \alpha(\tilde{a}, \mu_a) \text{ and } \forall b \in \alpha(\tilde{b}, \mu_b)\} \end{aligned} \quad (50)$$

$$s.t. a \leq x \leq b\}. \quad (51)$$

If the below constraints satisfy these conditions, it could be stated that the piece p_i is *contained* within the bin at the satisfaction degree μ_i .

$$x_i - w_i/2 \geq 0 \text{ and } x_i + w_i/2 \leq W, \quad (52)$$

$$[\alpha(y_i - h_i^*/2, \mu_i), \alpha(y_i + h_i^*/2, \mu_i)] \bigcap (-\infty, 0) = \emptyset. \quad (53)$$

And also if below constraints satisfy the two conditions, it could be said that the two pieces p_i and p_j are *nonoverlapping* at satisfaction degree μ_i and μ_j .

$$|x_i - x_j| \geq |(w_i + w_j)/2| \quad (54)$$

$$[\alpha(y_i - \tilde{h}_i/2, \mu_i), \alpha(y_i + \tilde{h}_i/2, \mu_i)] \cap [\alpha(y_j - \tilde{h}_j/2, \mu_j), \alpha(y_j + \tilde{h}_j/2, \mu_j)] = \emptyset \quad (55)$$

It can be said that, the packing is *feasible* with the satisfaction degrees (μ_1, \dots, μ_n) , if the bin contains all the pieces and no overlapping occurs with satisfaction degrees (μ_1, \dots, μ_n) .

Because a piece's height can be reduced by sacrificing satisfaction, the objective of the fuzzy bin-packing problem is defined by minimizing the *total cost* \hat{X} for a feasible fuzzy bin-packing.

- The total cost is defined as the sum of the *height cost* X_h .
 - The *reduction cost* X_r .
 - The height cost X_h represents the maximum height of the packing, which is similar to the conventional bin-packing problem.
 - The reduction cost X_r represents the extra cost due to the decrease in satisfaction.
- From these expressions, the total cost can be formulated as

$$\hat{X} = X_h + X_r.$$

The height cost and the reduction cost can be defined in algebraic forms. Suppose a piece p_i is located at the top of packing.

The upper edge \hat{y}_i of the piece p_i can be represented as $\hat{y}_i = \max[\alpha(y_i + (\tilde{h}_i/2), \mu_i)]$.

Therefore, we can represent the height cost as follows: $X_h = (\hat{y}_i)$. Also, the *reduction cost* X_r can be defined in an algebraic form. If all the functions sum taken, we get the reduction cost of the fuzzy bin-packing as follows:

$$X_r = \sum_i \Psi(\mu_i, h_i^0),$$

where h_i^0 is the initial height of the piece and $\Psi(\mu_i, h_i^0)$ should be defined according to the problem.

13 Fuzzy Multicommodity Flows and Edge-Disjoint Paths

In optimization techniques, we have to well define the given precise data because these problems do not include inexact and unsure data. But using the fuzzy sets as a technology coping with granular information is useful [167]. Also, generally speaking, information granules are collections of entities that usually originate at the numeric level and are arranged together due to their similarity, functional adjacency, indistinguishability, coherency, or the like [168]. As a theoretical perspective, it encourages an approach to data that recognizes and exploits the knowledge present in data at various levels of resolution or scales. In this sense, it encompasses all methods which provide flexibility and adaptability in the resolution where knowledge or information is extracted and represented, see Bargiela and Pedrycz [169] for details.

While solving optimization problems, following the principle of information granulation is important [170]. Fuzzy data, which are various in the literature [79], are used as a concept of the solution of these programs. Fuzzy network solutions, for example, fuzzy shortest path problem [171] or fuzzy minimal cost flow problem [172], are limited when compared to the classical fuzzy optimization programming problems. These problems can be stated as the minimal cost multicommodity flow problem (MCMFP).

A fuzzy number is a convex normalized fuzzy set of the real line R , whose membership function is piecewise continuous. The set of fuzzy numbers on \mathbb{R} is denoted with $\mathcal{F}(\mathbb{R})$. An LR type flat fuzzy number [171] is denoted as $\tilde{a} = (a_1, a_2, a_3, a_4)_{LR}$, if

$$\mu_{\tilde{a}}(x) = \begin{cases} L\left(\frac{a_2-x}{a_2-a_1}\right), & a_1 \leq x \leq a_2, \\ 1, & a_2 \leq x \leq a_3, \\ R\left(\frac{x-a_3}{a_4-a_3}\right), & a_3 \leq x \leq a_4, \end{cases} \quad (56)$$

where the symmetric nonincreasing function $L : [0, \infty] \mapsto [0, 1]$ is the left shape function, that is, $L(0) = 1$. Naturally a right shape function $R(.)$ is similarly defined as $L(.)$ (see Fig. 3). We denote the LR type flat fuzzy numbers on real line with $\mathcal{LR}(\mathbb{R})$.

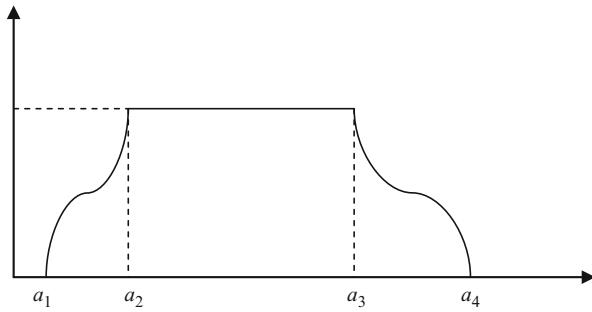

According to the extension principle, the binary operation $* \in \{+^\sim -^\sim \times^\sim \div^\sim\}$ on fuzzy number \tilde{a} and \tilde{b} with the membership functions $\mu_{\tilde{a}}(x)$ and $\mu_{\tilde{b}}(y)$ with the following:

$$\mu_{\tilde{a} * \tilde{b}}(Z) = \sup_{z=x * y} (\mu_{\tilde{a}}(x)\mu_{\tilde{b}}(y)). \quad (57)$$

Also the fuzzy scalar product of two fuzzy vectors $\tilde{x} = (\tilde{x}_1, \dots, \tilde{x}_n)$ and $\tilde{y} = (\tilde{y}_1, \dots, \tilde{y}_n)$ in $\mathcal{F}(\mathbb{R}^n)$ is defined [23] as follows:

$$\tilde{x} \times^\sim \tilde{y} = \sum_{i=1, \dots, n}^{\sim + \sim} \tilde{x}_i \tilde{x} \tilde{y}_i \quad (58)$$

Fig. 3 An *LR* type flat fuzzy number $\tilde{a} = (a_1, a_2, a_3, a_4)_{LR}$

Let $\tilde{a} = (a_1, a_2, a_3, a_4)_{LR}$ belong to $\mathcal{LR}(\mathbb{R})$. The exact formula for the extended addition and approximated formula for the extended multiplication are as follows:

$$(a_1, a_2, a_3, a_4)_{LR} \tilde{+} (b_1, b_2, b_3, b_4)_{LR} = (a_1 + b_1, a_2 + b_2, a_3 + b_3, a_4 + b_4)_{LR} \quad (59)$$

$$(a_1, a_2, a_3, a_4)_{LR} \otimes (b_1, b_2, b_3, b_4)_{LR} = (a_1.b_1, a_2.b_2, a_3.b_3, a_4.b_4)_{LR} \quad (60)$$

where $\tilde{a} \geq 0$ and $\tilde{b} \geq 0$.

LR fuzzy number could not be attained with multiplication of two *LR* fuzzy numbers. In a situation like this, interpolation methods to get a fuzzy number could be used, whose some α -cuts are equal to the multiplication of two μ -cuts of corresponding operands. The details of this idea [173] and scalar multiplication are derived as follows:

$$\lambda(a_1, a_2, a_3, a_4)_{LR} = (\lambda a_1, \lambda a_2, \lambda a_3, \lambda a_4)_{LR'}$$

where $\lambda \geq 0$.

$\tilde{b} - \tilde{a}$ is not really a difference and is rather unnatural with respect to a linear structure. For example, $\tilde{b} \tilde{+} (-1)\tilde{a}$ is not compatible with the difference in the function space. But the Hukuhara difference [174], defined as the solution for \tilde{x} in the equation $\tilde{a} \tilde{+} \tilde{x} = \tilde{b}$ if it exists, does coincide with the difference in the function space. This property justifies the application of this difference instead of the fuzzy number, $\tilde{b} \tilde{+} (-1)\tilde{a}$.

Hukuhara [174], Diamond and Korner [175], and Ghatee et al. [176] entitled as Hukuhara difference is observed to identify these differences as follows:

Definition 14 For \tilde{a} and \tilde{b} belong to $\mathcal{LR}(\mathbb{R})$ if the Hukuhara difference $\tilde{b} \ominus_H \tilde{a}$ exists, it is given by

$$[\tilde{b} \ominus_H \tilde{a}]_\alpha = \{\varsigma \in \mathbb{R} \mid [\tilde{a}]_\alpha \tilde{+} \{\varsigma\} \subseteq [\tilde{b}]_\alpha\}, \quad (61)$$

where \pm in the above equation for two sets \bar{X} and \bar{Y} means as follows:

$$\bar{X} + \bar{Y} = \{x + y | x \in \bar{X}, y \in \bar{Y}\}$$

For some cases, it can be proved that

$$(b_1, b_2, b_3, b_4)_{LR} \ominus_H (a_1, a_2, a_3, a_4)_{LR} = (c_1, c_2, c_3, c_4)_{LR'}$$

where

$$c_1 = b_1 - a_1, \quad c_2 = b_2 - a_2, \quad c_3 = b_3 - a_3, \quad c_4 = b_4 - a_4.$$

From this definition it can be said that Zadeh's difference is not true because $\tilde{a} \ominus_H \tilde{a}$ is zero.

Therefore, this operator for solving systems seems to be more accurate and reasonable results in comparison with Zadeh's difference.

Definition 15 For \tilde{a} and \tilde{b} belong to $\mathcal{LR}(\mathbb{R})$, we have:

$$\tilde{b} \ominus_H \tilde{a} = (b_1, b_2, b_3, b_4)_{LR} \ominus_H (a_1, a_2, a_3, a_4)_{LR} = (b_1 - a_1, b_2 - a_2, b_3 - a_3, b_4 - a_4)_{LR}.$$

13.1 Minimal Cost Multicommodity Flow Problem

The minimal cost multicommodity flow problem (MCMFP) which transships the flows of the commodities by minimal cost has been evaluated in this section.

The MCMFP satisfies the demand for each commodity at each vertex without violating the constraints imposed by the supply–demand and capacity.

Let N and A be the sets of nodes and links, and for a given network $G = (N, A)$: general MCMFP can be expressed:

$$\min \sum_{t=1}^T \sum_{ij \in A} c_{ij}^t x_{ij}^t, \quad (62)$$

$$\text{s.t. } \begin{cases} \sum_{t=1}^T x_{ij}^t \leq u_{ij}, \forall (i, j) \in A \\ \sum_{j:(i,j) \in A} x_{ij}^t - \sum_{j:(j,i) \in A} x_{ji}^t = b_i^t, \quad \forall i \in N = 1, \dots, T. \end{cases} \quad (63)$$

The notations are as follows:

- x_{ij}^t is a positive integral regarding the amount of flow from t th commodity which streams through link (i, j) .
- u_{ij} is the capacity of link (i, j) .
- T is the number of commodities.
- Moreover, for commodity t , c_{ij}^t and b_i^t are the unit cost of flow through link (i, j) .
- The supply or demand of node i .

If not change the variables, it can be assumed that each commodity has one resource and one customer without loss of generality [177]. Also r^t , s^t , and d^t denote the resource node, the customer node, and the travel demand for a given commodity t , respectively. Then, the following model regarding the path-flow variables is met:

$$\min \sum_{t=1}^T \sum_{p \in p^t} c_p^t f_p^t, \quad (64)$$

$$\text{s.t. } \begin{cases} \sum_{p \in p^t} f_p^t = d^t, & \forall t = 1 \dots, T, \\ x_{ij} = \sum_{t=1}^T \sum_{p \in p^t} \delta_p^{i,j} f_p^t \leq u_{ij}, & \forall (i, j) \in A, \end{cases} \quad (65)$$

where the flow of commodity t along the path p is denoted by f_p^t .

Additionally, $\delta_p = (\delta_p^{i,j})_{(i,j) \in A}$ is link-path incident vector and assigns 1 when the link (i,j) shares in path p and 0 otherwise. p^t includes all of the directed paths joining r^t and s^t .

From the first constraint, it can be said that the demand for each commodity is supplied by the path flows activated for that commodity. Including the link (i,j) , x_{ij} denotes the sum of flow of individual paths, and the other constraint shows the total flow is less than its capacity.

Equally important, vast majority of this classic model is deterministic. While this problem is influenced by social and economic interactions and is dependent on users' perceived information and granular information, one assumes the travel cost and demand to be known a priori for the entire links and nodes [177]. On the other hand, granular computing offers a landmark change from the current machine-centric to human-centric approach in information and knowledge and is an emerging conceptual and computing paradigm of information processing. It has been motivated by the urgent need for intelligent processing of empirical data that is now commonly available in vast quantities, into a humanly manageable abstract knowledge.

In other words, the granular computing's theoretical foundations involve fuzzy sets, rough sets, and random sets that linked together in a highly comprehensive treatment of this emerging paradigm [178]. In transportation concepts, due to granular information and the different provision of traffic information, the different types of transportation might be deduced. Now, we consider a case that the data of MCMFP have been exhibited with $\mathcal{LR}(\mathbb{R})$ numbers, which handle vagueness as an important category of uncertainty. So, first, we elaborate the origin of fuzziness in real problems. In the next section, two extended variants to take uncertain travel cost, and uncertain travel demand into account will be explained.

13.2 Fuzziness in Real Transportation Problems

In uncertainty modeling, transportation models adopted with fuzzy relations and quantities can contribute stochastic versions. In other words, since the classical random utility-based approach is not sufficient for uncertainty handling, some

alternate solution to probability-based models, for example, Ghatee and Hashemi [179], may be obtained with possibility-based methods. Initially Das et al. [180] applied fuzzy logic tools to transportation problems. Then, many researches are conducted particularly on this problem. From a high level categorization, in real networks, such as urban networks, we face the following three uncertainty sources:

- Unsure network topology (a network with fuzzy nodes and fuzzy links)
- Inexact travel cost (a network with fuzzy link cost)
- Imprecise travel demand (a network whose nodes include fuzzy excess or fuzzy deficit)

When the supply and demand of nodes and the capacity and cost of links are represented as fuzzy numbers, finding the lowest transportation cost of some commodities through a capacitated network is the aim of fuzzy transportation. This problem is a new branch in combinatorial optimization and network flow problems [79]. Some applications of such standpoint were presented in industries [181] such as the one we will discuss in the next section.

13.3 MCMFP in Fuzzy Environment

MCMFP is widely used in engineering and economics contexts. In urban transportation systems problems and production–distribution problems, this method emerges. Also, in designing telecommunication networks, it also has an important role. In all of aforementioned problems, finding the lowest transportation cost of some commodities through a capacitated network in order to satisfy demands at certain nodes, using available supplies at other nodes, is crucial.

Since this model is influenced by complex social and political interactions, this problem is dependent on user perception of information and nondeterministic factors of the network. Considering fuzzy numbers as the amount of supplies, demands, capacities, and costs provides a reasonable infrastructure is used to handle vagueness as an important category of uncertainty. Such an implementation of MCMFP can be applied to recognize the appropriate models of traffic assignment with intelligent agents; see, for example, [179] for details.

Ghatee and Hashemi treat with the minimal cost multi commodity flow problem (MCMFP) in the setting of fuzzy sets, by forming a coherent algorithmic framework, referred to as a fuzzy MCMFP. Given the character of granular information captured by fuzzy sets, the objective is to find multiple flows satisfying the demands of commodities, by using available supplies consuming the least possible cost. Having this aim in mind, the supply and demand of nodes may be presented linguistically; the travel cost and capacity of links can be defined under uncertainty as well. Then, to solve the problem, two efficient algorithms are motivated. In the first algorithm, they utilize fuzzy shortest paths and K-shortest paths to generate preferred and absorbing paths, and then they find the flow on them by solving a classic MCMFP. Coupled with the first, the second algorithm exhibits with fuzzy supply–demand and employs a total order on trapezoidal fuzzy numbers to reduce the fuzzy MCMFP into four classic MCMFPs [182].

13.4 MCMFP with Uncertain Travel Cost

Under traffic conditions, it is necessary to reflect a driver's perception of link travel time. For this purpose fuzzy sets of perceived link travel time are developed due the fuzziness of a driver's perception over link travel time.

There are various traffic conditions such as congestion and construction or incident, so for most frequent traffic conditions, it is necessary to construct fuzzy sets. To show these fuzzy set, Liu et al. [183] used linguistic descriptions. Obviously, if necessary, more fuzzy sets can be constructed to show other traffic conditions. Additionally, Henn [184] considered the meaning of fuzzy costs in fuzzy traffic assignment models.

In this chapter, assume that the cost, the length, or the travel time of a link (i,j) for commodity t is given by

$$\tilde{c}_{i,j}^t = (c_{(i,j),1}^t, c_{(i,j),2}^t, c_{(i,j),3}^t, c_{(i,j),4}^t) \in \mathcal{LR}(\mathbb{R}). \quad (66)$$

Then for shipping T commodities through the network, we can write:

$$\min \sum_{t=1}^T \sum_{p \in p^t} \tilde{c}_p^t f_p^t \quad (67)$$

$$s.t. \begin{cases} \sum_{p \in p^t} f_p^t = d^t, & \forall t = 1, \dots, T, \\ x_{ij} = \sum_{t=1}^T \sum_{p \in p^t} \delta_p^i f_p^t \leq u_{ij}, & \forall (i, j) \in A, \end{cases} \quad (68)$$

(69)

where $\tilde{c}_p^t = \sum_{(i,j) \in p} \tilde{c}_{i,j}^t$ for each $p \in p^t$.

This problem has an important concept that is the way of generating the absorbing and preferred paths p^t . Usually, the column generation approach [185] is used for solving the classic MCMFP. But we can take path enumeration techniques, which include a great number of algorithms with the capability of finding reasonable and preferred paths through a network, to understand p^t . In this method, the preference can be defined in terms of time, cost, distance, or some combination of these items. These reasonable paths are the base of problems consisting of path-flow variables.

14 Fuzzy Network Design Problems

In recent years, with the advance of computation evolutionary, new methods such as the optimal design of neural networks and fuzzy systems have been represented in the literature. For solving more complex real-world problems, computation evolutionary provides more robust and efficient approaches.

Network design is a combinatorial optimization problem involving optimization of several objectives such as cost, average delay, and reliability of network. Similarly, search space of the problem is huge even for small number of computers

and is intractable for nonevolutionary approaches. A network is basically a graph G of a set of nodes N and a set of links L . The links denote the connections between the nodes and are assumed to be directional.

In formulating and solving engineering or management problems, network flow models provide a rich and powerful framework. For problems such as transportation systems, communication networks, project schedules, inventory systems and man/machine allocation, there have been studies in the literature [185]. In theory and practice, this model is particularly important and it is considered in uncertain environment by many researchers [186]. Transportation models adopted with fuzzy relations and quantities can contribute stochastic versions in uncertainty modeling. More specifically, since the classical random utility-based approach is not sufficient for uncertainty handling, some alternate solution to probability-based models may be obtained with possibility-based methods; see, for example, Ghatee and Hashemi [179]. However, in order to refer their historical background, fuzzy logic tools have initially been applied to transportation problems by Das et al. [187]. Then, great attention has been focused on this problem. From a high-level categorization, in real networks, such as urban networks, there are three uncertainty sources:

- Unsure network topology (a network with fuzzy nodes and fuzzy links)
- Inexact travel cost (a network with fuzzy link cost)
- Imprecise travel demand (a network whose nodes include fuzzy excess or fuzzy deficit)

The aim of fuzzy transportation is to find the lowest transportation cost of some commodities through a capacitated network when the supply and demand of nodes, capacity, and cost of links are represented as fuzzy numbers. Given the character of granular information captured by fuzzy sets (where one could capitalize on the nonbinary character of their membership functions), such methods are capable of handling the decision-maker's risk taking. This problem is a new branch in combinatorial optimization and network flow problems [79, 179]. Some applications of such standpoint were presented in industries [188].

Furthermore, the network design problem is one of the most important problems in combinatorial optimization, which has been considered by many researchers and engineers [189]. The aim of this problem is to design a network to satisfy the demand of users who wish to travel through the network by consuming minimum construction cost. Steiner tree is the traditional variants of this problem, which have been applied to design communication and water networks [185]. In some cases, a network exists, and the management wishes to extend the network to satisfy future demand. The extension of a network can also be considered by interchanging the objectives such as cost, reliability, mobility, and accessibility. To consider such concepts, the designer needs to consider a great number of concepts. One important point in this problem is the granular information about this problem, because designing is done for a long-term period and the future statues cannot to be considered in a clear manner. It is worth reporting the sources of uncertainty in measurement of data in this problem [190]:

- The demand for transportation of each node, which is dependent on many items such as time, season, and weather conditions
- Linguistic definition of important travel

- Imperfect realization of the definition of important travel
- Nonrepresentative sampling (the sample measured may not represent the defined travels)
- Inadequate knowledge of the effects of environmental conditions on the measurement or imperfect measurement of environmental conditions.
- Personal bias in reading analogue instruments
- Finite instrument resolution or discrimination threshold
- Inexact values of measurement standards
- Inexact values of traffic constants and other parameters obtained from external sources and used in the data-reduction algorithm
- Approximations and assumptions incorporated in the measurement method and procedure
- Variations in repeated observations of travel under apparently identical conditions
- The minimum cost flow problem (MCFP) as mentioned before is a general structure in these models which provides a unified approach to many applications.

To design a network after processing these granular information, one can consider fuzzy numbers as transportation and construction costs, and with respect to these parameters, the following model may be expressed:

$$\begin{aligned}
 & \min \sum_{t=1:T}^{\mp} \sum_{(i,j) \in A}^{\mp} \tilde{c}_{ij}^t \tilde{x}_{ij}^t + \sum_{(i,j) \in A} \tilde{\mu}_{ij} z_{ij}, \quad \forall k = 1, \dots, K, \\
 & \text{s.t. } \begin{cases} \sum_{\{j:(i,j) \in A\}}^{\mp} \tilde{x}_{i,j}^t \ominus H \sum_{\{j:(j,i) \in A\}}^{\mp} \tilde{x}_{j,i}^t = \tilde{b}_i^t, & \forall i \in N, \forall t = 1, \dots, T, \\ \sum_{t=1:T}^{\mp} \tilde{x}_{(i,j),k}^t \leq \tilde{u}_{(i,j),k}, & \forall (i, j) \in A, \forall k = 1, \dots, 4 \\ 0 \leq \sum_{t=1:T}^{\mp} \tilde{x}_{ij}^t \leq \tilde{u}_{(i,j),k} z_{ij}, & \forall (i, j) \in A, \forall k = 1, \dots, 4 \end{cases}
 \end{aligned} \tag{70}$$

where \tilde{x}_{ij}^t is the fuzzy flow of commodity t and variables $z_{ij} \in \{0, 1\}$ are associated with the construction of link $(i, j) \in A$; $z_{ij} = 1$, if (i, j) belongs to the final solution; otherwise, $z_{ij} = 0$. The objective function (Eq. 70) is the sum of variable and fixed fuzzy costs. In this function c is the linear fuzzy cost associated with fuzzy flow of t th commodity through link (i, j) , and $\tilde{\mu}_{ij}$ is the fixed fuzzy cost associated with the selection of link (i, j) in the final solution. θ is a control parameter implying the trade-off between two objective functions.

14.1 Steiner Tree Problem

One of the most basic versions of finding a subgraph that optimizes some global cost function is known as the minimum weight Steiner tree [191] (or the minimum Steiner tree problem, MST) is a problem in combinatorial optimization, which may be formulated in a number of settings, with the common part being that it is required to find the shortest interconnect for a given set of objects.

Given an undirected graph with positive weights on the edges, the MST problem consists in finding a connected subgraph of minimum weight that contains a selected set of “terminal” vertices [192]. Such construction may require the inclusion of some nonterminal nodes which are called Steiner nodes. Clearly, an optimal subgraph must be a tree. Solving MST is a key component of many optimization problems involving real networks. Concrete examples are network reconstruction in biology (phylogenetic trees and regulatory subnetworks), Internet multicasting, circuit design, and power or water distribution networks design, just to mention few famous ones. MST is also a beautiful mathematical problem in itself which lies at the root of computer science being both *NP* complete [193] and difficult to approximate [194]. In physics the Steiner tree problem has similarities with many basic models such as polymers, self-avoiding walks, or transport networks (e.g., [195]) with a nontrivial interplay between local and global frustration. The Steiner tree problem has applications in circuit layout or network design. Most versions of the Steiner tree problem are NP complete.

The Steiner tree problem is superficially similar to the minimum spanning tree problem: given a set V of points (vertices), interconnect them by a network (graph) of shortest length, where the length is the sum of the lengths of all edges. Difference between the Steiner tree problem and the minimum spanning tree problem is that, in the Steiner tree problem, extra intermediate vertices and edges may be added to the graph in order to reduce the length of the spanning tree. These new vertices introduced to decrease the total length of connection are known as Steiner points or Steiner vertices. It has been proved that the resulting connection is a tree, known as the Steiner tree. There may be several Steiner trees for a given set of initial vertices.

The fuzzy steiner tree (FST) problem on a graph is the version of the classical ST problem where edge weights are defined as fuzzy numbers. Seda [196] provided a modification of the shortest paths approximation for solving FST problem. Linear triangular fuzzy numbers as the edge weights and Cheng’s centroid point fuzzy ranking method were used in his study [196].

15 Fuzzy Traveling Salesman Problem

Traveling salesman problem (TSP) is finding the shortest route for a given number of cities. It is one of the most widely studied combinatorial optimization problems [197]. Main characteristics of TSP are that every city has to be visited and no profit is associated to the cities.

TSP is one of the most widely studied combinatorial optimization problems. This has led to numerous extensions and modifications of the basic TSP.

A variant of TSP where a profit value is associated to each city and cities are selected depending on their profit is proposed in the literature. Feillet et al. [198] define these kinds of problems as TSP with profit [198].

The problem in which cities are selected to be visited depending on the profit associated with them is called traveling salesman problem with profit (TSP with profit). TSP with profit is encountered in many different situations. For instance,

it may not be possible to visit every city in a TSP application. In this kind of application, some constraints can enforce selection of cities to be visited. Balas and Martin [199] introduce the scheduling of daily operations of a steel rolling mill, which is an application of TSP with profit. This problem gives rise to a prize collecting traveling salesman problem (prize collecting TSP) with penalty terms in the objective function.

In the literature, TSP with profit is studied as a single-objective problem. The only attempt to solve TSP with profit as a biobjective problem is studied by Keller and Goodchild [200]. The main difference of biobjective approach compared to a single-objective approach is finding not only one but Pareto optimal solutions. By finding more solutions, the trade-off among them can be analyzed to make better decision. The purpose of this study is to develop a multiobjective approach for the biobjective TSP with profit in order to obtain the Pareto optimal solutions.

The TSP can be described as follows:

In the graph $G = (V, E)$, V is the set of nodes, or cities, and E is the set of edges, $E = \{(a, b) : a, b \in V\}$. The Euclidean distance between a and b is D_{ab} , supposing that $D_{ab} = D_{ba}$. The object of TSP is to find a minimal-length closed tour that visits each city once and only once, and the closed tour is also called Hamiltonian cycle. TSP has been proven to be an NP complete problem.

15.1 Fuzzy Matrix to Represent TSP Solution

When domains X, Y are finite sets, fuzzy relation can be expressed by fuzzy matrix. Suppose $X = \{X_1, X_2, \dots, X_m\}; Y = \{Y_1, Y_2, \dots, Y_n\}$, then the fuzzy relation from X to Y can be expressed as follows:

$$R = (r_{ij})_{m \times n} = \begin{bmatrix} r_{11} & \cdots & r_{1n} \\ \vdots & \ddots & \vdots \\ r_{m1} & \cdots & r_{mn} \end{bmatrix}. \quad (71)$$

Here $r_{ij} \in [0, 1]$ represents the degree of membership of the i th element X_i in domain X and the j th element Y_j in domain Y to relation R . First we introduce the following definitions:

Definition 16 Set S is a sequence of a TSP solution,

if $S = \{S_1, S_2, \dots, S_n\}$, n is the number of the cities, $S_i(i \in \{1, 2, \dots, n\})$ is the i th node in the visit tour (TSP solution).

Definition 17 Set N is the serial number of a TSP,

if $N = \{N_1, N_2, \dots, N_n\}$, n is the number of the cities, $N_i(i \in \{1, 2, \dots, N\})$ represents the concrete node (city) in a TSP problem.

Explanation: For each element in Set S , S_i means that current tour has visited $i-1$ nodes and will visit the i th nodes. The state space can be expressed as S_s ,

$$S_s = S \times N = \{(S_i, V_j) | S_i \in S, N_j \in N\}. \quad (72)$$

The fuzzy relation R of S and N has the following meaning: for each element in the matrix R ,

$$r_{i,j} = \mu_R(S_i, N_j), (0 < r_{i,j} < 1). \quad (73)$$

μ_R is the membership function; the value of r_{ij} means the degree of membership that the i th node S_i in the feasible solution S “choose” the node with the serial number of N_j in a concrete problem.

15.1.1 Fuzzy Branch-and-Bound Algorithm

In this algorithm, each node is a particular schedule and tree structure is used in this model. The strategy of “breath first search” is used to determine the best partial schedule node to branch, the lower-bound values for completion times of whole partial schedule limits are calculated, and the node having the least value is chosen. Branching from lowest bound, the procedure is repeated at each time. The nodes having highest values of the lower bounds than the completion time of this schedule are fathomed after obtaining an order where all jobs are scheduled.

As shown below, A indicates the set of scheduled jobs. In Eq. 2, the lower-bound value of fuzzy completion time of each schedule beginning with A is calculated.

$$\tilde{AS}_{(A)} = \max \begin{cases} \tilde{\alpha}_{(A)} \oplus \sum_{i \in U} \tilde{P}_{i1} \oplus \min_{i \in U} \{\tilde{P}_{i2} + \tilde{P}_{i3}\} \\ \tilde{\beta}_{(A)} \oplus \sum_{i \in U} \tilde{P}_{i2} \oplus \min_{i \in U} \{\tilde{P}_{i3}\} \\ \tilde{\gamma}_{(A)} \oplus \sum_{i \in U} \tilde{P}_{i3} \end{cases} \quad (74)$$

In this equation:

- r_{ij} : Fuzzy operation time of i th job on j th workstation
- U : The set of jobs which are not scheduled
- $\tilde{\alpha}_A$: Completion time of the last job in schedule A on the first machine
- $\tilde{\beta}_A$: Completion time of the last job in schedule A on the second machine
- $\tilde{\gamma}_A$: Completion time of the last job in schedule A on the third machine

In this model, firstly the first machine assumed to operate first and third machine as last.

The completion times of the jobs on the machines are calculated by using Eqs. 3 and 4. If there is only one job in the set of A , then the completion times are computed by Eq. 3. If there is more than one job, then Eq. 4 is used.

$$\tilde{\alpha}_i = \tilde{P}_{i1}, \tilde{\beta}_i = \tilde{P}_{i1} \oplus \tilde{P}_{i2}, \tilde{\gamma}_i = \tilde{P}_{i1} \oplus \tilde{P}_{i2} \oplus \tilde{P}_{i3} \quad (75)$$

$$\tilde{\alpha}_{(A)} = \tilde{\alpha}_{(A-i)} \oplus \tilde{P}_{i1} \quad (76)$$

$$\tilde{\beta}_{(A)} = \max\{\tilde{\beta}_{(A-i)}, \tilde{\alpha}_{(A)}\} \oplus \tilde{P}_{i2} \quad (77)$$

$$\tilde{\gamma}_{(A)} = \max\{\tilde{\gamma}_{(A-i)}, \tilde{\beta}_{(A)}\} \oplus \tilde{P}_{i3} \quad (78)$$

After fuzzy lower-bound values for nodes are calculated, branching from the lowest bound to form new nodes for all jobs is not scheduled yet. This process is continued until all jobs are scheduled. Addition and maximum operations are fuzzy operations in this computation process.

Lee and Li's [201] approach is used for ranking in the maximum operation. They propose the use of generalized mean and standard deviation based on the probability measures of fuzzy events to rank fuzzy number. Let us assume that two fuzzy sets, where each member is a number,

$$\tilde{\alpha}_1 = \{(\mu_{x_1}, x_1), (\mu_{x_2}, x_2)\} \quad (79)$$

$$\tilde{\alpha}_2 = \{(\mu_{y_1}, y_1), (\mu_{y_2}, y_2), (\mu_{y_3}, y_3)\} \quad (80)$$

are given. The dimensions of the fuzzy numbers can be various. By using the extension principle, the addition of $\tilde{\alpha}_1$ and $\tilde{\alpha}_2$ is calculated as follows:

$$\begin{aligned} \tilde{\alpha}_1 \oplus \tilde{\alpha}_2 = & \{(\min(\mu_{x_1}, \mu_{y_1}), (x_1 + y_1)), \\ & (\min(\mu_{x_2}, \mu_{y_2}), (x_1 + y_2)), (\min(\mu_{x_1}, \mu_{y_3}), (x_1 + y_3)), \\ & (\min(\mu_{x_2}, \mu_{y_1}), (x_2 + y_1)), (\min(\mu_{x_2}, \mu_{y_2}), (x_2 + y_2)), \\ & (\min(\mu_{x_2}, \mu_{y_3}), (x_2 + y_3)) \end{aligned} \quad (81)$$

If there are more than one $(x_i + y_j)$ having the same value, then only the one having the largest membership degree is kept.

According to Agin [202], branch and bound is a powerful method capable of solving combinatorial problems with nonlinear, discontinuous, or nonmathematically defined objective functions and under several types of constraints. In branch-and-bound method, a tree structure which consists of properly connected nodes is established. Throughout the search, constraints imposed by the problem should be taken into account. Agin [202] divides these into two groups, namely, implicit and explicit constraints. In a successfully developed branch-and-bound algorithm, implicit constraints are satisfied by the manner in which the search tree is established. Explicit constraints, however, are to be considered in each step of the search. An example to implicit constraints might be given as the precedence relations, whereas explicit constraints might be exemplified by resource limitations in RCPSP [203]. A feasible solution to the problem, therefore, has to assign numerical values to the set of decision variables (e.g., start dates of all activities in RLP and RCPSP) so that both implicit and explicit constraints are satisfied.

Nodes, of which a search tree consists of, are subsets of the set of all solutions of the combinatorial problem. Branching, on the other hand, is the partitioning of any set of feasible solutions into separate subsets [202].

Branching process starts from the root node (the node in the uppermost level of the tree) which represents the set of all solutions. In some instances during the search, there might be nodes from which no branching has occurred yet. These nodes which are to be discovered further are called intermediate nodes. On the contrary to intermediate nodes which imply a partial solution, final nodes represent a complete solution. In order to reach a final node (leaf), all decisions required to establish a valid solution set have to be made. In RLP, for example, a leaf stores start dates of all noncritical activities. Obviously final nodes are located in the lowermost level of the search tree.

Two main characteristics of branch-and-bound algorithms presented by Agin [202] are branching characteristic and bounding characteristic. According to the definitions provided, branching characteristic ensures that an optimal solution is going to be reached at the end of the search since all possible combinations are going to be considered, whereas bounding characteristic implies a possibility to reach the optimal solution without visiting each node by pruning some parts of the tree.

Finally definition of the lower bound should be given since this concept is in the very heart of the branch-and-bound logic. Lower bound is a value of the objective function for all solutions included in a specific node such that none of the solutions that could be branched from that node will have a better objective function value than that bound. As this definition implies, there is no use to branch a node any further if its lower-bound value is worse than the objective function value of one of the explored final nodes (complete solutions). Objective function value of the best complete solution explored so far, that is, upper bound, is used to decide whether a node is promising or not. Obviously, upper bound at the end of the search provides the optimal solution to the problem.

According to Agin [202], a branch-and-bound algorithm might be said to consist of rules for:

1. Deciding on how to continue the search given an intermediate node (branching rule)
2. Deciding on how to calculate lower bounds on each established node
3. Deciding on the intermediate node from which to branch next
4. Recognizing when a node contains only infeasible or nonoptimal solutions
5. Recognizing optimal solutions encountered on final nodes

16 Fuzzy Facility Location

In earlier studies in location problems literature, we saw that this area firstly related to industrial contexts, referring to the supply of a single commodity from a set of potential locations, where facilities may be placed, to clients of known locations and demands, at minimum cost. Location problems consist of determining the locations of the facilities and the flows of the commodity from facilities to clients at a minimum cost.

Facility location selection that exhibits a significant impact on market share and profitability is critical and also has strategic issues in supply chain design and management [204, 205].

Solving the problems in which the demands and the costs are deterministic, many efficient methods are used. In the literature there are some examples such as the following: Akinc and Khumawala [206] used a branch- and-bound algorithm for a capacitated warehouse location problem. Dearing and Newruck [207] developed an implicit enumeration algorithm with Lagrange relaxation for a capacitated bottleneck facility location problem. Badri [208] used analytic hierarchy process with multiobjective goal programming methods for a facility location. Dupont [209] introduced a new type of facility location model with a concave global cost function and proposed a branch-and-bound algorithm for this model. For other types of methods also some examples in the literature, for example, Drezner and Hamacher [210], Ernst and Krishnamoorthy [211], Lozano et al. [212], and Misra et al. [213].

Facility location problem copes with the imprecise or qualitative nature of the linguistic assessment in real applications. Also this problem processes imprecise, uncertain, or vague data, such as the imprecise experience-based demands of the clients or the costs of operating the facilities. The imprecise nature of these data is due to the fact that the precise and complete historical data are usually unavailable in real situations. To the former, fuzzy sets and fuzzy logic [104, 214–216] are suitable methods of dealing with the linguistic assessment.

For example, Batanovi et al. [217] discussed a class of fuzzy maximum covering location problems in networks by assuming that the relative weights of demand nodes are imprecise and described by linguistic expressions and developed algorithms for choosing the best facility locations based on comparison operations on discrete fuzzy sets. Bhattacharya et al. [218] considered facilities located under multiple fuzzy criteria and proposed a fuzzy goal programming approach to deal with the problem. Ishii et al. [219] developed a location model by considering the customer satisfaction degree with respect to the distance of each customer from the facility. Kahraman et al. [220] solved facility location problems by using four different approaches to fuzzy multiattribute group decision-making, that is, fuzzy model of group decision, fuzzy synthetic evaluation, Yager's weighted goals method, and a fuzzy analytic hierarchy process.

Uncertainty is closely related to risks that include environmental and organizational. For the companies it is important to reduce risks that involves in their location decisions in order to enhance customer service and improve their business processes, to result increasing competitiveness and profitability. Uncertain parameters based on fuzzy set theory [95, 221–223] have been developed, which aim to deal with the cases of imprecise or vague data. For instance, Bhattacharya et al. [224] considered facilities located under multiple fuzzy criteria and proposed a fuzzy goal programming approach to deal with the problem. Ishii et al. [225] developed a location model by considering the satisfaction degree with respect to the distance from the facility for each customer. Assuming that demands of customers are represented as fuzzy variables, Wen and Iwamura [226] presented a continuous α -cost facility location model employing Hurwicz criterion, while

Zhou and Liu [227] presented three types of continuous capacitated location-allocation problem with different decision criteria.

Stochastic problems deal with the cases where the parameters are treated as random variables. In real applications, randomness and fuzziness may coexist in a facility location problem. Due to the fact that there are some variables such as subjective judgment, imprecise human knowledge and perception in capturing statistical data may embrace randomness and fuzziness at the same time or some data that belong to the history for the location problems may be insufficient. Therefore, the experience-based fuzzy information can be incorporated into the originally available statistic data. In both cases, there is a genuine need to deal with a hybrid uncertainty containing simultaneously randomness and fuzziness. The concept of fuzzy random variables [228–230] was introduced to quantify and deal with the phenomena in which vagueness and randomness appear at the same time. This formalism serves as a basic tool to construct a framework of decision-making models operating in a fuzzy and random environment.

Abstract

This chapter focuses on geometric optimization problems including localization, routing, and boundary recognition. These topics are not new in networks. But wireless networks bring a lot of new ingredients and challenges to the problems. For example, because of the lack of central control unit, limited capabilities of sensors, limited transmission range, mobility features, etc., it is desirable to achieve the global tasks by utilizing local information in a distributed way. The focus is put on the main ideas of recent methods.

1 Introduction

Geometric optimization problems such as localization and routing are classic topics in the study of networks. With the emergence of wireless networks, new challenges are brought into these problems. First, in a large-scale wireless network, it is difficult to control all the processing by a center; distributed computation is more preferred. Second, the sensors are often small and cheap, which cannot afford expensive measuring devices such as GPS, and have limited computation and storage capability. Third, sensors are often equipped with a limited power. In many cases, the battery cannot be replenished. To save energy, the transmission range cannot be too long (thus nodes can only communicate with a limited number of neighbors), and algorithms should be light weighted on the nodes. Mobility is also a negligible feature of wireless network. When some sensors move or are depleted of energy, local adjustment is preferred to restore the functionality of the network.

The focus of this chapter is on geometric optimization problems in three fields: localization, routing, and boundary recognition. Due to the immense reservoir of literatures in these fields, this chapter is far from a comprehensive survey. The focus is put on the main ideas of recent methods.

2 Localization

In a wireless network, knowing the positions of the nodes is a basis for a lot of applications, for example, reporting the site of an event, drawing a map of a region, tracking targets, and helping the routing. Since the network usually consists of a huge amount of nodes which are deployed randomly or in an ad hoc fashion, it is hard to know the locations of the nodes *a priori*. Global Positioning System (GPS) is a widely used technique for localization. However, in some applications, GPS is not preferred due to the following reasons: (a) Inaccessibility: in a region dense of foliage or other obstacles, the signals will be blocked from the GPS satellites. (b) Power consumption: long distance signal transmission depletes the battery of the nodes quickly and reduces the lifetime of the entire network. (c) Cost and size: in a wireless sensor network, sensors are usually very cheap and as small as coins, which cannot afford the equipment of a GPS. In such a circumstance, *self-positioning* in a distributed manner is more preferred.

In many applications, a small fraction of the nodes are supposed to know their positions, either through manual placement or using GPS. These nodes are called *landmarks* or *anchors*. The other nodes are called *unknowns*. Due to power restrictions, a node can only communicate with those nodes which are very near to itself. In this setting, a large number of nodes are not in direct communication with the landmarks. The problem is how to utilize local information collected at each node over multi-hops to determine the positions of all the nodes. This task is significantly complicated when the field is *anisotropic*, that is, either the nodes are distributed irregularly or there are holes in the field.

[Section 2.1](#) first introduces the basic technique *multilateration* used to determine the positions of the unknowns using local *range measurement* and some refinements on the technique. Then, the technique of *rendered path* is introduced which is used in [59] to deal with anisotropic field. [Section 2.2](#) introduces the technique used to locate the unknowns using local *angle measurement*. To further minimize the cost of network configuration (without range or angle measurement), it is desirable to locate the nodes based *only* on the connectivity information. This topic is addressed in [Sect. 2.3](#). One problem occurs in the implementation is the location ambiguity: There exist different embeddings of the nodes satisfying the same connectivity and measure requirements (see, e.g., [Fig. 3](#)). Works focusing on the ambiguity issues are introduced in [Sect. 2.4](#).

Error issues in range-based, angle-based, range-/angle-free, and multimodal algorithms were further addressed in [68]. Robust statistical methods were proposed in [61] to make a localization system attack tolerant. This survey omits addressing these works in details. The interested reader may refer to the corresponding papers.

2.1 Range-Based Localization

In range-based localization, the local information known to a node includes the list of its neighbors as well as the distances between its neighbors and itself, which can be estimated by received signal strength (RSS) or time of arrival (ToA) or time difference of arrival (TDoA).

2.1.1 Multilateration

The idea of *iterative multilateration* was proposed in [76, 77] in which position information is propagated from landmarks to the unknowns and the unknowns determine their positions by solving least square optimization problems. In [66], the propagated information is the estimated distances, which is utilized by a GPS-like mechanic to locate the unknowns.

The terminology *beacons* used in [76] refer to the landmarks initially. The localization is executed in an iterative way: Unknowns which are in the neighborhood of enough beacons can determine their positions in a so-called atomic multilateration way; as soon as an unknown knows its position, it becomes a beacon and is used to determine the positions of more neighboring unknowns. This process is called *iterative multilateration*.

The atomic multilateration is introduced in the following: If an unknown has three beacon neighbors which are not colinear, its position can be determined by

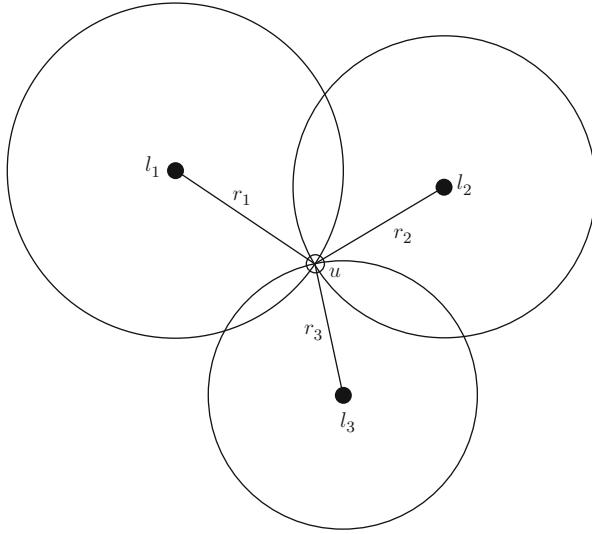

Fig. 1 Trilateration: A node which has distances r_1, r_2, r_3 to three noncollinear landmarks l_1, l_2, l_3 locates at the intersection point of the three circles C_1, C_2, C_3 , where C_i is the circle with center l_i and radius r_i

trilateration (see Fig. 1). If an unknown has four or more beacon neighbors, then due to measurement error, the position might be overdetermined. In such a situation, least square method is a natural solution: Suppose an unknown u with coordinate (x, y) has n beacon neighbors l_1, l_2, \dots, l_n , the estimated distance between u and l_i is d_i . The goal is to determine (x, y) such that

$$\sum_{i=1}^n err_i^2$$

is minimized, where

$$err_i = d_i - \sqrt{(x_i - x)^2 + (y_i - y)^2} \quad (1)$$

is the error between the measured distance and the estimated distance and (x_i, y_i) is the coordinate of beacon node l_i . This can be easily solved by linearization. In fact, the ideal situation is $err_i = 0$ for any $i = 1, 2, \dots, n$. For each i , setting $err_i = 0$ in (1) and squaring it, one obtains n equations:

$$(x_i - x)^2 + (y_i - y)^2 = d_i^2, \quad i = 1, 2, \dots, n. \quad (2)$$

Subtracting the last one from the other ones, one obtains a linear system of $n - 1$ equations:

$$2(x_n - x_i)x + 2(y_n - y_i)y = x_n^2 + y_n^2 - x_i^2 - y_i^2 - d_n^2 + d_i^2, \quad i = 1, 2, \dots, n - 1.$$

Fig. 2 An illustration of collaborative multilateration. The blacken nodes are beacon nodes, and the circled nodes are participating unknowns

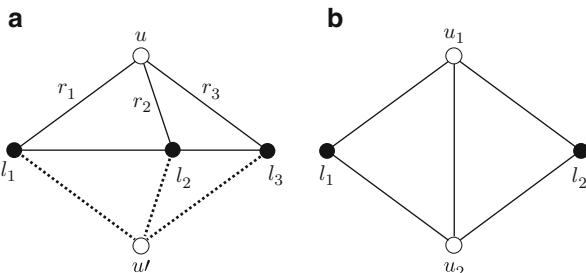

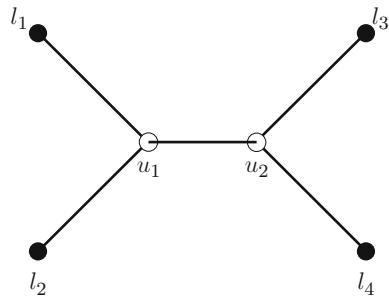

Fig. 3 Localization ambiguity

This linear system might be overdetermined, which can be solved by a classic least square method or generalized inverse in the field of numerical algebraic computation.

Based on atomic multilateration, Savvides et al. [76] proposed both a centralized way and a distributed way to realize the iteration phase of the iterative multilateration.

When there are no sufficient beacons near an unknown to determine the position, *collaborative multilateration* is used [76, 77]. The idea is illustrated using the small example in Fig. 2. For each edge, one establishes an equation as in (2). Notice that the equation corresponding to the edge u_1u_2 is related with two unknowns. There are four variables to be determined, namely, (x_1, y_1) and (x_2, y_2) (the coordinates of the two unknowns u_1 and u_2). Since there are five equations for this example, they can be determined as long as noncolinear requirement is satisfied. In general, Savvides et al. defined a node to be *participating* if it is either a beacon or an unknown with at least three participating neighbors. Thus, unknowns which are participating collaborate to determine their positions. Notice that the equation system is no longer linear; hence, optimization methods such as gradient descend or simulated annealing are used.

A drawback of the above multilateration method is the *error accumulation* due to the usage of inaccurate position information of unknowns as beacons. Another drawback is the *localization ambiguity* phenomenon. For example, if an unknown is adjacent to three beacons which are colinear, the position cannot be determined uniquely. Consider Fig. 3a for an example, both node u and u' have the same distances from beacons l_1, l_2, l_3 . Consider Fig. 3b for another example, exchanging

the locations of u_1 and u_2 , the equation system is still satisfied. The solution is not unique.

In [77], Savvides et al. further refined their method to overcome the above drawbacks. The refined method is executed in three main phases and a post-processing phase. In the first phase, nodes are grouped into so-called collaborative subtrees. The condition that a set of nodes could be assigned to a same subtree is that they can collaborate to *uniquely* determine the positions of the unknowns in the same group. This is achieved by obtaining a system of equations which is well determined or even overdetermined. For this purpose, some local conditions are imposed to exclude those nodes which violate the uniqueness if participating in a group. This phase aims to conquer the underdetermine problem (there is no sufficient information to determine the positions of the unknowns) and the localization ambiguity problem. In the second phase, *estimates* of the initial positions are obtained by a geometrical analysis on the known information including the measured distances between nodes and the positions of the beacons. In the third phase, the estimated positions are refined iteratively by least square method. Finally, in the post-processing phase, new location information is used to refine the positions of underconstrained nodes. The recursive refinement of the positions reduces the accumulated errors.

The methods proposed by Niculescu and Nath in [66] are based on the propagation of distances. The distance between two nodes which are not in direct contact with each other is estimated by propagating neighboring distance information through multi-hops. Once a node knows its estimated distances to at least three landmarks, it uses a mechanic which is similar to GPS triangulation to determine its coordinate. Three methods were proposed to estimate the distances. In *DV-distance propagation method*, based on the measured Euclidean distances between neighboring nodes, the distance between two non-neighboring nodes u, v is estimated by the length of a shortest (u, v) -path, where the length refers to the sum of the Euclidean distances along the path. In Euclidean propagation method, the Euclidean distance of a node u to a landmark l is estimated as follows. Suppose an unknown u has two neighbors u_1, u_2 which already know their estimated Euclidean distances to landmark l . Suppose u also knows the estimated Euclidean distances of uu_1, uu_2 , and u_1u_2 . Then the estimated distance between u and l can be obtained by a geometric analysis (see Fig. 4a). Clearly, for each of such a configuration, there are two possible positions for u . This localization ambiguity problem was dealt with in [66] by voting when more neighboring nodes of u have acquired their estimated distances to landmark l . The third method, *DV-hop propagation method*, proposed in [66] will be introduced in Sect. 2.3.

2.1.2 Rendered Path

The distances estimated in a hop-by-hop manner (such as the DV-distance propagation method introduced in the above) might be seriously distorted when the field is anisotropic: Shortest path may bend significantly around a hole, resulting in the estimated distances deviating largely from the true Euclidean distances.

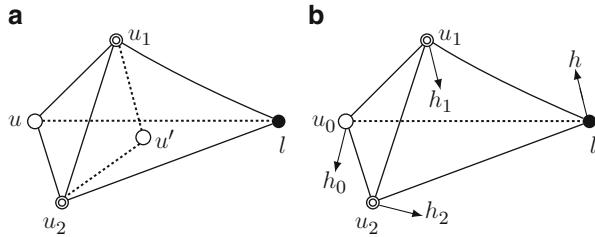

Fig. 4 The blackened nodes are landmarks. The circle nodes are unknowns. The double-circle nodes know their estimated distances in (a) or estimated orientations in (b). (a) Illustrates the estimation of the distance between u and l in Euclidean propagation method. There are two possible positions for node u . (b) Illustrates the estimation of the orientation of u from l in orientation propagation method

In [59], Li and Liu proposed the *rendered path* (REP) protocol to extract the true Euclidean information from the distances estimated by shortest paths in an anisotropic field. It was assumed that the boundaries of the holes are known in advance, and except for the holes, the rest of the network is isotropic. The main idea is to create *virtual holes* around the boundaries of holes, augment the shortest path by bypassing the virtual holes, and then extract range and angle information by comparing the shortest path with the augmented path.

First consider the basic situation when the shortest (u, v) -path intersects a convex hole at a point o (see Fig. 5a). The true Euclidean distance between u, v is

$$\|uv\| = \sqrt{\|uo\|^2 + \|vo\|^2 - 2\|uo\| \cdot \|vo\| \cdot \cos \angle uov}. \quad (3)$$

To estimate the angle $\angle uov$, a virtual hole with center o and radius r is created, and the shortest path is augmented to $uxyv$. Then

$$\angle uov = 2\pi - \frac{\|\widehat{xy}\|}{r} - \arccos \frac{r}{\|uo\|} - \arccos \frac{r}{\|vo\|}, \quad (4)$$

where $\|\widehat{xy}\|$ is the length of the arc \widehat{xy} (the shorter part along the hole centered at o). Since the lengths $\|uo\|, \|vo\|, \|ux\|, \|vy\|, \|\widehat{xy}\|$ are fairly accurate (because of the assumption of isotropy in the rest of the network excluding holes), the true Euclidean distance $\|uv\|$ can be obtained from (3) to (4).

In a general situation, a shortest path might intersect a lot of holes or intersect one hole more than once. To recognize the ways how the shortest paths meet the holes, a coloring strategy is used: Nodes on the boundaries of different holes are assigned different colors. Then a shortest path can be segmented into pieces according to the colors of the boundary nodes on it.

If a shortest path intersects a convex hole, it was proved in [59] that it intersects either at one point or along a continuous segment of the boundary. In the second case, two virtual holes centered at the tangent points were created to augment the

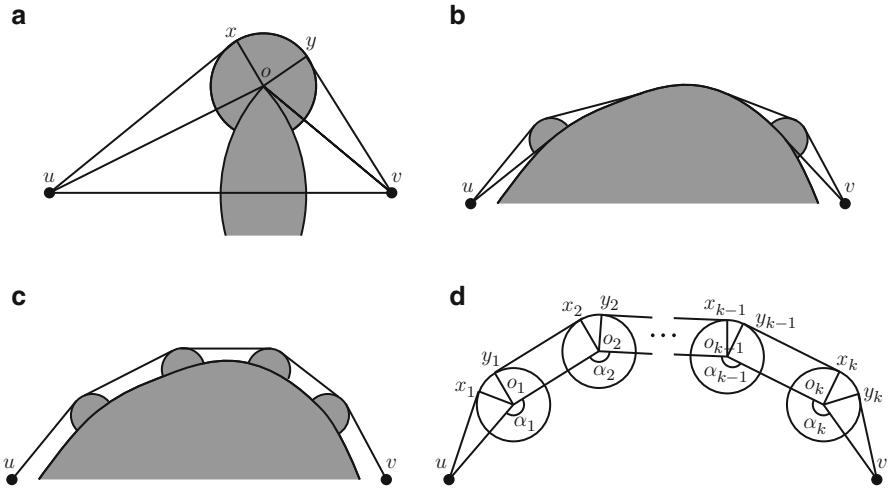

Fig. 5 Deriving true Euclidean distance using estimated distances on a shortest path

path (see Fig. 5b). If the augmented path still intersects the hole, more virtual holes were iteratively created (see Fig. 5c). By a geometrical analysis, the angles (see Fig. 5d) can be calculated by

$$\begin{aligned}\alpha_1 &= 1.5\pi - \frac{\|\widehat{x_1 y_1}\|}{r} - \arccos \frac{r}{\|u o_1\|}, \\ \alpha_i &= \pi - \frac{\|\widehat{x_i y_i}\|}{r} \text{ for } i = 2, \dots, k-1, \\ \alpha_k &= 1.5\pi - \frac{\|\widehat{x_k y_k}\|}{r} - \arccos \frac{r}{\|v o_k\|}.\end{aligned}$$

Then the true Euclidean distance $\|uv\|$ can be obtained by a simple geometrical calculation. A key observation in deriving the above formula is that the augmented path can only bend towards one direction.

In the case that a shortest path intersects more convex holes or some concave holes, the augmented path may bend towards different directions. Nevertheless, a geometrical analysis can produce a similar formula to obtain the angle information and thus the true Euclidean distance.

2.2 Angle-Based Localization

This subsection introduces the angle-based localization method used in [67]. Nodes are assumed to be able to sense the directions of the signals where they come from, using local interactions such as *angle of arrival* (AoA) or *directional antennas*.

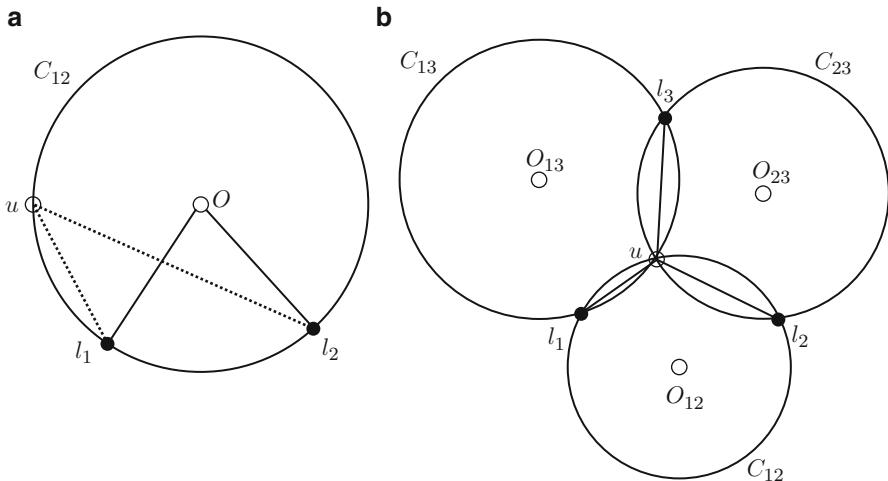

Fig. 6 Determine the position of node u by the direction information of landmarks l_1, l_2, l_3

The localization of a node using the direction information from its neighboring landmarks is called *triangulation*.

A node u which knows the directions of three of its neighboring landmarks can determine its position as shown in Fig. 6: If u sees two landmarks l_1, l_2 , then it must lie on the circle C_{12} as in Fig. 6a, where $\angle l_1 O l_2 = 2\angle l_1 u l_2$ and O is the center of the circle. Thus, if u sees three landmarks l_1, l_2, l_3 , then it is at the intersection point of the three circles C_{12}, C_{23} , and C_{13} (as in Fig. 6b).

If u sees more landmarks, a simplest method is to estimate the location by every triple of the landmarks and then place the node at the center of the estimated locations. Another method is to formulate the problem into a system of nonlinear equations, using the law of cosines, and solve it by least square method. This method is time-consuming. In [6], Betke and Gurvits proposed the idea of transforming the angle-based localization problem to the atomic multilateration problem, using the angle information to estimate the distances between the unknown and the landmarks. Representing the landmarks as complex numbers, an equation system linear in the number of landmarks was proposed in [6].

Since landmarks are only a small fraction of the nodes, most unknowns are not in direct contact with enough landmarks to determine their positions. The method proposed in [67] is based on the propagation of orientations. As long as an unknown has acquired the knowledge of its orientations from at least three landmarks, the above triangulation method is used to determine its position. This idea is similar to that in [66]. The difference is that distances are propagated in [66], while orientations are propagated in [67].

What remains to show is how to propagate the orientation information. See Fig. 4b for an illustration. Each node has a local heading h and can find out the angle between h and the direction of the signal (this angle is called the *orientation*).

Suppose node u_0 has two adjacent neighbors u_1, u_2 which know their orientations from landmark l . Then the orientation of u_0 from l (viz., $\angle h_0u_0l$) can be derived from the known orientation information $\angle h_iu_iu_j$ for $i, j = 0, 1, 2, i \neq j$ and $\angle h_iu_il, \angle hlu_i$ for $i = 1, 2$. After that, u_0 can use its orientation from l to help other neighbors to determine their orientations.

Similar to Sect. 2.1, error accumulation is a major problem of the above method. Some principles dealing with errors were discussed in [67].

2.3 Connectivity-Based Localization

In a connectivity-based localization, nodes are not equipped with any measuring devices (neither range nor angle). The problem is how to determine the positions of the unknowns based only on the connectivity information of the underlying topology of the network.

The *centroid-based method* proposed by Bulusu et al. [13] estimates the position of a node by calculating the centroid of its neighboring landmarks.

The *DV-hop-based method* proposed by Niculescu and Nath [66] first approximates the Euclidean distances by hop distances, which is called as *DV-hop propagation method*. Initially, the local information stored in a node is the list of its neighbors. Besides, landmark l_i is aware of its coordinate (x_i, y_i) . By multi-hop communication, all the nodes are informed of its *hop distances* from the landmarks. Then, each landmark l_i estimates its *average hop length* c_i by

$$c_i = \frac{\sum_j \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2}}{\sum_j h_{i,j}},$$

where the sum is over all the landmarks $l_j \neq l_i$ and $h_{i,j}$ is the hop distance between l_i and l_j . The values of c_i 's are flooded in a controlled manner: Once an unknown u receives a value c_i (from its nearest landmark), it ignores all the subsequent ones. Using this value, u estimates its Euclidean distances from the landmarks. That is, suppose u is h_j -hops away from landmark l_j , the estimated Euclidean distance between u and l_j is $c_i h_j$. Similar to Sect. 2.1, knowing the estimated Euclidean distances to at least three landmarks, the position of an unknown is determined by a GPS-like mechanic.

The method proposed by Shang et al. [80] is based on multidimensional scaling (MDS), which is a set of statistical techniques used in information visualization for exploring similarities in data [9]. Their algorithm takes three steps. First, a shortest path algorithm is used to estimate the distances between every pair of nodes, producing an estimated distance matrix. Then MDS is applied to the matrix, retaining the first 2 (or 3) largest eigenvalues and eigenvectors to generate a 2-dimensional (or 3-dimensional) map (the map is relative up to rotations and translations). Finally, knowing at least three absolute positions of the nodes (which

are called *seeds*), the absolute positions (i.e., the coordinates) of all the nodes are derived. Notice that without the aid of ranging measurement, the distances estimated in the first step are in fact hop distances.

Since both [66] and [80] use hop distances to approximate the true distances, these methods are only applicable to an *isotropic* field. As reported in [59], such hop distance-based methods perform poorly in an *anisotropic* field.

To deal with an anisotropic field, Shang and Ruml further refined their MDS-based method in [79]. The idea is to use MDS to construct a local map for each node based on its nearby neighbors and then merge the local maps into a global map. Since this method avoids using shortest path information between far away nodes, the distortion to the estimated distances is greatly alleviated.

The method CATL proposed in [85] also focuses on anisotropic field. The key idea is to detect *notch nodes*, where shortest paths bend from their straight-line courses. Those shortest paths passing through notch nodes are avoided or used with a low priority in estimating the distances. The detection of notch nodes is based on the observation that for a global shortest path tree, notch nodes usually have much *fatter* subtree, where *fatness* is measured by the size of the subtree up to a depth of a constant hops. It should be noted that this method can be conveniently generalized to the 3-dimensional space.

2.4 Location Ambiguity

As one has seen in Sect. 2.1, location ambiguity may occur, especially in a sparse region and with measurement noise. It is desirable that the nodes could be *uniquely localized*. Let G be the communication graph of the network. Given the positions of the landmarks and the mutual distances between neighboring nodes (distance may refer to hop distance if measurement devices are not provided), the *unique localizability* problem is to determine whether there is exactly one configuration for the unknowns which is consistent with the given information. Section 2.4.1 introduces the relationship between unique localizability and rigidity theory.

Knowing that a network is uniquely localizable is not sufficient to meet the requirement of network localization, one has to *realize* it, that is, find out the actual embedding of the graph. It was proved in [4, 22, 78] that realizing graphs on the plane is NP-hard, even when it is known that the graph is globally rigid. Some works focused on special classes of graphs which do admit an efficient realization [22, 38, 39, 64]. Some works used semidefinite programming to realize a graph [7, 81]. They will be introduced in Sect. 2.4.2.

In [57, 89], the authors asked the question of whether the knowledge of network boundaries (both the outer boundary and the inner boundaries around holes) could help to find out the true locations. The idea is to *choose* landmarks on the boundaries which can be embedded faithfully to reflect the layout of the network. Then the other nodes can be localized using trilateration based on at least three nearby landmarks.

With the layout being found fairly accurately, the danger of location ambiguity is reduced. These works will be introduced in Sect. 2.4.3.

2.4.1 Localizability and Rigidity

The *unique localizability* problem is closely related with rigidity theory [41]. A framework is a triple $\mathcal{F} = (V, E, p)$, where $G = (V, E)$ is a graph and p is an embedding of V in the d -dimensional space \mathbb{R}^d . Two frameworks $\mathcal{F}_p = (V, E, p)$ and $\mathcal{F}_q(V, E, q)$ are *equivalent* if the Euclidean distance $\|p(u)p(v)\| = \|q(u)q(v)\|$ holds for any edge $uv \in E$; they are *congruent* if one is obtained from the other by *rigid motion*, that is, translations, rotations, and reflections. A framework is *rigid* if it cannot be deformed continuously into another framework; it is *globally rigid* if any equivalent framework is congruent to it. A rigid framework might not necessarily be globally rigid (see Fig. 7). A framework \mathcal{F} is *generic* if any framework in the neighborhood of \mathcal{F} has the same rigidity as \mathcal{F} , that is, changing the locations of the points by an infinitesimal amount does not alter the rigidity of the framework. An important property is that for any two generic frameworks with the same underlying graph, they are either both rigid or both nonrigid. Thus, there is no ambiguity in defining a graph to be *rigid* (resp. *globally rigid*) if any of its generic embedding is rigid (resp. *globally rigid*).

One powerful characterization of rigidity was due to Laman.

Theorem 1 (Laman [56]) *A graph $G = (V, E)$ is rigid for \mathbb{R}^2 if and only if there is an edge subset $E' \subseteq E$ with $|E'| = 2|V| - 3$ and for any subset $E'' \subseteq E'$, $|E''| \leq 2|V(E'')| - 3$, where $V(E'')$ is the set of nodes spanned by E'' .*

Based on various formulations of Laman's Theorem, rigidity can be checked in polynomial time. For example, the Pebble Game proposed by Jacobs and Hendrickson [46] has running time $O(n^2)$, where n is the number of nodes in G .

Combinatorial characterization of global rigidity was studied in [5, 14, 43, 45]. A graph is *redundantly rigid* if the remaining graph resulted from the removal of any single edge is still rigid. Hendrickson [43] proved that a globally rigid graph in \mathbb{R}^d must be $(d + 1)$ connected and redundantly rigid. He also conjectured that the converse is true. For $d = 1$, it is trivial. For $d \geq 3$, it was disproved by Connelly [14]. The remaining case of $d = 2$ was proved to be true by Jackson and Jordán based on an inductive characterization of 3-connected graphs whose rigidity matroid is connected.

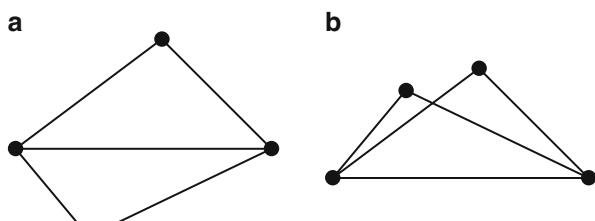

Fig. 7 A rigid but not globally rigid framework

Theorem 2 ([43, 45]) A graph G is globally rigid in \mathbb{R}^2 if and only if G is 3 connected and redundantly rigid.

The relationship between the unique localizability of a network and the global rigidity of a graph was established independently by Eren et al. [22] and Jackson and Jordán [45]. The *grounded graph* G_g is a super-graph of the communication graph G , containing extra edges between every pair of landmarks.

Theorem 3 ([22, 45]) A network G is uniquely localizable in \mathbb{R}^2 if and only if its grounded graph G_g is globally rigid.

2.4.2 Realization of Globally Rigid Graph

By Theorem 3, finding the positions of the nodes is reduced to realizing the weighted version of the grounded graph G_g , where the weight on each edge is the Euclidean distance between its two ends. The pioneer work [22] introduced a class of graphs called *trilateration graphs* and proved that they can be efficiently realized.

Definition 1 A *trilateration ordering* of a graph G in dimension d is an ordering of the nodes as u_1, u_2, \dots, u_n such that u_1, \dots, u_{d+1} form a complete subgraph K_{d+1} and for every $j \geq d + 2$, u_j has at least $d + 1$ neighbors in $\{u_1, u_2, \dots, u_{j-1}\}$. A graph is said to be a *trilateration graph in dimension d* if it admits a trilateration ordering in dimension d .

Theorem 4 ([22]) Trilateration graphs in dimension d are globally rigid in dimension d . Furthermore, they can be realized in polynomial time.

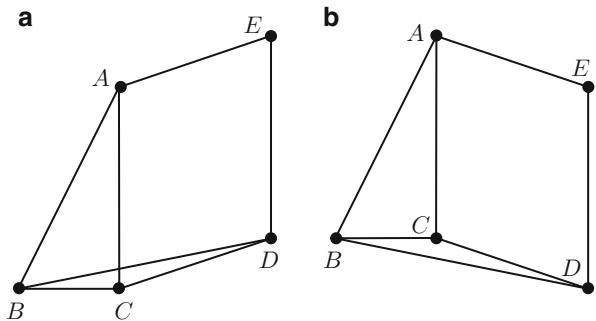

Eren et al. [22] proved that trilateration graphs exist in the real world with high probability. Let $U = \{u_1, u_2, \dots, u_n\}$ be a set of points in $[0, 1] \times [0, 1]$ generated by a two-dimensional Poisson distribution. Denote by $G_n(r)$ the graph on U such that two vertices are adjacent if and only if the distance between the two corresponding points is at most r .

Theorem 5 ([22]) If $\lim_{n \rightarrow \infty} \frac{nr^2}{\log n} > 8$, then $G_n(r)$ is a trilateration graph with a high probability. Thus, if $r \in O\left(\sqrt{\frac{\log n}{n}}\right)$, then with high probability, a realization of $G_n(r)$ can be computed in polynomial time.

In [64], Moore et al. suggested using *robust quadrilaterals* as building blocks for localization. The advantage of quadrilateral (referring to the complete graph on four vertices) is that (a) it is globally rigid itself; (b) if a quadrilateral Q has three common vertices with a globally rigid subgraph H , by pasting Q to H , one obtains a larger globally rigid graph. However, even for a globally rigid graph, location ambiguity is still possible because of measurement noise. To overcome this problem, Moore et al. introduced a measure of *robustness*. For a threshold d_{\min} which is chosen according to the measurement noise, a triangle is said to be *robust* if

$$b \sin^2 \theta > d_{\min}, \quad (5)$$

Fig. 8 Flex ambiguity.
Removing edge BD , the remaining graph can deform to another position.
Reinserting BD may keep all the distances

where θ and b are the smallest angle and the length of the shortest side of the triangle, respectively. A quadrilateral $ABCD$ can be divided into four triangles, namely, ABC , BCD , CDA , and DAB . It is *robust* if and only if all the four triangles are robust.

Theorem 6 ([64]) *If the measurement noise is normally distributed, using robust quadrilaterals as building blocks succeeds in localization with a bounded worst-case probability.*

In fact, there are two types of ambiguities in embedding a rigid graph on the plane. The *flip ambiguity* occurs when the neighbors of some node are all colinear (see Fig. 3a). The *flex ambiguity* occurs when the removal of some edge results in a nonrigid graph (see Fig. 8) or, in other words, when the graph is not redundantly rigid. By Laman's Theorem (Theorem 1), quadrilateral is redundantly rigid, and thus flex ambiguity does not occur for a graph which is constructed on quadrilaterals. Condition (5) is used to avoid flip ambiguity with a high probability.

Since trilateration graph is a stronger requirement than global rigidity, Goldenberg et al. [39] tried to relax it to *bilateration graph*, which was defined by taking $d = 1$ in Definition 1. By Theorem 4, such a graph is globally rigid on a straight line. However, it is no longer globally rigid on the plane. The way that [39] used to deal with the problem is to output all possible locations and prune the incompatible ones, which was called *finite localization*.

In practice, to uniquely localize the entire network is often unrealistic. In [38], Goldenberg et al. proposed the concept of *partially localizable network*. The focus is on the recognition of *uniquely localizable nodes*. Based on the characterization of global rigidity (Theorem 2), a sufficient condition was presented in [38]: A uniquely localizable node u must belong to a redundantly rigid 3-connected subgraph which contains three landmarks.

Biswas and Ye [7] and So and Ye [81] used semidefinite programming to find the realization. First, they modeled the network localization problem as

$$\begin{cases} \|\alpha_k - x_i\|_2^2 = \bar{d}_{ki}^2, \\ \|x_j - x_i\|_2^2 = d_{ji}^2, \end{cases} \quad (6)$$

where $\|\cdot\|_2$ is the 2-norm of vector space \mathbb{R}^d , α_k is the coordinate of landmark u_k , x_i is the coordinate of unknown node v_i , \bar{d}_{ki} is the distance between landmark u_k and unknown node v_i , and d_{ji} is the distance between two unknown nodes v_j, v_i . Equation (6) is a non-convex optimization problem. Biswas and Ye [7] and So and Ye [81] transformed it into a semidefinite programming problem (SDP) and showed that the network is globally rigid in \mathbb{R}^d if and only if the max-rank solution matrix of the SDP has rank d . Thus, as long as the network is uniquely localizable, the realization can be computed in polynomial time by solving the SDP, using, for example, the interior-point algorithm.

2.4.3 Boundary-Aided Localization

This subsection introduces the works of [57, 89] which used boundary information to help faithful localization. The main ideas of the overall algorithm will be introduced first, followed by an introduction on how to select landmarks on the boundary.

Suppose the sensors are distributed in a region \mathcal{R} , and the boundary of \mathcal{R} , denoted by $\partial\mathcal{R}$, is known, for example, by the methods introduced in Sect. 4. Use $g(u, v)$ to denote the *geodesic distance* between u, v inside \mathcal{R} , that is, the length of the shortest path avoiding obstacles. For a node u in the landmark set \mathcal{L} , the *Voronoi cell* of u is the set of points in \mathcal{R} which have u as the nearest landmark, that is,

$$V(u) = \{x \in \mathcal{R} \mid g(x, u) \leq g(x, w) \forall w \in \mathcal{L}\}.$$

The *combinatorial Delaunay complex* on \mathcal{L} is the complex $DC(\mathcal{L})$ defined on the set

$$\{L \subseteq \mathcal{L} \mid \bigcap_{u \in L} V(u) \neq \emptyset\}.$$

The dimension of a Delaunay simplex $L \subseteq \mathcal{L}$ is $\dim(L) = |L| - 1$. Hence, a landmark is a 0-dimensional simplex, a Delaunay edge is a 1-dimensional simplex, and a Delaunay triangle is a 2-dimensional simplex. Notice that in the degenerate case, $k (\geq 4)$ nodes are colinear, the complete subgraph K_k may be present in $DC(\mathcal{L})$, which is a $(k-1)$ -dimensional simplex. The *combinatorial Delaunay graph* $D(\mathcal{L})$ as in Sect. 3.3 only contains the 0-dimensional and 1-dimensional simplices. It was proved that when the landmarks are dense enough, $D(\mathcal{L})$ is rigid, but not generally globally rigid [57]. The intuitive idea is that the higher-order simplices K_k with $k \geq 3$ contained in $DC(\mathcal{L})$ will help to exclude more ambiguities. This fact was proved rigorously in [57] as long as the landmarks are sufficient dense, where *density* is measured as follows: The *inner medial axis* of \mathcal{R} is the collection of points in \mathcal{R} which have at least two nearest points on $\partial\mathcal{R}$. The *inner local feature size* of a point $x \in \partial\mathcal{R}$, denoted as $ILFS(x)$, is the distance of x to its nearest point on the inner medial axis. A set \mathcal{L} of landmarks is said to be an γ -sample, if for every point $x \in \partial\mathcal{R}$, the disk with center x and radius $\gamma \cdot ILFS(x)$ contains at least one landmark from \mathcal{L} . A *boundary cycle* is a cycle surrounding a hole or the outer boundary.

Theorem 7 ([57]) Suppose the set of landmarks \mathcal{L} is a γ -sample for some $\gamma < 1$ and each boundary cycle contains at least three landmarks. Then, the combinatorial Delaunay graph $D(\mathcal{L})$ is rigid, and the combinatorial Delaunay complex $DC(\mathcal{L})$ is globally rigid.

The algorithm in [57] is executed in five steps: (a) select landmarks on the boundary, (b) compute the landmark Voronoi diagram which is the union of the Voronoi cells, (c) extract the combinatorial Delaunay complex (CDC), (d) embed CDC by gluing the simplices in an incremental way, mass spring relaxation is used to smooth out the noise, and (e) the other nodes are localized by trilateration. It should be noted that in a wireless network with connectivity information only, distances are measured by hops. The algorithm uses hop distances to approximate geodesic distances.

The limitation of the above algorithm lies in its dependency on the quality of the detected boundary. In [89], an incremental algorithm was presented to select landmarks on the boundary without knowing the boundary in advance (the boundary is delimitated with the incremental selection of the landmarks). The algorithm does not depend on the inner local feature size (and thus the computation of the inner medial axis is not needed). In fact, the selected set of landmarks not only guarantees the global rigidity (viz., γ -sample for some $\gamma < 1$) but also guarantees a good coverage, the so-called δ -coverage defined as follows. A point in \mathcal{R} is said to be on a *Voronoi edge* if it has the same distance to two of its nearest landmarks. A point in \mathcal{R} is an *inner Voronoi vertex* if it has the same distance to at least three landmarks. For an inner Voronoi vertex x , the *Voronoi disk* $B_r(x)$ centered at x has its radius r equal to the distance from x to its nearest landmark. The combinatorial Delaunay complex $DC(\mathcal{L})$ is said to δ -cover \mathcal{R} if for every point $y \in \mathcal{R}$, there is an inner Voronoi vertex x such that y is within distance $(1 + \delta)r$ from x , where r is the radius of the Voronoi disk $B_r(x)$. Wang et al. [89] proved that if the landmarks are selected complying with the following two conditions, then both the rigidity and the coverage requirements can be satisfied:

- (a) The Voronoi edges for each landmark u are connected.
- (b) Each node in $V(u)$ is δ -covered by a Voronoi disk $B_r(x)$, where x is a Voronoi vertex with u being one of its nearest landmarks.

Based on the above two conditions, an incremental landmark selection algorithm was presented [89]. Notice that these two conditions can be checked locally.

3 Geometric Routing

In geometric routing, a widely adopted model is the unit disk graph model. Assume that two nodes can communicate with each other only when their Euclidean distance is within a constant transmission range, which is scaled to one. Then the topology underlying the geometric routing problem can be modeled as a *unit disk graph* G , in which each vertex corresponds to a node on the plane and two vertices are adjacent in G if and only if the Euclidean distance between the two nodes corresponding to them is at most one. A more general model is quasi unit disk graph. Suppose

$p : V \mapsto \mathbb{R}^2$ is a straight-line embedding of $G = (V, E)$ on the plane, $d \leq 1$ is a parameter. If the following two conditions hold

$$uv \in E \implies \|p(u)p(v)\| \leq 1, \quad (7)$$

$$\|p(u)p(v)\| \leq d \implies uv \in E, \quad (8)$$

then p is said to be a *d-quasi unit disk embedding* (*d-QUDE*) and G is called a *d-quasi unit disk graph* (*d-QUDG*). In particular, if $d = 1$, then G is exactly a unit disk graph. Notice that a quasi unit disk graph is not necessarily planar.

Geographic routing uses the geographic locations of the nodes as addresses. Every node knows its position and the positions of its neighbors. Packets are sent from their sources to their destinations through multi-hops. Every packet knows the position of its destination from the very beginning of the transmission. Most geographic routing algorithms consist of two modes: the *greedy forwarding mode* and the *recovery mode*. [Section 3.1](#) illustrates the main ideas of the two modes using the *greedy perimeter stateless routing* (GPSR) protocol proposed in [48]. A similar protocol was proposed independently by Bose et al. in [11].

In practice, the quality of the route should be taken into consideration. For example, the route found by the algorithm should not be too long compared with the optimal one; the load should be balanced which will increase the overall lifetime of the network. [Section 3.2](#) introduces some algorithms with a guarantee on the length of the route. As to the studies on load-balanced routings, the interested reader may refer to [34, 63, 70, 74, 90].

The recovery mode is needed because greedy forwarding strategy will encounter *local minimum phenomenon*, that is, the packet will get stuck because the current node is closer to the destination than any of its neighbors. This problem is especially serious when the region contains holes. Furthermore, although some algorithms of geographic routing theoretically guarantee the successful delivery of the packets, the actual delivery rate in the real network is hindered by the location inaccuracies. This motivates the design of routings based on *virtual coordinates*, which was first proposed by Rao et al. [72]. Virtual coordinate does not reflect the absolute positions of the nodes but can be chosen to increase the delivery rate of greedy strategy. [Section 3.3](#) illustrates the basic ideas of this topic by the works in [23, 65]. A related question is: is there an embedding of a graph in which the greedy forwarding strategy always succeeds? Such an embedding is called a *greedy embedding*; the studies of which will be introduced in [Sect. 3.4](#).

3.1 Two Modes of Geographic Routing

In [48], the communication graph G is taken to be the unit disk graph.

Greedy forwarding is a simple strategy to route the packets which can be realized in a distributed manner: When a packet reaches a node u , the local optimal choice for the next hop is the neighbor of u which is closest to the destination, where *closest*

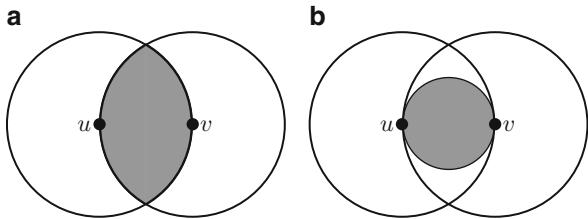

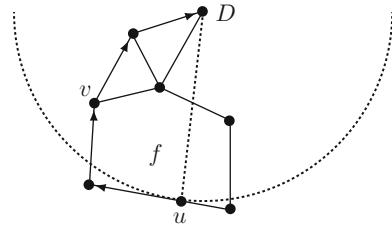

Fig. 9 (a) RNG. (b) GG

Fig. 10 u is a stuck node from which the algorithm enters the recovery mode, and from v , the algorithm goes back to the greedy forwarding mode

may be measured by different criteria. Greedy forwarding strategy works well in an evenly distributed dense network but may get stuck in a sparse network, in which there might be a case that any neighbor of u is farther from the destination than u itself. Such a node is called a *stuck node*. Such a case is called a *local minimum phenomenon*.

When a packet reaches a stuck node, the recovery mode is activated. A natural idea is to make a detour around the boundary of a *face*. To do so, a planar subgraph of the communication graph G is required, since faces are defined only for a plane graph (a plane embedding of a planar graph) which has no crossing edges.

Two planar subgraphs are used in [48]: the *relative neighborhood graph* (RNG) and the *Gabriel graph* (GG). See Fig. 9 for an illustration. Two nodes u, v are adjacent in RNG only when the shaded lune in Fig. 9a contains no other nodes, where the two circles have radius $\|uv\|$, the Euclidean distance between u and v . They are adjacent in GG only when the shaded circle in Fig. 9b contains no other nodes. Clearly, both RNG and GG are planar and RNG is a subgraph of GG. Let $G_{RNG} = G \cap RNG$ and $G_{GG} = GG \cap G$.

The recovery procedure is illustrated by Fig. 10. When the packet reaches a stuck node u , let f be the face of the plane subgraph which contains u and intersects the line uD , where D is the destination of the packet. The packet is forwarded along the boundary of f by, for example, the right-hand rule [48], until it reaches a node which is closer to D than u . From that node, the algorithm goes back to the greedy forwarding mode.

To ensure that the packet is always capable of reaching its destination as long as there exists a source-destination path in the communication graph G , an important property that the planar subgraph must satisfy is any nodes which are reachable to each other in G are also reachable to each other in the planar subgraph. G_{RNG} can

be viewed as a subgraph obtained from G by removing those edges uv for which there is a node w in the lune. Since u and v are connected by the path uvw , removing edge uv does not disconnect the graph. Thus, G_{RNG} satisfies the above property. Since G_{RNG} is a subgraph of G_{GG} , G_{GG} also satisfies the above property.

There are a lot of protocols using the same idea as the above two modes in geographic routing. The differences lie in the choice of greedy criterion and recovery mechanic. Some greedy criteria include closest to destination [11, 48, 84], nearest forward progress [44, 83], most forward within radius [84], closest direction [51], and some literatures use n -neighborhood information to find the next forwarding node [27, 82]. Some recovery mechanics include simple flooding [82], tree search [47], terminode routing [8], and face routing [48, 51].

3.2 Routing with Bounded Stretch

The work [53] is an improvement on the face routing of [51]. Notice that the face routing method used in [51] is different from that in Sect. 3.1. It never uses the greedy mode and just traverses the boundaries of those faces which intersect the line segment \overline{uv} (see Fig. 11a).

As one can see from Fig. 11a, the route found by the face routing method might be much longer than an optimal one. It is desirable that the cost of the computed

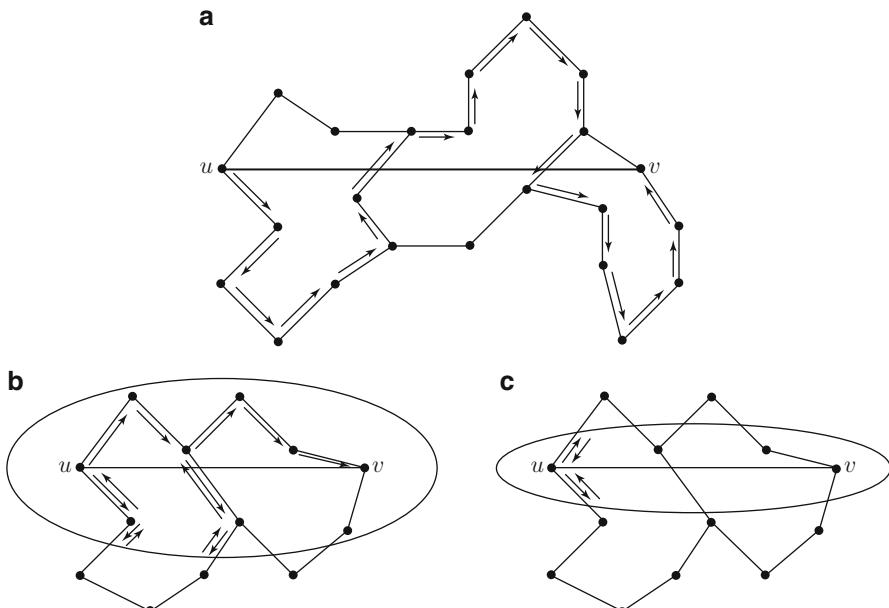

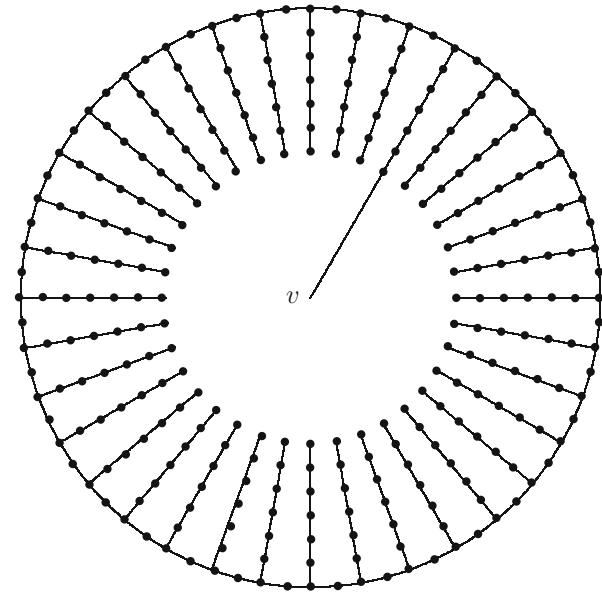

Fig. 11 (a) An illustration of face routing used in [51]. (b) An illustration of BFR. The arrows indicate the edges traversed. (c) When the ellipse is too small, BFR may get stuck

Fig. 12 An example showing a lower bound for the stretch. The route found by a local algorithm may travel all the nodes before it reaches the destination node v

route is not too large compared with the optimal cost, in other words, the *stretch* is desired to be small. In a general case, the cost c is a nondecreasing positive function defined on E . In particular, if for each edge $uv \in E$, $c(uv) = 1$, then c is the *link metric* measuring hop distances between two nodes; if $c(uv) = \|uv\|$, then c is the *Euclidean metric* measuring the sum of Euclidean distances along the path; and if $c(uv) = \|uv\|^2$, then c is the *energy metric* measuring the energy spent on a path.

In [53], Kuhn et al. constructed an example (see Fig. 12) showing that any deterministic geometric routing algorithm based on local information has a worst cost of $\Omega(c_*^2)$, where c_* is the cost of an optimal route. The same example shows that the claim is also true [53] for any randomized local algorithm in terms of expected cost. In [53, 54], local algorithms were presented producing routes with guaranteed bound $O(c_*^2)$, which are asymptotically optimal in view of the above lower bound.

All these algorithms rely on the existence of a planar subgraph whose stretch factor is bounded by a constant. Such a subgraph is called a *geometric spanner*, which will be introduced in Sect. 3.2.1. Section 3.2.2 shows how geometric spanners were used to guarantee the asymptotic optimality of the routes found by the algorithms in [53, 54].

3.2.1 Geometric Spanner

A k -spanner of graph G is a spanning subgraph H of G such that $c(P_H(uv)) \leq k \cdot c(P_G(uv))$ holds for any pair of nodes u, v , where $P_H(uv)$ and $P_G(uv)$ are the minimum cost (u, v) -paths in H and G , respectively. A k -spanner with k upper bounded by a constant is simply called a *spanner*. The parameter k is called the

stretch factor of the spanner. In particular, if c is taken to be link metric, Euclidean metric, or energy metric, the corresponding stretch factor is called *topological stretch factor*, *Euclidean stretch factor*, and *energy stretch factor*, respectively.

As one has seen in Sect. 3.1, both the relative neighborhood graph RNG and the Gabriel graph GG are planar. However, they are not good spanners [20]. In fact, Bose et al. [12] proved that the topological stretch factor can be $\Omega(\sqrt{n})$ for GG and $\Theta(n)$ for RNG, while the Euclidean stretch factor is $\Theta(\sqrt{n})$ for GG and $\Theta(n)$ for RNG.

The following lemma shows that the subgraph G_{GG} is a good spanner with respect to energy metric:

Theorem 8 ([53]) *The energy stretch factor of G_{GG} is 1.*

In [53], Kuhn et al. assumed an $O(1)$ -model (also known as *civilized graph* or λ -*precision graph*), meaning that there is a constant d_0 such that the Euclidean distance between any pair of nodes is at least d_0 . It is easy to see that in an $O(1)$ -model, the three commonly used metrics are equivalent.

Lemma 1 ([53]) *For the $O(1)$ -model, the link metric c_l , Euclidean metric c_d , and energy metrics c_e are equivalent up to a constant depending on d_0 .*

The next corollary follows directly from Theorem 8 and Lemma 1.

Corollary 1 ([53]) *For an $O(1)$ -model, G_{GG} is a spanner with respect to link, Euclidean, and energy metrics.*

A *bounded degree graph* is a graph whose maximum degree is upper bounded by a constant. Kuhn et al. [54] proved that in a bounded degree unit disk graph, any nondecreasing cost functions are equivalent up to constant factors. Then by Theorem 8, one has the following result:

Corollary 2 ([54]) *For a bounded degree unit disk graph G , G_{GG} is a spanner with respect to any nondecreasing cost functions.*

The Delaunay triangulation is known to be a planar spanner in terms of Euclidean metric [18, 49]. However, it cannot be used directly in the setting of wireless network, since a Delaunay edge may be longer than the transmission range. To overcome this problem, [36, 60] introduced the *restricted Delaunay graph* (RDG), which is obtained from the Delaunay triangulation by removing all the edges of length longer than 1. Let $G_{RDG} = RDG \cap G$. Gao et al. [36] and Li et al. [60] proved that G_{RDG} is a good spanner with respect to Euclidean metric.

Theorem 9 ([36, 60]) *The Euclidean stretch factor of G_{RDG} is $(1 + \sqrt{5}/2)\pi \approx 5.08$.*

However, the topological stretch factor of G_{RDG} might be as large as $\Theta(n)$. The reason is that although two nodes u, v are *visible* to each other on the plane, if the

network is very dense, then one has to cross a lot of Delaunay triangles to go from u to v .

If G has a *constant density*, meaning that every unit disk contains at most $O(1)$ nodes, then G_{RDG} is also a topological spanner.

Theorem 10 ([36]) *For a unit disk graph G which has constant density, the topological stretch factor of G_{RDG} is bounded by a constant.*

3.2.2 Routing Algorithms with Bounded Stretch

The algorithms in [53, 54] are improvements of the face routing algorithm in [51] and thus were named as *adaptive face routing* (AFR) and *GOAFR⁺*, respectively. The results in [53] are valid for all the three commonly used metrics, namely, the link, Euclidean, and energy cost. The limitation is that it assumes an $O(1)$ -model. This assumption is very crucial to their theoretical analysis. Later, this assumption was dropped off in [54] by using a clustering method.

Recall that face routing needs a planar subgraph to provide faces to be routed around. In [53], the planar subgraph of G is taken to be G_{GG} .

The idea of AFR is to restrict the route within an ellipse \mathcal{E} with foci u (the source) and v (the destination), that is, \mathcal{E} is the locus of all the points x with $\|xu\| + \|xv\| = \hat{c}$, where \hat{c} is a constant.

The basic procedure of AFR is called *bounded face routing* (BFR) (see Fig. 11b for an illustration). For a fixed \hat{c} , let $\mathcal{E}_{\hat{c}}$ be the ellipse corresponding to \hat{c} . While exploring a face F , one begins with any one of the two directions. There are two possibilities, one either goes around the *whole* boundary or comes across the boundary of $\mathcal{E}_{\hat{c}}$. In the latter case, one goes back to explore the other direction of the face until the boundary of $\mathcal{E}_{\hat{c}}$ is met again. Among all the intersection points of the line segment \overline{uv} and the *traversed* boundaries of face F , let x be the one which is nearest to v . The next face to be explored is the one incident with x which intersects line segment \overline{xv} . Kuhn et al. proved the following result:

Theorem 11 ([53]) *For an $O(1)$ -model, let \tilde{c} be the cost of a minimum cost (u, v) -path in G_{GG} . If \hat{c} is an upper bound for \tilde{c} , then BFR succeeds in finding a (u, v) -path with cost at most $O(\hat{c}^2)$.*

To fully understand the key points in the method, the sketch of the proof of Theorem 11 is addressed in the following: In view of Lemma 1, it suffices to deal with the link metric. Notice that with the assumption that $\hat{c} \geq \tilde{c}$, the shortest (u, v) -path of G_{GG} must lie completely in \mathcal{E} , since any path through a point outside of $\mathcal{E}_{\hat{c}}$ will have length greater than $\hat{c} \geq \tilde{c}$ by the definition of ellipse. This guarantees that a (u, v) -path lying within $\mathcal{E}_{\hat{c}}$ can be found by BFR. Furthermore, the $O(1)$ -model assumption implies that the disks with centers at the explored nodes and radius $d_0/2$ are mutually disjoint. Combining this with the observation that the length of the semimajor axis of $\mathcal{E}_{\hat{c}}$ is $\hat{c}/2$, the number of explored nodes inside $\mathcal{E}_{\hat{c}}$ is upper bounded by

$$\frac{\pi(\frac{\hat{c}}{2} + \frac{d_0}{2})^2}{\pi(\frac{d_0}{2})^2} = O(\hat{c}^2). \quad (9)$$

Since G_{GG} is a planar graph, the number of edges is linear in the number of nodes (it is well known that $m \leq 3n - 6$, where m, n are the number of edges and the number of nodes in a planar graph). Hence, there are at most $O(\hat{c}^2)$ edges within \mathcal{E} . Finally, by noticing that each edge is traversed at most four times in BFR, the theorem follows.

Since \tilde{c} is not known a priori, BFR might get stuck if the ellipse is too small (see Fig. 11c). In such a case, the algorithm enlarges \hat{c} to obtain a larger ellipse and restarts BFR. By adaptively adjusting \hat{c} , the algorithm obtains an estimate of \tilde{c} such that $\tilde{c} \leq \hat{c} \leq 2\tilde{c}$. For this \hat{c} , BFR produces a route with cost at most $O(\tilde{c}^2)$ and thus $O(c_*^2)$ by Corollary 1.

From the above analysis, it can be seen that the $\mathcal{O}(1)$ -model assumption is crucial to obtain the asymptotic optimality of AFR because of the following two reasons: First, the planar subgraph providing the faces must be a spanner of G . This is guaranteed by Corollary 1. Second, the number of edges explored must be bounded. This is guaranteed by inequality (9). A natural question is: besides $\mathcal{O}(1)$ -model, are there any other graphs supporting these two properties? In view of Theorems 9 and 10, if Euclidean metric or link metric is used, a graph G with constant density and its subgraph G_{RDG} will do. In view of Corollary 2, a bounded degree graph and its subgraph G_{GG} might be another candidate with respect to any nondecreasing cost function (however, some more efforts have to be made to adapt the algorithm).

Another idea is based on the observation that in AFR, the whole boundary of a face must be explored before the algorithm moves to the next face, which seems to be a waste of time. On the other hand, greedy forwarding strategy is averagely more efficient than face routing [55]. This is particularly true for dense graphs, since a packet can be forwarded to a visible node instead of going through a lot of small hops. So, the idea is an *early fallback to greedy mode*.

The algorithm $GOAFR^+$ is the combination of the above ideas and the bounded face routing. Face routing is only used when encountering a local minimum. Two counters p and q were introduced, counting the number of explored nodes which are closer and not closer to the destination than the starting node, respectively. If $p > \sigma q$, where σ is a constant (taken to be 1/100 in [54]), the algorithm advances to the explored node which is closest to the destination. Kuhn et al. proved that $GOAFR^+$ is asymptotically optimal for bounded degree unit disk graphs with respect to any nondecreasing cost function.

Theorem 12 ([54]) *Let G be a bounded degree unit disk graph. If u, v are connected in G , then $GOAFR^+$ finds a route with cost $O(c_*^2)$.*

To extend $GOAFR^+$ to deal with the general (unbounded degree) unit disk graphs, a clustering strategy is used. A routing backbone graph G_{BG} is constructed such that $V(G_{BG})$ is a connected dominating set of G and G_{BG} has bounded degree. Such G_{BG} can be constructed in a distributed way, for example, by the algorithms

in [1, 35, 87]. Every *ordinary node* $u \in V(G) - V(G_{BG})$ is assigned to one of its dominators $h(u) \in V(G_{BG})$ (viewed as joining the cluster with cluster head $h(u)$). These assignments enlarge G_{BG} to the *clustered backbone graph* G_{CBG} . It is known that G_{CBG} is a spanner of G with respect to link metric [87]. A packet with source u and destination v is first sent to $h(u)$, then routed through G_{BG} to $h(v)$, and finally sent to v . Using *GOAFR⁺* on G_{BG} , one obtains an asymptotic optimal route for G_{CBG} and thus G . This result also holds for any *linearly bounded cost function*, defined to be a function c for which there exists an $m > 0$ such that $c(d) \geq m \cdot d$ for any $d \in [0, 1]$. Both link metric and Euclidean metric are linearly bounded cost functions. Nondecreasing functions which are not linearly bounded are called *superlinear cost functions*. The energy metric is an example. An example was constructed in [54] showing that there are no geometric routing algorithms whose cost is bounded above by a function of c_* . To sum up:

Theorem 13 ([54]) *For any linearly bounded cost function, there is a distributed algorithm finding a route of cost at most $O(c_*^2)$, while for superlinear cost function, such an algorithm does not exist.*

3.3 Routing Based on Virtual Coordinates

In a virtual coordinate system, a set of landmarks serve as the references, the nodes are named not by their absolute positions but by their relations with the landmarks. The idea of using virtual coordinate in large networks first originated in [86], in which Tsuchiya proposed a hierarchical landmark-based scheme to generate names for the nodes. The work [72] made use of virtual coordinate to guide the greedy forwarding. The focus was on how to generate the virtual coordinate system in the absence of location information. Some nodes on the boundary are detected to serve as the landmarks. These nodes are localized by least square method based on their mutual distances. Any other node iteratively updates its virtual coordinate by putting itself at the center of its neighbors' current coordinates.

Section 3.3.1 first introduces the algorithm GLIDER proposed by Fang et al. [23] to convey the main idea of routing algorithms based on a virtual coordinate system. Then some related works will be introduced.

The choice of landmarks is crucial to the performance of the routing algorithms. Section 3.3.2 introduces the work in [65] which proposed a distributed randomized choice of landmarks and an associated routing algorithm GLDR such that the stretch factor of the routing is bounded for continuous domain.

3.3.1 GLIDER

The concern of GLIDER is how to efficiently route in a network with irregular shapes such as long narrow corridors or big holes. The routing is divided into two hierarchical levels: the *global routing* and the *local routing*. In the global routing, *combinatorial Delaunay graph* (CDG) on a set of nodes called *landmarks* is constructed to capture the global topology of the network, which is used to guide

the general orientation of the routing such that the influence of harsh topological regions can be alleviated. CDG divides the plane into *tiles*. The local routing in a tile or between two tiles follows the greedy forwarding strategy. By choosing the landmarks appropriately, each tile will have a good topology such that the hop distances approximate the Euclidean distances fairly accurate and greedy forwarding may work well.

Use $d(u, v)$ to denote the hop distance between nodes u and v in the communication graph G . The combinatorial Delaunay graph is the discrete extension of the classic (continuous) Delaunay triangulation.

Definition 2 For the communication graph $G = (V, E)$ and a set of landmarks $\mathcal{L} \subseteq V$, the *Voronoi cell* $V(u)$ at a node $u \in \mathcal{L}$ is defined to be

$$V(u) = \{v \in V \mid d(v, u) \leq d(v, w) \forall w \in \mathcal{L}\}.$$

Use $v_1 \sim v_2$ to stand for $v_1 = v_2$, or v_1 is adjacent with v_2 in G . The *combinatorial Delaunay graph* is the graph $D(\mathcal{L})$ with vertex set \mathcal{L} ; two nodes $u_1, u_2 \in \mathcal{L}$ are adjacent in $D(\mathcal{L})$ if and only if there exist nodes $v_1 \in V(u_1)$ and $v_2 \in V(u_2)$ such that $v_1 \sim v_2$. The nodes v_1, v_2 are said to be *witnesses* to the edge u_1u_2 .

By the above definition, it is easy to see that for each node $v \in V(u)$, the shortest (u, v) -path is completely contained in $V(u)$. As a consequence, the subgraph of G induced by the nodes in $V(u)$ is connected. Thus Voronoi cells partition the sensor field into connected *tiles*. The following theorem shows that $D(\mathcal{L})$ is indeed a compact high-level atlas of G , which can be used to guide the general direction of the routing.

Theorem 14 ([23]) *If G is connected, then $D(\mathcal{L})$ is connected.*

The local routing is guided by a virtual coordinate system which was called *local landmark coordinate system*. To better convey the idea, Fang et al. [23] first introduced a continuous version of the system. Let u_1, u_2, \dots, u_k be k landmarks. For a point x , let $B_i(x) = \|x - u_i\|^2$ be the squared Euclidean distance between x and u_i , $B(x) = (B_1(x), B_2(x), \dots, B_k(x))$, and $\bar{B}(x) = \frac{1}{k} \sum_{i=1}^k B_i(x)^2$. The *centered landmark-distance coordinate* $C(x) = (B_1(x) - \bar{B}(x), B_2(x) - \bar{B}(x), \dots, B_k(x) - \bar{B}(x))$. The *modified virtual distance function* is $md(x, y) = \|C(x) - C(y)\|_2^2$, where $\|\cdot\|_2$ is the 2-norm of the vector space \mathbb{R}^k . In *gradient descent*, a node forwards the packet to its neighbor which is closest to the destination, where *closeness* is measured by md . Fang et al. proved that gradient descent works well for the continuous field.

Theorem 15 ([23]) *In the continuous plane, the gradient descent is guaranteed to converge to its destination as long as there are at least three noncollinear landmarks.*

The discrete local landmark coordinate system is an analog of the above, replacing Euclidean distance by hop distance. For the nodes in a Voronoi cell $V(v)$,

the landmarks used in establishing the local coordinate system are v itself and the neighbors of v in $D(\mathcal{L})$.

For a packet to be sent from node v to node v' , suppose $v \in V(u)$ and $v' \in V(u')$. By [Theorem 14](#), there is an (u, u') -path $u_1 u_2 \dots u_k$ in $D(\mathcal{L})$. The packet is sent by gradient descent from tile to tile. In the first tile $V(u_1)$, the destination of the gradient descent is u_2 . As soon as the packet hits the boundary of $V(u_2)$, the destination is switched to u_3 . The process continues until the packet hits $V(u_k)$, and the destination is v' in the last tile.

In GLIDER, the atlas $D(\mathcal{L})$ is stored at every node, which is unrealistic in wireless sensor networks because of the limited storage capacity of the sensors. In [\[32, 33\]](#), Funke and Milosavljević modified GLIDER into a local algorithm. There are two main modifications. The first modification chooses the landmarks to be a *k-hop maximal independent set* for some fixed parameter k , that is, every pair of landmarks are at least $(k + 1)$ -hops away from each other and every other node is within k -hops of at least one landmark. The advantage of such a choice is twofold: first, it makes the tiles small (the diameter of each cell is at most $2k$), so flooding a tile is relatively cheap, and second, it results in a bounded maximum degree of $D(\mathcal{L})$, which further results in a low storage load on each node. The second modification is that instead of finding a path in $D(\mathcal{L})$, the packet is forwarded from one tile to another in a greedy way with respect to the locations of the landmarks. To be more precise, suppose the packet is currently in tile $V(u)$, the algorithm searches the neighbors of u in $D(\mathcal{L})$ to find a landmark v such that v is closer to the landmark of the destination tile than u . Then the packet is forwarded from $V(u)$ to $V(v)$. Such a strategy eliminates the need to store the whole atlas at every node. It should be noted that different from [Sect. 3.1](#), the greedy strategy here is used on $D(\mathcal{L})$ instead of on the communication graph G . To avoid stuck at local minimum, face routing strategy is used, again on $D(\mathcal{L})$ instead of on G . Notice that $D(\mathcal{L})$ is not planar in general. So, for the purpose of face routing, [\[32, 33\]](#) constructed a planar subgraph of $D(\mathcal{L})$ called *combinatorial Delaunay map* (CDM). For a landmark u and a node v , v is called an *u-vertex* if u has the smallest ID in v 's nearest landmarks. Two landmarks u_1, u_2 are adjacent in CDM if and only if there is an (u_1, u_2) -path in G whose 1-neighborhood consists only of u_1 -vertices and u_2 -vertices, and going from u_1 to u_2 along the path, all u_1 -vertices precede u_2 -vertices. Funke and Milosavljević [\[33\]](#) proved that CDM is indeed planar for quasi unit disk graphs.

Theorem 16 ([33]) *The combinatorial Delaunay map is planar for any d-quasi unit disk graph with $1/\sqrt{2} \leq d \leq 1$.*

The Beacon vector routing (BVR) algorithm proposed in [\[29\]](#) uses greedy forwarding strategy based on a distance function in a virtual coordinate system as follows: Suppose $\mathcal{L} = \{u_1, u_2, \dots, u_m\}$ is the set of landmarks which are chosen randomly. The coordinate of a node v is the vector $c(v) = (d(v, u_1), d(v, u_2), \dots, d(v, u_m))$, where the i -th component $c(v)_i = d(v, u_i)$ is the hop distance between v and u_i . Suppose D is the destination. For a parameter k , let $C_k(D)$ be the index set of k nearest landmarks to D . The distance function on node x is defined as

$$\delta_k(x, D) = M\delta_k^+(x, D) + \delta_k^-(x, D),$$

where M is a sufficiently large constant, and

$$\begin{aligned}\delta_k^+(x, D) &= \sum_{i \in C_k(D)} \max\{c(x)_i - c(D)_i, 0\}, \\ \delta_k^-(x, D) &= \sum_{i \in C_k(D)} \max\{c(D)_i - c(x)_i, 0\}.\end{aligned}$$

The packet with destination D which is currently at node v is forwarded to a node x which minimizes $\delta_k(x, D)$. Intuitively, among the k nearest landmarks of D , those which are nearer to D exerts a *pulling* force and the remaining ones exert a *pushing* force.

3.3.2 Choice of Landmarks

In [65], Nguyen et al. proposed a distributed randomized method to choose the landmarks and an associated routing algorithm called greedy landmark descent routing (GLDR). In the continuous domain, a constant stretch factor can be guaranteed. The performance in the discrete setting was shown by simulation.

The region was assumed to be *approximately regular* in the following sense: For a positive integer r and a node u , the r -hop neighborhood of u is the set of nodes at most r -hops away from u . For two real numbers $1 \leq a \leq b$, a node distribution is said to be (a, b) -regular if for any real number $r \in \mathbb{R}$, the number of nodes in the $\lfloor r \rfloor$ -hop neighborhood of any node is between ar^2 and br^2 .

The idea of the landmark selection is to guarantee both a good coverage and a good separation, which can be realized by selecting an r -hop maximal independent set (r -MIS). Since the sequential selection of r -MIS is time-consuming and the totally randomized parallel selection chooses too many redundant nodes, a method was proposed to balance the time and the size as follows: Each node u generates a random number p_u uniformly in $[0, 1]$. If it does not receive any claim of landmark at the end of Kp_u unit time, where a unit time is the time needed for a packet to be sent from one node to its neighbor, then it claims itself to be a landmark. Nguyen et al. [65] proved that the expected number of landmarks produced by the above method is upper bounded in a local area.

Theorem 17 ([65]) *For an (a, b) -regular distribution, the expected number of landmarks in any r -hop neighborhood is upper bounded by $\frac{9br^2}{K} + 16b - 1$.*

In particular, if K is taken to be $K = \Theta(r^2)$, then the upper bound is a constant.

The outline of GLDR is as follows: The virtual coordinate of each node is addressed by a subset (not all) of its nearest landmarks. These landmarks are called *addressing landmarks*. Suppose u is to send a packet to v . It first selects the landmark l from the addressing landmarks of v such that the ratio $d(u, l)/d(v, l)$ is maximized. Then the packet is routed through a shortest path towards l until it reaches a node z with $d(z, l) = d(v, l)$. If z is not v itself, the process repeats.

To deal with the case near boundary, an *Augmented GLDR* was proposed by *virtually expanding* the region and using the *mirror images*.

In the continuous domain (in which every point on the plane can serve as a relay node, the distance is the Euclidean distance, and the shortest path is just along a straight line), the addressing landmarks can be chosen such that the stretch factor is bounded by a constant. Suppose u, v are the source and the destination, respectively, and l is the current addressing landmark chosen as in the above paragraph. Let u' be the point on the line segment ul such that $\|lu'\| = \|lv\|$. The *one-step stretch factor* of routing from u to v using landmark l is defined as $s = \|uu'\| / (\|uv\| - \|u'v\|)$. Denote by R the minimum distance between the destination v and its addressing landmarks. Let $f(s)$ be a function on s defined as follows:

$$f(s) = \frac{4}{1 + p - \sqrt{q}}, \quad p = 1 - \frac{1}{s^2}, \quad z = 1 - \frac{1}{s},$$

$$q = (1 - p^2) + 2p^2(1 - z^2) + 2p\sqrt{(1 - z^2)(1 - p^2z^2)}.$$

Theorem 18 ([65]) *Suppose the domain is continuous. If $R > 2r$, then f^{-1} exists and the one-step stretch factor $s \leq f^{-1}(R/r)$. If R is large enough compared to r , then augmented GLDR successfully delivers the packet through a path with bounded stretch factor. In particular, if $R \geq 320r$ and $s < 2.5$, then the stretch factor of augmented GLDR is at most $7s/(5 - 2s)$.*

Based on the above theorem, the addressing landmarks can be chosen according to the requirement of the stretch factor, and combining with [Theorem 17](#), the expected number of the addressing landmarks for each node can be bounded by a constant.

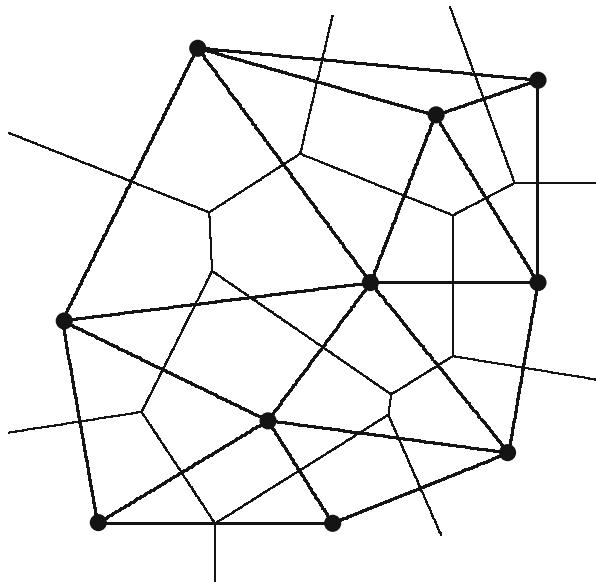

3.4 Greedy Embedding

The success of a greedy routing depends not only on the greedy criterion but also on the embedding. If the embedding is such that for any two distinct nodes u and v , node u has a neighbor which is nearer to v than u is, then greedy forwarding always succeeds in delivering packets, where *nearness* depends on the greedy criterion. Such an embedding is called a *greedy embedding* or a *greedy drawing*. Some literatures also use the terminologies *support the greedy routing* and *defeat the greedy routing* to indicate whether the greedy strategy always succeeds.

In the *Euclidean greedy routing*, the *nearness* is measured by the Euclidean distance to the destination. An embedding which supports Euclidean greedy routing is the Delaunay triangulation.

Delaunay triangulation is similar to Delaunay graph in [Sect. 2.4.3](#). The difference is that Euclidean distance is used here. Let V be a set of nodes on the plane. For a node $u \in V$, the *Voronoi cell* $V(u)$ is the convex region containing all the points on the plane which are closer to u than to any of the other nodes in V , that is,

Fig. 13 The *thick lines* form the Delaunay triangulation. The *thin lines* indicate the Voronoi diagram

$V(u) = \{p \in \mathbb{R}^2 \mid \|pu\| \leq \|pv\|, \forall v \in V, v \neq u\}$, where $\|pu\|$ is the Euclidean distance between p and u . The *Voronoi diagram* partitions the whole plane into Voronoi cells. *Delaunay triangulation* is the dual graph of the Voronoi diagram (see Fig. 13). It is well known that as long as no four nodes are cocircular, the Delaunay triangulation is well defined. It is also well known that the circumcircle of any Delaunay triangulation contains no node of V inside [71]. In fact, this property is often used as an equivalent definition of Delaunay triangulation, which can be generalized to higher-dimensional space.

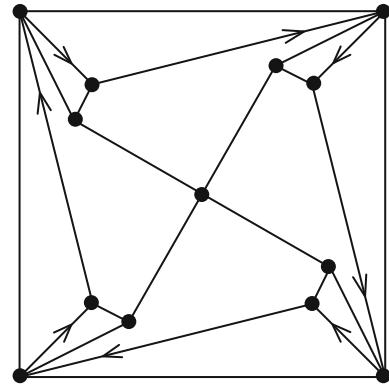

Theorem 19 ([10]) *Delaunay triangulation supports Euclidean greedy routing.*

The following result was first conjectured by Papadimitriou and Ratajczak [69]: In [19], Dhandapani discovered that any planar triangulation has an Euclidean greedy embedding. The proof is probabilistic. A constructive algorithm was given by Angelini et al. in [2]. The conjecture was completely solved by Leighton and Moitra [58].

Theorem 20 ([58, 69]) *Any planar 3-connected graph supports Euclidean greedy routing.*

In *compass routing*, the *nearness* is measured by the angle $\angle wuv$, where u is the current location of the packet, v is the destination, and w is a neighbor of u . Compass routing cannot guarantee the delivery either. Consider Fig. 14, there might be cases that the route goes infinitely around a loop. In fact, it was proved by Bose and Morin [10] that in any triangulation which defeats the compass routing, the packet must be trapped in a cycle. However, compass routing will never be defeated by

Fig. 14 An illustration of loop in compass routing. The arrows indicate the route

Delaunay triangulation [51]. Bose and Morin [10] generalized this result to regular triangulation. A *regular triangulation* is obtained by projecting the faces of the convex hull of a 3-dimensional polytope onto the plane. Delaunay triangulation is a special case of regular triangulation when the nodes of the polytope are all on a paraboloid.

Theorem 21 ([10]) *Any regular triangulation supports the compass routing.*

Suppose the current location of the packet is u and the destination is v , let w_1 (resp. w_2) be the neighbor of u which minimizes the clockwise (resp. counterclockwise) angle $\angle vuw_1$ (resp. $\angle vuw_2$). In the *randomized compass routing*, the packet is forwarded to one of w_1 and w_2 with the same probability. A triangulation is said to defeat a randomized routing if there exists a pair of source-destination nodes u, v such that the probability of successful delivery is zero in finite number of steps.

Theorem 22 ([10]) *No triangulation defeats the randomized compass routing.*

In [50], Kleinberg proved that any connected graph has an embedding in the *hyperbolic space* such that greedy strategy always succeeds with respect to the hyperbolic distance. However, for the applications in wireless networks, embeddings in the 2- or 3-dimensional Euclidean space are more interesting.

Despite of the elegance of the above results, the storage load is heavy [21]. *Succinct greedy embedding* with low load on the nodes was studied only very recently. Some related works may be found in [3, 40, 42].

For the study of greedy embeddings in a region with holes, discrete *Ricci flows* are used in [73]. The idea is to establish a *conformal map* from the region \mathcal{R} to a domain \mathcal{D} such that every hole of \mathcal{R} is mapped to a circle in \mathcal{D} (notice that greedy strategy never gets stuck at a circle).

In [28], Flury et al. presented an algorithm to find a greedy embedding of a graph in $\mathbb{R}^{O(\log^3 n)}$ with stretch factor $O(\log n)$; each coordinate of a node uses $O(\log n)$ bits. For *combinatorial unit disk graph* (unit disk graph without geometric information), the embedding can be made into $\mathbb{R}^{O(\log^2 n)}$ with a constant stretch factor.

4 Boundary Recognition

Boundary recognition (both outer boundary and inner boundary) is important for keeping track of nodes entering or leaving a region and communication between the inside and the outside. It is also important for efficient algorithms in wireless networks. As one has seen, a greedy forwarding strategy encounters a failure particularly around a *hole*, a void region in which there are no sufficient sensors. Holes are a common phenomenon in the real-world wireless sensor network. Even when the sensors are distributed uniformly at random, there might be holes due to irregular environment (such as dense vegetation or high buildings blocking direct communications) or depletion of sensor powers. Detecting holes helps with efficient routing. Furthermore, detecting holes can identify regions of interests to the users. For example, if a sensor marks itself to be unavailable when the local temperature is above a preestablished critical value, then detecting holes helps to forecast a burst of fire. If a sensor marks itself to be unavailable if the power is below a threshold, then detecting holes helps to identify regions in which new sensors should be deployed to improve the connectivity. Neglecting the existence of holes may arouse serious problems in the network. In fact, since nodes on the boundaries are usually loaded with more traffic, their energy depletes more rapidly, and thus a small hole tends to grow larger and larger.

In boundary recognition, one has to first make clear *what is a boundary*? Some authors defined boundaries by using *face boundaries* [24] and *chordless cycles* [52]. In [25, 26], boundaries are implicitly defined by identifying those nodes which are more likely to near the boundaries. One problem about the definitions is that, provided with connectivity information *only*, holes might depend on the embedding of the graph. The paper [75] contains a detailed discussion on these definitions and their limitations. To overcome this problem, Saukh et al. [75] proposed the definition of *generalized boundary* which contains nodes on a boundary of at least one straight-line embedding.

To recognize the boundaries, various methods were proposed, including geometric methods [24], statistical methods [25, 26], graph methods [30, 31, 52, 75], and topological methods [88]. They are introduced in the following.

4.1 Geometric Method

The first paper on boundary detection is [24], in which Fang et al. defined holes in a way that the greedy forwarding can get stuck only at a node on the boundary of a hole. This subsection introduces their method and its application in geometric routing.

The strict mathematical definition of a hole given in [24] is closely related with *stuck nodes*, the nodes at which greedy forwarding strategy fails. There are two types of stuck nodes: weakly stuck nodes and strongly stuck nodes.

Definition 3 ([24]) A node u is a *weakly stuck node* (resp. *strongly stuck node*) if there exists a node (resp. location) p outside of u 's transmission range such that no neighbor of u is closer to p than u itself.

Notice that the only difference in the above definitions is that p is a *node* for a weakly stuck node and is a *location* for a strongly stuck node. A weakly stuck node is always a strongly stuck node. Fang et al. defined two kinds of holes in terms of weakly stuck nodes and strongly stuck nodes, respectively.

As one has seen in Sect. 3.4, Delaunay triangulation supports compass routing. But the problem is that some Delaunay edges might be longer than 1, which is not available in the unit disk graph. To overcome this problem, [24] used the *restricted Delaunay graph* (RDG) as in Sect. 3.2.1. A node which is adjacent with a Delaunay edge longer than 1 might be a potential stuck node. The first kind of hole, called *weak-hole*, is defined to be a face of RDG with degree at least 4 (the degree of a face is the number of edges on the boundary of the face).

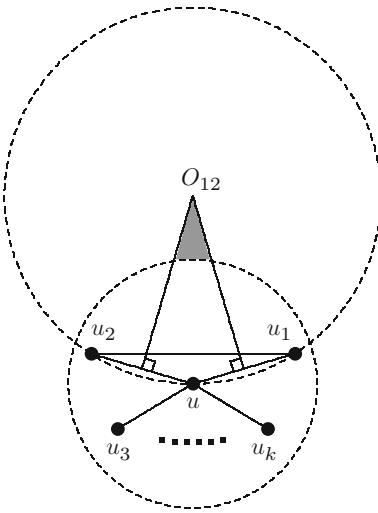

Theorem 23 ([24]) All the weakly stuck nodes lie on the boundaries of the weak-holes.

By Theorem 23, one can detect all the weakly stuck nodes and their corresponding weak-holes by computing the Delaunay triangulation and then removing all the edges of length greater than one. However, the computation is heavy [62, 71]. So Fang et al. continued to give another definition of hole using strongly stuck nodes and pseudo Jordan curve (recall that Jordan curve is a non-self-intersecting continuous loop in the plane).

Definition 4 ([24]) A directed polygonal curve C is a *pseudo Jordan curve* if by duplicating nodes into copies with infinitesimal perturbation, each copy corresponding to one occurrence of the node on C , the revised polygonal curve is a Jordan curve. A *strong-hole* is a region bounded by a pseudo Jordan curve, which is called the *boundary* of the strong-hole, such that all the strongly stuck nodes are on the boundaries of all the strong-holes.

In [24], the authors proposed a *Tent Rule* to detect strongly stuck nodes. Suppose a node u has k neighbors u_1, u_2, \dots, u_k in the unit disk graph, ordered counterclockwise. Let us first consider the question of when there can exist a location p as in Definition 3 in $\text{Cone}(u_1uu_2)$, the cone spanned by radials uu_1 and uu_2 . See Fig. 15 for an illustration. For $i = 1, 2$, draw a perpendicular bisector l_i of the line segment uu_i . Suppose l_1, l_2 intersect at point $O_{1,2}$. Then $O_{1,2}$ is the center of the circumcircle of triangle Δu_1uu_2 . A location p in $\text{Cone}(u_1uu_2)$ which is outside of the transmission range of u and is closer to u than to u_1 and u_2 can only lie in the shaded area of Fig. 15. So, if the distance $\|uO_{1,2}\| > 1$, then u is a potential strongly stuck node. In such a case, $\angle u_1uu_2$ is called a *stuck angle*. Notice that all the information needed to find a stuck angle at a node is its 1-hop neighborhood, which is completely local.

Fig. 15 An illustration of Tent Rule and stuck angle

Theorem 24 ([24]) *If u is a strongly stuck node, then there exists a stuck angle at u .*

Theorem 24 provides a necessary condition to guarantee that all the strongly stuck nodes can be found using Tent Rule.

Having found a strongly stuck node u , the strong-hole containing u can be found by the algorithm BoundHole proposed in [24], which can be implemented locally by using only angles between adjacent edges.

With the holes detected by BoundHole, geometric routing can be done as follows: When the greedy forwarding fails at a stuck node u , u must be on the boundary of a hole (by Theorem 23 or Definition 4). After that, recovery mode is activated and the packet is routed along the boundary of the hole, say, by the right-hand rule. When the packet gets to a node v which is closer to the destination D than u , the greedy forwarding mode is resumed. When D is outside the hole, such a node v always exists. When D is inside the hole, the packet might go around the boundary of the hole back to u without coming across any node closer to D than u . As long as D is reachable from u , there must be a path from u to D which intersects the boundary of the hole, say, edge $x'y'$ on the path intersects edge xy on the boundary of the hole. One of x', y' , say x' , must be a 1-hop neighbor of x or y in the unit disk graph. In this case, a *restricted flooding mode* is initiated, in which every node on the boundary of the hole sends the packet to all its 1-hop neighbors. In particular, x' can receive the packet and forward it to D .

4.2 Statistical Method

Assuming a uniform random distribution of sensors, Fekete et al. proposed statistical methods to recognize nodes near the boundaries [25, 26].

The method used in [25] is based on the intuition that nodes on the boundaries have a much lower average degree than those in the interior. Suppose A is the whole region containing n nodes. Use $|A|$ to denote the Lebesgue measure of A . Under the assumption of uniform distribution, a node u in the *interior* has an estimated neighborhood size of

$$\mu = (n - 1) \frac{|B_R(u)|}{|A|},$$

where R is the transmission range of the nodes and $B_R(u)$ is the disk with center u and radius R . Given a constant $\alpha < 1$, nodes with degree less than the threshold $\alpha\mu$ claim themselves to be boundary nodes. Notice that μ is not known a priori since the region A is exactly what needs to be determined. The performance of the method depends on the estimation of μ and the choice of α . In [25], μ is estimated based on a node degree histogram, and α is computed by sampling possible values of α and keeping track of the number of connected boundary components.

The method proposed in [26] utilizes centrality measures which are commonly used in social networks. The idea is that the centrality of nodes on the boundary is much lower than those in the interior. There are two major classes of centralities: local and global. In fact, degree used in [25] is one type of measures of local centrality. Eigenvalues of a matrix is an example of global centrality. Three centrality measures were used in [26]. The idea is based on the intuition that more shortest paths will pass through interior nodes than boundary nodes. Use $\sigma_{uv}(w)$ to denote the number of shortest (u, v) -paths containing node w . The *stress centrality* at node w is defined as

$$st(w) = \sum_{u, v \in V} \sigma_{uv}(w),$$

where V is the set of nodes in the region. Let σ_{uv} be the number of shortest (u, v) -paths. Assume that a packet with source u and destination v chooses any shortest (u, v) -path with the same probability. Then the probability that node w is used to transmit the packet is $\sigma_{uv}(w)/\sigma_{uv}$. The *betweenness centrality* at node w is defined as

$$betw(w) = \sum_{u, v \in V} \sigma_{uv}(v)/\sigma_{uv}.$$

To make the estimation localized, one restricts the attention to those nodes which are nearby. The *restricted stress centrality* at node w is defined as

$$st_r(w) = \sum_{u, v \in N_\delta(w)} \sigma_{uv}(w),$$

where $N_\delta(w)$ is the set of nodes at most δ -hops away from w . Boundary nodes are distinguished by a properly set threshold. For example, for $\delta = 1$, any node with $st_r(w) \leq \theta \binom{\mu}{2}$ claims itself to be a boundary node, where μ is the estimated average degree and θ is a parameter playing the same threshold role as α in [25]. It was

proved in [26] that if the density is sufficiently large, nodes are classified correctly with a high probability using the restricted stress centrality with $\delta = 1$.

The major limitation of the above two methods is the assumption on the sensor distribution and the high density of the sensors.

4.3 Graph Method

This subsection introduces two kinds of graph-based methods in identifying the boundaries.

4.3.1 Contour-Based Method

The methods proposed by Funke and Klein in [30, 31] are based on the observation that contours are broken at boundaries.

Unlike the continuous field, contour has no definition in wireless sensor networks since the distances are counted by hops in the communication graph (which is a unit disk graph G in [30, 31]). Funke proposed isoset which resembles contour. For a node u (called *beacon* in [30] or *seed* in [31]) and a fixed integer k , the set $\mathcal{I}(k) = \{v \mid d_{\text{hop}}(u, v) = k\}$ is called an *isoset of level k* , where $d_{\text{hop}}(u, v)$ is the hop distance between u and v in G . Suppose the subgraph of G induced by $\mathcal{I}(k)$ has t -connected components $C_1(k), C_2(k), \dots, C_t(k)$. If $t \geq 2$, the isoset $\mathcal{I}(k)$ is *broken* and holes might exist between the connected components. The *ends* of each $C_i(k)$ indicate the locations of the holes, and the ends can be identified as the nodes in $C_i(k)$ having the largest *radius* in $C_i(k)$ (the radius of a node w in a connected graph H is the hop distance between w and the node in H which is farthest from w). The ends are *marked* as near boundaries.

The above method is not local. To overcome it, more seeds are chosen, and for each seed s , only the isosets in a *bounded* neighborhood around s are examined, namely, the isosets $\mathcal{I}(k)$ with $h_{\min} \leq k \leq h_{\max}$. By choosing the seed set to be a maximal independent set, the running time can be bounded. In fact, it was proved in [31] that with h_{\max} being a constant, the running time is $O(n + m)$, where n and m are the number of vertices and the number of edges of the unit disk graph, respectively. Funke and Klein [31] also provided a theoretical guarantee under the assumption that the holes are all circles which are not too small, the distances between different holes are large enough, and the density of sensors in the non-hole area is high enough. To be more precise, they defined an ε -good sensor distribution and proved the following theorem. A set \mathcal{S} of sensors is ε -good if for every point $p \in \mathbb{R}^2$ which is not in a hole, there is a sensor $s \in \mathcal{S}$ with $\|sp\| \leq \varepsilon$.

Theorem 25 ([31]) *For circular holes with radius at least $r_{\text{hole}} = 72$, if the minimum distance between holes is at least $\Delta_{\text{hole}} = 18$, the sensor distribution is ε -good for $\varepsilon = 1/64$, and by taking $h_{\min} = 4$ and $h_{\max} = 8$, Funke and Klein's algorithm marks for each boundary point a sensor node within distance at most 4.8, and every marked sensor node has a boundary point within distance 2.8.*

4.3.2 Identifying Inner Nodes

The methods used in [52] and [75] aim to recognize *inner nodes*. All the other nodes are considered to be on the boundaries.

The graph model considered in these two papers is quasi unit disk graph (QUDG) (see Sect. 3.3 for the definition). It was assumed that $d \geq 1/\sqrt{2}$ in [52] and [75]. This value is crucial to the geometrical analyses, as can be seen from the following lemma:

Lemma 2 ([52]) *Let $G = (V, E)$ be a d -QUDG with $d \geq 1/\sqrt{2}$, u, v, x, y be four distinct nodes in V with $uv, xy \in E$. If the two straight-line segments $p(u)p(v)$ and $p(x)p(y)$ intersect, then at least one of the four edges ux, uy, vx, vy is in E .*

A cycle $C = u_0u_1\dots u_{k-1}u_0$ is *chordless* if $u_iu_j \notin E$ for any i, j with $|i - j| > 1$, where the operation “ $-$ ” is modulo k . The embedding $p(C)$ of a chordless cycle C divides the plane into an infinite face and at least one finite face (there might be more than one finite faces if C is self-intersecting). For a node set U , $N(U)$ is the set of nodes which are adjacent with at least one node in U , and $N[U] = N(U) \cup U$ is the closed neighborhood of U . The following result is a corollary of Lemma 2:

Corollary 3 ([52]) *Let $G = (V, E)$ be a d -QUDG with $d \geq 1/\sqrt{2}$, C be a chordless cycle in G , and U be a connected node set of G . If $N[C] \cap U = \emptyset$, then either U is completely contained in the inside of C or completely contained in the outside of C .*

Denote by $fit_d(k)$ the size of a maximum independent set I which can be placed inside a chordless k -cycle in a d -QUDE such that $I \cap N[C] = \emptyset$. Based on the above property, the following result is easy to see, which provides a criterion for a connected set of nodes to lie outside of a chordless cycle.

Lemma 3 ([52]) *Under the assumption of Corollary 3, if U has an independent node subset I with $|I| > fit_d(|C|)$, then U is completely outside of C .*

To decide whether there is a node inside of a chordless cycle is much more complicated. For this purpose, [52] proposed a structure called *m-flower* and proved that for a flower, there is a node inside of its related chordless cycle.

The algorithm in [52] looks for a family of node sets $\mathcal{U} = \{U_i\}$ and a family of chordless cycles $\mathcal{C} = \{C_b\}$ such that the nodes in $\bigcup_i U_i$ are guaranteed to lie inside of the cycles. Such a pair $(\mathcal{C}, \mathcal{U})$ is called a *feasible geometry description* (FGD). The goal is to find an FGD with as many inside nodes as possible (recall that the remaining nodes are regarded as boundary nodes; hence, the boundary might be clearer with more inner nodes identified). The algorithm starts from some FGD and then iteratively extends it to another FGD with more inside nodes. The initial FGD is found by detecting a flower. As explained in the previous paragraph, this provides the initial \mathcal{I} and \mathcal{C} . Then, the FGD is enlarged by the so-called augmenting cycles.

The success of the above method depends on the existence of a flower. Graph G is called *locally ε -dense* in a region $A \subseteq \mathbb{R}^2$, if every ε -disk contained in A contains a node of G , that is, for any point $x \in A$ with $B_\varepsilon(x) \subseteq A$, there is a node $u \in V(G)$ with $\|ux\| \leq \varepsilon$.

Lemma 4 ([52]) *For $d = 1$ and $0 < \varepsilon < \frac{3}{2} - \sqrt{2}$, if there exists a point $x \in \mathbb{R}^2$ such that G is locally ε -dense in the disk $B_3(x)$, then G contains a 4-flower.*

Notice that the above lemma insures the existence of a flower only when the network is dense enough, which cannot be guaranteed in a real-world network. To overcome this problem, Saukh et al. [75] proposed a generic classes of *patterns* to ensure some node inside of the pattern, which makes the algorithm in [75] works much better in a sparse network.

4.4 Topological Method

Homology, being a rigorous mathematical method for detecting and categorizing holes, steps naturally into the way of hole recognition in wireless sensor networks. The task is how to adapt it to suit the discrete settings and the special requirements of wireless networks.

The method used in [88] is based on the observation that holes incur a *void* in a shortest path tree. The rough idea is as follows: The *flow* of a shortest path tree T forks near a hole and meets again after going along opposite borderlines of the hole. The nodes where the tree flow meets again were called *cuts*. By tracking their *least common ancestor* (LCA) on the tree (which is far away because of the hole) will trap the hole. To be more concise, Wang et al. [88] defined a pair of *neighboring* nodes u, v to be a *cut pair*, if:

- (a) The hop distances $d_{hop}(u, w)$ and $d_{hop}(v, w)$ are above a threshold δ_1 , where $w = LCA(u, v)$ is the least common ancestor of u, v on T .
- (b) $\max\{d_{hop}(x_u, x_v)\}$ is above a threshold δ_2 , where the maximum is taken over all node pairs (x_u, x_v) with x_u being a node on the (u, w) -path on T and x_v being a node on the (v, w) -path on T .

The first condition indicates that the LCA is far away from the cut pair. The second condition indicates how *fat* is the hole that one wants to detect. Topologically, cut is a counterpart of *cut locus* [15] in the continuous setting (roughly speaking, the cut locus of a point x in a manifold is the set of points for which there are multiple minimizing geodesics connecting them from p). It should be noted that the communication graph is not required to be a quasi unit disk graph in [88].

The problem considered in [16, 17, 37] is different from the above boundary recognition problem. The question asked by Ghrist et al. is: assuming disk sensing range of the sensors, can the domain be covered without holes? The problem is abstracted into a Čech complex, and the detection of sensing holes is equivalent

to determining whether the domain boundary circle is null-homologous in the Čech complex. Since this computation requires accurate locations of the nodes and a global coordinate system, which is not suitable for the setting of wireless network, Ghrist et al. continued to find a sufficient but not necessary condition to detect sensing holes using Vietoris-Rips complex, based only on the pairwise communication data.

5 Conclusion

This chapter addresses three classes of geometric optimization problems in wireless sensor networks: localization, routing, and boundary recognition. The survey outlines the main ideas of recent methods for handling the new challenges brought into these problems by large-scale sensor wireless transmission. A number of successful approaches are covered to overcome difficulties in the geometric optimization due to the absence of central control unit, limited transmission range, limited computation and storage capability, etc.

Abstract

In two- or three-dimensional space, an embedded network is called *gradient constrained* if the absolute gradient of any differentiable point on the edges in the network is no more than a given value m . This chapter gives an overview of the properties of gradient-constrained networks that interconnect a given set of points and that minimize some property of the network, such as the total length of edges. The focus is particularly on geometric Steiner and Gilbert networks. These networks are of interest both mathematically and for their applications to the design of underground mines.

1 Introduction

In two- or three-dimensional space, an embedded network is called *gradient constrained* if the absolute gradient (with respect to a vertical axis) of any differentiable point on the edges in the network is no more than a given value m . This chapter is an overview of the properties of interconnection networks that are minimum under such a constraint. The sorts of networks that will be considered here are geometric Steiner and Gilbert networks. Both of these involve constructing a network that interconnects a given set of points (known as *terminals*) and that minimizes some property of the network, such as the total length of edges. Unlike minimum spanning trees, Steiner and Gilbert networks may contain nodes other than the terminals; these extra nodes are referred to as *Steiner points*. The challenge in optimizing these networks lies in determining both the locations of the Steiner points and the graph topology of the network.

Gradient-constrained minimum interconnection networks are interesting both from a mathematical point of view and because of their potential applications. Mathematically, they lie between Euclidean networks and fixed orientation networks. In practical terms, they have an important role in the efficient design of underground mines. Both of these aspects will be explored in the course of this chapter.

The structure of this chapter is as follows. Section 2 outlines the motivation to this problem, particularly in terms of its application to the design of underground mines, and presents some of the required mathematical background such as properties of Minkowski spaces and the Fermat-Weber problem. Sections 3 and 4 focus on the gradient-constrained Steiner problem (in two and three dimensions) where the objective is to minimize the total edge length of the network. In Sects. 5–7, the gradient-constrained Gilbert problem is introduced; this involves designing the network so as to minimize the cost associated with a flow on the edges.

2 Motivation and Background

One of the main motivations for studying gradient-constrained interconnection problems lies in their application to the design of underground mines. Mining is a significant industry worldwide. Reducing the cost of mining operations is an

important issue for mining companies in an extremely competitive marketplace. For many years, there have been well-developed methods for modeling and optimizing the operation of open-cut mines. Commercial optimization mine planning software packages have been developed based on a technique developed in 1965 by Lerchs and Grossmann [46]. These packages have revolutionized the design of open-pit mines, allowing mining engineers and planners to manipulate and visualize data associated with optimal designs.

Until recently, comprehensive optimization tools for the design and planning of underground mining operations have not been available to the mining industry. The design process is typically facilitated by planning CAD software packages (see, e.g., [31]) which require high levels of user intuition and experience. The usefulness of these programs lies in their ability to efficiently generate a range of potential designs, from which the “best” feasible solution can be selected and refined. However, since these programs do not harness the benefits of optimization, there is no guarantee that the final solution is even close to optimal.

A number of research groups, however, are now in the process of designing and developing optimization tools for the design of underground mines. An example is the access optimization tool, *Decline Optimisation Tool* (DOT), which has been developed at The University of Melbourne. This application efficiently determines a near-optimal (where optimal means least cost) underground mining network servicing a given set of points associated with an ore body [19].

Several constraints are imposed on the geometry of the tunnels in the network, to ensure that the tunnels are navigable by haulage trucks. One such constraint is that the slope (steepness or grade) of a tunnel cannot be too large, since the maximum grade at which haulage vehicles can operate is typically 1:7. A network satisfying this constraint is called *gradient constrained*.

The first mathematical study of such networks was conducted by the Network Research Group at The University of Melbourne, who initially studied them in a vertical plane [10] and later in three dimensions [13]. An algorithm for computing least-cost gradient-constrained networks was implemented into a software application [16], called *Underground Network Optimiser* (UNO). Although this application does not account for other practical constraints, such as truck turning circle navigability, UNO is especially useful for efficiently determining optimal layouts for large-scale mining networks where the effects of constraints other than the gradient constraint on the optimal layout of the mine are not significant.

Initially, research on gradient-constrained networks focused on networks which minimize length. While length-minimizing networks optimize the total development (or infrastructure) cost associated with an underground mine, they do not account for the effects of haulage on the optimal design of the mine. Haulage costs can have a significant impact on the structure and layout of an underground mine, and considerable savings can be achieved by including both cost components in the objective function. A network facilitating flows between given pairs of vertices in the network is called a *flow-dependent network*. In the mining context, these networks can incorporate both development and haulage costs into the objective function.

This section looks first at the nature of the underground mining problem, and the application of gradient-constrained interconnection networks to this problem, and then introduces some of the main mathematical ideas required for this problem.

2.1 Underground Mining Networks

This background on mining is drawn primarily from [2] and [8]. An underground mine consists of a series of interconnecting tunnels, ore passes (near-vertical chutes down which ore is dropped), and vertical shafts (used to hoist ore up to the surface). Its purpose is to allow extraction of ore containing valuable minerals (such as gold, silver, lead, zinc, and copper) from underground locations to a predetermined surface portal (or breakout point), from where it is transported to a processing mill.

Ore zones (or stopes) are identified by geological tests such as surface and infill drilling. From this information, mining engineers can determine suitable draw points, which are the locations on the boundary of each stope from which the ore is accessed. The ore is then excavated using one of a number of possible mining methods (such as stoping, caving, room, and pillar) and is transported to the surface via large haulage trucks.

Given that these laden trucks must be able to traverse the ramps, the following important constraints must be imposed on the mine:

- Ramps must have absolute gradient not greater than some constant m . This constant is typically in the range 1:9–1:7 depending on equipment specifications.
- Ramps must satisfy a minimum turning radius (typically in the range 15–30 m), so that they are navigable by the trucks.
- Ramps must avoid certain no-go regions such as the interior of an ore body or other ramps in the mine.

A set of tunnels satisfying these constraints and interconnecting the draw points and a point at the surface can be modeled by a mathematical network T , where the draw points correspond to fixed vertices and the tunnels correspond to edges. The cost C associated with a network with a set E of edges is typically modeled by a function of the form

$$C(T) = \sum_{e \in E} (d + ht_e)l_e$$

where d is a development cost rate (typically \$4,000/m), h is a haulage cost rate (typically \$0.75/t.km), t_e is the total quantity of ore to be transported along an edge e over the life of the mine, and l_e is the length of e . The first term $\sum dl_e$ can be viewed as the total development cost of the mine and the second component $\sum ht_e l_e$ as the total haulage cost associated with the mine over its life. If h is set to zero, then the cost of the network is proportional to its length, and a network minimizing this objective function is a *length-minimizing network*.

2.2 Network Optimization Applied to Underground Mine Design

This section is a brief survey of the use of network theory in underground mine design. A number of the papers mentioned here will be discussed in more detail later in the chapter.

Lizotte and Elbrond [47] reported an early application of network theory to some underground mine layout problems but limited their work to network techniques in a horizontal plane. Brimberg et al. [24] considered a network model to minimize the cost of an underground mine with a vertical hoisting shaft connected to ore deposits by a series of horizontal tunnels. A heuristic method for a more general version of this problem was developed in [36], using fuzzy set theory.

Lee first raised the more general problem of setting up and optimizing a three-dimensional network modeling the access infrastructure costs of an underground mine layout in a 1989 presentation at the NATO Workshop on Topological Network Design, Denmark. Since then, a significant body of research has been developed in this area, some of which has been implemented into the aforementioned software products, UNO and DOT. Much of this work has been conducted by the Network Research Group at The University of Melbourne. The following is a summary of this research to date:

- A network optimization model for minimizing development and haulage costs in underground mines was established. The possibility of modeling the haulage cost of an edge as a function of the slope of the edge was also facilitated in the cost function, and conditions under which the cost function is convex were discussed. Application of the model was demonstrated via a prototype network interconnecting draw points and a vertical hoisting shaft and several case studies in which the model was applied to mines at Pajingo and Kanowna Belle [2, 8, 11, 14, 17].
- The gradient-constrained Steiner problem (in a vertical plane) was introduced. This problem asks for a shortest network interconnecting a set of points, called *terminals*, in a vertical plane such that no part of the network has absolute gradient greater than a given positive constant m satisfying $m \leq 1$. Geometric structures of these networks were used to construct a finite algorithm for solving the problem which, when suitably discretized, was shown to be NP-complete [10].
- The study of the gradient-constrained Steiner problem was extended to three dimensions. The *gradient metric* was introduced to measure the lengths of edges in gradient-constrained networks, and the terms *flat*, *maximum*, and *bent* were introduced to label edges whose respective gradients are less than, equal to, or greater than m . It was shown that a Steiner point, which is a vertex in the network not among the given set of terminals, has either three or four incident edges, and Steiner points were classified in terms of the labelings of their incident edges. The UNO software product was concurrently developed with this work [13].
- The terms *labeled minimal* and *locally minimal* were introduced to describe Steiner points for which a label-preserving perturbation and, respectively, *any*

perturbation of the Steiner point cannot shorten the length of the network. Properties of labeled-minimal Steiner points were studied, and necessary and sufficient conditions for Steiner points to be locally minimal were obtained. A formula for computing labeled-minimal degree 3 Steiner points was derived, and an algorithm for computing locally minimal Steiner points was developed [21, 61].

- The *Steiner ratio* for gradient-constrained networks connecting three points in three dimensions was investigated. The Steiner ratio is the smallest ratio of the length of a Steiner tree to the length of a minimum spanning tree when the two networks interconnect the same set of given points. It was shown that this minimum ratio for gradient-constrained networks tends to 0.75 as the value of m tends to zero [50, 51].
- A method for optimizing *declines* in underground mines was developed, a decline being a gradient-constrained, turning-circle-constrained path connecting level access points to a surface portal while avoiding certain no-go regions. A procedure for finding an optimal decline was implemented into the DOT software product, which was applied to several case studies including a decline servicing the Jandam gold mine at Pajingo and an access decline at Olympic Dam. The software was further developed to handle networks of declines [15, 16, 19, 20, 62].
- The other area that has been receiving more attention in recent years is that of understanding the effect of weighted edges, associated with flows, on the optimal design of gradient-constrained networks. The principal aim of this research is to obtain a comprehensive understanding of minimum-cost gradient-constrained flow-dependent networks. Of particular interest are the geometric structures possible in such networks. The geometric properties of optimal networks play a crucial role in improving the efficiency of heuristic algorithms for computing gradient-constrained networks [66–68].

2.3 Minkowski Spaces and the Gradient Metric

An important insight into understanding gradient-constrained networks in Euclidean space is that if the distance between two points is measured as the minimum length of a gradient-constrained path between the two points, then this measure forms a metric. For the purpose of determining lengths of edges, the network can be viewed as being embedded in a normed or Minkowski space. This subsection briefly reviews some of the relevant properties of Minkowski spaces, and defines the gradient metric, for measuring the lengths of edges in gradient-constrained networks. See [63] for a more comprehensive introduction to Minkowski geometry.

A *Minkowski space* (or *finite-dimensional Banach space*) is \mathbb{R}^n endowed with a *norm* $\|\cdot\|$, which is a function $\|\cdot\| : \mathbb{R}^n \rightarrow \mathbb{R}$ that satisfies:

- $\|x\| \geq 0$ for all $x \in \mathbb{R}^n$, $\|x\| = 0$ only if $x = 0$.
- $\|\alpha x\| = |\alpha| \|x\|$ for all $\alpha \in \mathbb{R}$ and $x \in \mathbb{R}^n$.

- $\|x + y\| \leq \|x\| + \|y\|$.

Informally, a norm provides a way of measuring the lengths of vectors in \mathbb{R}^n . A common norm is the ℓ_p norm

$$\|x\|_p = \left(\sum_{i=1}^n |x_i|^p \right)^{\frac{1}{p}}$$

where $p \geq 1$ is a real number and the x_i are the components of x . The value $p = 2$ gives the familiar Euclidean norm, denoted throughout this chapter by $|\cdot|$, and $p = 1$ gives the rectilinear norm, also called the Manhattan, taxicab, or ℓ_1 norm.

The *unit ball* associated with a given Minkowski space X is the set $B = \{x \in X : \|x\| \leq 1\}$. It is a centrally symmetric, closed, and convex subset of X with origin o at its center. A unit ball is called *smooth* if its boundary, $\text{bd}(B)$, has no sharp (nondifferentiable) points and *strictly convex* if $\text{bd}(B)$ contains no straight line segments. A *supporting hyperplane* of B is a hyperplane in X touching the boundary of B such that the interior of B lies on one side of the supporting hyperplane. An *exposed face* of B is the intersection of B with a supporting hyperplane.

It is possible to measure the length of edges in a gradient-constrained network in terms of a metric known as the gradient metric, first introduced in [13]. This means that these networks can be thought of as being in a Minkowski space. Formal definitions are given below for the three-dimensional case, but these results also generalize easily to other dimensions.

Let x_p, y_p, z_p denote the Cartesian coordinates of a point p in three-dimensional space. Assume that the z -axis is vertical. Then, the *gradient* of an edge pq is defined here to be the absolute value of the slope from p to q and is denoted by $g(pq)$. That is,

$$g(pq) = \frac{|z_q - z_p|}{\sqrt{(x_q - x_p)^2 + (y_q - y_p)^2}}.$$

Suppose pq is an edge of a minimum gradient-constrained network embedded in Euclidean space, where the maximum permitted gradient m is given. If $g(pq) \leq m$, then pq is a straight line joining p and q and is referred to as a *straight edge*. However, if $g(pq) > m$, then pq cannot be represented as a straight line without violating the gradient constraint, but it can be represented by a zigzag line joining p and q with each segment having gradient m . Such edges are referred to as *bent edges*.

The lengths of edges in a gradient-constrained tree can be measured in a special metric, called the *gradient metric*. Suppose o is the origin and $p = (x_p, y_p, z_p)$ is a point in space. Define the *vertical metric* of the line op to be $|op|_v = cz_p$ where c is a given constant. Then the gradient metric can be defined in terms of the Euclidean and vertical metrics. Suppose m is the maximum gradient allowed in gradient-constrained trees. The length of op in the gradient metric is defined to be

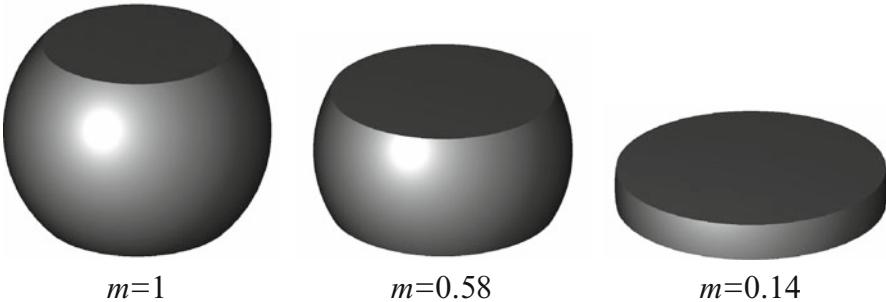

Fig. 1 Unit ball in gradient-constrained three-space for selected maximum gradients

$$|pq|_g = \begin{cases} |pq| = \sqrt{(x_q - x_p)^2 + (y_q - y_p)^2 + (z_q - z_p)^2}, & \text{if } g(pq) \leq m; \\ |pq|_v = \sqrt{1 + m^{-2}}|z_q - z_p|, & \text{if } g(pq) \geq m. \end{cases}$$

It is easily checked that this defines a metric, as it is the maximum of two metrics. Note that $|op| \leq |op|_g$ and the gradient metric is convex though it is not strictly convex.

In gradient-constrained three-space, three examples of the unit ball B_g are shown in Fig. 1 for $m = 1$, 0.58 , and 0.14 .

2.4 The Fermat-Weber Problem

The types of interconnection problems considered in this chapter are those that allow for the possibility of adding extra nodes anywhere in the space in order to minimize the length (or, more generally, cost) of the interconnection network. The simplest and most famous example of such a problem is the Fermat problem, which asks one to find a point such that the sum of its distances from a set of given points is a minimum. The more general version of this problem is called the *Fermat-Weber problem*; this problem asks for a point, called a *Fermat-Weber point*, minimizing the sum of weighted distances to a set of given points. The weights are specified by given values w_i associated with each of the given points p_i . A brief exposition of the historical background to this problem is given by Kuhn [42]. A more detailed account is included in a paper of Kupitz and Martini [44], and another good general reference is [27].

Although special instances of the Fermat-Weber problem can be solved with simple geometric constructions, in general for $k \geq 4$, the problem cannot be solved by exact methods [3]. Thus, significant research has been undertaken to develop numerical procedures for finding Fermat-Weber points. A famous iterative method for the Fermat-Weber problem (outlined below) was posed in 1937 by Andre Weiszfeld [74]. This algorithm was independently discovered by Kuhn and Kuenne [43] in 1962.

Let $N = \{p_1, \dots, p_k\}$ be the set of given points in \mathbb{R}^n with respective positive weights w_1, \dots, w_k . Let \mathbf{u}_i denote the unit vector from a point $x_0 \in \mathbb{R}^n$ to p_i , $i = 1, \dots, k$. The first step of the algorithm checks whether x_0 coincides with a given point. If not, x_0 is determined iteratively.

Weiszfeld's Algorithm

1. If there exists a point $p_j \in N$ such that

$$\left| \sum_{i=1, i \neq j}^k w_i \mathbf{u}_i \right| \leq w_j,$$

then p_j is a Fermat-Weber point.

2. Otherwise, select an error estimate ϵ .
3. Select an initial point $x^{(0)} \in \text{int}(\text{conv}(N))$.
4. For $\kappa = 0, 1, \dots$ do

$$x^{(\kappa+1)} := \frac{\sum_{p_i \in N} \frac{w_i p_i}{|p_i - x^{(\kappa)}|}}{\sum_{p_i \in N} \frac{w_i}{|p_i - x^{(\kappa)}|}}.$$

5. Stop when $|x^{(\kappa)} - x^{(\kappa+1)}| \leq \epsilon$.
-

The following example demonstrates the application of Weiszfeld's algorithm and is illustrated in Fig. 2. Let $p_1 = (0, 1)$, $p_2 = (2, 0)$, and $p_3 = (2, 2)$ be given points in the plane with respective weights $w_1 = 1$, $w_2 = 1$, and $w_3 = 1.65$. By testing the collapse condition, it can be shown that $x_0 \neq p_1, p_2, p_3$. Selecting $\epsilon = 0.001$ and $x^{(0)} = (0.25, 1)$, the path of the iteration point converges to x_0 , as shown in the figure.

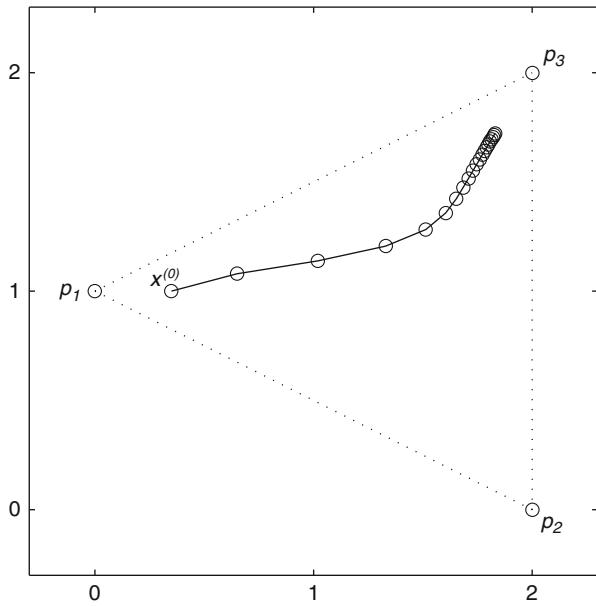

In 1995, Brimberg [23], building on the work of Kuhn [41] and Chandrasekaren et al. [25], proved that Weiszfeld's algorithm converges to the unique optimal solution for all but a denumerable set of starting points if and only if the convex hull of the given points is of dimension n .

The Fermat-Weber point can be viewed as the central node of a star network with links from the Fermat-Weber point to each of the given nodes. This network is then a minimum cost interconnection network with this star topology. In this context, one can define the *gradient-constrained Fermat-Weber problem*, introduced by Volz in [66] and [68], which is the Fermat-Weber problem with the added condition that links are measured using the gradient metric. The problem is formulated as follows:

- *Given:* A set $N = \{p_1, \dots, p_k\}$ of points in Euclidean space with respective positive weights w_1, \dots, w_k and a gradient bound m satisfying $0 < m \leq 1$
- *Find:* A point x_0 minimizing the sum of weighted distances from x_0 to the points in N such that each distance is the minimum length of a piecewise smooth curve whose gradient at each differentiable point is no more than m

In the mining context, p_1, \dots, p_k represent draw points with associated tonnages t_1, \dots, t_k . Material is hauled from the draw points via independent paths to the

Fig. 2 Iterations of Weiszfeld's algorithm for a three-point Fermat-Weber problem

Fermat-Weber point, x_0 , which might represent, for instance, the base of a vertical hoisting shaft. The total cost of the mine can be minimized by positioning the facility at an optimal location.

The weight on the path from p_i to x_0 is given by $w_i = d + ht_i$, where d and h are development and haulage cost rates, respectively. Since the t_i can take on any value, there are no restrictions on the values of the weights associated with the points in N . This is in contrast to the Gilbert arborescence problem described in the next section, in which edge weights in the network satisfy certain implicit conditions resulting from the flow structure in the network.

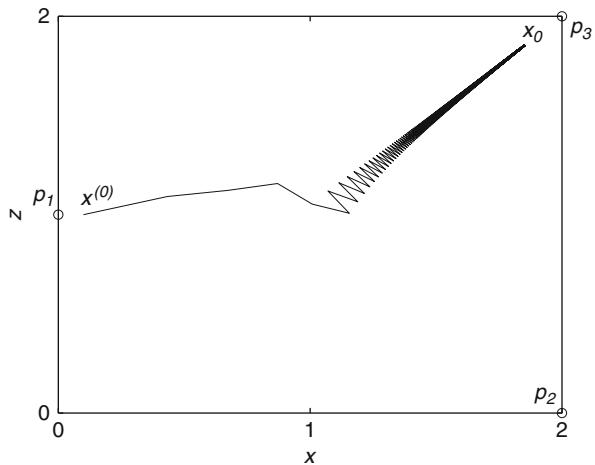

Numerical tests have shown that the Weiszfeld algorithm, described above, does not lend itself well to the gradient-constrained problem. In [66] and [68], Volz has proposed a new iterative scheme for finding a point x_0 minimizing

$$f(x) = \sum_{i=1}^k |p_i - x|_g.$$

Standard gradient descent procedures, such as those discussed in [6], cannot be easily applied here due to the fact that $f(x)$ is not everywhere differentiable. The problem for nondifferentiable convex functions, however, can be solved by the *subgradient method*, described in [57] and [5], which minimizes $f(x)$ using the iteration

$$x^{(\kappa+1)} = x^{(\kappa)} + s_\kappa \mathbf{v}^{(\kappa)}$$

Fig. 3 Iterations of the subgradient method with diminishing step sizes for a three-point gradient-constrained Fermat-Weber problem

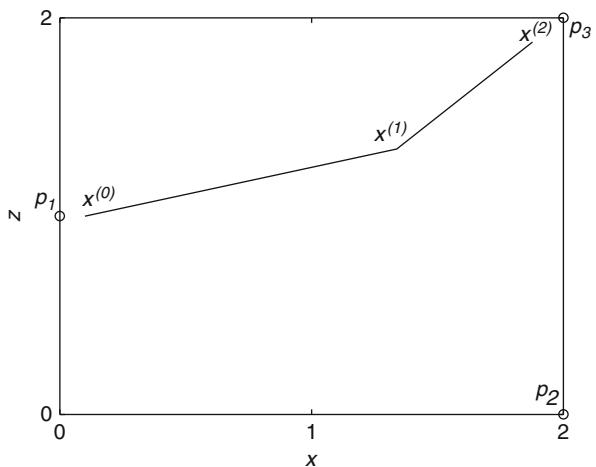

where $x^{(\kappa)}$ is the κ th iterate, $\mathbf{v}^{(\kappa)}$ is any subgradient of f at $x^{(\kappa)}$, and s_κ is the κ th step size. For diminishing step sizes satisfying $\lim_{\kappa \rightarrow \infty} s_\kappa = 0$, $\sum_{\kappa=1}^{\infty} s_\kappa = \infty$, the algorithm is guaranteed to converge to the optimal value.

For the gradient-constrained problem, use of the subgradient method may be problematic, despite guaranteed convergence. The convergence can be extremely slow due to the gradient being almost perpendicular to the direction toward the minimum. This problem is demonstrated by the following example.

Consider three points in a vertical plane: $p_1 = (0, 1)$, $p_2 = (2, 0)$, and $p_3 = (2, 2)$, as shown in Fig. 3. The three points have respective weights $w_1 = 1$, $w_2 = 1$, and $w_3 = 1.94$. The maximum allowable gradient is $m = 1$. The exact solution, which can in this case be determined exactly by simple calculus, is $x_0 = (1.9, 1.9)$. Starting at $x^{(0)} = (0.1, 1)$ and using an initial step size $s_0 = 0.345$, consider the use of the subgradient method where step sizes diminish at each iterate κ according to $s_\kappa = s_0/\sqrt{\kappa}$. The iterative path, shown in the figure, shows that convergence is very slow due to extreme oscillation about the line through p_3 with gradient m . At each iteration, the gradient is almost perpendicular to the direction toward the minimum. In fact, after 50,000 iterations, $x^{(\kappa)}$ is still noticeably distant from x_0 . If s_κ is chosen to minimize $f(x^{(\kappa)} + s_\kappa \mathbf{v}^{(\kappa)})$ (i.e., an exact line search is adopted), then $x^{(\kappa)}$ converges to the nonstationary point $(1.3385, 1.3385)$ after one iteration, due to the optimum step size diminishing to zero too early.

Volz [66] and Volz et al. [68] propose a new method that overcomes these problems by exploiting the fact that f is differentiable everywhere except in the set S of points x in \mathbb{R}^3 for which $p_j x$ is an m -edge for any $p_j \in N$. The method uses exact directional minimization at each iteration and considers a second search direction at maximum gradient when $x^{(\kappa)}$ converges to a (possibly non-minimal) point in some neighborhood of S . This notion of searching in an m -edge direction was first employed in an algorithm for finding gradient-constrained minimum Steiner trees in [16]. The procedure for the gradient-constrained Fermat-Weber

Fig. 4 Iterations of a new descent method for a three-point gradient-constrained Fermat-Weber problem

problem is outlined in [66, 68], where it is also shown that the method guarantees rapid convergence in dimensions 2 and 3.

Applying this method to the previous example results in the sequence converging to the exact solution in two iterations, $\{(0.1, 1), (1.3385, 1.3385), (1.9, 1.9)\}$ (Fig. 4).

2.5 The Steiner Tree Problem

The *minimum Steiner tree problem* asks for a shortest network spanning a given set of nodes, usually referred to as *terminals*, in a given metric space. It differs from the minimum spanning tree problem in that additional nodes, referred to as *Steiner points*, can be included to create an interconnection network that is shorter than would otherwise be possible. This is a fundamental problem in physical network design optimization, and has numerous applications, including the design of telecommunications or transport networks for the problem in the Euclidean plane (the l_2 metric), and the design of microchips for the problem in the rectilinear plane (the l_1 metric) [40].

The terminology used for the minimum Steiner tree problem in this chapter is largely based on that used in [40]. Let T be a network interconnecting a set $N = \{p_1, \dots, p_n\}$ of points, called *terminals*, in a Minkowski space. A node in T which is not a terminal is called a *Steiner point*. In a minimum network, it can always be assumed that the degree of a Steiner point is at least three. Let $G(T)$ denote the *topology* of T , that is, $G(T)$ represents the graph structure of T but not the embedding of the Steiner points. Then $G(T)$ for a shortest network T is necessarily a tree, since if a cycle exists, the length of T can be reduced by deleting an edge in the cycle. A network with a tree topology is called a *tree*, its links are called

edges, and its nodes are called *vertices*. An edge connecting two vertices a, b in T is denoted by ab and its length by $\|a - b\|$.

The *splitting* of a vertex is the operation of disconnecting two edges av, bv from a vertex v and connecting a, b, v to a newly created Steiner point. Furthermore, though the positions of terminals are fixed, Steiner points can be subjected to arbitrarily small movements provided the resulting network is still connected. Such movements are called *perturbations* and are useful for examining whether the length of a network is minimal.

A *Steiner tree* is a tree whose length cannot be shortened by a small perturbation of one or more of its Steiner points, even when splitting is allowed. By convexity, a Steiner tree is a minimum-length tree for its given topology. A *minimum Steiner tree* is a shortest tree among all Steiner trees. For many Minkowski spaces, bounds are known for the maximum possible degree of a Steiner point in a Steiner tree, giving useful restrictions on the possible topology of an SMT. For example, in Euclidean space of any dimension, every Steiner point in an ST has degree 3. Given a set N of terminals, the *Steiner problem* (or *minimum Steiner tree problem*) asks for a minimum Steiner tree spanning N .

The gradient-constrained Steiner problem is studied in more detail in [Sects. 3](#) and [4](#).

2.6 The Gilbert Arborescence Problem

In 1967, Gilbert [34] proposed a generalization of the SMT problem whereby symmetric nonnegative *flows* are assigned between each pair of terminals. The aim is to find a least cost network interconnecting the terminals, where each edge has an associated total flow such that the flow conditions between terminals are satisfied, and Steiner points satisfy Kirchhoff's rule (i.e., the net incoming and outgoing flows at each Steiner point are equal). The cost of an edge is its length multiplied by a nonnegative *weight*. The weight is determined by a given function of the total flow being routed through that edge, where the function satisfies a number of conditions. The *Gilbert network problem* (GNP) asks for a minimum-cost network spanning a given set of terminals with given flow demands and a given weight function.

A variation on this problem that will be shown to be a special case of the GNP occurs when the terminals consist of n sources and a unique sink, and all flows not between a source and the sink are zero. This problem is of intrinsic interest as a natural restriction of the GNP; it is also of interest for its many applications to areas such as drainage networks [45], gas pipelines [4], and underground mining networks [11].

If the weight function is a concave, increasing function of the flow, then the resulting minimum network has a tree topology and provides a directed path from each source to the sink (this is discussed in more detail in [Sect. 5](#)). Such a network can be called an *arborescence*, and this special case of the GNP is referred to as the *Gilbert arborescence problem*. Traditionally, the term “arborescence” has been used to describe a rooted tree providing directed paths from the unique root (source) to a

given set of sinks. Here, it is used for the case where the flow directions are reversed, that is, flow is from n sources to a unique sink. It is clear, however, that the resulting weights for the two problems are equivalent; hence, it is reasonable to also use the term “arborescence” for the latter case. Moreover, if one takes the sum of these two cases and rescales the flows (dividing flows in each direction by 2), then again the weights for the total flow on each edge will be the same as in the previous two cases. This justifies the earlier claim that the Gilbert arborescence problem can be treated as a special case of the GNP. It will be convenient, however, for the remainder of this chapter to treat arborescences as networks with a unique sink.

A gradient-constrained version of the Gilbert arborescence problem is studied in Sects. 6 and 7. In three-space, the simplest version of this problem can be formulated as follows:

- *Given:* A set of points $N = \{p_1, \dots, p_k\}$ in Euclidean three-space, where p_1, \dots, p_{k-1} are sources with respective positive flows t_1, \dots, t_{k-1} and p_k is a unique sink, a gradient bound satisfying $0 < m \leq 1$, and positive constants d and h
- *Find:* A minimum-cost network T interconnecting N which provides flow paths from the sources to the sink, such that the cost of an edge e in T is given by $(d + ht_e)l_e$, where t_e is the total flow through e and l_e is the length of e under the gradient metric

A network satisfying the above conditions is called a *minimum Gilbert arborescence* (MGA). Vertices in T not in N are called *Steiner points*, and a Steiner point is a Fermat-Weber point with respect to its adjacent vertices in T . A key difference between the two problems is that a Steiner point s in a Gilbert arborescence has *source edges*, which are directed into s , and a *unique sink edge*, directed outward from s , whereas all incident paths connected to a Fermat-Weber point are directed toward that point.

3 The Two-Dimensional Gradient-Constrained Steiner Problem

The simplest version of a gradient-constrained interconnection problem, beyond that of constructing a minimum spanning tree, is the planar Steiner problem. This problem asks for a shortest network interconnecting a given set of points (referred to as *terminals*) lying on a vertical plane in Euclidean space and operating under a gradient constraint. Unlike a spanning tree network, this network can contain nodes other than the given terminals. It will be shown in Sect. 3.2 that the inclusion of these extra variable nodes makes this an NP-hard problem.

In formal terms, the *two-dimensional gradient-constrained Steiner problem* can be stated as follows:

- *Given:* A set of points $N = \{p_1, \dots, p_k\}$ lying on a vertical plane \mathcal{P} in Euclidean three-space and a gradient bound satisfying $0 < m \leq 1$
- *Find:* A network T interconnecting N of minimum total length, where the length of each edge e is computed using the gradient metric (with gradient bound m)

As usual, the nodes of T that are not terminals are referred to as *Steiner points* and are assumed to have degree at least 3. A network T , solving this problem, is referred to as an *m -constrained minimum Steiner tree*.

From an applications point of view, this problem is interesting, not only as a specific example of the three-dimensional problem but also for potential applications in its own right. For example, consider the following problem. Imagine an exterior wall of a large multistory warehouse, or other building, with entrances at given positions on the wall. Suppose one is required to join the entrances externally by designing an interconnecting system of ramps whose gradients are sufficiently small to allow trolleys and carts to be wheeled along them, or alternatively to allow disabled access. By modeling the entrances as points and the ramps as line segments, the problem of finding the shortest system of ramps is equivalent to solving the planar version of the gradient-constrained Steiner problem.

The precise formulation of the above problem deserves a few comments. The reason that the plane \mathcal{P} is restricted to being a vertical plane is that it can then be assumed that the network T lies on \mathcal{P} . This follows from the observation that the projection of T onto \mathcal{P} does not increase the length of any link of T (since the vertical displacement between the endpoints remains the same and the horizontal displacement does not increase). This observation is no longer true in general if \mathcal{P} is not restricted to being vertical. For \mathcal{P} vertical, the problem, although set in Euclidean three-space, can be assumed to be two-dimensional.

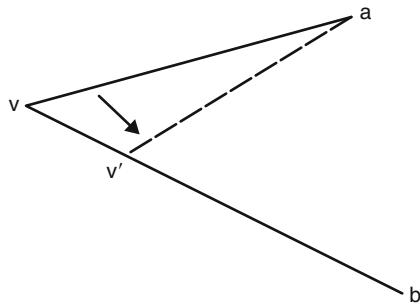

The other important restriction on the problem is that the gradient bound m satisfies $m \leq 1$. Let $\alpha = \arctan m$ be the angle of an edge of maximum gradient from the horizontal. The condition is equivalent to saying that $\alpha \leq \pi/4$. This condition is imposed largely for convenience. In particular, it immediately gives the following local property of T at any node.

Lemma 1 *Let T be an m -constrained minimal Steiner tree (for $0 < m \leq 1$) in a vertical plane \mathcal{P} . Then the angle at which any two links of T meet at a vertex is at least 2α .*

Proof Suppose, on the contrary, that there exists a node v of T such that two of the links incident with v , say, av and bv , meet at an angle less than 2α . Clearly, at least one of the two links, say, av , has gradient of absolute value strictly less than m . The length of T can now be reduced by moving the point where this link connects a to bv away from v , toward b to a new point v' such that either av' has absolute gradient m or $v' = b$ (whichever occurs first), as illustrated in Fig. 5. The shorter tree is still gradient constrained, contradicting the minimality of T . \square

This constraint on the gradient is usually easily met in practice in applications such as ramp design or underground mine access infrastructure where the typical maximum allowable gradient is generally in the range of $1/9$ – $1/7$. It follows from Lemma 1 that all nodes of T have degree at most 4 and hence that all Steiner points of T have degree 3 or 4. Indeed, the lemma has the following easy consequence, giving local geometric properties at each Steiner point.

Fig. 5 Replacing av by av' decreases the length of T

Corollary 1 Let s be a Steiner point of an m -constrained minimum Steiner tree T . Let L_s be the vertical line through s . If s is of degree 3, then s has two incident links, one of gradient m and the other of gradient $-m$, lying on one side of L_s , and a third incident link lying on the other side of L_s . If s is of degree 4, then s has two incident links, one of gradient m and the other of gradient $-m$, lying on each side of L_s .

3.1 Local Minimality and Exact Solutions

Like most other planar Steiner problems in normed spaces, the two-dimensional gradient-constrained Steiner problem is NP-hard, meaning that there is almost certainly no polynomial time algorithm for constructing an optimal solution. Despite this, the problem of finding relatively efficient exact algorithms for planar Steiner problems under a range of different norms has attracted considerable interest and success. The most effective and scalable algorithms are those based on the so-called Geosteiner approach [71, 72].

The key to the Geosteiner approach is to view a minimum Steiner tree as a union of *full Steiner trees* (FST's), which are minimum Steiner trees where all terminals are leaves and all Steiner points are interior nodes. The algorithm involves two distinct phases: a *generation phase* which generates a set of FSTs guaranteed to include those used in a minimum Steiner tree; and a *concatenation phase* which determines how to optimally combine the FSTs in the given set into a minimum Steiner tree. The concatenation phase is independent of the underlying metric and has been efficiently solved, using a branch-and-cut algorithm, by Warme [69] and Warme et al. [70, 71]. The success of the Geosteiner approach depends on keeping the number of FSTs constructed in the generation phase as small as possible. This relies on finding effective *pruning* techniques. The idea is to build the FSTs in a bottom-up manner and at each step to apply a range of geometric tests which will allow whole families of potential FSTs to be eliminated. An example of such a test is the “lune test,” which basically states that terminals cannot be too close to long edges in a minimum Steiner tree. For the Euclidean metric, a suite of pruning techniques, based on the strong local geometric restrictions on minimum Steiner trees, have been developed which keep the number of generated FSTs relatively small, for

randomly generated terminal sets. For other metrics, such as the rectilinear metric and the λ -geometry metrics (where the network is restricted to using λ equally spaced orientations, see [7]), the efficiency of the generation phase depends not only on good pruning techniques but also on the characterization of FSTs in terms of canonical forms. These canonical forms (established for general λ -geometry metrics in [18]) strongly restrict the number of FSTs that need to be considered and give a simple bottom-up method of building FSTs out of “half FSTs”; for more details, see Nielsen et al. [49]. In practice, for any fixed λ , the resulting number of generated FSTs is almost linear, and the size of the largest generated FST is bounded by a constant. Geosteiner has been used to solve randomly generated problem instances with 1,000 terminals in less than a hour (for $\lambda \leq 8$), and a single problem instance with 10,000 terminals has been solved in less than 48 h for $\lambda = 4$.

The Geosteiner approach has not been developed for the two-dimensional gradient-constrained Steiner problem, probably because the main applied interest is in the three-dimensional version of the problem, where the generation phase of Geosteiner appears to be much less effective. But the two-dimensional problem is amenable to the same general method as there are very strong structural and geometric constraints on the form of locally minimal FSTs. The theory behind this was developed in [10], and the main properties will now be discussed in the remainder of this section.

It is useful to divide the study of the structure of two-dimensional gradient-constrained minimal FSTs into two distinct cases, the first where all edges in the full tree have absolute gradient $\geq m$ and the second where there is at least one edge of gradient k where $|k| < m$. Each of these two cases will be considered in turn.

Case 1: All Edges Have Absolute Gradient $\geq m$

Recall that any edge e of absolute gradient greater than m with endpoints a and b can be embedded in the Euclidean plane as a path from a to b composed of two straight line segments, each of gradient m or $-m$, such that the Euclidean length of this path is equal to the length of e under the gradient metric. Such edges are referred to as a *bent* edges and the internal point where a bent edge changes gradient as the *corner-point* of the edge. Also, a straight line segment in a gradient-constrained minimal FST, each of whose endpoints is either a node or corner-point and which has no nodes in its relative interior, is referred to simply as a *segment*. Note that the angle between the two segments at a corner-point is 2α . This viewpoint of the FSTs being embedded in the Euclidean plane allows properties of Euclidean geometry to be employed in the study of these networks.

Let T be a two-dimensional gradient-constrained minimal FST such that every segment in T has absolute gradient m . This is very similar to the situation for rectilinear Steiner trees. Indeed, the characterization of the structure of a full rectilinear minimal Steiner tree does not use, in any essential way, the fact that the two available directions are perpendicular. It follows that by defining substructures of T in line with the standard definitions used in rectilinear Steiner trees, it is

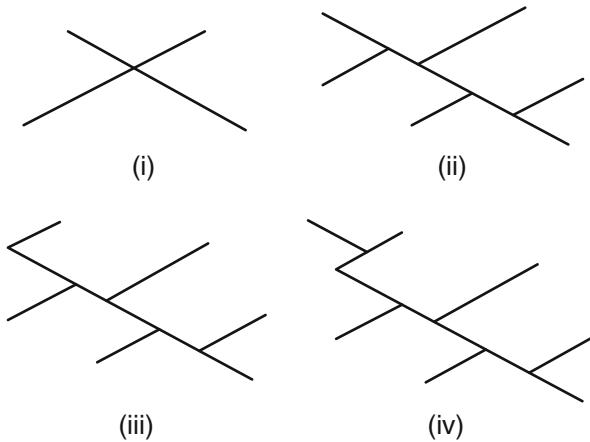

Fig. 6 The four canonical forms for full components given in [Theorem 1](#)

possible to prove a structure theorem giving a canonical form for T identical to that which has been proved for rectilinear Steiner trees. The definitions for substructures of T imitate the corresponding definitions for rectilinear trees used in [40], which are based largely on the geometric characterizations developed in [52].

A *complete line* of T is defined to be a sequence of one or more adjacent collinear segments of maximal length; it does not have terminals in its relative interior (since T is full), but it may have terminals as endpoints. A corner-point is incident to exactly two complete lines, one of gradient m and the other of gradient $-m$, referred to as the *legs* of the *corner*. If the remaining two endpoints of the legs are terminals, the corner is a *complete corner*. A cross-point is a degree 4 Steiner point of T , and the two complete lines passing through a cross-point are said to form a *cross*. Finally, given a complete line L of T , let $C(L)$ denote the set of segments (not in L) which are incident to L at any endpoints of L that are corners. Then a set A of *alternating segments incident to L* is defined to be the set of segments of T such that:

1. A contains all segments not in L but incident to L at vertices other than the endpoints of L (all of which, it follows, have a gradient which is minus the gradient of L).
2. Each element of A intersects L at a Steiner point of degree 3.
3. No two segments in $A \cup C(L)$ incident to endpoints of a single segment of L lie on the same side of L .

By performing a series of local length-preserving transformations on T , each of which either changes the embedding of a bent edge or “slides” an edge whose two endpoints are both Steiner points (see [40] or [52] for the formal definitions of these transformations in the rectilinear setting), one can obtain the following characterization of a canonical form for T , as illustrated in [Fig. 6](#). This theorem, in the rectilinear setting, was originally due to Hwang [37].

Theorem 1 Let N be a set of n terminals such that $n \geq 2$. Suppose every m -constrained minimal Steiner tree on N is full and contains only segments of absolute gradient m . Then there exists an m -constrained minimal Steiner tree on N that either:

- (i) Is a cross; or
- (ii) Consists of a single complete line with $n - 2$ alternating segments; or
- (iii) Consists of a complete corner with $n - 2$ alternating segments incident to a single leg; or
- (iv) Consists of a complete corner with $n - 3$ alternating segments incident to a one leg and a single alternating segment incident to the other leg

Note that the first form in [Theorem 1](#), a cross, only occurs if $n = 4$.

The consequence of this theorem is that for any terminal set N , there exists an m -constrained minimal Steiner tree on N such that every full component either has one of the forms listed in the previous theorem or contains an edge with absolute gradient strictly less than m . The generation of all candidate FSTs with all segments having absolute gradient m (as part of a Geosteiner approach) can be done efficiently in practice using the same techniques that have been developed for rectilinear minimum Steiner trees by Zachariasen [77].

Case 2: There Exists an Edge with Absolute Gradient $< m$

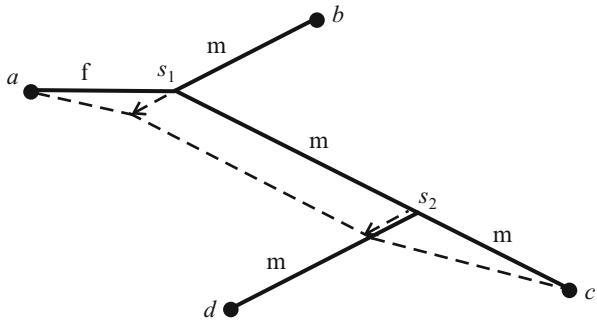

For this case, let T be a two-dimensional gradient-constrained minimal FST such that T contains a segment with gradient k where $|k| < m$. Such a segment is said to have *intermediate* gradient. Clearly, the segment must be a straight edge since segments at a corner have absolute gradient m . Furthermore, if a is an endpoint of an edge in T of intermediate gradient, then all edges of T incident with a are straight. This is an easy consequence of [Lemma 1](#), since if there is a bent edge at a , then there exists an embedding of that edge such that two of the segments incident with a have an angle between them of less than 2α , leading to a contradiction to the minimality of T by the argument in the proof of [Lemma 1](#). By a similar argument, it is also clear that a has degree at most three.

A key property of T is that every edge in T with intermediate gradient has the same gradient. More specifically, the following structure theorem holds.

Theorem 2 Let T be a full m -constrained minimal Steiner tree containing an edge of gradient k where $|k| < m$. Then every Steiner point of T is adjacent to three straight edges, one of gradient m , one of gradient $-m$, and one of gradient k .

The idea of the proof of this theorem, which appears in [10], is to show that if there are two adjacent Steiner points in T that do not satisfy the theorem, then there exists a simultaneous perturbation of both Steiner points that strictly reduces the length of T . This is illustrated in [Fig. 7](#). Suppose T is the m -constrained tree with terminals a, b, c, d as shown in the figure. Here, the points a, b, c, d all lie in a vertical plane, and all edges have gradient m apart from a single edge of intermediate

Fig. 7 A non-minimum tree where each Steiner point is locally minimal

gradient, labeled “f” in the figure. Each of the two Steiner points satisfies the conditions of [Corollary 1](#), and it is straightforward to confirm that each Steiner point is locally minimal. In other words, no perturbation of s_1 or s_2 (which fixes the other Steiner point) can reduce the length of T . However, consider the 2-point perturbation \mathbf{v} shown in the figure, where s_1 is perturbed along the line through s_1b away from b , s_2 is perturbed along the line through s_2d toward d , and s_1s_2 remains an m-edge. If L represents Euclidean length, then clearly under this perturbation, $\dot{L}(s_1b \cup s_1s_2 \cup s_2d)_{\mathbf{v}} = 0$, but it is easy to see that $\dot{L}(s_1a \cup s_2c)_{\mathbf{v}} < 0$ and hence that \mathbf{v} is a strictly length-reducing perturbation. A similar argument always applies unless s_1a and s_2c are parallel, that is, have identical gradient.

This idea that the directions of edges at a single Steiner point must propagate throughout the full component if there is no length-reducing perturbation for any pair of Steiner points is a concept that has been shown to also apply to metrics other than the gradient metric. It is well known that it is true for all smooth metrics [\[29\]](#). More recently, it has been shown that it also applies for all metrics where the unit ball is a simple polygon whose vertices lie on the Euclidean unit circle. Such a metric is referred to as a *fixed orientation* metric; the terminology comes from the observation in [\[75\]](#) and [\[76\]](#) that if D is the set of orientations (or *legal directions*) corresponding to the vertices of the polygon, then for any pair of points in the Euclidean plane, there exists a path composed of a pair of line segments with adjacent legal directions so that the Euclidean length of the path equals the distance between the points under the fixed orientation metric. In a minimal FST under such a metric containing at least two Steiner points, each Steiner point has degree 3, and hence the incident edges at that Steiner point use a set of up to six legal directions in their representations as Euclidean embeddings. This set of legal directions is known as the *direction set* of the Steiner point. It has been shown in [\[18\]](#) (for λ -geometry Steiner trees) and in [\[9\]](#) (for Steiner trees under more general fixed orientation metrics) that for any set of terminals, there exists a minimum Steiner tree such that in each full component all Steiner points use only a single direction set, and hence the full component itself uses at most six legal directions. In a similar manner to the proof of [Theorem 2](#), the proofs of these results are based on showing

that if two adjacent Steiner points have different direction sets then there exists a length-reducing perturbation on the FST.

For fixed orientation metrics, the usefulness of knowing that an FST uses only a single direction set lies in the fact that there are only a relatively small number of direction sets that need to be considered; in fact, if there are σ legal orientations (or equivalently σ vertices on the polygonal unit ball), then the number of candidate direction sets that need to be considered is $\Theta(\sigma)$, and these can be identified in $\Theta(\sigma)$ time [9]. For the gradient metric, however, the “direction set” at each Steiner point includes an unknown intermediate direction k which belongs to the uncountable set $(-m, m)$. This potential difficulty was resolved in [10] where it was shown that for any m -constrained minimal FST, there is a simple formula for computing the gradient of the intermediate edge in terms of the coordinates of the terminals and information about the topology of the tree. The correct statement of this result requires the following definition.

A full Steiner topology, each of whose edges has been assigned with the labels m , $-m$, or k with the property that the three edges meeting at a Steiner point all have different labels, is referred to as a *labeled Steiner topology*. A full m -constrained minimal Steiner tree is said to have a given labeled topology if there exists a real number k with $|k| < m$ such that the gradient of each edge corresponds to the label on that edge. It can be shown, using the threshold technique developed by Hwang and Weng [39], that m -constrained minimum Steiner trees with any labeled topology can occur.

Theorem 3 *Let T be a full m -constrained minimal Steiner tree containing an edge of gradient k where $|k| < m$ at every Steiner point. Then given the terminal set and labeled Steiner topology of T , the gradient k can be computed in linear time. Hence, the locations of all Steiner points of T can also be computed in linear time.*

The details of how to compute k and the correctness of the result are given in [10]. The locating of the Steiner points is then a simple recursive procedure based on determining (via the labeled Steiner topology) the position of each point that has two neighboring nodes in known locations.

3.2 Computational Complexity

The properties discussed in the previous section essentially give an efficient way of solving the two-dimensional gradient-constrained Steiner problem for a given Steiner topology. In practice, it should be possible to use these properties as part of a Geosteinertype algorithm to solve the general problem in a scalable way for most randomly distributed sets of terminals. In this section, however, it will be shown that the general problem is NP-complete, which suggests that there will always be families of instances for which any exact solution algorithm is unable to scale efficiently.

This result is not surprising, given that both the rectilinear and Euclidean Steiner problems are NP-hard, as shown in [32] and [33]. Indeed, it is possible to prove a somewhat stronger result, namely, that the (discretized) two-dimensional gradient-constrained Steiner problem is NP-complete even when the terminals are restricted to lying on two vertical lines. This restriction is an interesting one as it has been shown by Aho et al. [1] that imposing it on the rectilinear Steiner problem allows one to find a linear time algorithm, whereas Rubinstein et al. [55] have shown that the discretized Euclidean Steiner problem is still NP-complete under this restriction.

The formal decision version of the problem is as follows:

The Vertical Line Gradient-Constrained Steiner Problem

- *Instance:* A set of points $N = \{p_1, \dots, p_k\}$ contained in two vertical lines, a gradient bound m satisfying $0 < m \leq 1$ and a real number l .
- *Question:* Is there an m -constrained Steiner tree T with terminals N and length at most l ?

As discussed in [33], there are difficulties in describing the complexity of problems such as this caused by the necessity of computing with irrational numbers. A method of circumventing these difficulties is to introduce the discretized Euclidean metric \mathbf{d}' , where $\mathbf{d}'(a, b) = \lceil \mathbf{d}_E(a, b) \rceil$. For the discretized vertical line gradient-constrained Steiner problem, the vertices of the tree are restricted to points with integer coordinates, and the lengths of edges in the tree (or the lengths of segments, in the case of bent edges) are replaced by their discretized Euclidean lengths.

Theorem 4 *The discretized vertical line gradient-constrained Steiner problem is NP-complete.*

This theorem was first proved in [10] using a similar strategy to that devised for the Euclidean Steiner problem in [55]. A somewhat simpler, more constructive proof of both of these complexity results was given in [12].

The basic strategy of the proof is to show that solving a specific instance of the discretized vertical line gradient-constrained Steiner problem depends on being able to solve the subset sum problem, that is, the problem of deciding for any given subset $S = \{d_1, \dots, d_n\}$ of integers and integer s whether there exists a subset $J \subseteq S$ such that $\sum_J d_i = s$. The subset sum problem is known to be NP-complete, from which the theorem follows. The key to the construction of the instance encoding the subset sum problem is to place closely spaced triples of terminals on one of the vertical lines in such a way that in a gradient-constrained minimal Steiner tree, each triple will have a Steiner point adjacent to two of the terminals, and there will be a bent edge connecting the third terminal to one of that pair. For each triple, there is a choice as to which pair of terminals has an adjacent Steiner point. The locations of all terminals are contrived so that in the minimum Steiner tree, all edges with intermediate gradient are horizontal, and finding a choice of connection to each triple that makes all intermediate gradient edges horizontal is equivalent to solving the subset sum problem. This construction can easily be done in polynomial time from any instance of the subset sum problem, which completes the proof. The details of the construction and proof of correctness can be found in [12].

4 The Three-Dimensional Gradient-Constrained Steiner Problem

The *three-dimensional gradient-constrained Steiner problem* can be stated as follows:

- *Given:* A set of points $N = \{p_1, \dots, p_k\}$ in Euclidean three-space and a gradient bound satisfying $0 < m \leq 1$
- *Find:* A network T interconnecting N of minimum total length, where the length of each edge e is computed using the gradient metric (with gradient bound m)

A tree solving the three-dimensional gradient-constrained Steiner problem for some given set of terminals will be referred to as a *gradient-constrained minimum Steiner tree*.

Moving from two to three dimensions significantly increases the inherent difficulty in solving Steiner problems. The three-dimensional Euclidean Steiner tree problem, for example, is known to be considerably more difficult than the planar version. Some of the basic properties of such trees have been studied in [35] and [58]. The three-dimensional gradient-constrained Steiner problem is even more complicated. Despite the high levels of complexity involved in solving the Steiner problem, it is nevertheless important to study the properties of exact minimum Steiner trees. In higher-dimensional cases, such properties have proved crucial in the development of approximation algorithms. For example, Smith's approximation algorithm for d -dimensional Steiner trees in [58] uses the fact that all angles at Steiner points in exact minimum Steiner trees are $2\pi/3$.

This section is a survey of the most important properties of gradient-constrained minimum Steiner trees, beginning with the fundamental properties of their Steiner points.

4.1 Properties of Steiner Points

The results in this section are mostly from [13]. Let T be a gradient-constrained minimum Steiner tree. It can be assumed that all edges of T are straight lines whose lengths are given by the gradient metric. Let $|T|_g$ be the sum of the lengths of all edges in T . An edge pq in T is called an *f-edge*, *m-edge*, or *b-edge* if pq is labeled “f” ($g(pq) < m$), “m” ($g(pq) = m$), or “b” ($g(pq) > m$) respectively. The label of an edge can be thought of as indicating which of the two metrics that compose the gradient metric is “active” for that edge, with an “m” label indicating that both metrics hold simultaneously.

A very useful tool for understanding properties of Steiner points in a gradient-constrained minimum Steiner tree is the variational method, which was developed by Rubinstein et al. in [54]. The variational argument in the Steiner tree problem is as follows: for a minimum tree T , the directional derivative of $|T|_g$ is greater than or equal to zero when its Steiner points are perturbed in any directions. Note that under an arbitrarily small perturbation, the only edges which can change labeling are

m-edges. If no m-edges change their labeling under a given perturbation, then it is easily checked that the variation is reversible, and hence the directional derivative is strictly zero. Suppose $e = sa$ is an edge in T and s is a Steiner point which is perturbed to s' in direction \mathbf{u} . Let $\dot{e}_{\mathbf{u}}$ (or simply \dot{e} if \mathbf{u} is known) denote the directional derivative of the length of e . It is easy to show the following lemma and corollary:

Lemma 2

- (i) If e is an f-edge, then $\dot{e}_{\mathbf{u}} = -\cos(\angle ass')$.
- (ii) If e is a b-edge, then $\dot{e}_{\mathbf{u}} = -\cos(\angle zss')\sqrt{1+m^{-2}}$ where z is a point on the vertical line through s such that $\angle asz \leq \pi/2$.
- (iii) If e is an m-edge, then $\dot{e}_{\mathbf{u}}$ is equal to either $-\cos(\angle ass')$ or $-\cos(\angle zss')\sqrt{1+m^{-2}}$, depending on whether $g(s'a) \leq m$ or $g(s'a) > m$.

Corollary 2

- (i) When s moves horizontally, the length of e does not change if e is a b-edge or if e is an m-edge and becomes a b-edge in the move.
- (ii) When s moves vertically to the same side (or the opposite side) of the horizontal plane through s as a , e becomes shorter (or, respectively, longer) regardless of the gradient of e .

From Lemma 2, it is clear that as in the Euclidean metric, the directional derivative of e in the gradient metric is determined only by the direction of \mathbf{u} and is independent of the length of sa .

Because an f-edge is still an f-edge under a small perturbation, Lemma 2 gives the following easy corollary:

Lemma 3 Any f-edge of a Steiner point s meets other edges incident to s at an angle no less than $\pi/2$.

An important application of the variational argument is that of splitting a small angle in a nonoptimal tree. If a Steiner point s of T is perturbed in direction \mathbf{u} , denote the directional derivative of $|T|_g$ by $\dot{T}_{\mathbf{u}}$ or just \dot{T} . Now, suppose s is a Steiner point joining a, b , and c in a Euclidean Steiner tree $T = sa \cup sb \cup sc$. If $\angle acb \geq 2\pi/3$, then s collapses into c . On the other hand, if $\angle acb < 2\pi/3$ but $s = c$, then T cannot be minimum by the following variational argument: let s_1 be a point on the bisector \mathbf{u} of $\angle asb$ and close to s , then $\angle ass_1 = \angle bss_1 < \pi/3$ and $\dot{T} = 1 - \cos(\angle ass_1) - \cos(\angle bss_1) < 0$. In general, this process is referred to as *splitting* the angle at s in the subtree $sa \cup sb$ along a vector \mathbf{u} .

An example of the application of this technique to gradient-constrained minimum Steiner trees comes from understanding when a Steiner point in such a tree can have an incident b-edge. For any point p , denote the horizontal plane through p by \mathcal{H}_p . For simplicity, a point or an edge will be said to be above (or below) p if it is above (or below) \mathcal{H}_p . It is also useful to follow the convention of saying that two edges incident with s lie on the same side of \mathcal{H}_s if they lie in the same closed half-space determined by \mathcal{H}_s ; that is, this includes the possibility that one or both edges lie on \mathcal{H}_s . The two edges are said to be on different sides of \mathcal{H}_s only if their interiors lie in different open half-spaces (determined by \mathcal{H}_s).

Lemma 4 *If sa is a b-edge in a gradient-constrained minimum Steiner tree T , then no other edge incident with s lies on the same side of \mathcal{H}_s as a . Moreover, all other edges incident with s are m-edges.*

Proof Let sb be another edge of T incident with s . Let \mathbf{u} be a vector with gradient m , perturbing s to s' , such that s' lies on the same side of \mathcal{H}_s as a and the angle $\theta = \angle s'sb$ is as small as possible. Applying the variational argument to T by splitting the angle $\angle asb$ at s along \mathbf{u} , note that $\dot{T} = \dot{s}b_{\mathbf{u}}$. If sb is a b-edge lying on the same side of \mathcal{H}_s as a , then $\dot{T} < 0$ by Lemma 2 (ii). If, on the other hand, sb is an m-edge or f-edge on the same side of \mathcal{H}_s as a , or sb is an f-edge on the opposite side of \mathcal{H}_s to a , then $\theta < \pi/2$ (since $m \leq 1$ in the latter case). So again, $\dot{T} < 0$ by Lemma 2. In each case, there is a contradiction to the minimality of T .

Finally, if sb is a b-edge lying on the opposite side of \mathcal{H}_s to a , then s has only two incident edges by the above argument and s is not a Steiner point. \square

A close analysis, using a similar approach, for any Steiner point in T , gives the following lemma, which is proved in [13].

Lemma 5 *If s is a Steiner point in a gradient-constrained minimum Steiner tree T , then there are at most two incident edges lying strictly above (or below) \mathcal{H}_s . Consequently, the degree of any Steiner point is either three or four.*

Suppose s is a degree 3 Steiner point in T with two incident edges sa, sb lying on one side of \mathcal{H}_s and the third sc lying on the other side of \mathcal{H}_s . (This includes the possibility that all three edges lie on \mathcal{H}_s .) Let g_a, g_b, g_c denote the respective labels of these edges. Then the labeling of this degree 3 Steiner point is denoted by (g_ag_b/g_c) . By symmetry, it can be assumed that a and b both lie on or above \mathcal{H}_s . The theorem below shows that of the 18 possible distinct labelings for a degree 3 point, only a small number can occur in a gradient-constrained minimum Steiner tree.

Theorem 5 *If s is a degree 3 Steiner point in a gradient-constrained minimum Steiner tree T , then up to symmetry, there are five feasibly optimal labelings: (ff/f), (ff/m), (fm/m), (mm/m), and (mm/b).*

Proof By Lemmas 4 and 5, the only possible labelings of s , other than those listed in the statement of the theorem, are (mm/f) and (fm/f). So suppose, contrary to the theorem, there is only one edge, the f-edge sc , lying below s , and there is an m-edge, say, sa , lying above s . Because $g(sa) > g(sc)$, sa shrinks strictly faster than sc stretches when s moves vertically upward. Since the third edge, sb , lies on the same side of \mathcal{H}_s as a and $\dot{s}b \leq 0$ under this move, it follows that $\dot{T} < 0$, contradicting the minimality of T . \square

Now, suppose s is a degree 4 Steiner point in T with two edges sa, sb lying on one side of \mathcal{H}_s and the other two edges sc, sd lying on the other side of \mathcal{H}_s . Let g_a, g_b, g_c, g_d be the respective labels of these edges. Then the labeling of s is denoted (g_ag_b/g_cg_d) .

For degree 4 Steiner points, it can be shown, by a somewhat more sophisticated use of the variational approach, that there is only one feasibly optimal labeling. The proof of this result is highly technical and again can be found in [13]. Note that here a stronger bound on the maximum gradient m is required, but as with the previous bound, it is one that is usually easily satisfied in applications.

Theorem 6 *If s is a degree 4 Steiner point in a gradient-constrained minimum Steiner tree T and if $m < 0.38$, then the labeling of s is (mm/mm).*

By [Theorems 5](#) and [6](#), there are six possible labelings at a Steiner point when $m < 0.38$. The two theorems below use the variational argument to show that for each labeling, it is possible to uniquely locate the Steiner point s in the gradient-constrained minimum Steiner tree T in terms of the adjacent vertices of T . Suppose the edges incident with s are sa, sb, sc (or sa, sb, sc, sd if s is of degree 4), where s has labeling (g_ag_b/g_c) (or (g_ag_b/g_cg_d) if s is of degree 4). For any point p , let \mathcal{C}_p denote the cone generated by rotating a line through p with gradient m about the vertical line through p . So \mathcal{C}_p is a right vertical cone whose vertex is p .

The results for a Steiner point of degree 3 are as follows.

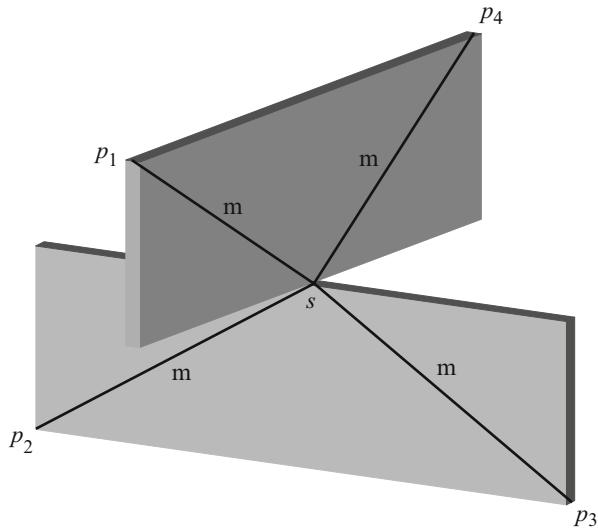

Theorem 7 *Let s be a degree 3 Steiner point in a gradient-constrained minimum Steiner tree T .*

- (i) *If s has labeling (ff/f), then s is the point on the plane through a, b, c such that $\angle asb = \angle bsc = \angle csa = 2\pi/3$.*
- (ii) *If s has labeling (mm/b), then s is a point at the intersection of $\mathcal{C}_a, \mathcal{C}_b$ and the vertical plane through b, c .*
- (iii) *If s has labeling (mm/m), then s is a point at which the three cones $\mathcal{C}_a, \mathcal{C}_b$, and \mathcal{C}_c all intersect, and $\angle asb \geq \arccos(-1 + m^2)/2 \geq \pi/2$.*
- (iv) *Suppose s has labeling (ff/m), and let \mathbf{v} be a horizontal vector tangent to \mathcal{C}_c at s . Then s is a point on \mathcal{C}_c such that $\angle(\mathbf{v}, \vec{sa}) = \angle(-\mathbf{v}, \vec{sb})$ and $\cos \angle(\vec{cs}, \vec{sa}) + \cos \angle(\vec{cs}, \vec{sb}) = 1$.*
- (v) *If s has labeling (fm/m), then s is a point lying on $\mathcal{C}_b \cap \mathcal{C}_c$, which is an ellipse, such that sa is perpendicular to this ellipse.*

Proof If the labeling at s is (ff/f), then it is clear that the location of s is the same as in the unconstrained three-dimensional Steiner problem, proving Case (i). For the remaining labelings, one can employ the variational argument. Since any vector in space can be decomposed into a sum of three noncoplanar components, to prove s can be a Steiner point of a minimum tree T , by the variational argument, it is sufficient to show that $\dot{T} \geq 0$ for perturbations of s in three noncoplanar directions. For Case (ii), it follows from [Lemma 2](#) that $\dot{T} \geq 0$ when s moves either up or down or in any horizontal direction. This proves Case (ii). The other cases can be proved by similar arguments; see [13] for details. \square

Finally, consider the case where s has degree 4. If, in this case, the edges incident with s can be partitioned into two pairs, such that each pair lies in a vertical plane through s and has the property that the projections of the two edges onto \mathcal{H}_s meet

Fig. 8 A degree 4 Steiner point with bi-vertically coplanar incident edges

at an angle of π at s , then the edges of s are said to be *bi-vertically coplanar* (see Fig. 8). Note that if two m -edges incident with s lie on opposite sides of \mathcal{H}_s and lie in the same vertical plane, then those edges are collinear. The other, noncollinear possibility is illustrated in Fig. 8. The following theorem not only shows how to construct a Steiner point of degree 4 but also shows that the existence of such a point requires a very specific configuration for the neighboring nodes. The proof is given in [13].

Theorem 8 *Let s be a degree 4 Steiner point (with labeling (mm/mm)) in a gradient-constrained minimum Steiner tree T . Then s is a point at the intersection of the four cones $\mathcal{C}_a, \mathcal{C}_b, \mathcal{C}_c, \mathcal{C}_d$, and furthermore the edges incident with s are bi-vertically coplanar.*

This work has been further extended in [21], where it is shown that a degree 3 or degree 4 locally minimal Steiner point in a gradient-constrained tree in 3-space is unique with respect to its adjacent nodes, even though the gradient metric is not strictly convex. More recently, Thomas and Weng [61] have derived explicit formulae for computing minimal Steiner points with given labelings in a gradient-constrained tree.

4.2 Local Minimality for a Fixed Topology

The characterization of Steiner points in the previous section provides a useful first step in solving the three-dimensional gradient-constrained Steiner problem with a given topology. For a fixed topology, the two-dimensional Euclidean Steiner problem has an efficient polynomial-time solution based on the methods of Melzak [48],

and similarly, it should be possible to efficiently solve the two-dimensional gradient-constrained Steiner problem using the methods in Sect. 3.2. In three-dimensional space, the problem of solving the Euclidean Steiner problem for a fixed topology is much more difficult. It has been shown in [56] that even on four terminals, a minimum Euclidean Steiner tree in 3-space cannot generally be solved by radicals. The same arguments also apply to minimum gradient-constrained Steiner trees in 3-space. This suggests that iterative methods are required to find good approximations of the solution for the general problem.

To solve any minimization problem, one can attempt a descent method. This works well for the problem at hand if the gradient constraint is relaxed. In particular, it is well known that for the analogous problem in d -dimensional Euclidean space, the network is minimal (for a given topology) if and only if there is no arbitrarily small perturbation of a single Steiner point that reduces the length of the network (see, e.g., [58]). This will be expressed by saying that if the network is minimal with respect to one-point moves, then it is minimal, or, more briefly, that one-point moves suffice.

For the gradient-constrained minimum Steiner tree problem, given terminals and a topology, one can start with an initial nonoptimal tree and then iteratively move toward a global minimum by moving Steiner points. By the convexity of the gradient metric, it follows that such a strategy will work, in theory, if one can determine the appropriate descent directions in which to move the Steiner points. This involves finding length-reducing perturbations of the positions of the Steiner points. One-point moves do not suffice for this problem, essentially due to the non-differentiability of the metric. This poses a difficulty algorithmically, and it helps to know which simultaneous multi-point moves might be required. One of the key results from [22] shows that, apart from a few easily classified exceptions, one-point moves and two-point moves suffice; that is, if the tree is not minimal for the given topology, then there exists a length reducing perturbation that fixes all but one or two Steiner points. This makes the task of finding suitable length-reducing perturbations much simpler.

There are two situations where one-point moves or two-point moves may not suffice, that is, where a consideration of all possible perturbations of one or two Steiner points is not sufficient for finding a descent direction from a non-minimal configuration. The first is where the tree contains an *extreme point*, which is defined to be a degree 3 Steiner point whose incident edges all have the maximum permitted gradient and all lie in a single vertical plane. In this case, a special length-reducing perturbation involving arbitrarily many points may be required; however, these perturbations are easily described. The other situation is where the tree degenerates to include zero-length edges. This case is very difficult to deal with in theory but does not seem to cause a problem in practical applications. Both of these situations are described in more detail later in this section.

The results in this subsection mainly come from [22]. Before discussing these results in a little more detail, it is important to be precise about what is meant here by a perturbation and the change of length under perturbations. A perturbation \mathbf{v} on T is a collection of vectors in three-dimensional Euclidean space, one for

each Steiner point of T . It is assumed that all Steiner points smoothly move with velocities specified by a given perturbation, resulting in a change of the length of T .

Perturbations are used to examine arbitrarily small alterations in the positions of the Steiner points of T and the consequential change in the total length of T . Note that the rate of change in length of T depends only on the directions and relative lengths of the vectors at the Steiner points – the length of each individual vector can be assumed to be arbitrarily small.

If T consists of a single edge uw , then the length of T with respect to the gradient metric is denoted by $L(T) = L(uw)$, and the derivative of this length with respect to a perturbation \mathbf{v} is denoted by $\dot{L}(uw)_{\mathbf{v}}$. It is also useful to define the active metric for a perturbation. Suppose $L(uw) \neq 0$. If uw is a b-edge or an f-edge, then the active metric for \mathbf{v} is the same as that of the edge. If uw is an m-edge, then the active metric for \mathbf{v} is defined to be b if the derivative of the gradient of uw is ≥ 0 and f if the derivative of the gradient is ≤ 0 (and hence both b and f if the derivative of the gradient equals 0). This is equivalent to saying that the active metric for the perturbation is the same as the metric active on the projection of the image of uw (after the perturbation has been applied) onto the vertical plane containing uw .

Note that although a perturbation can deactivate a metric on an m-edge, it cannot activate an inactive metric, since the perturbations are considered to be arbitrarily small.

For a larger tree T with edge set E , the derivative of $L(T)$ with respect to \mathbf{v} is defined to be

$$\dot{L}(T)_{\mathbf{v}} = \sum_{uw \in E} \dot{L}(uw)_{\mathbf{v}|_{\{u,w\}}},$$

where, as usual, $\mathbf{v}|_{\{u,w\}}$ is the perturbation that acts in the same way as \mathbf{v} on u and w and acts trivially on all other nodes of T . Since the terminals of a Steiner tree have fixed predetermined positions, it is assumed that all perturbations act trivially on terminals.

The convexity of the gradient metric immediately implies the following result.

Lemma 6 *Let T be a gradient-constrained Steiner tree with topology t . Then T is minimum with respect to t if and only if $\dot{L}(T)_{\mathbf{v}} \geq 0$ for every perturbation \mathbf{v} .*

As was illustrated in Fig. 7, Sect. 3.1, the existence of a perturbation \mathbf{v} on the Steiner points of T which decreases $L(T)$ does not imply that there exists a 1-point perturbation that decreases the length of T . It is helpful to examine why, in the example in Fig. 7, \mathbf{v} cannot be decomposed into 1-point perturbations on the original tree. Let \mathbf{v}_1 be the action of this perturbation on s_1 and \mathbf{v}_2 the action on s_2 . The question is why $\dot{L}(T)_{\mathbf{v}} \neq \dot{L}(T)_{\mathbf{v}_1} + \dot{L}(T)_{\mathbf{v}_2}$. The reason lies in the fact that the only active metric of s_1s_2 is the f-metric for \mathbf{v}_1 and the b-metric for \mathbf{v}_2 .

If, in the above example, s_1s_2 had a common active metric for both \mathbf{v}_1 and \mathbf{v}_2 , then there would exist a length-reducing 1-point perturbation. This would have occurred, for example, if the label of the edge s_1s_2 had been f or b.

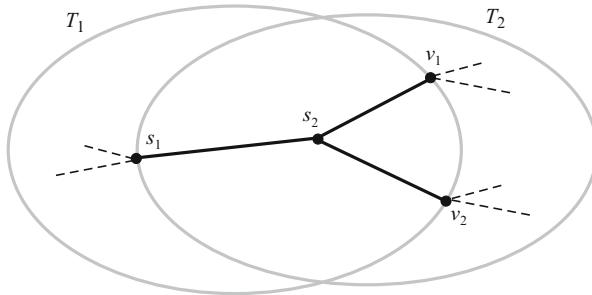

Fig. 9 The ellipses indicate the two subtrees T_1 and T_2 used for determining whether or not the edge s_1s_2 is decomposing with respect to s_2

Hence, it is evident that it is m-edges which cause difficulties when trying to decompose a length-reducing perturbation into a sum of 1-point perturbations because of the possibility of active metrics being changed in the decomposition. However, if 2-point perturbations are included in the decomposition, the problem of m-edges can often be overcome.

Let T be a full gradient-constrained Steiner tree with no zero-length edges. Suppose T has an interior node s_2 , whose three adjacent nodes are s_1 , v_1 , and v_2 (each of which may or may not be a Steiner point). Let U_1 and U_2 be the two connected components of $T - s_1s_2$ containing s_1 and s_2 , respectively. Let $T_1 = T|_{V(U_1) \cup \{s_2, v_1, v_2\}}$ and let $T_2 = T|_{V(U_2) \cup \{s_1\}}$. This is illustrated in Fig. 9. Note that s_2 is an interior node of both T_1 and T_2 . It is possible that a perturbation \mathbf{v} may decrease $L(T)$ but increase both $L(T_1)$ and $L(T_2)$. The edge s_1s_2 is said to be *decomposing* with respect to s_2 if for any perturbation \mathbf{v} acting on the interior nodes of T , there exist perturbations \mathbf{v}_1 and \mathbf{v}_2 acting on the interior nodes of T_1 and T_2 , respectively, such that

$$\dot{L}(T)\mathbf{v} = \dot{L}(T)\mathbf{v}_1 + \dot{L}(T)\mathbf{v}_2.$$

Furthermore, s_1s_2 is said to be *properly decomposing* with respect to s_2 if s_1s_2 is decomposing with respect to s_2 and $T_1 \neq T$ and $T_2 \neq T$ (i.e., s_1 is not a terminal, and at least one of v_1 and v_2 is not a terminal). The following lemma shows that if all interior edges in T are properly decomposing, then only 1- and 2-point perturbations need to be considered, when attempting to determine whether or not T is minimal.

Lemma 7 *Suppose every interior edge of full gradient-constrained Steiner tree T is properly decomposing with respect to at least one of its endpoints. If T is minimal with respect to all 1- and 2-point perturbations, then T is minimal.*

Proof Suppose, on the contrary, that T is not minimal. Then, by Lemma 6, there exists a perturbation \mathbf{v} on T , such that $\dot{L}(T)\mathbf{v} < 0$. The result follows by a straightforward induction argument on the number of Steiner points acted on (non-trivially) by \mathbf{v} , giving the existence of a length reducing 1- or 2-point perturbation. \square

Define a degree 3 Steiner point s in T to be an *extreme point* if s is labeled (mm/m) and the three edges incident with s all lie in a vertical plane.

Theorem 9 *Let T be a full gradient-constrained Steiner tree, minimal with respect to 1- and 2-point perturbations, and containing no extreme points or zero-length edges. Then T is minimal (with respect to its topology).*

Proof A geometric argument, given in [22], shows that if T contains no extreme points, then each interior edge of T is decomposing with respect to both endpoints. If T contains at least three Steiner points, then each interior edge e is incident with a Steiner point s_e which is adjacent to a third Steiner point (not an endpoint of e); thus e is properly decomposing with respect to s_e . Hence, by Lemma 7, T is minimal. On the other hand, if T contains less than three Steiner points, then T is minimal by assumption. \square

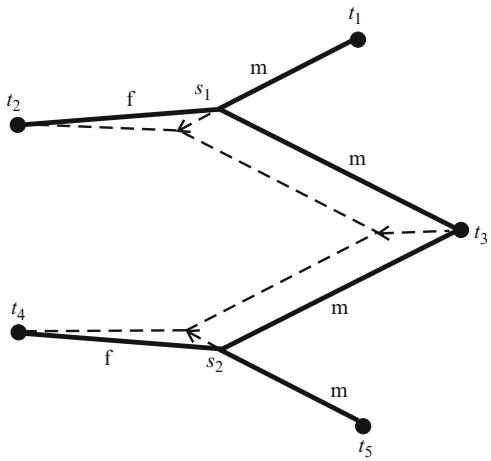

Let T_{ext} denote the subnetwork of T induced by extreme points. In other words, T_{ext} is a forest whose nodes are the extreme points of T and whose edges are the edges of T whose endpoints are both extreme. Note that each connected component of T_{ext} lies in a vertical plane. In order to understand the structure of T if it contains extreme points, one can define a class of easily identified perturbations known as backbone moves and show that T is minimal if and only if none of these moves is length reducing.

Definition Let P be a connected component of T_{ext} with node set $V(P)$, containing $k - 2$ nodes ($k \geq 3$). It is straightforward to show that P is a path in a vertical plane \mathcal{P} whose nodes are collinear. Let s_1 and s_k be the two nodes of T not in P that are neighbors of the two endpoints of P and are collinear with P (or are the collinear neighbors of the single node of P if $k - 2 = 1$). Then $T|_{V(P) \cup \{s_1, s_k\}}$ is defined to be the *backbone* of P (i.e., the backbone is the union of P and the two extra collinear edges of T incident with the endpoints of P). A *k -point backbone move* is a perturbation of $V(P) \cup \{s_1, s_k\}$ restricted to \mathcal{P} such that the active metric on all edges in or incident with P remains m; each node of $V(P)$ is perturbed an appropriate relative distance directly toward or away from its neighboring terminals. Hence the backbone remains collinear, if the perturbation is applied.

Note that a k -point backbone move is determined entirely by its action on s_1 and s_k . Finding a length-reducing k -point backbone move is no more complex than finding a length-reducing 2-point perturbation. Furthermore, such backbone moves can be shown to exist in some cases where there are no length-reducing 1- or 2-point perturbations.

A careful geometric argument, given in [22], shows that for any non-minimal tree containing no zero-length edges, there exists either a 1- or 2-point perturbation or a k -point backbone move that is length reducing.

Fig. 10 A degenerate tree minimal with respect to 1- and 2-point perturbations but not with respect to 3-point perturbations

Theorem 10 Let T be a gradient-constrained Steiner tree, minimal with respect to 1- and 2-point perturbations, and containing no zero-length edges. If T is not minimal then there exists a length-reducing k -point backbone move on T , for some $k \geq 3$.

The remaining case to consider is where T contains zero-length edges. There are a number of reasons why it is sensible to permit zero-length edges for a given topology: it ensures a minimum network exists for each topology, it is necessary to guarantee compactness of the configuration space for a fixed topology, and it means that all topologies can essentially be dealt with by considering only full topologies. For instance, some minimal Steiner trees have a Steiner vertex of degree 4, and this can be considered instead as a degenerate example of a Steiner tree whose topology has all Steiner points of degree 3 but where two such points have an edge of length zero joining them.

However, if the restriction on no zero-length edges is relaxed, then [Theorem 10](#) no longer holds. This is illustrated by the following example.

Consider a gradient-constrained tree T in the vertical plane with terminals t_1, t_2, t_3, t_4 , and t_5 , as shown in [Fig. 10](#). The tree T contains two Steiner points s_1 and s_2 such that s_1t_2 is an f-edge sloping downward from s_1 , s_2t_4 is an f-edge sloping upward from s_2 , and the remaining edges are m-edges. Now T can be viewed as a full (but degenerate) tree containing a third Steiner point s adjacent to s_1, s_2 , and t_3 , such that st_3 is a zero-length edge. It is easy to see that T is minimal with respect to 1- and 2-point moves. However, there is a 3-point move, moving s_1 along the line through s_1t_1 away from t_1 , moving s_2 along the line through s_2t_5 away from t_5 , and moving s away from t_3 so that s_1s and s_2s remain m-edges that reduces the length of T as the f-edges come closer to being parallel. This move is indicated in the figure in broken lines.

This example does not rely on s being extreme. It is possible to move some of the terminals out of the vertical plane, without changing the edge labels, so that this

problem persists. It is also possible to construct more complicated examples that require the simultaneous perturbation of arbitrarily many Steiner points (not in a vertical plane) in order to reduce the length of the tree.

4.3 Algorithms and Software Solutions

The importance of solving the three-dimensional gradient-constrained Steiner problem for a fixed topology is that it forms a key step toward the solution of the general problem of finding the minimum network joining a given set of nodes, without specifying the network topology. From the example at the end of the previous subsection, it appears that for the case of zero-length edges, characterizing the constraints on Steiner trees that are minimal with respect to the gradient metric, and having a given topology, is a difficult and probably intractable problem. However, this is not necessarily a major setback for constructing an effective approximation algorithm that seeks to find the minimum gradient-constrained Steiner tree. An example of such a software tool is UNO (Underground Network Optimiser), which makes use of the theoretical results in the previous two subsections. A description of an early version of UNO is given in [11], and a computational study using UNO is presented in [62].

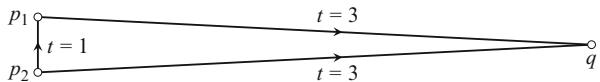

The problem of finding the best topology is in general NP-complete, since this is true for the same problem restricted to the horizontal plane. Hence, any practical algorithm requires a method of changing topologies, or at least considering many different topologies, that is unlikely to be highly efficient. UNO incorporates this aspect by including some random steps. By running for some time and repeatedly randomly encountering approximately minimal trees, the algorithm occasionally finds trees that are reasonably close to the minimal tree, even in the case of the example illustrated in Fig. 10. A sensible descent method (using the results in the previous section characterizing minima with no zero-length edges) then brings the algorithm even closer to the true global minimum. The characterization of local minima described in the previous section appears to be enough for the algorithm to perform well in practical cases.

In UNO, the problem of finding a “good” topology, for instance, the topology of the minimum tree, is tackled via a heuristic method based on simulated annealing and a genetic algorithm. In this way, the problem is reduced to one of efficiently minimizing the cost for a single topology, using descent methods.

5 The Gilbert Problem in Minkowski Spaces

Gilbert [34] proposed a generalization of the Euclidean Steiner problem incorporating into the network cost a flow between terminals. This section considers the extension of this concept to networks in general Minkowski spaces. Much of the discussion here is based on [67].

Fig. 11 An example where split routing is cheaper

Let T be a network interconnecting a set $N = \{p_1, \dots, p_n\}$ of n terminals in a Minkowski space. For each pair p_i, p_j , $i \neq j$ of terminals, a nonnegative flow $t_{ij} = t_{ji}$ is given. The cost of an edge e in T is $w(t_e)l_e$, where l_e is the length of e , t_e is the total flow being routed through e , and $w(\cdot)$ is a unit cost weight function defined on $[0, \infty)$ satisfying

$$w(0) \geq 0 \quad \text{and} \quad w(t) > 0 \text{ for all } t > 0, \quad (1)$$

$$w(t_2) \geq w(t_1) \quad \text{for all } t_2 > t_1 \geq 0, \quad (2)$$

$$w(t_1 + t_2) \leq w(t_1) + w(t_2) \quad \text{for all } t_1, t_2 > 0, \quad (3)$$

$$w(\cdot) \text{ is a concave function.} \quad (4)$$

That the function w is concave means by definition that $-w$ is convex. A network with a cost function satisfying Conditions (1)–(3) is called a *Gilbert network*. For a given edge e in T , $w(t_e)$ is called the *weight* of e and is also denoted simply by w_e . The *total cost* of a Gilbert network T is the sum of all edge costs, that is,

$$C(T) = \sum_{e \in E} w(t_e)l_e$$

where E is the set of all edges in T . A Gilbert network T is a *minimum Gilbert network*, if T has the minimum cost of all Gilbert networks spanning the same point set N , with the same flow demands t_{ij} and the same cost function $w(\cdot)$. By the arguments of [26], a minimum Gilbert network always exists in a Minkowski space when Conditions (1)–(4) are assumed for the weight function.

Conditions (1)–(3) above ensure that the weight function is nonnegative, non-decreasing, and triangular, respectively. These are natural conditions for most applications. Unfortunately, the first three conditions alone do not guarantee that a minimum Gilbert network is a tree. This can be seen by considering the following example of a Gilbert network problem with two sources and one sink in the Euclidean plane, where there exists a split-route flow that has a lower cost than any arborescence.

For this example, assume there are two sources p_1, p_2 and a sink q which are the vertices of a triangle $\Delta p_1 p_2 q$ with edge lengths $\|p_1 - p_2\|_2 = 1$ and $\|p_1 - q\|_2 = \|p_2 - q\|_2 = 10$, as illustrated in Fig. 11. The tonnages at p_1 and p_2 are 2 and 4, respectively. The weight function is $w(t) = \lceil (3t + 1)/2 \rceil$, that is, $(3t + 1)/2$ rounded up to the nearest integer. This function is positive, nondecreasing, and triangular, but not concave. For the example, only the following values need to be considered:

Fig. 12 The minimum Gilbert arborescence

t	1	2	3	4	6
w(t)	2	4	5	7	10

Routing 1 unit of the flow from p_2 via p_1 to q (and all other flow directly to q) gives a Gilbert network (Fig. 11) of total cost

$$w(1)\|p_1 - p_2\|_2 + w(3)\|p_1 - q\|_2 + w(3)\|p_2 - q\|_2 = 102.$$

For a Gilbert arborescence, the flows from p_1 and p_2 to q are routed via some variable point s as in Fig. 12. A minimum Gilbert arborescence can be calculated by using the weighted Melzak algorithm as described in [34] to correctly locate s . The calculation, which involves a straightforward geometric calculation (see [22]), results in a total cost of $\sqrt{9982.5} + 7\sqrt{3890.25} = 102.074\dots$. This shows that split routing can be necessary when the weight function is not concave.

For the remainder of the chapter, it will be assumed that the weight function w is concave in addition to the other three conditions (in fact, the weight function will generally be linear). When all of Conditions (1)–(4) apply and there is a single sink, it has been shown in [34] and [60] that there always exists a minimum Gilbert network that is a Gilbert arborescence. This means that for the remainder of this chapter, it is only necessary, without loss of generality, to consider MGAs. (Note that in [26], Condition (3), the *triangular condition*, was incorrectly interpreted as concavity of the cost function.)

The *Gilbert network problem* is to find a minimum Gilbert network for a given terminal set N , flows t_{ij} , and cost function $w(\cdot)$. Since its introduction in [34], various aspects of the Gilbert network problem have been studied, with an emphasis generally on discovering geometric properties of minimum Gilbert networks (see [26, 60, 64, 65] and [67]). As in the Steiner problem, additional vertices can be added to create a Gilbert network whose cost is less than would otherwise be possible, and these additional points are again called *Steiner points*. A Steiner point s in T is called *locally minimal* if a perturbation of s does not reduce the cost of T . A Gilbert network is called *locally minimal* if no perturbation of the Steiner points reduces the cost of T .

One of the main results established in [67] is that in a smooth Minkowski plane, that is, a two-dimensional Minkowski space where the given norm is differentiable at any $x \neq o$, every Steiner point in an MGA has degree 3. In Sect. 6, however, it will be shown that for the gradient-constrained Gilbert problem (where the corresponding Minkowski space is not smooth) degree 4 Steiner points can occur.

6 The Two-Dimensional Gradient-Constrained Gilbert Problem

The *Gilbert arborescence problem* asks for a minimum-cost flow-dependent network interconnecting given sources and a unique sink. The gradient-constrained version of the problem in a vertical plane is called the *two-dimensional gradient-constrained Gilbert arborescence problem* and is formulated as follows:

- *Given:* A set of points $N = \{p_1, \dots, p_k\}$ in a vertical plane in Euclidean space, where p_1, \dots, p_{k-1} are sources with respective positive flows t_1, \dots, t_{k-1} and p_k is a unique sink, a gradient bound satisfying $0 < m \leq 1$, and positive constants d and h
- *Find:* A minimum-cost network T interconnecting N which provides flow paths from the sources to the sink, such that the cost of an edge e in T is given by $(d + ht_e)l_e$, where t_e is the total flow through e and l_e is the length of e under the gradient metric

A network satisfying the above conditions is called a *gradient-constrained minimum Gilbert arborescence* (gradient-constrained MGA, for short). Vertices in T not in N are, as before, called *Steiner points*, and as was discussed in Sect. 5, a Steiner point is a Fermat-Weber point with respect to its adjacent vertices in T . The quantity $d + ht_e$ represents the *weight* associated with the edge e .

As in the case of the Steiner problem, there exists a gradient-constrained MGA lying in the vertical plane containing the sources and sink; it will be assumed that the gradient-constrained MGA T lies in this vertical plane.

6.1 Edge Vectors and Fundamental Properties of MGAs

As discussed in Sect. 2.3, Euclidean space equipped with the norm associated with the gradient metric is an example of a Minkowski space. Recall that in a Minkowski space X , the *unit ball* is defined to be the set $B = \{x \in X : \|x\| \leq 1\}$. The *dual space* of X , denoted by X^* , is the vector space of all linear functionals on X , a linear functional being a mapping from X into \mathbb{R}^+ . Identifying X and X^* with \mathbb{R}^n , the *dual ball* B^* is the polar body of B , that is,

$$B^* = \{y : \langle x, y \rangle \leq 1, \quad \forall x \in B\}$$

where $\langle \cdot, \cdot \rangle$ is the dot product.

In a gradient-constrained vertical plane, the unit ball B_g and dual ball B_g^* are as shown in Fig. 13a, b. Note that the diagonal lines (shown dashed) have gradient m and that the shapes of the unit ball and dual ball depend on the value of m .

For any Minkowski space X , a *norming functional* of $x \in X$ is a $\phi \in X^*$ such that $\|\phi\| = 1$ and $\phi(x) = \|x\|$. The set of norming functionals of x is denoted by ∂x . By the Hahn-Banach separation theorem [53], each nonzero $x \in X$ has an associated norming functional. Each ∂x corresponds to an *exposed face* of B^*

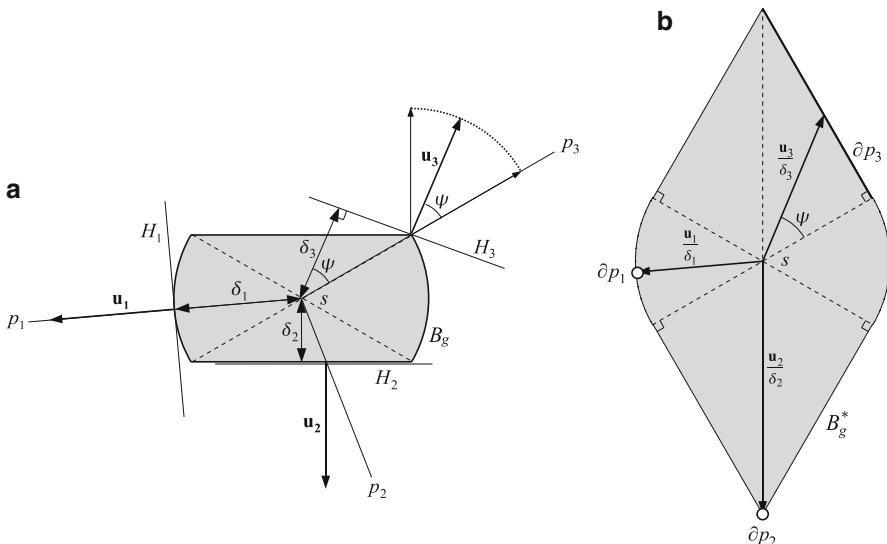

Fig. 13 Edge vectors and outward normal vectors for f-, b- and m-edges in the gradient metric. (a) The unit ball. (b) The dual ball

(i.e., the intersection of B^* with a supporting hyperplane). Furthermore, a norming functional is equivalent to a vector $\frac{\mathbf{u}}{\delta}$, where \mathbf{u} is an outward unit vector normal to the hyperplane supporting $s + B_g$ at the point where the ray from s through p intersects B_g and δ is the distance from s to this hyperplane. These vectors are referred to as *edge vectors*. Edge vectors are important for establishing an equilibrium condition at Steiner points.

In the gradient metric for a vertical plane, the following lemma characterizes vectors for edges connecting a fixed point and a Steiner point (refer to Fig. 13).

Lemma 8 Let ps be an edge with an associated weight w in a gradient-constrained MGA connecting a terminal p and a Steiner point s . Then an edge vector \mathbf{v} corresponding to an element of $w\partial|p-s|_g = w\partial(p-s)$ is computed as follows:

- If sp is an f-edge, \mathbf{v} points from s to p and has length w .
- If sp is a b-edge, then \mathbf{v} points vertically up or down, if p is above or below s , respectively, and has length $w\sqrt{1+m^{-2}}$.
- If sp is an m-edge, then any \mathbf{v} can be selected from the continuum of vectors having all possible directions between an m-edge and a vertical edge. The length of \mathbf{v} is given by $w/\cos\psi$, where ψ is the angle that \mathbf{v} makes with the m-edge.

Note that the possible vectors \mathbf{v} associated with an m-edge all point to one of the straight line segments on the boundary of B^* and the union of all these vectors forms a region bounded by a right-angled triangle.

Edge vectors, along with the variational argument, provide tools for analyzing the basic properties of Steiner points in MGAs. An optimal Steiner point s in a

gradient-constrained MGA is necessarily a Fermat-Weber point with respect to its adjacent points p_1, \dots, p_k . This leads to the following lemma, which follows from the results of Durier and Michelot [30].

Lemma 9 *Let T be a gradient-constrained MGA, and let s be a Steiner point in T with incident edges $p_1s, \dots, p_{k-1}s, sp_k$ having respective weights w_1, \dots, w_k . If s is locally minimal with respect to its adjacent vertices, then there exist edge vectors $\mathbf{v}_1, \dots, \mathbf{v}_k$, computed by Lemma 8, for which*

$$\sum_{i=1}^k \mathbf{v}_i = \mathbf{0}$$

This is referred to as the *equilibrium condition*. Note that the equilibrium condition is necessary but not sufficient for s to be locally minimal with respect to its adjacent vertices. This is in contrast to Fermat-Weber points in the gradient-constrained problem, for which the equilibrium condition is both necessary and sufficient.

The next results require the following definition.

Definition Let T be a gradient-constrained MGA in a vertical plane, and let s be a Steiner point in T . Then the horizontal and vertical lines passing through s are denoted by \mathcal{H}_s and \mathcal{V}_s , respectively.

The local properties of any Steiner point s in a gradient-constrained MGA are contained in the following two theorems and their corollary. These results were established and proved in [66], using the variational argument. Note that these properties depend on the gradient of the sink edge.

Theorem 11 *Let T be a gradient-constrained MGA in a vertical plane, and let s be a Steiner point in T with incident sink edge sp_k . If sp_k is a b-edge, then the degree of s is three, and the two source edges are m-edges on the opposite side of \mathcal{H}_s to sp_k .*

Theorem 12 *Let T be a gradient-constrained MGA in a vertical plane, and let s be a Steiner point in T with incident sink edge sp_k , where sp_k is not a b-edge. Let L denote the infinite line passing through s, p_k , and let H^+, H^- denote the two open half-planes into which L divides the vertical plane, such that H^+ is the upper half-plane if and only if the slope of L is positive. Then:*

1. *The Steiner point has at most one incident edge in H^+ , and this edge is either an f-edge or an m-edge on the opposite side of \mathcal{V}_s to sp_k .*
2. *If sp_k is an f-edge, s has no incident edges on L and either one or two incident edges in L^- . In the latter case, one of the two edges must be an m-edge on the same side of \mathcal{V}_s as sp_k , and the other must be either an f-edge or an m-edge on the opposite side of \mathcal{V}_s .*

3. If sp_k is an *m-edge*, s has at most one incident edge on L , which is necessarily an *m-edge*, at most one incident edge in L^- , which is necessarily an *m-edge* on the same side of \mathcal{V}_s as sp_k , and at most one incident edge in L^+ , which is either an *f-edge* or an *m-edge*.

These two theorems imply the following results.

Corollary 3 Let T be a gradient-constrained MGA in a vertical plane and let s be a Steiner point in T . Then:

1. The Steiner point s has at most one incident *b-edge*.
2. If the incident sink edge to s is an *m-edge*, then s has at most one incident *f-edge*.
3. The degree of s is either three or four.

6.2 A Classification of Steiner Points

Unlike minimum Steiner trees, gradient-constrained MGAs in a vertical plane do not appear to have a strong geometric structure or a canonical form. However, there are further structural restrictions at Steiner points (beyond those in [Corollary 3](#)) that have the potential to be exploited as part of an exact or heuristic algorithm. Steiner points can be classified in terms of the labels of the incident edges, in a similar way as was done in [Sect. 4.1](#). This section outlines a classification, both for degree 3 and 4 Steiner points. The results are proved in [66], using methods of subdifferential calculus and Minkowski sums – see [53] for some background on these topics.

6.2.1 Degree 3 Steiner Points

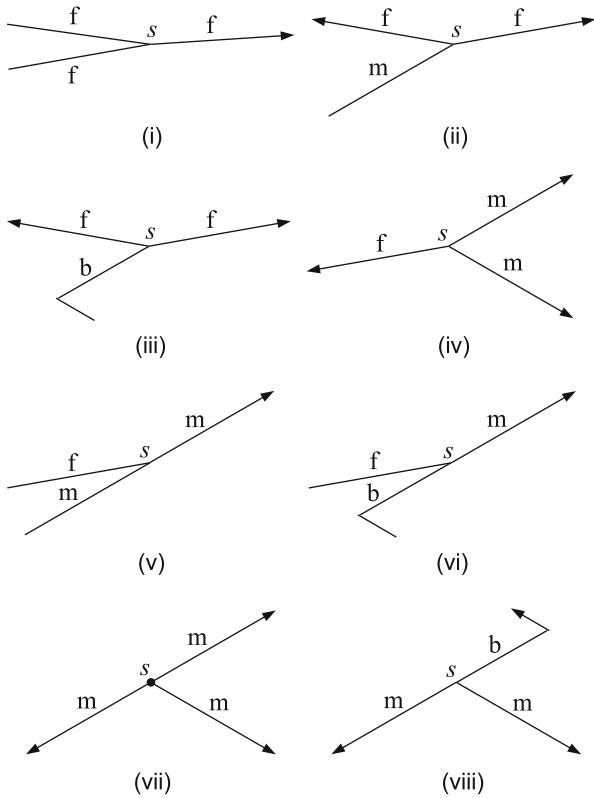

Let T be a gradient-constrained MGA in a vertical plane, and let s be a degree 3 Steiner point in T , with incident edges p_1s, p_2s, sp_3 , where p_1s, p_2s are source edges with positive flows t_1, t_2 and sp_3 is the sink edge. The incident edges p_1s, p_2s, sp_3 have respective weights $w_1 = d + ht_1$, $w_2 = d + ht_2$ and $w_3 = d + h(t_1 + t_2)$.

Let g_1, g_2, g_3 denote the respective *labels* of p_1s, p_2s, sp_3 . Then, here, the *labeling* of s is denoted $(g_i g_j g_k)$, where $i, j, k \in \{1, 2, 3\}$. In [Sect. 4.1](#), a ‘/’ sign was used to distinguish between edges lying above and below the horizontal plane \mathcal{H}_s through a Steiner point s in a gradient-constrained SMT. The situation is more complex for gradient-constrained MGAs, and distinguishing between edges above and below \mathcal{H}_s becomes less useful. Hence, in this section, there is no ‘/’ sign in the labeling. The convention employed here is that the edge labels are stated in order of increasing gradient, that is, “f” followed by “m” followed by “b.”

Since each $g_i \in \{f, m, b\}$, there are ten possible labelings of s to examine:

$$\begin{array}{lll} (\text{fff}) & (\text{ffm}) & (\text{ffb}) \\ (\text{fmm}) & (\text{fmb}) & (\text{fbm}) \\ (\text{mmm}) & (\text{mmb}) & (\text{mbm}) \\ (\text{bbb}) & & \end{array}$$

Fig. 14 Feasibly optimal labelings for degree 3 Steiner points

A labeling that can occur in a gradient-constrained MGA is called *feasibly optimal*. Note that for gradient-constrained minimum Steiner trees in a vertical plane, only three of these labelings are feasibly optimal by Corollary 1, namely, (fmm), (mmm), and (mbb). For gradient-constrained MGAs, however, additional labelings are possible.

Three of the labelings, those involving more than one “b” label, can immediately be eliminated as not being feasibly optimal by Corollary 3. It is shown in [66] that all the other labelings can occur but with some restrictions on the labeling of the sink edge.

Theorem 13 Let T be a gradient-constrained MGA in a vertical plane, and let s be a degree 3 Steiner point in T . Then s has seven feasibly optimal labelings: (fff), (ffm), (ffb), (fmm), (fmb), (mmm), and (mbb).

The labeling (fmm) has two feasibly optimal geometries, and hence there are eight possible configurations for s , as shown in Fig. 14. In the figure, edges which can feasibly be sink edges are indicated by arrows.

It is worth noting that, of the eight possible geometries for degree 3 Steiner points in gradient-constrained MGAs in a vertical plane, the three configurations (iv), (vii),

and (viii) are the only labelings in which any edge can feasibly be the sink edge. Also note that these are the only three feasibly optimal labelings for Steiner points in gradient-constrained SMTs in a vertical plane.

6.2.2 Degree 4 Steiner Points

Suppose s is a degree 4 Steiner point in a gradient-constrained MGA T in a vertical plane with four edges $p_{1s}, p_{2s}, p_{3s}, sp_4$, where p_{1s}, p_{2s}, p_{3s} are source edges with respective positive flows t_1, t_2, t_3 and sp_4 is the sink edge. Let g_1, g_2, g_3, g_4 be the respective labels of these edges. Then the labeling of s is denoted by $(g_1g_2g_3g_4)$. There are 15 potential labelings to examine:

$$\begin{array}{lll} (\text{ffff}) & (\text{fffm}) & (\text{fffb}) \\ (\text{ffmm}) & (\text{ffmb}) & (\text{ffbb}) \\ (\text{fmmm}) & (\text{fmm}) & (\text{fmbb}) \\ (\text{fbbb}) & (\text{mmmm}) & (\text{mmbb}) \\ (\text{mmbb}) & (\text{mbbb}) & (\text{bbbb}) \end{array}$$

For gradient-constrained SMTs in a vertical plane, only one of these labelings is feasibly optimal, namely, (mmmm) , which forms a *cross* (therefore, a gradient-constrained vertical plane is an example of an *X-plane* discussed in [59]). Again, additional labelings are possible for gradient-constrained MGAs in a vertical plane. Nevertheless, most of the labelings can be eliminated as not being feasibly optimal.

Theorem 14 *Let T be a gradient-constrained MGA in a vertical plane and let s be a Steiner point in T . Then the labeling of s is not $(\text{ffff}), (\text{fffb}), (\text{ffmb}), (\text{ffbb}), (\text{fmmb}), (\text{fmbb}), (\text{fbbb}), (\text{mmmm}), (\text{mmbb}), (\text{mbbb}),$ or (bbbb) .*

Theorem 15 *Let T be a gradient-constrained MGA in a vertical plane and let s be a degree 4 Steiner point in T . Then the following three labelings are feasibly optimal for s : $(\text{ffmm}), (\text{fmmm}),$ and (mmmm) .*

Examples have been constructed of Steiner points with each of these labelings, and the optimality of each case has been proved in [66]. Feasible configurations for degree 4 Steiner points are shown in Fig. 15. In the figure, edges which can feasibly be sink edges are indicated by arrows.

Whether or not the labeling (fffm) is feasibly optimal remains open to question. If the labeling is feasible, then one of the f-edges is the sink edge sp_4 , the m-edge is on the same side of \mathcal{V}_s as sp_4 (and on the opposite side of \mathcal{H}_s to sp_4), and the two remaining f-edges are on the opposite side of \mathcal{V}_s to sp_4 .

There is a sense in which the feasibly optimal labeling (fmmm) is nongeneric.

Definition Let T be a gradient-constrained MGA, and let s be a Steiner point in T . Then the labeling of s is said to be *unstable* if an arbitrarily small change in one of the edge weights causes the labeling to change.

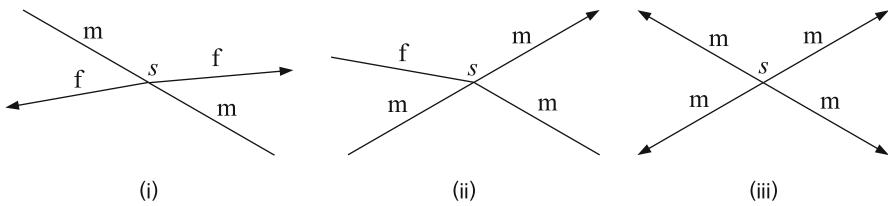

Fig. 15 Feasibly optimal labelings for degree 4 Steiner points. Edges which can feasibly be sink edges are indicated by arrows

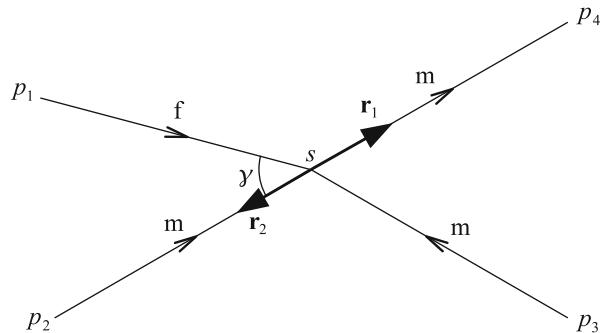

Fig. 16 Steiner point with labeling (fmmp)

Theorem 16 Let T be a gradient-constrained MGA in a vertical plane and let s be a Steiner point in T . Then the labeling (fmmp) is unstable.

The situation is illustrated in Fig. 16. If s is perturbed in direction \mathbf{r}_1 , then the variation is greater than or equal to zero when

$$t_1 \leq \frac{d}{h} \frac{\cos \gamma}{1 - \cos \gamma}.$$

Similarly, if s is perturbed in direction \mathbf{r}_2 , then the variation is greater than or equal to zero when

$$t_1 \geq \frac{d}{h} \frac{\cos \gamma}{1 - \cos \gamma}.$$

Therefore, for the variation to be greater than or equal to zero, it must be exactly zero, and this can only occur when

$$t_1 = \frac{d}{h} \frac{\cos \gamma}{1 - \cos \gamma}.$$

An arbitrarily small change in t_1 will cause the labeling of s to change, and hence Theorem 16 follows.

7 The Three-Dimensional Gradient-Constrained Gilbert Problem

The previous two sections introduced the gradient-constrained Gilbert arborescence problem and gradient-constrained minimum Gilbert arborescences (MGAs) lying in a vertical plane. While the vertical plane problem has a number of potential applications, such as designing the haulage infrastructure for underground mines where the access points to the ore bodies roughly lie in a vertical plane, most mining networks are genuinely three-dimensional. The aim of this section is to establish fundamental properties for gradient-constrained MGAs in three dimensions.

Here, a classification of degree 3 and 4 Steiner points in gradient-constrained MGAs in three-space is presented. As before, the classification of a Steiner point is in terms of the *labels* of its incident edges, where a label indicates whether the gradient of the straight line segment connecting the endpoints of an edge is less than, equal to, or greater than m . However, unlike gradient-constrained Steiner minimum trees or MGAs in the plane, there is no upper bound on the degree of a Steiner point in a gradient-constrained MGA in three dimensions. This issue is addressed in Sect. 7.2.

Let \mathcal{H}_s denote the horizontal plane passing through a point s . The other notation used in this section is identical to that in Sect. 6. The results in this section are mainly from [66].

7.1 Classification of Steiner Points of Degree at Most Four

As before, Steiner points of degree 3 and 4 are considered separately.

7.1.1 Degree Three Steiner Points

In [13], it was shown that there are five feasibly optimal labelings for degree 3 Steiner points in gradient-constrained SMTs in \mathbb{R}^3 . They are (fff), (ffm), (fmm), (mmm), and (mmn). These and additional labelings are possible for gradient-constrained MGAs in three-space.

Let T be a gradient-constrained MGA in three-space, and let s be a Steiner point in T . By Theorem 13, the labelings (fff), (ffm), (ffb), (fmm), (fmb), (mmm), and (mmn) are feasibly optimal for gradient-constrained MGAs in a vertical plane. Since the vertical plane case is a special case of the three-dimensional case, these seven labelings are also feasibly optimal in gradient-constrained MGAs in three-space. The remaining labelings are (ffb), (mbb), and (bbb). It can be shown, by a similar argument to that used in proving Lemma 4, that if s has an incident b-edge, then it has no other incident b- or m-edges on the side of \mathcal{H}_s containing the b-edge. Hence, labelings (mbb) and (bbb) are not feasibly optimal, since two edges with respective labels m,b or b,b cannot coexist on the same side of \mathcal{H}_s . The labeling (ffb) is not feasibly optimal by noting that there is no horizontal vector component to counterbalance that of the f-edge vector (since the two b-edge vectors

are vertical). Hence the equilibrium condition cannot be satisfied. This implies the following theorem.

Theorem 17 *Let T be a gradient-constrained MGA in three-space, and let s be a degree 3 Steiner point in T . Then s has seven feasibly optimal labelings: (fff), (ffm), (ffb), (fmm), (fmb), (mmm), and (mmb).*

Steiner points with these labelings are shown in Fig. 17, where the m-cones associated with the Steiner point are included to distinguish between f-, m-, and b-edges in three-space. Note that in three-space, for the labelings (fff), (ffm), (fmm), (mmm), and (mmb), any of the three edges can potentially be the sink edge. However, it can be shown that for the labelings (ffb) and (fmb), the sink edge must be labeled “f” and “m,” respectively.

7.1.2 Degree 4 Steiner Points

In Sect. 4.1 (and [13]), it was shown that the labeling (mmmm) is the only feasibly optimal labeling for degree 4 Steiner points in gradient-constrained SMTs in three-space. For this labeling, two of the m-edges must lie above \mathcal{H}_s and the other two below. Moreover, recall that the four edges incident to s are necessarily *bi-vertically coplanar*, meaning the two m-edges above \mathcal{H}_s lie in the same vertical plane and the two m-edges below \mathcal{H}_s lie in the same vertical plane (Fig. 8). When the two planes align to form a single vertical plane, then the four m-edges form a *cross*, a structure that is feasibly optimal for gradient-constrained MGAs in a vertical plane, as discussed in the previous section.

Additional labelings are possible for degree 4 Steiner points in gradient-constrained MGAs in three-space and are listed in the theorem below. As before, the potential minimality of these labelings can be proved by direct construction and checking for each construction that certain necessary and sufficient conditions are satisfied.

Theorem 18 *Let T be a gradient-constrained MGA in three-space, and let s be a Steiner point in T . Then the labelings (ffff), (ffmm), (fmmp), and (mmmm) are feasibly optimal.*

Specific examples of Steiner points with each of these feasible configurations for degree 4 Steiner points are shown in Fig. 18. For each of the two labelings (ffmm) and (fmmp), two distinct configurations of edges are shown. In all cases, the sink edge is indicated by arrows. The m-cones (generated by taking a line through s with gradient m and rotating it 360° about the vertical line through s) are shown to help distinguish between f-, m-, and b-edges. Note that in general, the sink edge can have any of the available labels except for the labeling (ffff), in which case the sink edge must be an f-edge.

The question now is whether the list in Theorem 18 is complete. As before, a b-edge incident with s cannot lie on the same side of \mathcal{H}_s as another incident b- or m-edge, which immediately eliminates the labelings (fmbb), (fbhb), (mmbb), (mbbb),

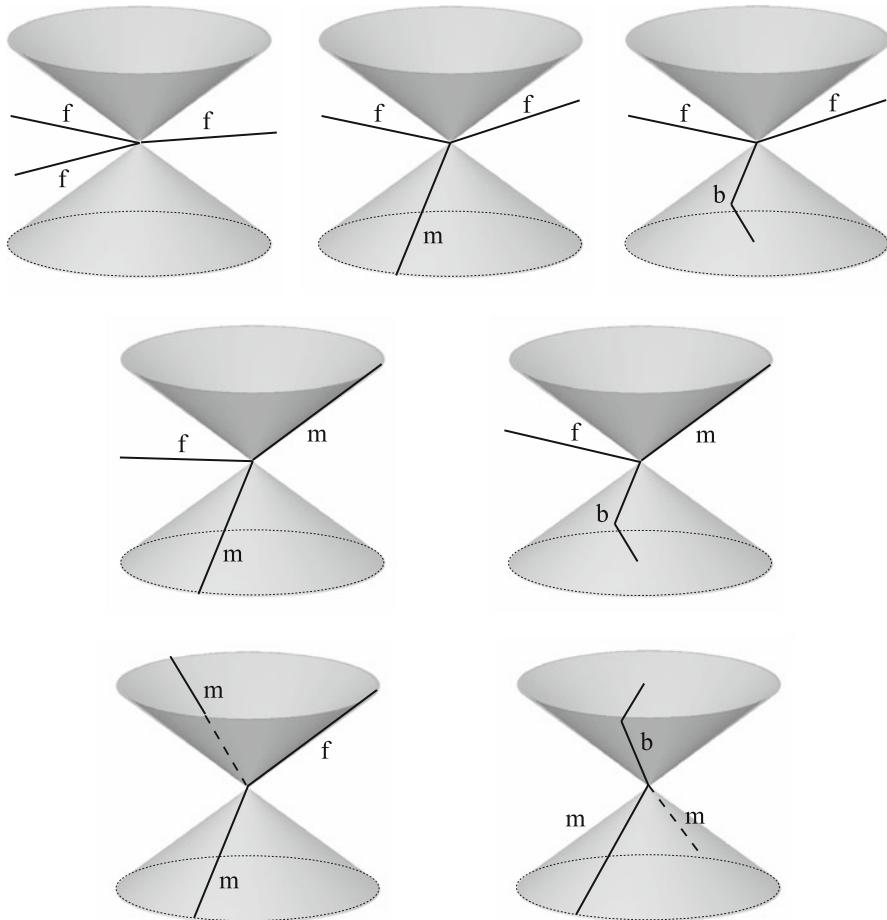

Fig. 17 Feasibly optimal labelings for degree 3 Steiner points in three-space

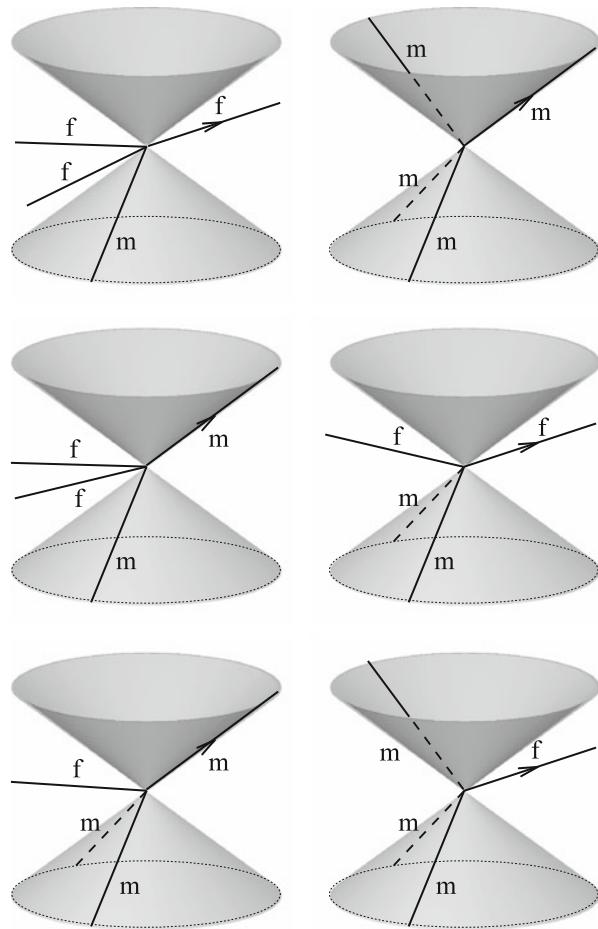

and (bbbb). A similar argument also shows that (ffffb) is never feasibly optimal. In [67], it is shown that all Steiner points in Euclidean MGAs in three-space have degree 3. It follows that the labeling (ffff) is not feasibly optimal.

The remaining labelings not accounted for are (fffb), (ffmb), (fmmb), and (mmmb). The following conjecture, if true, would prove that none of these four labelings are feasibly optimal.

Conjecture 1 *Let T be a gradient-constrained MGA in three-space, and let s be a Steiner point in T . If the degree of s is greater than 3, then s has no incident b-edges.*

There is strong evidence to suggest that this conjecture is true. The main support for this belief is that, in three-space, a b-edge path from a source to a sink can

Fig. 18 Feasibly optimal labelings for degree 4 Steiner points in three-space

be embedded in many different ways. Numerical experiments indicate that by embedding such a path using at least three zigzag components, other edges can attach to different corner-points on the zigzag so as to reduce the cost of the network.

To demonstrate this, consider the following example.

Let $p_1 = (-0.707, 0.707, 0)$, $p_2 = (-0.707, -0.707, 0)$, and $p_3 = (1, 0, -0.5)$ be sources with respective flows $t_1 = 1$, $t_2 = 1$, and $t_3 = 100$, and let $p_4 = (1, 0, 0.5)$ be the sink. The cost parameters are $d = h = 1$ and the maximum gradient is $m = 0.5$. It can be verified that the network shown in Fig. 19, in which the Steiner point s has labeling (ffmm), is a gradient-constrained MGA.

If p_3 is perturbed by ϵ in the negative x -direction, it can be observed that the topology suddenly changes to the one shown in Fig. 20 (in which $\epsilon = 0.1$). The path from p_3 to p_4 now has more space such that it has three straight-line segments instead of two. Consequently, the edges incident to p_1 and p_2 can connect to different corner-points on the path to reduce the cost of the network. This behavior

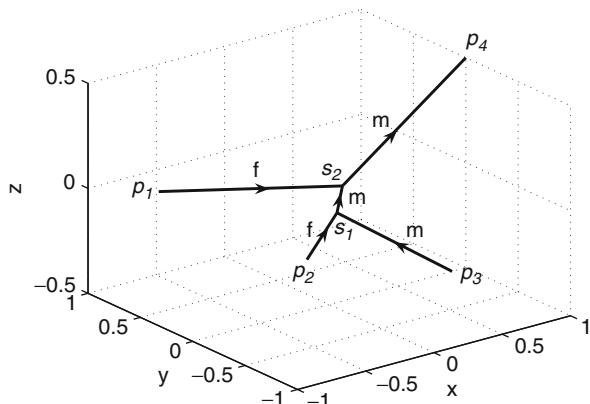

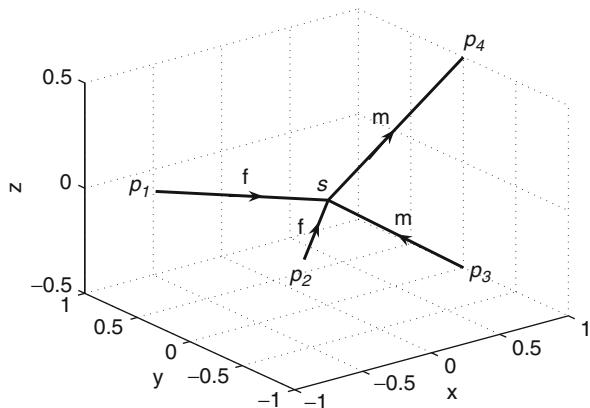

Fig. 20 Change in topology resulting from a perturbation of a terminal

has been frequently observed when attempting to construct MGAs with the above labelings.

7.2 Maximum Degree of Steiner Points

The degree of a Steiner point in a gradient-constrained Steiner minimum tree (SMT) in three dimensions is either three or four, subject to some constraints on m (see Lemma 5). It has been shown by Cox in [26] that in general there is no upper bound on the degree of a Steiner point in a minimum Gilbert network. The Steiner problem is a special case of the Gilbert arborescence problem, which is itself a special case of the Gilbert network problem. This prompts the question as to whether, for a Steiner point in a gradient-constrained MGA in three dimensions, the degree is limited to three or four as for gradient-constrained SMTs, is unbounded as for general minimum Gilbert networks, or is bounded above by some finite integer value greater than four.

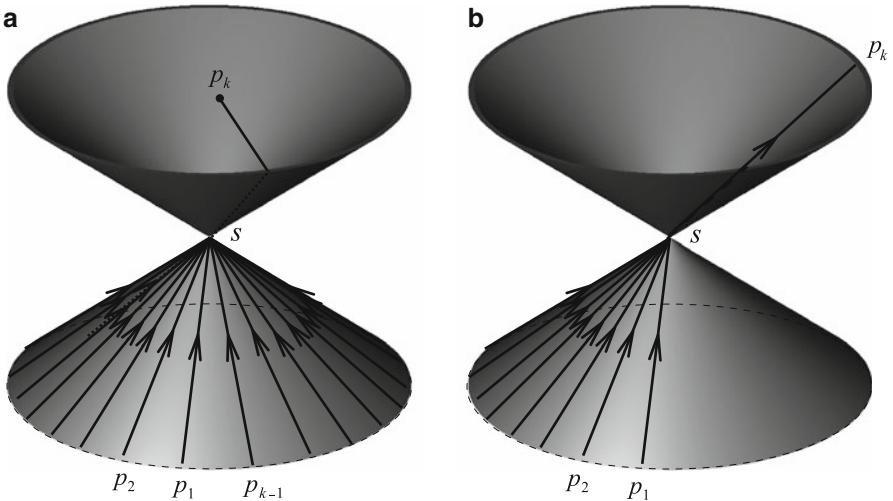

Fig. 21 Large-degree Steiner points, where the sink edge is (a) a b-edge and (b) an m-edge

Resolving this issue is far from trivial. For example, at first it may appear that the configuration illustrated in Fig. 21a, in which the Steiner point s has $k - 1$ incident source m-edges, where k is arbitrarily large, and the sink edge is a b-edge, could potentially be minimum. In this network, each path from p_i , $i = 1, \dots, k - 1$ to p_k is a geodesic under the gradient metric. Therefore, the flow cost component cannot be improved.

It is shown in [66], however, that in this case the development cost can be improved and that in fact the following result holds.

Theorem 19 *Let T be a gradient-constrained MGA in three-space and let s be a Steiner point in T with incident sink edge sp_k . If sp_k is a b-edge, then s has degree 3, and the two source edges are vertically coplanar m-edges on the opposite side of \mathcal{H}_s to the sink edge.*

Suppose, however, that the network in Fig. 21a is changed so that the sink edge is now an m-edge instead of a b-edge (Fig. 21b). The paths from p_i , $i = 1, \dots, k - 1$ to p_k are still geodesics under the gradient metric, so the flow cost cannot be improved. However, it can be shown in this case that if the flow costs are very large compared to the fixed cost, then it is possible for the network to have the shortest length among all networks connecting p_1, \dots, p_k for which the paths from the sources to the sink are geodesics. This implies that the development costs are minimum and leads to the following result.

Theorem 20 *There is no upper bound on the degree of a Steiner point in a gradient-constrained MGA in three dimensions.*

Using the UNO software product, many examples of high-degree Steiner points satisfying the properties described above have been found.

8 Conclusion

This chapter has described the theory and applications of minimum gradient-constrained interconnection networks. The focus has been on two problems: the geometric Steiner problem, which asks for a network interconnecting a given set of points of minimum total length, and the Gilbert arborescence problem, which asks for a minimum-cost flow-dependent network interconnecting a set of given sources and a unique sink. These problems have been studied in the setting of gradient-constrained space, which is a type of Minkowski space with several intriguing properties. The aim is to understand the local geometric and topological structure of these networks in order to develop efficient exact and heuristic algorithms.

Acknowledgements The research for and writing of this chapter was supported by an ARC Linkage Grant. We gratefully acknowledge the contributions of our collaborators to much of the theory described in this chapter, particularly Professor Doreen Thomas at The University of Melbourne.
